Schizophrenia: Neuroscience Perspective

Schizophrenia is a complex mental illness characterized by acute phases of delusions, hallucinations, and thought disorder, and chronically by apathy, flat affect, and social withdrawal. Schizophrenia affects 1 percent of the world's population, independent of country or culture, and constitutes a severe public health issue (WHO 1975). Schizophrenic patients normally start to display symptoms in their late teens to early twenties, but the time of onset and the course of the illness are very variable (American Psychiatry Association 1987). Approximately a third of patients experience one acute episode after which they make a more or less full recovery. Another third are affected by the illness throughout their lives, but their symptoms are to some extent alleviated by anti-psychotic drugs. The remaining third are so chronically ill that they show little or no improvement, even with medication (Johnstone 1991).

1. *Intellectual Function*

There is a striking deterioration in intellectual and cognitive function in schizophrenia (e.g., Johnstone 1991). Patients have difficulty in initiating and completing everyday tasks, being distracted easily and tending to give up when confronted by any obstacles. These deficits are similar to the problems in initiation and planning associated with frontal-lobe lesions (Shallice and Burgess 1991). This has led many researchers to suggest that the core deficit of schizophrenia is a failure to activate frontal cortex appropriately during cognitive tasks involving planning and decision making ('task-related hypofrontality'), a notion supported in part by many functional imaging studies (see below). Schizophrenic patients also show deficits in attention and memory tasks that engage prefrontal, hippocampal, and medial temporal systems, even in drug-free populations (Saykin et al. 1994). In the rest of this entry we shall consider the direct evidence for brain abnormalities in schizophrenia.

2. *Post-mortem Neuropathology*

Studies of post-mortem brains (Harrison 1999) have observed a decrease in overall brain size and have linked schizophrenia to structural abnormalities in the prefrontal cortex and temporal lobe, especially the hippocampus and amygdala. Several studies have found that schizophrenic brains tend to have enlarged lateral ventricles compared to nonschizophrenic brains. Histological studies have shown evidence for

abnormal synaptic appearance in the cingulate and hippocampal pyramidal cells in schizophrenia. The most reproducible positive anatomical finding in post-mortem hippocampal formation has been the reduced size of neuronal cell bodies in schizophrenia. However, these changes have not been found in all studies.

3. *In Vivo Studies Of Brain Structure*

3.1 *Computerized Tomography (CT) Studies*

The main finding from CT scan studies is that the lateral ventricles are enlarged in schizophrenic patients compared to normal controls (Van Horn and McManus 1992). Although the finding of increased ventricular volume in schizophrenic patients is widespread and replicated, the difference between schizophrenic patients and normal controls is small. Overlap with the normal population is appreciable. Correlation between CT findings and symptoms has been investigated (Lewis 1990). Enlarged ventricles have been associated with chronicity of illness, poor treatment response, and neuropsychological impairment in many, but not all of these studies.

3.2 *Magnetic Resonance Imaging (MRI) Studies*

MRI studies (see Harrison 1999) have tended to confirm the finding of enlarged ventricles in schizophrenic patients, but also permit a more detailed analysis of brain structure. Temporal lobe reductions have been reported, and are especially prominent in the hippocampus, parahippocampal gyrus, and the amygdala, but have not been observed in all studies. Robust relationships between temporal lobe reductions and clinical features have not yet been found. Some studies have found frontal lobe reductions in schizophrenic patients.

Reversal or reduction of normal structural cerebral asymmetries may be related to the pathogenesis of schizophrenia (Crow 1995). Various unusual symmetries have been observed consistent with the hypothesis that failure to develop normal asymmetry is an important component of the pathology underlying some forms of schizophrenia.

There are some MRI data that provide support for a hypothesis of disconnection between brain areas in schizophrenia. These results support the existence of a relative 'fronto-temporal dissociation' in schizophrenia. Evidence for such dissociation has also been obtained in functional imaging studies (see below).

All these studies used a 'regions of interest' approach in which measurements were restricted to prespecified brain regions. More recently, techniques have been developed in which differences can be detected automatically throughout the brain. Using such techniques, Andreasen et al. (1994) observed decreased thalamus size in schizophrenic patients consistent with observations in post-mortem brains.

4. *Functional Imaging*

4.1 *Resting Studies Using Positron Emission Tomography (PET)*

More sensitive measures of brain integrity can be obtained by measuring cerebral blood flow in a patient at rest. However, these results are difficult to interpret because the pattern of blood flow may be altered by the current mental state of the patient and by medication. Early studies of this sort observed a relative reduction of blood flow in the frontal lobes of patients with schizophrenia (Ingvar and Franzen 1974). This pattern of activity became known as hypofrontality. However, subsequent studies have not always replicated this observation.

Several studies have looked at clinical correlates associated with hypofrontality, but the results are inconsistent. Among features showing a positive relationship with hypofrontality are chronicity, negative symptoms, and neuropsychological task impairment. Relations have also been observed between the pattern of blood flow and the symptomatology of patients at the time of scanning. For example, patients manifesting 'psychomotor poverty' showed reduced blood flow in dorsolateral prefrontal cortex (Liddle et al. 1992).

4.2 *The Dopamine Hypothesis*

One of the most robust findings in schizophrenia research has been the observation that drugs which block dopamine receptors are effective in reducing the severity of symptoms such as hallucinations and delusions (Seeman 1986). This led to the dopamine (DA) hypothesis of schizophrenia, which posits that schizophrenia is caused by an overactivity of dopamine receptors (Van Rossum 1966). The best way to investigate the dopamine hypothesis is the *in vivo* visualization of radioactive ligand binding to quantify dopamine receptor densities in drug-naive patients using PET.

These studies suggest that compared to healthy controls, patients with schizophrenia show a significant but mild increase in, and a larger variability of, D2 receptor density (Laruelle 1998). There is also evidence that D1 receptor density is reduced in the prefrontal cortex of schizophrenic patients (Okubo et al. 1997).

5. *Cognitive Activation Studies*

Functional neuroimaging experiments generally evaluate brain activity associated with performance of cognitive or sensori-motor tasks. Cognitive activation studies have provided further evidence for decreased frontal activity ('hypofrontality') in schizophrenia. In addition, there is increasing evidence that schizophrenics show abnormal integration between the

frontal cortex and other brain regions, including the temporal lobes, the parietal lobes, and hippocampus, during cognitive tasks.

5.1 Task-based Studies of Executive Function

Schizophrenia is characterized largely by impairments in planning and execution, and therefore tasks that involve this kind of planning and modification of behavior have been exploited in the scanner. Several studies have found that schizophrenic patients show reduced activity in the dorsolateral prefrontal cortex (DLPFC) while performing the Wisconsin card sorting task, a popular test of planning. In addition to decreased DLPFC activity, schizophrenic patients also showed abnormal responses in the temporal lobes and parahippocampal gyrus (Ragland et al. 1998). The results suggest that schizophrenia may involve a breakdown in the integration between the frontal and temporal cortex, which is necessary for executive and planning demands in healthy individuals. This interpretation moves away from the simple notion that dysfunction in isolated brain regions, explains the cognitive deficits in schizophrenia, and towards the idea that neural abnormality in schizophrenia reflects a disruption of integration between brain areas.

5.2 Willed Action

Willed actions are self-generated in the sense that the subject makes a deliberate and free choice to perform one action rather than another. Willed actions are a fundamental component of executive tasks. In normal subjects, willed actions are associated with increased blood flow in the DLPFC. Schizophrenic patients, especially those with negative signs, have difficulty with tasks involving free choices, and show an associated lack of activity in DLPFC. Activity in this region normalizes as the symptoms decrease (Spence et al. 1998). This suggests that hypofrontality depends on current symptoms. Studies of willed action also suggest that the underactivity in DLPFC observed in some schizophrenic patients is accompanied by overactivity in posterior brain regions. There is evidence of a lack of the normal reciprocal interaction between the frontal and the superior temporal cortex in schizophrenia, which supports the notion of impaired functional integration (McGuire and Frith 1996).

5.3 Memory Tasks

Memory impairments are an especially enduring feature of schizophrenia. Functional neuroimaging studies of memory have demonstrated hypofrontality, abnormal interaction between temporal and frontal cortex, and a dysfunctional cortico-cerebellar circuit in schizophrenic patients compared to control subjects. The hippocampus is a brain structure that is well known to be involved in memory. Evidence for impaired hippocampal function in schizophrenia was found in a well-controlled functional imaging study (Heckers et al. 1998). In this study, schizophrenic patients failed to recruit the hippocampus during successful retrieval, unlike normal control subjects. The schizophrenic patients also showed a more widespread activation of prefrontal areas and parietal cortex during recollection than did controls. The authors propose that this overactivation represents an 'effort to compensate for the failed recruitment of the hippocampus.' This result supports the idea that neural abnormality in schizophrenia reflects a disruption of integration between brain areas. Fletcher et al. (1999) also found evidence for abnormal integration between brain areas in schizophrenia during the performance of a memory task. They demonstrated an abnormality in the way in which left prefrontal cortex influenced activity in left superior temporal cortex, and suggested that this abnormality was due to a failure of the anterior cingulate cortex to modulate the prefronto-temporal relationship.

6. Imaging Symptoms

Functional neuroimaging is also useful for evaluating neural activity in patients experiencing specific psychotic symptoms, such as hallucinations and passivity.

6.1 Hallucinations

Hallucinations, perceptions in the absence of external stimuli, are prominent among symptoms of schizophrenia. Functional neuroimaging studies of auditory hallucinations suggest that they involve neural systems dedicated to auditory speech processing as well as a distributed network of other cortical and subcortical areas (Dierks et al. 1999). There is also evidence that the activity associated with auditory hallucinations resembles that seen when normal subjects are using inner speech (McGuire et al. 1996).

6.2 Passivity

Passivity symptoms, or delusions of control, in which patients claim that their actions and speech are being controlled by an external agent, are common in schizophrenia. Schizophrenic patients with passivity showed hyperactivation of inferior parietal lobe (BA 40), the cerebellum, and the cingulate cortex relative to schizophrenic patients without passivity and to normal controls. When patients no longer experienced passivity symptoms, a reversal of the hyperactivation of parietal lobe and cingulate was seen (Spence et al. 1997). Hyperactivity in parietal cortex may reflect the 'unexpected' nature of the

movement experienced by patients. The movement feels as though it is being caused by an external force (Frith et al. 2000).

7. Conclusions

There is considerable evidence for structural abnormalities in the brains of patients with schizophrenia, but the abnormalities identified so far are not specific to this disorder, are very variable and cannot easily be related to the symptoms. The neurotransmitter dopamine is clearly important in schizophrenia, but its precise role remains unclear. Studies of brain function are still at an early stage, but suggest that schizophrenia may be characterized by disorders of connectivity between cortical and subcortical regions. Some of the symptoms of schizophrenia can be understood in terms of these disconnections. Current advances in imaging techniques aimed at measuring connectivity in the brain are likely to have a major impact on our understanding of schizophrenia.

Schizophrenia, Treatment of

Schizophrenia is a brain disorder of unknown origin which severely deteriorates numerous complex functions of the central nervous system (CNS) including thought, emotion, perception, cognition, and behavior. Schizophrenia is one of the most debilitating psychiatric disorders. Due to the high lifetime prevalence (about 1.5 percent), the typical onset in early adulthood, and the strong tendency towards a chronic

course, the disorder requires a very high degree of health care provisions. About one-quarter of hospital beds are occupied by schizophrenic patients, and the total costs of treatment are enormous (e.g., US$50 billion per year in the United States). Although there is no cure for schizophrenia, the combined administration of pharmacological and psychosocial interventions considerably improves outcome, enhances quality of life in the patients affected, and enables social integration to a large extent.

1. *Causes and Pathophysiology of Schizophrenia*

The causes of schizophrenia are unknown so far. Therefore, the term 'schizophrenia' refers to an empirically defined syndrome characterized by a combination of certain symptoms which occur in a particular temporal pattern. The idea that schizophrenia is a distinct brain disorder is rooted in Emil Kraepelin's concept of dementia praecox (Kraepelin 1893). This concept emphasized one particular aspect of the disorder: the onset of persistent cognitive disturbances early in life. The term 'schizophrenia' was coined by Eugen Bleuler (1916), who wanted to emphasize the loss of coherence between thought, emotion, and behavior which represents another important feature of the disorder. Bleuler actually spoke about 'schizophrenias,' implying a group of diseases rather than one distinct disease entity. The present diagnostic systems compiled by the World Health Organization (*ICD-10* 1992) and the American Psychiatric Association (*DSM-IV* 1994) distinguish various subtypes of schizophrenia (see Table 1) which are classified according to particular symptom combinations, and according to certain aspects of the course and prognosis of the disease. However, these subtypes are defined in a phenomenological manner which neither implies distinct causes for any of the subtypes nor any particular treatment.

Although we do not know individual causes of schizophrenia, we know that the basis for the disorder is an interaction between genetic susceptibility factors and environmental components. According to numerous genetic studies the estimates of hereditability converge to about 80 percent (Owen and Cardno 1999). However, although linkage studies have yielded evidence for a number of susceptibility loci on various chromosomes, neither a single gene nor a combination of genes have been discovered so far which are definitively involved. Similarly, a number of environmental factors (e.g., birth and pregnancy complications, viral infections) are likely to play a role, but details of this role remain to be established.

Although the symptoms of schizophrenia clearly demonstrate a severe disturbance of brain functions, only subtle alterations of brain morphology have been detected. The most stable finding is a slight enlargement of brain ventricles. Recent sophisticated studies combining morphological and functional brain imaging have been suggested to indicate that subtle structural or functional lesions particularly in prefrontal and limbic neural circuits impair the integrity of these circuits (Andreasen et al. 1998). Although it is still a matter of debate whether these lesions are due to a neurodevelopmental or a neurodegenerative process (Lieberman 1999), it is clear that disturbed functioning of neuronal circuits goes along with altered neurotransmission. Dopamine, serotonin, and glutamate are the neurotransmitters most frequently implicated in the pathophysiology of schizophrenia. However, it is still not clear whether disturbed neurotransmission is the cause or the consequence of the major disease process.

Due to this scantiness of etiological and pathophysiological knowledge, the treatment of patients suffering from schizophrenia is based exclusively on empirical clinical knowledge. As outlined in detail below, the treatment approach is multimodal and based on the symptom patterns present in any individual patient (see *Mental Illness, Etiology of*).

2. *Symptoms of Schizophrenia—the Targets for Treatment*

Schizophrenia affects almost all areas of complex brain functions, and thought, perception, emotion, cognition, and behavior in particular. There have been numerous approaches to systematize the plethora of symptoms according to a variety of theoretical concepts. One widely accepted concept is the distinction between positive and negative symptoms (Andreasen

Table 1
Subtypes of schizophrenia according to the major classification systems

ICD-10	[*DSM-IV*]
Paranoid schizophrenia	Schizophrenia, paranoid type
Catatonic schizophrenia	Schizophrenia, catatonic type
Undifferentiated schizophrenia	Schizophrenia, undifferentiated type
Residual schizophrenia	Schizophrenia, residual type
Hebephrenic schizophrenia	—
—	Schizophrenia, disorganized type
Simple schizophrenia	—

Table 2
Positive and negative symptoms of schizophrenia. Areas of symptoms are listed and selected examples appear in parentheses

Positive symptoms
Hallucinations (*auditory*, *somato-tactile*, *visual*, *olfactory*)
Delusions (*persecutory*, *religious*, *thought broadcasting*, *thought insertion*)
Bizarre behavior (*unusual clothing or appearance*, *repetitive*, *stereotyped behavior*)
Positive formal thought disorders (*incoherence*, *illogicality*, *tangentiality*)
Negative symptoms
Affective flattening (*unchanging facial expression*, *paucity of expressive gestures*)
Alogia (*poverty of speech*, *increased response latency*)
Avolition-apathy (*physical anergia*, *problems with personal hygiene*)
Anhedonia-asociality (*reduction in social activities*, *sexual interest*, *closeness*)
Attention (*social inattentiveness*, *inattentiveness during testing*)

et al. 1995, Table 2) (see *Psychiatric Assessment: Negative Symptoms*). This approach groups symptoms according to whether they represent a loss of or a deficiency in a normal brain function (negative symptoms) or the appearance of abnormal phenomena (positive symptoms). From the perspective of treatment the positive–negative dichotomy is of importance because these two domains react somewhat differently to treatment. In general, positive symptoms respond fairly well to treatment with antipsychotic drugs, whereas negative symptoms are rather difficult to influence. The latter is particularly problematic, because negative symptoms are usually the limiting factor for personal and social rehabilitation. In addition to the typical symptoms, patients suffering from schizophrenia often present numerous other psychiatric problems. Among these, anxiety, sleep disturbances, obsessions and compulsions, depression and drug or substance abuse are particularly frequent. Although these additional symptoms and problems may in many cases be the consequence of the typical symptoms rather than signs of independent additional psychiatric disorders, they complicate the course of the disease and often necessitate specific treatment approaches.

The course of schizophrenia varies considerably between patients. Typically, the disease begins during early adulthood with the appearance of rather unspecific negative symptoms resulting in social withdrawal and impaired social and scholastic adjustment. Months to years later positive symptoms such as delusions and hallucinations appear either gradually or abruptly. Across time, positive symptoms tend to show an episodic course, whereas negative symptoms either remain quite stable or even progress. The associated psychiatric problems mentioned above do not show any systematic temporal relationship to the course of schizophrenia itself. Since the syndrome of schizophrenia has been defined, data on the final outcome have varied considerably, depending mainly on the diagnostic concepts applied. There is no doubt that full remission occurs, but probably in less than 20 percent of patients. In the majority of patients schizophrenia takes a chronic course (Schultz and Andreasen 1999). The major benefit from modern treatment strategies is probably not a substantial increase in the rate of full remissions, but a significant reduction in the number of extremely ill patients, and in the severity and number of episodes characterized by prominent positive symptoms.

3. *The Principles of Treatment*

Treatment of schizophrenia is usually multimodal and comprises approaches from two major areas, which are drug treatment and psychosocial interventions. In general, appropriate drug treatment is a prerequisite for the ability of the patients to comply with and actively take part in psychosocial treatments. The more effective drug treatment is, the more specialized and sophisticated psychosocial interventions can be successfully applied. Vice versa, appropriate psychosocial treatment considerably improves the compliance with drug treatment, because it enhances insight into the disease process, which initially is poor in many patients suffering from schizophrenia.

Antipsychotic drugs (also called neuroleptics) are the most important and most effective therapeutic weapon. The major targets of these drugs are positive symptoms, although newer substances might also reduce negative symptoms to some extent (see below). Treatment with antipsychotic drugs is usually a long-term treatment, whereas drugs to control accessory symptoms (anxiolytics, hypnotics, and antidepressants) are prescribed intermittently when needed. The use of electroconvulsive therapy was widespread before antipsychotic drugs were available, but today is very limited, although this treatment is effective in certain conditions (Fink and Sackeim 1996).

Among the psychosocial interventions, supportive and psychoeducative approaches are feasible for the majority of patients, whereas structured social skill training, family therapy, or complex programs in-

cluding cognitive-behavioral therapies require a considerable degree of insight and compliance. Although recent psychosocial treatment approaches incorporate also psychodynamic aspects, classical psychodynamic psychotherapy, in general, is not effective and sometimes even counterproductive.

Prior to the discovery of antipsychotic drugs, most schizophrenic patients had been hospitalized for decades or even for their entire life. Today, very differentiated treatment facilities are available, which to a large extent are community based. These include, besides classical hospitals and outpatient departments, short-term crisis intervention facilities, day-time clinics, and supported living facilities. This network of facilities considerably increases the chance for social integration and reduces the time spent overall in hospitals. However, recent aggressive approaches to shorten the duration of hospital stays dramatically might lead to a high frequency of rehospitalization, poor long-term outcome, and an overall increase in the costs of treatment.

An important limiting factor for all treatment approaches is the patients' compliance. In particular in severely ill patients compliance is often poor. In schizophrenia noncompliance is particularly due to a lack of insight into the fact of being ill, reduced ability to actively take part in the treatment process due to negative symptoms, or active avoidance of treatment due to positive symptoms such as delusions or imperative voices. To enable stable treatment compliance in patients suffering from schizophrenia, a confidential and empathetic attitude of the people involved is an important prerequisite.

4. *Particular Aspects of Treatment*

4.1 *Pharmacotherapy*

The introduction of chlorpromazine into clinical practice in 1952 is the hallmark of the pharmacological treatment of schizophrenia (Delay and Deniker 1952). Chemically, chlorpromazine is a phenothiazine and other substances of this group also possess antipsychotic properties. In the 1950s and 1960s, numerous antipsychotic drugs with different structures (in particular butyrophenones [e.g., haloperidol] and thioxanthenes [e.g., flupentixol]) were developed. Despite this diversity in chemical structure, these first-generation drugs do not differ qualitatively with respect to their profile of beneficial and undesired effects. They target mainly the positive symptoms of schizophrenia mentioned in Table 2 without preferentially affecting one or the other of these symptoms. Their effectiveness does not depend on the subtype of schizophrenia (see Table 1).

The common mode of action of the first-generation antipsychotics is believed to be blockade of the D2 subtype of dopamine receptors (Pickar 1995). Blockade of these receptors in the mesolimbic dopamine system is thought to cause a reduction in positive symptoms, and blockade in the nigrostriatal dopamine system is believed to be responsible for the typical side effects of these drugs. These are severe disturbances of motor behavior caused by a drug-induced dysfunction of the dopaminergic extrapyramidal system, which plays a pivotal role in the control of movements. Table 3 summarizes these extrapyramidal syndromes. Those which occur acutely are often very disturbing, but respond fairly well to treatment (e.g., acute dystonia to anticholinergic drugs), or at least cease upon drug discontinuation or dose reduction. Tardive extrapyramidal syndromes, however, are frequent (5–10 percent on long-term treatment with first-generation antipsychotics), often resistant to treatment approaches, and they usually persist if the antipsychotic drug is stopped. Another severe side effect of unknown cause, which might be related to the extrapyramidal system, is the neuroleptic malignant syndrome (Pelonero et al. 1998; see also Sect. 4.3). Extrapyramidal side effects are common to all first-generation drugs, whereas other, less specific side effects (e.g., sedation, weight gain, postural hypotension) occur with some but not all substances (see *Psychopharmacotherapy: Side Effects*).

Due to the central role attributed to D2 dopamine receptor blockade, it has been thought for a long time that antipsychotic effectiveness and extrapyramidal syndromes are inevitably linked to each other. However, in the late 1960s it turned out that the dibenzodiazepine clozapine is a potent antipsychotic drug that almost never induces extrapyramidal symptoms and is effective in a proportion of otherwise treatment-resistant patients (Angst et al. 1971). Moreover, it was

Table 3
Extrapyramidal syndromes induced by first-generation antipsychotic drugs.

Acute (within days)	[Late or tardive (within months to years)]
Drug-induced Parkinsonism (*bradykinesia, increased muscular tone, tremor*)	Tardive dyskinesia or dystonia (*irregular choreiform, or dystonic movements in any voluntary muscle group*)
Dystonia (*sudden-onset, sustained muscular contractions preferably in the cephalic musculature*)	Tardive tics (*repetitive, short-lasting, stereotyped movements or other kind of behavior* [*e.g., vocalization*])
Akathisia (*internal restlessness and urge to move, often coupled with pacing behavior*)	Tardive myoclonus (*brief asynchronous movements which are not stereotyped*)

shown that clozapine not only improves positive but to some extent also negative symptoms. Therefore, the introduction of clozapine into clinical practice was the first qualitative advance after the discovery of chlorpromazine, and it is justified to call this substance a second-generation antipsychotic drug. Unfortunately it turned out quickly that clozapine has a very particular and important drawback: it induces life-threatening agranulocytosis in about one percent of patients treated (Baldessarini and Frankenburg 1991). Therefore, the use of this drug is only possible when white blood cell counts are monitored in short intervals.

It is still not known why clozapine is a potent antipsychotic drug, but lacks extrapyramidal side effects. Among the possible reasons are that clozapine affects mainly the mesolimbic dopamine system, that it blocks D1 receptors to the same extent as D2 receptors, that it has a high affinity to D4 receptors, and that it also has high affinity to serotonin receptors. This theoretical framework was the basis for the development of various second-generation antipsychotics (see Table 4). Most of them have high affinities for serotonin receptors, although only one substance (olanzapine) is similar to clozapine in the equivalent binding to D1 and D2 receptors. So far there is no indication that any of these newer drugs carries a substantial risk of agranulocytosis, the most dangerous side effect of clozapine. Moreover, these substances have shown to be effective when compared to first-generation antipsychotic drugs and indeed to induce fewer extrapyramidal side effects. For two of them (olanzapine and risperidone) there are data suggesting that they also might ameliorate negative symptoms. However, it still remains to be seen how the effectiveness of these newer drugs compares to clozapine.

Treatment with antipsychotic drugs in schizophrenic patients is usually a long-term treatment continuing for many years. Intermittently, patients may need additional other psychotropic medications. Most frequently anxiolytics, hypnotics, and antidepressants are administered. The recognition and treatment of intervening depressive episodes is particularly important because depressive and negative symptoms are sometimes difficult to differentiate, but need different treatment. When administering antidepressant drugs to schizophrenic patients, one should be aware that during treatment with antidepressants positive symptoms sometimes exacerbate.

4.2 Psychosocial Treatment

It is now generally accepted that psychosocial treatment of patients with schizophrenia is not an alternative to pharmacological treatment, but rather an important complementary approach (Bustillo et al. 2000). Psychosocial measures yield little benefit for positive symptoms; in contrast, intensive psychodynamic psychotherapy might induce exacerbations. The most important and successful interventions are psychoeducative teaching and training in social skills and problem solving. Although it is still debated whether these treatments are directly effective against negative symptoms, there is no doubt that they considerably improve coping with these symptoms.

The major goal of educational approaches is to increase the knowledge about and the insight into the disease process and, as a consequence, to improve treatment compliance. Educational programs are focused on knowledge about the disease process and it's course, the mode of action and side effects of medication, early signs of exacerbation such as restlessness and insomnia, and detailed information about the various community based or hospital facilities available. These programs are particularly effective when important family members are educated as well. Moreover, approaches to improve the communication styles within the patient's network of social relationships are often useful, although the concept that particular forms of communication ('high expressed emotions') play a causative role in schizophrenia has been seriously challenged.

Schizophrenic patients' social skills are often poor. This is one major reason for the often dramatically reduced amount of social contacts. Training of social skills in patients suffering from schizophrenia is performed in a group setting. Such groups are focused on the repetitive training of behavior in various social situations of importance for everyday life. In addition, some rather basic teaching of the theoretical background of successful social interaction might be included.

Impaired problem solving in schizophrenic patients is due to a combination of disturbances in divided attention, planning, and motivation. Problem solving training includes the analysis of problems relevant to daily life and, particularly, dividing a problem into subproblems that can be successively solved. Similar to the training of social skills, the steps of the solution are practiced repeatedly.

In recent years, more complex psychotherapeutic approaches have been developed, combining cognitive, behavioral, or psychodynamic approaches, which, however, are suitable for the minority of patients only.

In particular for chronic patients who in earlier times often were hospitalized for decades, providing supervised residential living arrangements has proven to be of considerable benefit because in this setting the degree of self-sustainment can be maximized in parallel with the permanent provision of professional help.

4.3 Emergency Treatment

Schizophrenia is not only a debilitating but also a life-threatening disorder. If severe positive symptoms are present, such as verbal imperative hallucinations,

Table 4
Relative receptor affinities of selected newer antipsychotic compounds compared to the first-generation drug haloperidol.

	[Dopamine]		[Serotonin]		[Noradrenaline]		Histamine	Acetylcholine
	D_1	D_2	$5HT_1$	$5HT_{2\alpha}$	α_1	A_2	H_1	M_1

a Prototype first generation antipsychotic drug

delusions of persecution, or severe formal thought disturbances, the patient's life is threatened by a misinterpretation of his or her environment (e.g., of dangerous objects or situations) and by suicidal intentions. Suicidality can also emerge when negative symptoms are prominent. Acute suicidality and an acute confusional psychotic state both necessitate immediate treatment, including the administration of anxiolytics, antipsychotics, or both, preferably in a hospital setting. Although every effort should be undertaken to get the informed consent of the patient, it is often necessary to initiate treatment against his or her explicit will. This has to be done in accordance with the legal regulations in the respective country.

Less frequently occurring life-threatening situations in patients suffering from schizophrenia are febrile catatonia and the neuroleptic malignant syndrome, a rare side effect of antipsychotic drugs (Pelonero et al. 1998). Both conditions show similarities, including fever, disturbances of motor behavior, and reduced responsiveness to external stimuli. The differential diagnosis is difficult, but very important because in febrile catatonia treatment with antipsychotic drugs is necessary, whereas such treatment has to be immediately stopped when a neuroleptic malignant syndrome is suspected. In both of these conditions admission to an intensive care unit is necessary.

5. *Future Perspectives on the Treatment of Schizophrenia*

Despite the rapid development of the knowledge about human genetics, it is unlikely that we will see a major advance in our understanding of the genetic causes of schizophrenia in the near future. The reason is that the available epidemiological data render a major contribution of single genes quite unlikely and suggest that multiple genes contribute to the susceptibility to schizophrenia. However, it is likely that genetic investigations will improve the management of schizophrenia by enabling prediction of the treatment response to antipsychotic drugs. Very recently, for example, it has been shown that a combination of six polymorphisms in neurotransmitter-receptor-related genes enable a significant prediction of the treatment response to clozapine (Arranz et al. 2000). Although these preliminary studies must be replicated and extended to other drugs, it is probable that this approach will significantly enhance the success of drug treatment in schizophrenia. It is also likely that the near future will bring new drugs which are the result of a 'fine-tuning' of the chemical structure and the binding profile to dopamine and serotonin receptors of those substances which are presently available. Another approach which is currently being pursued is to target glutamate receptors, although first clinical trials are only in part encouraging (Farber et al. 1999). Based on a theory implicating the immune system in the pathophysiology of schizophrenia, studies are being started that use immunomodulation as a treatment. This is an interesting and promising approach, which also might help to understand the mode of action of presently available antipsychotic drugs because some of them influence the production of cytokines which are important immune mediators (Pollmächer et al. in press). Another approach based on pathophysiological theories is to target phospholipids. These are an important cell-membrane component and there is some evidence suggesting that either their uptake is deficient or that they are excessively broken down in schizophrenic patients (Horrobin 1999).

School Achievement: Cognitive and Motivational Determinants

Although the analysis of school achievement (SA)—its structure, determinants, correlates, and consequences—has always been a major issue of educational psychology, interest in achievement as a central outcome of schooling has considerably increased during the last decade (see also *School Outcomes: Cognitive Function, Achievements, Social Skills, and Values*). In particular, large-scale projects like TIMSS (Third International Mathematics and Science Study) (Beaton et al. 1996) had a strong and enduring impact on educational policy as well as on educational research and have also raised the public interest in scholastic achievement.

1. School Achievement and its Determinants: An Overview

SA can be characterized as cognitive learning outcomes which are products of instruction or aimed at by instruction within a school context. Cognitive outcomes mainly comprise procedural and declarative knowledge but also problem-solving skills and strategies. The following facets, features, and dimensions of SA, most of which are self-explaining, can be distinguished:

(a) episodic vs. cumulative;
(b) general/global vs. domain-specific;
(c) referring to different parts of a given subject (in a foreign language e.g., spelling, reading, writing, communicating, or from the competency perspective, grammatical, lexical, phonological, and orthographical);
(d) test-based vs. teacher-rated;
(e) performance-related vs. competence-related;
(f) actual versus potential (what one could achieve, given optimal support);
(g) different levels of aggregation (school, classroom, individual level);
(h) curriculum-based vs. cross-curricular or extracurricular.

Figure 1 shows a theoretical model that represents central determinants of SA. Cognitive and motivational determinants are embedded in a complex system of individual, parental, and school-related determinants and depend on the given social, classroom, and cultural context. According to this model, cognitive and motivational aptitudes have a direct impact on learning and SA, whereas the impact of the other determinants in the model on SA is only indirect.

Figure 1
Interplay of individual cognitive and motivational and other determinants of SA

2. Cognitive Determinants

2.1 Intelligence

Intelligence (see *Intelligence, Prior Knowledge, and Learning*) is certainly one of the most important determinants of SA. Most definitions of intelligence refer to abstract thinking, ability to learn, and problem solving, and emphasize the ability to adapt to novel situations and tasks. There are different theoretical perspectives, for example Piagetian and neo-Piagetian approaches, information-processing approaches, component models, contextual approaches, and newer integrative conceptions such as Sternberg's triarchic theory of intelligence, or Gardner's model of multiple intelligences. Among them, the traditional psychometric approach is the basis for the study of individual differences. In this approach quantitative test scores are analyzed by statistical methods such as factor analysis to identify dimensions or factors underlying test performance (Sternberg and Kaufman 1998). Several factor theories have been proposed ranging from a general-factor model to various multiple-factor models. One of the most significant contributions has been a hierarchical model based on second-order factors that distinguishes between fluid and crystallized abilities. Fluid intelligence refers to basic knowledge-free information-processing capacity such as detecting relations within figural material, whereas crystallized intelligence reflects influences of acculturation such as verbal knowledge and learned strategies. Fluid and crystallized abilities can both be seen as representing general intelligence as some versions of a complete hierarchical model would suggest (see Gustafsson and Undheim 1996).

Substantial correlations (the size of the correlations differ from $r = 0.50$ to $r = 0.60$) between general intelligence and SA have been reported in many studies. That is, more than 25 percent of variance in post-test scores are accounted for by intelligence, depending on student age, achievement criteria, or time interval between measurement of intelligence and SA. General intelligence, especially fluid reasoning abilities, can be seen as a measure of flexible adaptation of strategies in novel situations and complex tasks which put heavy demands and processing loads on problem solvers.

The close correlation between intelligence and SA has formed the basis for the popular paradigm of underachievement and overachievement: Students whose academic achievement performance is lower than predicted on the basis of their level of intelligence are characterized as underachievers; in the reverse case as overachievers. This concept, however, has been criticized as it focuses on intelligence as the sole predictor of SA although SA is obviously determined by many other individual as well as instructional variables.

Intelligence is related to quality of instruction. Low instructional quality forces students to fill in gaps for themselves, detect relations, infer key concepts, and develop their own strategies. On the whole, more intelligent students are able to recognize solution-relevant rules and to solve problems more quickly and more efficiently. Additionally, it is just that ability that helps them to acquire a rich knowledge base which is 'more intelligently' organized and more flexibly utilizable and so has an important impact on following learning processes. Accordingly, intelligence is often more or less equated with learning ability (see Gustafsson and Undheim 1996).

Beyond general intelligence, specific cognitive abilities do not seem to have much differential predictive power, although there is occasional evidence for a separate contribution of specific abilities (Gustafsson and Undheim 1996). In Gardner's theory of multiple intelligences there are seven abilities (logical-mathematical, linguistic, spatial, musical, bodily-kinesthetic, interpersonal, and intrapersonal intelligence). Among domain-specific abilities, reading ability that is related to linguistic intelligence in Gardner's model, has some special significance. Specific abilities such as phonological awareness have turned out as early predictors of reading achievement.

2.2 Learning Styles and Learning Strategies

Styles refer to characteristic modes of thinking that develop in combination with personality factors (see *Cognitive Styles and Learning Styles*). While general cognitive or information-processing styles are important constructs within differential psychology, learning styles are considered as determinants of SA. Learning styles are general approaches toward learning; they represent combinations of broad motivational orientations and preferences for strategic processing in learning. Prominent learning style conceptions mainly differ with respect to intrinsic and extrinsic goal orientations and surface processing vs. deep processing. Intrinsic vs. extrinsic motivation deals with whether task fulfillment is a goal of its own or a means for superordinate goals. In deep processing, learners try to reach a comprehension of tasks as complete as possible to incorporate their representations into their own knowledge structures and give them personal significance. In surface processing, learners confine processing to the point where they can reproduce the material in an examination or achievement situation as well as possible (Snow et al. 1996).

Compared to general learning styles, learning strategies are more specific: They represent goal-oriented endeavors to influence one's own learning behavior. While former research mostly dealt with simple study skills that were seen as observable behavioral techniques, now cognitive and metacognitive strategies are included. Learning strategies therefore comprise cognitive strategies (rehearsal, organization, elaboration)

and metacognitive strategies (planning, monitoring, regulation) as well as resource-oriented strategies (creating a favorable learning environment, controlling attention, and sustaining concentration) (Snow and Swanson 1992). Frequently, learning strategies are assessed by means of questionnaires.

In spite of the great importance learning strategies have for understanding knowledge acquisition and learning from instruction, only few empirical data concerning the relation between learning strategies and SA are available. Most studies done in the context of schools and universities have shown positive but small correlations between learning strategies and SA. One reason may be that assessment by questionnaires is too general. On the whole, the exact conditions under which learning strategies are predictive to achievement have still to be worked out.

Besides motivational and metacognitive factors, epistemological beliefs are important determinants for learning strategies and achievement. They refer to beliefs about the nature of knowledge and learning such as: knowledge acquisition depends on innate abilities, knowledge is simple and unambiguous, and learning is quick. Epistemological beliefs can influence quality of achievement and persistence on difficult tasks (Schommer 1994).

2.3 Prior Knowledge

Although there have been early attempts to identify knowledge prerequisites for learning, the role of prior knowledge (see *Intelligence, Prior Knowledge, and Learning*) as a determinant of SA has long been neglected. Since the early 1980s, research on expertise has convincingly demonstrated that superior performance of experts is mainly caused by the greater quantity and quality of their knowledge bases (see *Expertise, Acquisition of*). Prior knowledge does not only comprise domain-specific content knowledge, that is, declarative, procedural, and strategic knowledge, but also metacognitive knowledge, and it refers to explicit knowledge as well as to tacit knowledge (Dochy 1992). Recent research has shown that task-specific and domain-specific prior knowledge often has a higher predictive power for SA than intelligence: 30 to 60 percent of variance in post-test scores is accounted for by prior knowledge (Dochy 1992, Weinert and Helmke 1998). Further results concern the joint effects of intelligence and prior knowledge on SA. First, there is a considerable degree of overlap in the predictive value of intelligence and prior knowledge for SA. Second, lack of domain-specific knowledge cannot be compensated for by intelligence (Helmke and Weinert 1999).

But learning is not only hindered by a lack of prior knowledge, but also by misconceptions many learners have acquired in their interactions with everyday problems. For example, students often have naive convictions about physical phenomena that contradict fundamental principles like conservation of motion. These misconceptions, which are deeply rooted in people's naive views of the world, often are in conflict with new knowledge to be acquired by instruction. To prevent and overcome these conflicts and to initiate processes of conceptual change is an important challenge for classroom instruction.

3. Motivational Determinants

3.1 Self-concept of Ability

The self-concept of ability (largely equivalent with subjective competence, achievement-related self-confidence, expectation of success, self-efficacy; see *Self-concepts: Educational Aspects*; *Self-efficacy: Educational Aspects*) represents the expectancy component within the framework of an expectancy *x* value approach, according to which subjective competence (expectancy aspect) and subjective importance (value aspect) are central components of motivation. Substantial correlations between self-concept of ability and SA have been found. Correlations are the higher, the more domain-specific the self-concept of ability is conceptualized, the higher it is, and the older the pupils are. Self-concept of ability is negatively related to test anxiety (see *Test Anxiety and Academic Achievement*) and influences scholastic performance by means of various mechanisms: Students with a high self-concept of ability (a) initiate learning activities more easily and quickly and tend less to procrastination behavior, (b) are more apt to continue learning and achievement activities in difficult situations (e.g., when a task is unexpectedly difficult), (c) show more persistence, (d) are better protected against interfering cognitions such as self-doubt and other worries (Helmke and Weinert 1997).

3.2 Attitude towards Learning, Motivation to Learn, and Learning Interest

There are several strongly interrelated concepts that are associated with the subjective value—of the domain or subject under consideration, of the respective activities, or on a more generalized level, of teachers and school. The value can refer to the affective aspect of an attitude, to subjective utility, relevance, or salience. In particular, attitude toward learning means the affective (negative or positive) aspect of the orientation towards learning; interest is a central element of self-determined action and a component of intrinsic motivation, and motivation to learn comprises subjective expectations as well as incentive values (besides anticipated consequences like pride, sorrow, shame, or reactions of significant others, the

incentive of learning action itself, i.e., interest in activity). Correlations between SA and those constructs are found to be positive but not very strong (the most powerful is interest with correlations in the range of $r = 0.40$). These modest relations indicate that the causal path from interest, etc. to SA is far and complex and that various mediation processes and context variables must be taken into account (Helmke and Weinert 1997).

3.3 Volitional Determinants

Motivation is a necessary but often not sufficient condition for the initiation of learning and for SA. To understand why some people—in spite of sufficient motivation—fail to transform their learning intentions into correspondent learning behavior, volitional concepts have proven to be helpful. Recent research on volition has focused on forms of action control, especially the ability to protect learning intentions against competitive tendencies, using concepts like 'action vs. state orientation' (Kuhl 1992). The few empirical studies that have correlated volitional factors with SA demonstrate a nonuniform picture with predominantly low correlations. This might be due to the fact that these variables are primarily significant for self-regulated learning (see *Self-regulated Learning*) and less important in the typical school setting, where learning activities and goals are (at least for younger pupils) strongly prestructured and controlled by the teacher (Corno and Snow 1986). Apart from that there certainly cannot be expected any simple, direct, linear correlations between volitional characteristics and SA, but complex interactions and manifold possibilities of mutual compensation, e.g., of inefficient learning strategies by increased effort.

4. Further Perspectives

In Fig. 1 only single determinants and 'main' effects of cognitive and motivational determinants on SA were considered. Actually, complex interactions and context specificity as well as the dynamic interplay between variables have to be taken into account. The following points appear important:

(a) *Interactions among various individual determinants*. For example, maximum performance necessarily requires high degrees of both intelligence and of effort, whereas in the zone of normal/average achievement, lack of intelligence can be compensated (as long as it does not drop below a critical threshold value) by increased effort (and vice versa).

(b) *Aptitude x treatment interactions and classroom context*. Whether test anxiety exerts a strong negative or a low negative impact on SA depends on aspects of the classroom context and on the characteristics of instruction. For example, high test-anxious pupils appear to profit from a high degree of structuring and suffer from a too open, unstructured learning atmosphere, whereas the reverse is true for self-confident pupils with a solid base of prior knowledge (Corno and Snow 1986). Research has shown a large variation between classrooms, concerning the relation between anxiety and achievement as well as between intelligence and achievement (Helmke and Weinert 1999). A similar process of functional compensation has been demonstrated for self-concept (Weinert and Helmke 1987).

(c) *Culture specificity*. Whereas the patterns and mechanisms of basic cognitive processes that are crucial for learning and achievement are probably universal, many relations shown in Fig. 1 depend on cultural background. For example, the 'Chinese learner' does not only show (in the average) a higher level of effort, but the functional role of cognitive processes such as rehearsal is different from the equivalent processes of Western students (Watkins and Biggs 1996).

(d) *Dynamic interplay*. There is a dynamic interplay between SA and its individual motivational determinants: SA is affected by motivation, e.g., self-concept, and affects motivation itself. From this perspective, SA and its determinants change their states as independent and dependent variables. The degree to which the mutual impact (reciprocity) of academic self-concept and SA is balanced has been the issue of controversy (skill development vs. self-enhancement approach).

School Administration as a Field of Inquiry

Inquiry on the administration of education reflects a variety of intellectual and social influences. Those influences and the main trends in the field's scholarship are examined.

1. *The Ecology of an Applied Field of Inquiry*

The ecology of an applied field of inquiry reflects its indigenous theory and research and that of related fields, demands from the worlds of policy, practice, and professional preparation, and the spirit of the times which usually mirrors societal and global trends. School administration (often educational administration) is a field of many specializations in such areas as politics, organizational studies, fiscal affairs, law, and philosophical issues or, in less-disciplined oriented areas, such as school effectiveness, leadership and supervision, human resource management and labor relations, and equity issues.

Explanations about subject matter are developed in areas of this sort. As in other fields, theoretical plausibility is judged using various logical and evidentiary criteria. However, applied fields also attend to relevance for practice and implications for assorted conceptions of organizational improvement.

2. *A Brief History*

Educational administration became a recognizable academic field in the early twentieth century in North America and later, in other parts of the world (Campbell et al. 1987, Culbertson 1988). Initially, the field was oriented to practical matters and broad issues reflecting pedagogical and societal values. An example was democratic administration, especially popular before and after World War II. In the 1950s, the field began to adopt social science theories and methods. In the mid-1970s, the subjectivistic, neo-Marxist (largely as critical theory), and identity politics perspectives, already popular in the social sciences and humanities, reached the field, with postmodernism a later addition. These perspectives typically were critical of science, which generated extensive debate.

The social science emphasis led to specialization along disciplinary lines that resulted in considerable research, much of it reported in the *Encyclopedias of Educational Research* issued in roughly 10-year cycles, with 1992 the most recent, in two *International Encyclopedias of Education* issued in 1975 and 1994, and in the first *Handbook of Research on Educational Administration* (Boyan 1988). The second *Handbook* (Murphy and Louis 1999) was more fragmented and factious, often mixing research with philosophical commentary.

3. *Current Trends*

Current trends in inquiry into school administration include conflicting views of knowledge and ethics, efforts to bridge the gaps between theory on the one hand and policy and practice on the other, more attention to making sense of complexity, and an emerging literature on comparative international aspects of school administration.

3.1 *Conflicting Views*

The controversies about knowledge and appropriate methods of seeking it, and about ethics, are ultimately philosophical. The contending positions are similar across the social sciences and humanities, although each field's literature reflects its peculiarities.

The main strands of contending thought are grounded in different general philosophies. Subjectivism, a version of idealism, stresses mind, reason,

and intuition. Science is criticized for devaluing humanistic concerns in favor of objectivity. In ethics, there is usually a hierarchy of values with the highest being absolute. In educational administration, Greenfield was this movement's leading early figure, while Hodgkinson remains its best known scholar, with special contributions to ethical theory (Willower and Forsyth 1999; see also relevant entries in the 1992 *Encyclopedia of Educational Research* and the 1994 *International Encyclopedia of Education*).

Critical theory, with its historical roots in the Frankfurt School's search for a more contemporary Marxism, is devoted to a reformist agenda (revolution is out of fashion) and an ethic of emancipation. Its ideology now goes beyond class to stress race and gender, although advocates of identity politics may not endorse critical theory. Suspicious of science, described as serving the purposes of the ruling class, critical theory's literature attends mainly to unjust social arrangements. There are many adherents across subfields of education, with William Foster noteworthy in educational administration. Generally, they contend that schools serve the powerful, giving short shrift to the disadvantaged. The antidote is political action, including radicalized educators.

Postmodernists and poststructuralists reject metanarratives or broad theories of every kind, including scientific and ethical ones, believing such theories totalize and ignore difference. This leads to an emphasis on text or words; all that is left after efforts to understand and improve the world are disallowed. Texts are deconstructed, or examined for their assumptions, including the ways they oppress and 'trivialize' otherness, by what is said and omitted. This view has only recently received much attention in educational administration: the August 1998 issue of *Educational Administration Quarterly* was on postmodernism and the September 1998 *Journal of School Leadership* featured a debate on that perspective.

In applied fields such as administration, postmodernism may be selectively combined with critical theory. This was discussed by Alvesson and Deetz (1996) and illustrated in the June 1998 issue of *Administrative Science Quarterly* on critical perspectives, where the writings of Foucault on power and control were often cited. It remains to add that Derrida, perhaps the leading scholar in the postmodern-poststructuralist camp, recently (1994) appeared to argue for a relaxing of strictures against metanarratives to allow for radicalized critique, which is what deconstruction has been all along. This suggests recognition that postmodern relativism and nihilism have made it irrelevant to the world of human activity and practice.

Adherents of the views sketched often associate science with positivism, a long dead perspective that flourished in the Vienna Circle (1924–1936). Using stringent standards of verification, positivists saw metaphysics as pointless, and values as mere preferences. Although it held on longer in fields such as psychology, positivism lost favor and was folded into the more trenchant analytical philosophy. Nevertheless, positivism has been disinterred to serve as a target in philosophical disputes.

Naturalistic and pragmatist philosophies have been the main sources of support for proponents of scientific inquiry in educational administration. Science is seen as a human activity that seeks explanations of how things work, that can be subjected to public assessment. It is an open, growing, enterprise that is fallible but self-corrective, as better methods and theories displace older ones. Based on logic and evidence, its results have been highly successful from the standpoints of the development of plausible theories and of benefiting humankind. Claims about uncovering an ultimate reality or final truths are not made; they are inconsistent with a self-rectifying conception of inquiry. In ethics, absolute principles and pregiven ideologies are rejected in favor of an inquiry-based process that examines moral choices in concrete situations. Competing alternatives are appraised in terms of likely consequences using relevant concepts and theories, and by clarifying applicable principles. Such principles are derived from cumulative moral experience and are guides, not absolutes (see Willower and Forsyth 1999).

These contrasting philosophical approaches were sketched to suggest the substance of contemporary debate, because of their implications for scholarship in school administration. Qualitative research, for instance, is a mainstay of subjectivists and those critical theorists who do 'critical ethnography.' Postmodernists are less explicit about research, but several articles in the *Educational Administration Quarterly* issue on postmodernism reported field research. Qualitative studies were done in educational administration long before these views gained popularity, but have become more widespread, and the literature now includes work aimed at demonstrating injustices, rather than building theory. Changing philosophical emphases can legitimate new subject matter and methods, as shown by comparing the second *Handbook of Research on Educational Administration* (Murphy and Louis 1999) with the first (Boyan 1988).

However, philosophical influences are filtered by variations of interest and practice. Work may borrow selectively, sometimes from conflicting philosophies, or tailor philosophical ideas to special purposes, or ignore them entirely. For instance, in ethics, single concepts such as equity, caring, or community often are stressed, sometimes along with visions of the ideal school. More philosophical explorations of moral principles and their applications are scarcer. In epistemology, many writers in antiscience camps argue against positivistic 'hegemony,' while ignoring formidable views of inquiry. Hence, many disputes are about politics rather than theories of knowledge. In educational administration, examples of broad philo-

sophical efforts are Evers and Lakomski's joint work on epistemology and Hodgkinson's and Willower's respective approaches to ethics and to inquiry (See Boyan 1988 and Willower and Forsyth 1999).

The substitution of politics for philosophical substance can be found in most social sciences and humanities, reflecting the influences of critical theory, postmodernism, and identity politics. Various commentators see these influences as declining because of their one-sidedness and practical irrelevance. However, they remain visible, claiming a share of the literatures of assorted specializations, including educational administration.

3.2 Theory and Practice

In school administration, current issues command much attention; theoretical discussions have a more specialized appeal. Devolution, school site based management, and restructured decision processes are examples of a type of contemporary reform that is the object of wide attention. Such reform results from recent trends in government and politics, but also is the current incarnation of a long line of participatory-type schemes, especially seen in Western countries. They range across democratic administration, human relations, organizational development, open climates and participatory styles of leadership, organizational health, and staff empowerment. This sort of reform is oriented to practice, but has theoretical grounding because openness and participation are often held to be paths to organizational improvements, such as increased staff motivation and commitment. However, most school improvement efforts make demands on time, erode teacher autonomy, and disturb orderly routines, adding to staff overload. Counter forces include pressures to display legitimating progress and educator hopes for positive student outcomes. Such contradictory pressures are characteristic of attempts to improve school practices, but how they play out depends on contexts and contingencies. Another contemporary reform is privatization. It stresses consumer choice, efficiency, and economy. Often linked to efforts to change governmental policies on education, it is squarely in the political arena.

While reforms of policy and organization aim at changing practice, students of cognition and learning have sought to understand how practitioners solve problems and make decisions. Influenced by Simon and the 'Carnegie School,' this work emphasizes domain-general problem-solving processes and domain-specific knowledge. Research comparing expert and novice decision makers shows the importance of both. In educational administration, the investigations of Leithwood and his associates (Leithwood and Steinbach 1995) have been noteworthy (for other sources, see Willower and Forsyth 1999).

Professional preparation programs for school administrators use many approaches to transfer learning to practice. They include case studies, simulations (sometimes computer based), films, approximations of virtual reality, internships, and other school site based activities. Program improvement has benefited from the cooperative efforts of professorial and administrator associations (Willower and Forsyth 1999). Improving the practice of school administrators and educational reform is, like inquiry, ever unfinished. Current successes do not guarantee future ones, despite progress made in developing explanative theories, and continuing efforts to improve schools and the preparation of administrators. A barrier to the implementation of theory-based reforms are practice is the multiplicity and complexity of the influences that impinge on the schools, considered next.

3.3 Making Sense of Complexity

School administration appears to be more complex than many forms of management. Schools tend to be vulnerable to community and societal forces, are usually subject to substantial regulation (no surprise since they serve society's children), and have difficulty demonstrating effectiveness. The latter occurs because of the complexity of showing the school's part in student learning vs. that of family, variations in student motivation and ability, and other factors. Further, schools are commonly expected to foster subject matter achievement and acceptable social skills and conduct. Beyond that, school administrators oversee personnel who ordinarily define themselves as professionals and value latitude in their work. Thus, school organizations are characterized by external pressures and internal forces that heighten complexity. In addition, social changes have placed new demands on schools as societal arrangements that provided regulatory settings for children and youth, have begun to erode. As this occurred, schools increasingly have had to cope with an array of social ills, for instance, substance abuse, vandalism, and violence, against a backdrop that too often includes dysfunctional families and subcultures with norms that devalue learning, along with the miseducative effects on young people of ubiquitous mass media. As a result, many schools face expanded responsibilities, adding new complexities to the administration of schools.

Such complexity can be daunting. One response in education, as in business, has been a susceptibility to fads, with total quality management as a recent example. These fads may include some reasonable ideas, commonly packaged as part of a larger program. Although often treated as panaceas, they are typically short-lived. Such fads can be explained as attempts to give perceived legitimacy to organizational efforts to confront what in reality are intractable problems.

While practitioners adapted to changing social conditions and increasing complexity, those who study school administration sought to gain a better understanding of such phenomena. More sophisticated

quantitative analyses facilitated by computer technology provided ways of examining relationships among many variables in numerous combinations, clusters, and sequences. Although empirical investigations rarely employed such analyses, their availability provides possible handles on complexity. More popular recently have been field studies, done as participant observation, ethnography, or case studies. While qualitative methods are favored by those wishing to advance a particular view using illustrations from selected 'narratives,' more traditional field work has long sought to plumb complexity by attending to the details of daily activity. Disputes about qualitative vs. quantitative research are not new, mirroring the richness vs. rigor debates in sociology in the 1930s (see Waller 1934). In educational administration, the dominant view appears to favor the use of a variety of methods recognizing that each has strengths and weaknesses. In any event, empirical studies in quantitative and qualitative modes have sought to make complexity more understandable, albeit in different ways.

The increased recognition of complexity has rekindled interest in chaos theory in educational administration and the social sciences. Chaos theory, it is well to recall, is not a denial of the possibility of orderliness. Rather it is a search for odd, intricate, or many faceted patterns. Reviewing chaos scholarship, Griffiths et al. (1991) concluded enthusiasm for the theory had not resulted in meaningful social research. They suggested that chaos theory has limited applications in educational administration because of the theory's dependency on precise measures. Conceptual efforts to accommodate fluidity and fluctuation are not new. To cite others, they range from Hegelian dialectical analysis with its clash of opposites, followed by a new synthesis, to threshold effects noted only when a variable reaches a certain level, with little or no gradation, to equifinality or functional equivalents where similar results stem from different sources. Ethical theory has also been concerned with complexity. Perspectives that recognize how moral choices are embedded in elaborate contexts, and attempt to include potential consequences of action as part of choice, are illustrative. Related are cognitive-type studies of problem solving and decision making and work on types of intelligence and their relationship to problem solving.

Clearly, human experience is fluid and complex, and human behavior is often irrational and contradictory. Yet, in inquiry, the irrational is apprehended through rational processes, and experience is known through the use of concepts and explanations. Obviously, concepts and theories simplify, but so do intuition, lore, pregiven ideologies, aphorisms, and other ways of confronting experience. Nothing comprehends everything. The trick, in science and administration, is to include the relevant elements and get to the heart of the problem. The record on understanding complexity in school administration, as in the social sciences, is one of incremental gain. The methods of scientific inquiry can make complexity more comprehensible and more manageable, but there are no panaceas.

3.4 Internationalization

Educational administration is becoming internationalized. New preparation programs and journals are cropping up around the world. Established outlets such as the *Journal of Educational Administration* and *Educational Administration Quarterly* regularly feature comparative-international pieces, and research done cooperatively by investigators in different countries is increasingly appearing, as for example, in the July 1998 issue of the *Journal of School Leadership*. In addition to the *International Encyclopedias of Education*, *World Yearbooks of Education*, and others, new works are being published, for example the 1996 *International Handbook of Educational Leadership and Administration*. Scholarly associations such as the University Council for Educational Administration (in North America) and the Commonwealth Council for Educational Administration and Management continue to develop cooperative activities.

Internationalization presents opportunities for inquiry that take advantage of different societal-cultural settings to examine the impact of contingencies on behavior and outcomes. Such research can show how the relationships of the variables under study are mediated by setting variables. This, in turn, can lead to new theoretical explanations, not to mention better international understanding.

School (Alternative Models): Ideas and Institutions

Ever since its beginnings at the turn of the eighteenth to nineteenth century, the modern educational system has been accompanied by alternative schools, the numbers and broad effects of which have varied over the course of the years. This coexistence is by no means based on independence, but is the manifestation of complex reciprocal relations which exist despite fundamental differences in the ideologies of the two approaches. Phases of intensive development in the domain of traditional schools have been mirrored by similar phases of intense activity in the alternative school movement; alternative schools fulfill important functions within the general spectrum of educational possibilities.

1. *Background and Conception*

Because proponents of alternative schooling are critical of contemporary manifestations of the traditional school system, the focus of their critique has shifted over time. In general, however, their criticism is based on objections to the structures and functions of the modern school. They do not restrict their demands to a return to earlier historical epochs and structures in which schools still played a minor role. Their objectives are for duress (compulsory education and instruction) to be replaced by freedom; teacher-directed schooling and instruction by self-directed action on the part of the student; the curriculum by the individual needs of the student; competition and rivalry by community; compartmentalization by wholeness and integral methods in instruction; the separation of life and school by an interweaving of the two spheres (e.g., Holzman 1997). The fundamental criticism of traditional schooling is based on the conviction that this form of education is burdened by a basic contradiction: Although adults—and particularly adults living in modern democracies—are granted dignity, majority, and self-determination, children and adolescents at school are denied these basic rights, albeit on the pretext that they first have to learn how to exercise them. Because it is not possible to recreate the historical conditions which preceded institutionalized education and its inherent ambivalences, however, the critics of traditional schooling have to resort to so-called 'counterschool' initiatives (German: *Gegenschulen*). Although some of these are embedded in a variety of alternative organizations (e.g., flat-sharing communes, communal child care, and even dietetic measures), in general it is not society that is deschooled, but school itself. The extent to which this radical rearrangement leads to the complete disintegration of institutions is dependent on its (partly unintended) consequences.

2. *Structural and Organizational Characteristics*

Pedagogical aims are reflected in the specific organizational characteristics of any given school (e.g., the general structure of the school, the relationships between teachers, parents, and students, the organization of classes, the methods implemented). In turn, these characteristics constitute the decisive prerequisites allowing many alternative institutions to exceed the norm with regard to content and in both the pedagogical and the social fields. Indeed, the typical approach of the alternative schools can be reduced to a simple formula: in contrast to the universal institutions of the traditional system, which are characterized by high levels of internal differentiation and complicated organizational structures, alternative institutions are distinguished by social clarity and immediacy owing to the fact that they are, from the outset, geared to the particularities of their respective clients. Accordingly, the student body in an alternative school on average numbers less than 200 (cf. Mintz et al. 1994). Thus, irrespective of content-related differences, the alternative school represents a special type of school or, more specifically, a type of school offering a special kind of education. While this offer may formally be an open one, it in fact only reaches the few who know how to take it up.

Due to these invisible processes of selection, alternative schools can be expected to be more or less immune to many of the problems arising in schools which really are open to all (as is made clear by the reports and evaluations of alternative schools; cf. as a very vivid example Duke and Perry 1978). In accordance with the very definition of the alternative school, however, these assets cannot readily be transferred to the mass school system as a whole. Instead of having to simultaneously meet the needs of students from different backgrounds and with various levels of qualification, alternative schools are able to respond

to individual differences and developments emanating from a more homogeneous context of attitudes and lifestyles. The additional potential for motivation and identification (in both students and teachers) which is inherent in a free choice of school or in the decision to embark upon a rather unusual experiment constitutes another factor which cannot easily be transferred to the traditional school. As a rule, 'counterschools' are spared the arduous coordination of pedagogical subfunctions on the basis of a division of labor: because of the small size of these institutions, instruction and education, counseling and care all rest in the hands of a few. Instead of having to strictly adhere to general and at least partly formulated rules in order to ensure the smooth running of the school and its classes, confidence in the closer personal ties and connections of the school community makes it possible to act more effortlessly, easily, and flexibly. Finally, the danger of merely running out of inspiration within the confines of internal school processes is reduced, as the high levels of input from the local environment mean that the system's contours remain rather diffuse. The close links between the home and the school, which are not limited to financial support, but also involve the parents' practical cooperation, can be seen as another important asset.

3. *Developments Since the 1960s*

The concepts behind alternative schooling and its implementation reach far back in time, and in some respects they refer to the founders of modern educational theory (e.g., Rousseau or Herbart). Progressive education in the United States and so-called *Reformpädagogik* in Germany, both of which emerged after the end of the nineteenth century, may certainly be considered to be phases of activity to which a number of existing institutions can be traced back (e.g., Semel and Sadovnik 1999). However, the main wave of alternative school foundation resulted from political and social conditions including the failure or petering out of large-scale attempts at educational reform (e.g., Carnie et al. 1996); this holds especially for the Anglo-American countries since the 1960s. Most of the alternative institutions founded during this phase were set up in the United States, and the majority are still to be found there (cf. Mintz et al. 1994). Although less than 5 percent of students at elementary and secondary school actually attend alternative schools, the institutions now number several thousands in the United States, most of them elementary schools. The institutions are highly divergent in terms of their targets, methods, integration of parents and students, links with the traditional system, locus of control, and circles of addressees. It would thus seem justified to focus this overview of alternative schooling since the 1960s on the situation in the United States, all the more so because both the fundamental principle of alternative schools ('as many institutions as there are needs and groups') and current trends in development (adopting the tasks of the traditional system) are to be observed there.

One important form of alternative education is home schooling (cf. Evans 1973), where parents instruct their children at home with the permission of the state. If—as is quite often the case—these children meet up with other home students in (elementary) schools on single days of the week, there is a sliding transition to school cooperatives aiming at unconstrained, playful, spontaneous learning in open instruction. Other institutions specifically target problematic cases, so-called at-risk students, including not only chronic truants and low-performing students, but also talented nonconformers (in the broadest sense). A well-balanced program of drill and freedom is intended to render school attractive again, thus helping these students to enhance their performance.

However, this development has also led to a reverse trend, a sort of back-to-basics shift to formal 'three Rs' schools, which specifically emphasize the basic skills, discipline, and respect for the authority of parents and teachers (cf., e.g., Deal and Nolan 1978). Similar trends are to be observed at the secondary level. The large number of schools-within-schools—smaller, less complex units running different experimental programs, and affiliated to larger state schools—is particularly notable. The spectrum also includes schools attempting to set themselves up as 'just community schools' based on the principles of Kohlberg's developmental theory (cf. Kohlberg 1985). The so-called 'schools without walls' represent another form of alternative education. They not only offer a 'normal' curriculum (differing from that of the traditional school in terms of content and time), but give students the opportunity to learn in the adult world. This is intended to provide students with extra-scholastic experience and to enable them to prove themselves in the world of work. Although this approach initially seemed very promising, experience has shown that it is in fact very hard to put into practice.

4. *Recent Trends and Perspectives*

Over the past few decades, there have been signs of a kind of division of function and labor between the traditional and the alternative schools in the United States. This has been expressed in an increase in the state-controlled administration of alternative institutions. The fact that such large numbers of US alternative schools were founded at the beginning of the 1980s is probably related to this development. The radical free schools (e.g., Dennison 1969), which signaled the upheavals of the 1960s and certainly provided considerable impetus for subsequent developments, play a lesser role in today's broader stream

of initiatives. The basic conceptions and expectations of alternative schooling have also been affected, resulting in the extremely short lifespan of some of these institutions. There is still a great deal of fluctuation, making it hard to make valid evaluations of these institutions (cf. the data in Mintz et al. 1994, p. 10ff.). Even the early approaches and experiments demonstrated the great weaknesses and dangers of such institutions—the cost of their structure-related advantages (cf. also Swidler 1979). Critics have reduced this to the polemic formula that precisely those principles and premises which allowed the pure 'counterschool' initiatives of the early period to emerge later threatened their ability to survive. Wherever the concept of freedom as a counterpole to the compulsory character of the traditional institutions went hand in hand with systematic shortcomings in the specification of learning targets, there was the risk that later conflicts be all the more severe due to the differing hopes and expectations of those involved (cf. Barth 1972, especially p. 108ff). When every school-related action was dependent on the consensus of every single member of the school community, the school's fate was put in the hands of changing minorities with the power of veto, all the more so when the small size of these private institutions kindled fears of sudden financial ruin. Allowing almost all of those concerned to take an active role in the decision-making process did not in fact ensure the equality of all participants—instead of increasing the capacity to solve problems, there was a growing risk of disappointment, and the necessary basic consensus was threatened by frequent conflicts and failures in minor matters. The firm and wide-ranging commitment of parents, extending well into issues of classroom practice, often resulted not so much in the enhancement as in the disturbance of school activities. Teachers were consequently made to feel insecure and were put on the defensive instead being provided with support and control. Attempts to simultaneously cope with the factual demands, organizational affairs, and personal standards inherent in these institutions—preferably without referring to preset guidelines—led to the systematic overexertion of those concerned, and the end of many 'counterschools' was marked by the burnout of the teaching staff (Dennison described this phenomenon as early as 1969). The unconditional openness with respect to the other members of the school community and the intimacy of the small group responsible for the school meant that factual disputes often escalated into personal trials. Moreover, school affairs were often overshadowed by secondary motives such as parental self-realization or the search for security.

By integrating and promoting alternative schools, the state aims to increase the diversification of the educational spectrum, to enhance the overall efficiency of schools (which has been subject to criticism for decades; cf., e.g., Goodlad 1984), and to better meet the specific needs of certain problem groups in both school and society. The US programs of community schools, magnet schools and, more recently, charter schools provide evidence for this trend, and are looked upon with growing interest by other countries as possible models for the resolution of system-related problems. However, more detailed analyses of these models point to significant limitations in their problem-solving capacity, limitations which are ultimately rooted in the basic concepts of market and choice (cf. Lauder et al. 1999). The community schools program has already been thwarted by the US authorities' desegregation measures: although these schools were directed at the advancement of members of the underprivileged minorities, most of whom are colored, they undermined the desired objective of racial integration. Magnet schools were supposed to be a free choice of school with a special educational program which acted like a magnet, attracting students from beyond the racial boundaries marked out in residential areas and school districts. They were intended to promote racial integration, which can scarcely be achieved through the compulsory measure of busing. A number of objections have been voiced against this school form. For example, it is argued that the enlargement of catchment areas weakens the link between the school and the parental home. Furthermore, although magnet schools may well establish a balanced relation between whites and blacks in their own student bodies, there are too few magnet schools to ensure social compensation on a large scale.

Moreover, there is an imperceptible shift in their circle of addressees: instead of reaching the underprivileged, out-of-school colored population with their specific educational provision, magnet schools in fact seem to appeal to white parents and their children who would otherwise switch to private schools or the more privileged suburbs (cf. Smrekar and Goldring 1999).

The charter schools, on the other hand, which in a way transfer the principles of the private school (i.e., the autonomy of schools and a free choice of school) to the state school system, are faced with comparable problems on a different level inasmuch as unforeseen side effects have been revealed in the social process. Despite the fact that the numbers of charter schools have increased considerably over the past few years, they are still far from ever being able to constitute the majority of state schools, belonging by definition to the optional domain of educational provision. The half-hearted legislative reservations perceptible in most of the federal states against according too many privileges to these schools threaten to render the entire charter program futile (cf. Hassel 1999).

School as a Social System

A 'social system' is a set of related elements that work together to attain a goal. Social scientists have frequently employed the concept of a social system to study the school. This has been done in three ways. First, the class has been portrayed as a social system; its elements include the teacher, the students, and formal and informal groups within the class. Second, the school itself has been viewed as a social system; its components are the administration, faculty, counselors, students, academic departments, the curriculum, the extra curriculum, and social networks and other subunits within the school. Third, the school has been seen as one of a number of subunits in the larger social system of society (Gordon 1957, Loomis and Dyer 1976, Parsons 1961, Smelser 1988).

1. *Viewing the School Class as a Social System*

The most familiar application of the social system model to schools is found in Parsons' (1959) classic essay on the school class as a social system. Parsons focuses on the class, rather than the larger unit of the school, because he sees the class as the primary place where students learn and mature. According to Parsons, the two most important functions of the class are 'socialization' and 'allocation.' These functions define and motivate the academic and social processes that occur in the classroom and the interactions that occur among its various components.

1.1 *Socialization*

Socialization is the process through which students internalize the kinds of commitments that they need to play a useful role in adult society. Although the family and community also socialize students, the length of time students spend in school makes the school class a major influence in the socialization process. Time spent in school during the students' formative years provides ongoing opportunities for systematic, intensive socialization. During this time, students are expected to accept societal values and use them to guide their behavior.

Parsons claims that several structural characteristics of the class facilitate the socialization of students. First, students assigned to the same class are fairly homogeneous with respect to age and social development. They are also somewhat homogeneous with respect to social class, since class composition is constrained by the socioeconomic characteristics of the neighborhood in which the school is located. The developmental and socioeconomic homogeneity of the students assists the teacher in transmitting values to the students who become, in turn, models of appropriate behavior for each other.

Second, students in the same class are under the tutelage of one or a small number of adult teachers. The age difference between the teacher and students supports the teacher's authority. The singular role of the teacher as the representative of adult society lends legitimacy to the teacher's values.

A third structural feature of the school class is the curriculum. Pupils are exposed to the same curriculum and assigned the same tasks. A shared curriculum and similar activities allows the teacher to reinforce cultural values and attitudes in multiple ways over the school year.

A fourth structural feature of the class is its reward structure. Teachers generally establish a set of rewards

and punishments governing student behavior in a classroom. Good behavior, defined by the teacher's values, is rewarded, while disruptive actions are sanctioned. Students learn the rules of conduct that apply to social and work situations, and are motivated to obey these rules by the rewards or punishments their behaviors incur.

1.2 Allocation

Allocation is the process of sorting individuals and assigning them to groups based on their ability or skills. In a school, allocation refers to the assigning of students to instructional units according to their abilities or achievement. The purpose of this sorting process is to prepare students to attain an occupational position in society commensurate with their capabilities (Gamoran et al. 2000, Hallinan 1994, Lynch 2000, Oakes 1994).

Parsons defines achievement as excellence, relative to one's peers, in meeting the expectations of the teacher. Achievement has two components: cognitive and moral. Teachers attempt to motivate students to achieve academically and to learn the skills needed to perform in adult society. They also teach students a moral code and a set of behaviors consistent with the values of adult society. Students are evaluated on each of these two components. Society may assign greater weight to one component than the other or may treat them as equally important. As with socialization, structural differentiation occurs through a process of rewarding students for excellence and punishing them for failure to meet teacher expectations.

In the elementary school classroom, the criteria for excellence are not clearly differentiated across cognitive and moral dimensions. Teachers aim to develop both good citizenship and an achievement motivation in children. They also begin the process of classifying youth on the basis of their ability to achieve. While assigning students to classes by ability typically does not occur in elementary school, many elementary school teachers instruct their students in small, ability-based groups within the classroom. Their purpose is to facilitate instruction and to prepare students for later channeling into ability-based classes. This initial sorting sensitizes students to the differential achievement that characterizes a class and to the way rewards are allocated for performance.

At the secondary level, the cognitive and moral components of achievement are separable, and greater emphasis is placed on cognitive achievement. Parsons claims that students who achieve academic excellence in high school are better suited for technical roles in society, while those who excel in the moral or social sphere are more fit for socially oriented roles. The actual sorting of students in high school typically occurs by assigning students to classes for instruction based on their ability level. Since ability-grouped classes vary by student and teacher characteristics and by the curriculum, they represent different social systems within the school.

The conceptual attraction of the social system model of the classroom has stimulated a body of research over the past few decades. The model depicts how the teacher, formal and informal groups, and individual students interact in the classroom and perform or cooperate with the functions of socialization and allocation. Examples of research based on this model include studies of teacher expectations, the quantity and quality of teacher–student interactions, gender and race effects on task-related and social interactions, peer influences and student friendship groups.

2. Viewing the School as a Social System

Researchers are more likely to focus on the school, rather than the classroom, when utilizing the social system model to analyze education. Like the class, the school must perform the functions of socialization and allocation in order to play its assigned role in society. Viewing the school as a social system directs attention to how the parts of a school interact to carry out these functions.

2.1 Socialization

For students to be socialized successfully in school, they must cooperate in their education. They are less likely to resist if they accept the authority of their teachers and believe that the school's policies and practices are fair. When students agree with school policies and practices, they are unlikely to resist socialization. With student cooperation, a school is expected to attain its goal of graduating students who have internalized societal values and norms beyond those held by their families.

2.2 Allocation

To attain its goal of allocation, a school must locate students on an achievement hierarchy, defining each person's capability and aspirations. A critical factor in the school's ability to allocate students is that both the family and school attach high value to achievement (Parsons 1959). When adults view student achievement as a high priority, students are more likely to internalize the motivation to achieve and to cooperate with adults as they orient students toward specific adult roles. When schools succeed in this effort, they match society's human resources with its adult occupational structure.

The primary mechanism for the allocation process is the organizational differentiation of students for

instruction by ability. Middle and high schools in the United States typically assign students to Academic, Vocational, and General tracks. Students assigned to the Academic track take college preparatory courses, those assigned to the Vocational track take skills and job-related courses, and students assigned to the General track are offered both low-level academic courses and skills courses. Track assignment is a major determinant of whether a student advances to college or enters the job market after graduation.

Theoretical and empirical studies demonstrate the way various parts of a school interact to socialize students and prepare them for the labor market. Research on the school as a bureaucracy, on the formal or informal organization of the school, and on social networks within the school, illustrates this approach. These and other studies demonstrate the heuristic value of conceptualizing the school as a social system and show how this model has integrated a wide variety of studies about schooling.

3. *Viewing the School as a Subsystem in Society*

Many social scientists have used the social system model to analyze the role of various institutions in society. Education is seen as one of society's primary institutions, along with religion, the economy, and the judicial system. The aim of a social system approach to the study of schools in society is to ascertain how schooling enables society to achieve its goals.

3.1 Structural Functionalist Perspective on Schools in Society

A theoretical perspective that dominated early twentieth century societal analysis was structural functionalism (Durkheim 1956, Parsons 1951). A major premise of structural functionalism is that a society must perform a set of functions in order to survive. According to Parsons (1956), these functions are: obtaining and utilizing resources from the system's external environment; setting goals for the system and generating the motivation and effort to attain these goals; regulating the units of the system to insure maintenance and to avoid destructive conflicts; and storing and distributing cultural symbols, ideas, and values. Schools perform these functions by socializing students to societal values, by providing a common culture and language, by enabling and encouraging competition, and by preparing students for the labor market.

Structural functionalism purports that a social system must exist in a state of equilibrium or, if disrupted, must make adjustments to restore balance. If one social institution in society undergoes major change, interrelated social institutions are expected to accommodate this change and to bring society back to a stable state. For example, if the economy of a society were to change, students would need to be socialized and allocated in different ways to support the new economic structure. The social system would then be restored to balance, though it would differ structurally from its original state.

3.1.1 Limitations of the structural functionalist model. The structural functionalist perspective has been challenged on many grounds. The most common criticism questions its assumption of systemic equilibrium. Critics claim that structural functionalism ignores the processes of social change internal to a social system. They argue that the relationship among the parts of a social system tends to change over time and that the social system that emerges as a result of these changes may differ fundamentally from the original system.

Another criticism of structural functionalism regards its claim that a social system continues to operate as intended if all the parts of the system perform their functions. This assumption fails to take into account the possibility of external shocks to the system. An external shock could alter the pattern of interactions among the system's parts in such a way as to disrupt its stability, leading to a basic restructuring of the system or, possibly, to its disintegration.

Finally, the structural functionalist perspective has been criticized on ideological or political grounds. Critics claim that a structural functionalist perspective portrays the school as an institution that supports and perpetuates the existing social order and its stratification system. They argue that while schools reward students for ability and achievement, they also maintain the influence of ascribed characteristics on adult success. Structural functionalists fail to analyze the extent to which schools preserve a class-based society.

Not only does structural functionalism ignore the way schools perpetuate the status quo; it also fails to explain how ascriptive characteristics mediate the effects of achievement after graduation. By linking occupational success to organizational characteristics of schools and academic achievement, structural functionalism fails to explain the poor fit that often exists between a student's skills and abilities and the student's future place in the labor market. Critics of structural functionalism argue that a job seeker can often negotiate with a prospective employer, and that this process allows an individual's ascribed characteristics and social status to influence job placement.

In short, structural functionalism is generally viewed as a static theory, which only partially describes the interactions in a school system, or between schools and the rest of society. Even when social change is incorporated into the model, the change is not seen as leading to a radical transformation of the school. As a result, the theory fails to depict the more dynamic and controversial dimensions of schooling. Nevertheless, structural functionalism has been a useful theoretical

perspective to explain how schools and classrooms function as social systems under certain conditions in society.

3.2 Conflict Perspective on the School as a Social System

Conflict theory (Bowles and Gintis 1976, Collins 1971) is an alternative theoretical model for the analysis of the school as a social system. Conflict theory posits competition as the major force driving societal development. While structural functionalism views technological needs and economic growth as the major influences on society, conflict theory argues that competition for wealth and power is the primary state of society and social change is its inevitable result.

According to conflict theory, ascribed characteristics are the basis of elite status. Collins (1971) argues that the continuing effort of the elite to exert control over lower status groups creates an ongoing struggle for power and prestige. Conflict theory specifies conditions under which subordinates are likely to resist the domination of superiors through noncompliance and resistance. Under conditions of economic hardship, political turmoil, or cultural conflict, nonelites are more likely to resist domination and to challenge the relationship that exists between education and occupation. Their discontent typically precipitates social change.

Conflict theory not only explains the relationship between education and occupation; it also yields insights into the power struggles that occur between schools and other social groups in society. For example, during the student movement in the USA in the 1960s and 1970s, students resisted authority and the status quo. Tensions and disruptions continued until students were granted a greater voice in university affairs and in political life. Current controversies about school prayer, sex education, curriculum content, racial integration, and school vouchers are led by competing interest groups. These controversies are likely to lead to compromises that involve some redistribution of authority and power.

The power struggle that occurs in society may also be observed in the school and in the classroom. In schools, students create their own value system that may be inconsistent with the school's academic goals. The tests and grades administered by schools as a sorting mechanism may be viewed as a way to maintain the status quo, to enforce discipline and order, or to co-opt the most intelligent of the lower classes. In the classroom, students may challenge teacher authority and negotiate teacher power through resistance.

By directly addressing the relationship between conflict and social change, 'conflict theory' supplements structural functionalism in explaining the behavior of schools in society and in predicting social change. Both theories point to important aspects of the dynamics of social systems. As stressed by structural functionalists, schools do socialize and allocate students, mostly by meritocratic criteria. But conflict theorists are correct in maintaining that nonmeritocratic factors also influence the allocation process. Structural functionalists are accurate in stating that students typically cooperate with teachers in the learning process, but conflict theorists recognize that some students resist authority and rebel. Further, conflict occurs in communities, schools, and classrooms, but it is not always class-based. Relying on the insights of both theories increases our understanding of schools in society.

4. Coleman's Analysis of the School as a Social System

In his last major work on social theory, Coleman (1990) argued explicitly that the aim of sociology is to explain the behavior of social systems. He pointed out that social systems might be studied in two ways. In the first approach, the system is the unit of analysis and either the behavior of a sample of social systems are studied or the behavior of a single social system is observed over time. Coleman's (1961) study of the adolescent subculture follows this strategy. The second approach involves examining internal processes in a social system, including the relationships that exist among parts of the system. Research on the association between track level in high school and a student's growth in academic achievement is an example of linking a sub-unit of a school to an individual. Studies of the transition from school to work illustrate the relationship between two subunits of society, education and the labor market.

Social system analysis involves explaining three transitions: macro to micro, micro to micro, and micro to macro level transitions (Alexander et al. 1987, Collins 1981, Knorr-Cetina and Cicourel 1981). The macro to micro transition involves the effects of the social system itself on subunits (typically individuals) in the system. An analysis of the effects of ability group level on students' educational aspirations is an example. The micro to micro transition links characteristics of subunits in the social system to the behavior of those subunits. An example is an analysis of the effects of gender on achievement. Finally, the micro to macro transition pertains to how the behavior of subunits in a social system influences the social system as a whole. Research on the effects of student achievement on the way the school organizes students for instruction is illustrative.

Coleman argued that the micro to macro transition is the most difficult to analyze, because it requires specifying the interdependency among subunits or individuals in a social system. His theory of purposive action provides a way to model this transition. In general, Coleman's insistence that the study of social

systems includes an explicit focus on the transitions that exist between macro level and micro level processes in the social system promises to draw greater attention to the social system approach to the study of schooling in society.

5. Conclusions

Conceptualizing the school as a social system is a useful approach to the study of schools. The social system model has led to new theoretical insights about how education, as an institution, affects other societal institutions. It has also generated a significant body of empirical research that demonstrates the interdependence of sub-units in a school and of schools within larger organizational units and their effects on social outcomes. These studies have yielded a better understanding of the role schools play and the contribution they make to contemporary social life.

School Effectiveness Research

1. School Effectiveness and School Effectiveness Research

In the most general sense 'school effectiveness' refers to the level of goal attainment of a school. Although average achievement scores in core subjects, established at the end of a fixed program are the most probable 'school effects,' alternative criteria like the responsiveness of the school to the community and the satisfaction of the teachers may also be considered.

Assessment of school effects occurs in various types of applied contexts like the evaluation of school improvement programs or comparing schools for accountability purposes, by governments, municipalities, or individual schools.

School effectiveness research attempts to deal with the causal aspects inherent in the effectiveness concept by means of scientific methods. Not only are assessment of school effects considered, but particularly the attribution of differences in school effects to malleable conditions. Usually, school effects are assessed in a comparative way, e.g., by comparing average achievement scores between schools. In order to determine the 'net' effect of malleable conditions, like the use of different teaching methods or a particular form of school management, achievement measures have to be adjusted for intake differences between schools. For this purpose student background characteristics like socioeconomic status, general scholastic aptitudes, or initial achievement in a subject are used as control variables. This type of statistical adjustment in research studies has an applied parallel in the strive for 'fair comparisons' between schools, known under the label of 'value-added.'

2. Strands of Educational Effectiveness Research

School effectiveness research has developed as a gradual integration of several research traditions. The roots of current 'state-of-the-art' school effectiveness

Figure 1
A basic systems model of school functioning

research are sketched by briefly referring to each of these research traditions.

The elementary design of school effectiveness research is the association of hypothetical effectiveness-enhancing conditions of schooling and output measures, mostly student achievement. A basic model from systems theory, where the school is seen as a black box, within which processes or 'throughput' take place to transform inputs into outputs. The inclusion of an environmental or context dimension completes this model (see Fig. 1). The major task of school effectiveness research is to reveal the impact of relevant input characteristics on output and to 'break open' the black box in order to show which process or throughput factors 'work,' next to the impact of contextual conditions. Within the school it is helpful to distinguish a school and a classroom level and, accordingly, school organizational and instructional processes.

Research tradition in educational effectiveness varies according to the emphasis that is put on the various antecedent conditions of educational outputs. These traditions also have a disciplinary basis. The common denominator of the five areas of effectiveness research that will be distinguished is that in each case the elementary design of associating outputs or outcomes of schooling with antecedent conditions (inputs, processes, or contextual) applies.

The following research areas or research traditions can be distinguished:

(a) Research on equality of opportunities in education and the significance of the school in this.

(b) Economic studies on education production functions.

(c) The evaluation of compensatory programs.

(d) Studies of unusually effective schools.

(e) Studies on the effectiveness of teachers, classes, and instructional procedures.

For a further discussion of each of these research traditions the reader is referred to Scheerens (1999). A schematic characterization of research orientation and disciplinary background is given in Table 1.

3. *Integrated School Effectiveness Research*

In recent school effectiveness studies these various approaches to educational effectiveness have become integrated. Integration was manifested in the conceptual modeling and the choice of variables. At the technical level multilevel analysis has contributed significantly to this development. In contributions to the conceptual modeling of school effectiveness, schools became depicted as a set of 'nested layers' (Purkey and Smith 1983), where the central assumption was that higher organizational levels facilitated effectiveness enhancing conditions at lower levels (Scheerens and Creemers 1989). In this way, a synthesis between production functions, instructional

Table 1
General characteristics of types of school effectiveness research

	Independent variable type	Dependent variable type	Discipline	Main study type
(a) (un)equal opportunities	socioeconomic status and IQ of pupils, material school characteristics	attainment	sociology	survey
(b) production functions	material school characteristics	achievement level	economics	survey
(c) evaluation compensatory programs	specific curricula	achievement level	interdisciplinary pedagogy	quasi-experiment
(d) effective schools	'process' characteristics of schools	achivement level	interdisciplinar pedagogy	case-study
(e) effective instruction	characteristics of teachers, instruction, class organization	achievement level	educational psychology	experiment, observation

Figure 2
An integrated model of school effectiveness (from Scheerens 1990)

effectiveness, and school effectiveness became possible by including the key variables from each tradition, each at the appropriate 'layer' or level of school functioning (the school environment, the level of school organization and management, the classroom level, and the level of the individual student). Conceptual models that were developed according to this integrative perspective are those by Scheerens (1990), Creemers (1994), and Stringfield and Slavin (1992). The Scheerens model is shown in Fig. 2.

Exemplary cases of integrative, multilevel school effectiveness studies are those by Brandsma (1993), Sammons et al. (1995), and Grisay (1996).

In Table 2 (cited from Scheerens and Bosker 1997) the results of three meta-analyses and a re-analysis of an international data set have been summarized and compared to results of more 'qualitative' review of the research evidence. The qualitative review was based on studies by Purkey and Smith (1983), Levine and Lezotte (1990), Scheerens (1992), and Sammons et al. (1995). The results concerning resource input variables are based on the re-analysis of Hanushek's (1979) summary of results of production function studies that was carried out by Hedges et al. (1994). As stated before this re-analysis was criticized, particularly the unexpectedly large effect of per pupil expenditure.

The results on 'aspects of structured teaching' are taken from meta-analyses conducted by Fraser et al. (1987). The international analysis was based on the IEA Reading Literacy Study and carried out by Bosker (Scheerens and Bosker 1997, Chap. 7). The meta-analysis on school organizational factors, as well as the instructional conditions 'opportunity to learn,' 'time on task,' 'homework,' and 'monitoring at classroom level,' were carried out by Witziers and Bosker and published in Scheerens and Bosker (1997, Chap. 6). The number of studies that were used for these meta-analyses varied per variable, ranging from 14 to 38 studies in primary and lower secondary schools.

The results in this summary of reviews and meta-analyses indicate that resource-input factors on average have a negligible effect, school factors have a small effect, while instructional variables have an average to large effect. The conclusion concerning resource-input factors should probably be modified and somewhat 'nuanced,' given the results of more recent studies referred to in the above, e.g., the results of recent studies concerning class-size reduction.

There is an interesting difference between the relatively small effect size for the school level variables reported in the meta-analysis and the degree of certainty and consensus on the relevance of these factors in the more qualitative research reviews.

It should be noted that the three blocks of variables depend on types of studies using different research methods. Education production function studies depend on statistics and administrative data from schools or higher administrative units, such as districts or states. School effectiveness studies focusing at school level factors are generally carried out as field studies and surveys, whereas studies on instructional effectiveness are generally based on experimental designs.

4. *Foundational and Fundamental School Effectiveness Studies*

Foundational school effectiveness studies refer to basic questions about the scope of the concept of school effectiveness. Can a school be called effective on the basis of achievement results measured only at the end of a period of schooling, or should such a school be expected to have high performance at all grade levels? Can school effectiveness be assessed by examining results in just one or two school subjects, or should all subject matter areas of the curriculum be taken into account? Also, shouldn't one restrict the qualification of a school being effective to consistently high performance over a longer period of time, rather than a 'one shot' assessment at just one point in time?

Fortunately all of these questions are amenable to empirical research. These type of studies that are associated with the consistency of school effects over grade-levels, teachers, subject-matter areas, and time

Table 2
Reviews of the evidence from qualitative reviews, an international study, and research syntheses; coefficients are correlations with student achievement (the plus signs in the table refer to a positive assessment of the variable in question in the reviews).

	Qualitative reviews	International analyses	Research syntheses
Resource input variables:			
Pupil–teacher ratio		−0.03	0.02
Teacher training		0.00	−0.03
Teacher experience			0.04
Teachers' salaries			−0.07
Expenditure per pupil			0.20
School organizational factors:			
Productive climate culture	+		
Achievement pressure for basic subjects	+	0.02	0.14
Educational leadership	+	0.04	0.05
Monitoring/evaluation	+	0.00	0.15
Cooperation/consensus	+	−0.02	0.03
Parental involvement	+	0.08	0.13
Staff development	+		
High expectations	+	0.20	
Orderly climate	+	0.04	0.11
Instructional conditions:			
Opportunity to learn	+	0.15	0.09
Time on task/homework	+	0.00/−0.01 (n.s.)	0.19/0.06
Monitoring at classroom level	+	−0.01 (n.s.)	0.11 (n.s.)
Aspects of structured teaching:			
—cooperative learning			0.27
—feedback			0.48
—reinforcement			0.58
Differentiation/adaptive instruction			0.22

have been referred to as 'foundational studies' (Scheerens 1993) because they are aimed at resolving issues that bear upon the scope and 'integrity' of the concept of school effectiveness.

A recent review of such foundational studies is given in Scheerens and Bosker (1997, Chap. 3). Their results concerning primary schools are presented in Table 3. Consistency is expressed in terms of the correlation between two different rank orderings of schools. Results are based on arithmetic and language achievement.

Table 3
Consistency of school effectiveness (primary level)

Type of consistency	Average correlation
across time (stability) (1 or 2 years)	$r = 0.70$ (0.34–0.87)
across grades	$r = 0.50$ (0.20–0.69)
across subjects	$r = 0.70$ (0.59–0.83)

Source: Scheerens and Bosker (1997, Chap. 3)

The results summarized in Table 3 indicate that there is a reasonable consistency across cohorts and subjects, while the consistency across grades is only average. Results measured at the secondary level likewise show reasonably high stability coefficients (consistency across cohorts), and somewhat lower coefficients for stability across subjects (e.g., in a French study (Grisay 1996), coefficients based on value-added results were 0.42 for French language and 0.27 for mathematics). The average consistency between subjects at the secondary level was somewhat lower than in the case of primary schools (r about 0.50). This phenomenon can be explained by the fact that, at the secondary level, different teachers usually teach different subjects, so that inconsistency is partly due to variation between teachers.

The few studies in which factor analysis was used to examine the size of a stable school factor relative to year specific and subject specific effects have shown results varying from a school factor explaining 70 percent of the subject and cohort specific (gross) school effects, to 25 percent.

The picture that emerges from these studies on the stability and consistency of school effects is far from

being indifferentially favorable with respect to the unidimensionality of the school effects concept.

Consistency is fair, when effects at the end of a period of schooling are examined over a relatively short time interval. When grade-level and subject matter area is brought into the picture, consistency coefficients tend to be lower, particularly when different teachers teach different grades or subjects. School effects are generally seen as teacher effects, especially at the secondary school level

The message from these 'foundational studies' is that one should be careful not to overgeneralize the results of school effectiveness studies when only results in one or two subject matter areas at one point in time are measured. Another implication is that hypothetical antecedent conditions of effects are not only to be sought at the school organizational level, but also at the level of teaching and the teaching and learning process.

Fundamental school effectiveness studies are theory- and model-driven studies. Bosker and Scheerens (1994) presented alternative causal specifications of the conceptual multilevel models referred to in an earlier section. These models attempt to grasp the nature of the relationships between e.g., schools and classroom conditions. For example, whether such relationships are additive, interactive, reciprocal, or form a causal chain.

Other studies that have attempted to formalize these types of relationships are by Hofman (1995) and Creemers and Reezigt (1996). In general, it appeared to be difficult to establish the better 'fit' of one of the alternative model specifications. More complex models, based on the axioms of microeconomic theory, have been tested by de Vos (1998), making use of simulation techniques.

So far, these studies are too few to draw general conclusions about the substantive outcomes; continuation of this line of study is quite interesting, however, also from a methodological point of view.

From a substantive point of view educational effectiveness studies have indicated the relatively small effects of these conditions in developed countries, where provisions are at a uniformly relatively high level. At the same time the estimates of the impact of innate abilities and socioeconomic background characteristics—also when evaluated as contextual effects—seem to grow, as studies become more methodologically refined. Given the generally larger variation in both conditions and outcomes of schooling in developing countries—and the sometimes appallingly low levels of both—there is both societal and scientific relevance in studying school effectiveness in these settings.

5. *The Future of School Effectiveness Research*

From this article it could be concluded that school effectiveness research could be defined in a broad and a narrow sense. In the broadest sense one could refer to all types of studies which relate school and classroom conditions to achievement outcomes, preferably after taking into account the effects of relevant student background variables. In a narrower sense, state-of-the-art integrative school effectiveness studies and foundational and fundamental studies could be seen as the core.

Following the broader definition the future of school effectiveness studies is guaranteed, particularly in the sense of 'applied' studies, like cohort studies, large-scale effect studies carried out for accountability purposes, monitoring studies, and assessment studies.

State-of-the-art, fundamental and foundational school effectiveness studies are a much more vulnerable species. One of the major difficulties is the organizational complexity and costs of the 'state-of-the-art types' of study. Given the shortage of these kind of studies the more fundamental and foundational types of studies are likely to be dependent on the quality of data-sets that have been acquired for 'applied purposes.'

Therefore the best guarantee for continued fundamental school effectiveness research lies in the enhanced research technical quality of applied studies. One example consists of quasi-experimental evaluation of carefully designed school improvement projects. Another important development is the use of IRT (Item Response Theory) modeling and 'absolute' standards in assessment programs. If school effects can be defined in terms of distance or closeness in average achievement to a national or even international standard, some of the interpretation weaknesses of comparative standards belong to the past.

School Improvement

1. School Improvement

Different terms are used to describe change processes in schools and educational systems as a whole. They include: 'educational change,' 'innovation,' 'reform,' and development.' These terms are quite often used in an interchangeable manner, and their meaning in the literature is frequently ambiguous. Many authors do not define them, but instead tend to trust everyday usage to convey the meaning of the words. Other authors define the concept by including in the definition important conditions and crucial characteristics of the processes.

In the definition of these different concepts generally, and to distinguish school improvement from other concepts, at least three points should be taken into consideration.

(a) The level in educational system where the change takes place: the school, the district, or the state. Ultimately, every change process has to reach the classroom and the level of the individual student. In order to make a distinction, educational change at national level is often called 'systemic reform.' The term 'school improvement' makes clear that the change takes place at school level.

(b) In all definitions, distinctions should be made between, on the one hand, the process of educational change, the strategies used, and the characteristics of the change process, and, on the other, the outcomes of the change process. In everyday use, the term can refer to one of these aspects or even to a combination of them: for example, to strategy and the product of change.

Fullan clarifies what he calls 'the confusion between the terms *change* and *progress*' (Fullan 1991, p. 4). Not every change is progress: the actual outcome of the change processes in terms of progress is not as important as the intended outcomes in the desired direction.

(c) When it comes to the outcomes of change, there is often no well-defined concept of what the change is aimed at: the context of education, the inputs and processes, or, ultimately, the outcomes in terms of student achievement.

The International School Improvement Project (ISIP) defines school improvement as a 'a systematic sustained effort aimed at change in learning conditions and other related internal conditions in one or more schools, with the ultimate aim of accomplishing educational goals more effectively' (Van Velzen et al. 1985). This definition specifies improvement as an innovation or planned change with specific means (change in learning and other internal conditions of the school) and specific goals (ultimately to accomplish educational goals more effectively).

2. Practice and Theory in School Improvement

School improvement as a process has been demarcated into three global phases: the initiation, the implementation, and the continuation processes. Stakeholders of school improvement are more narrowly circumscribed and consist of students, teachers, principals, and parents at school level, and of local educational authorities, consultants, and the local community at local level. In exceptional cases, where it is a regional or national strategy to improve all schools, the stakeholders at these levels are also relevant.

School improvement is a very widespread phenomenon and a wide variety of improvement efforts can be found. For example, there is a lot of improvement going on which does not aim at enhancing student outcomes at all. These types of improvement focus, for instance, on the career development of teachers, on restructuring the organization of the school, on the way decisions are made, or on the relationships between schools and their clients. Sometimes restructuring takes place at classroom level. Changes in the writing practices of elementary schoolteachers, for example, have been described in great detail. Nevertheless, the actual impact of the changes on students and on student achievement is usually left out.

Some schools practice improvement on their own and try to find their own solutions to their problems. Other schools have chosen to implement as accurately as possible improvement programs that have been developed elsewhere. This is called fidelity implementation. Often they do not consider alternative educational options. For example, they may opt for a specific program primarily because another school was satisfied with it (Stringfield 1995). Some schools are involved in improvement only because their government expects them to be (Hopkins et al. 1994). Depending on the extent to which educational policies are translated into clear outlines and contents, fidelity implementation is a more or less appropriate concept. When the educational policy is rather prescriptive with respect to curricular content and outcome levels, as it is in the UK (Hopkins et al. 1994), it is theoretically possible to check whether or not schools are implementing this policy. When the educational policy is rather open-ended, as is the Dutch policy on educational priorities (Van der Werf 1995) or the Dutch inclusion policy, it is virtually impossible to apply the notion of fidelity implementation.

Only a small part of school improvement is based on research (Stringfield 1995). Innovations are hardly ever tested before they are implemented in educational practice, and an adequate *evaluation* of their impact is rare. The same applies to the occurrence of experimental or quasi-experimental designs in improvement projects. Some school improvers have preferred forms of action research instead of research-based experiments. Sometimes projects based on changing only a couple of factors report great successes. It may be that changes in just a few important areas can alter a whole system, but the question is whether these changes—often cases of educational mass hysteria—will stand the test of time. In education, the margins for change are generally small, because of the impact of non-educational factors such as the individual characteristics of students.

Evaluations are often not carried out satisfactorily or are performed after a timespan that is too short. School improvement projects have shown that it takes time to design, develop, implement, and evaluate changes in schools—more time than is often available. Because of inadequate evaluations, questions about the causation of effects, extremely important for the school-effectiveness knowledge base, cannot be answered. School improvement, therefore, should consistently pursue assessment of its results, pay attention to its failures and try to learn from these, and limit its goals to prevent confusion of cause and effect (Hopkins et al. 1999).

In school improvement, the orientation towards educational practice and policy-making is emphasized. Although, in educational practice schools and classrooms can be found that succeed much better than others, theories cannot be based on exemplary practice only.

Insofar as theoretical notions have been developed, they have not yet been empirically and systematically tested. The typologies of school cultures (Hargreaves 1995), for example, have not been studied in educational practice, and their effects on the success of school improvement are as yet unknown. Moreover, their relationships to the first criterion for school improvement (enhancing student outcomes) are not always very clear. The same holds for the factors that are supposed to be important in different stages of educational change, outlined by Fullan (1991), and for his ideas about the essential elements in educational change at classroom level (beliefs, curriculum materials, and teaching approaches). Even though these ideas are derived from school improvement practice, their importance and their potential effects are not accounted for in detail, and have not yet been studied in research.

A contribution to theory development is the generic framework for school improvement provided by Hopkins (1996). In this framework, three major components are depicted: educational givens, a strategic dimension, and a capacity-building dimension. Educational givens cannot be changed easily. Givens can be external to the school (such as an external impetus for change) and internal (such as the school's background, organization, and values). The strategic dimension refers to the competency of a school to set its priorities for further development, to define student learning goals and teacher development, and to choose a strategy to achieve these goals successfully. The capacity-building dimension refers to the need to focus on conditions for classroom practice and for school development during the various stages of improvement. Finally, the school culture has a central place in the framework. Changes in the school culture will support teaching–learning processes which will, in turn, improve student outcomes (Hopkins 1996).

Despite the obvious gaps in theory development and testing in the field of school improvement, there are already some elements of a knowledge base. By trying to improve schools, knowledge on the implementation of classroom and school effectiveness factors in educational practice has become available. This has provided the possibility of studying, to

different degrees, the influence of factors and variables on educational outcomes (Stoll and Fink 1994).

3. *The Link Between School Improvement and School Effectiveness*

School effectiveness and school improvement conjoin because of their mutual interest, although their actual relationship may be very complicated (Reynolds et al. 1993, Creemers and Reezigt 1997). The major aim in the field of school effectiveness was always to link theory and research on the one hand, and practice and policy-making on the other. School improvement can be fostered by a knowledge base covering what works in education that can be applied in educational practice. The combination of theory, research, and development is not new in education. Almost all movements start out to make knowledge useful for educational practice and policy-making, or state their goal in terms of supplementing policy practice with a knowledge base supplied by theory and research from a cyclical point of view. The next step is to use practical knowledge for further advances in theory and research. In this way, research and improvement can have a relationship as a surplus benefit for both.

School effectiveness has led to major shifts in educational policy in many countries by emphasizing the accountability of schools and the responsibility of educators to provide all children with opportunities for high achievement, thereby enhancing the need for school improvement (Mortimore 1991). School effectiveness has pointed to the need for school improvement, in particular by focusing on alterable school factors. School improvement projects were necessary to find out how schools could become more effective. These projects were often supposed to implement effective school factors in educational practice (Scheerens 1992) and, in doing so, could yield useful feedback for school effectiveness. School improvement might point to inaccurate conceptions of effectiveness, such as the notion of linearity or one-dimensionality (Hargreaves 1995). In addition, school improvement might give more insight into the strategies for changing schools successfully in the direction of effectiveness.

The relatively short history of school effectiveness and improvement shows some successes of this linkage. Research results are being used in educational practice, sometimes with good results. School improvement findings are sometimes used as input for new research. Renihan and Renihan state that 'the effective schools research has paid off, if for no other reason than that it has been the catalyst for school improvement efforts' (Renihan and Renihan 1989, p. 365).

Most authors, however, are more skeptical (Reynolds et al. 1993). Fullan states that school effectiveness 'has mostly focused on narrow educational goals, and the research itself tells us almost nothing about how an effective school got that way and if it stayed effective' (Fullan 1991, p. 22). Stoll and Fink (1992) think that school effectiveness should have done more to make clear how schools can become effective. According to Mortimore (1991), a lot of improvement efforts have failed because research results were not translated adequately into guidelines for educational practice. Changes were sometimes forced upon a school, and when the results were disappointing the principals and teachers were blamed. Teddlie and Roberts (1993) suggest that effectiveness and improvement representatives do not cooperate automatically, but tend to see each other as competitors. Links between school effectiveness and school improvement were stronger in some countries than in others (Reynolds 1996). In the early years of school effectiveness, links were strong in the USA and never quite disappeared there. Many districts have implemented effective schools programs in recent years, but research in the field has decreased at the same time, and, because of this, school improvement is sometimes considered 'a remarkable example of (…) over-use of a limited research base' (Stringfield 1995, p. 70).

Reynolds et al. (2000) came to the conclusion based on the analyses of Dutch, British, and North American initiatives that the following principles are fundamental to a successful merger of school effectiveness and school improvement:

(a) a focus on teaching, learning, and the classroom level;
(b) use of data for decision making;
(c) a focus on pupil outcomes;
(d) addressing schools' internal conditions;
(e) enhanced consistency (through implementation of 'reliable' programs); and
(f) pulling levers to affect all levels, both within and beyond the school.

Recently, several projects (Stoll et al. 1996, Hill 1998) have started to integrate school effectiveness and school improvement. They form successful examples of the concept of sustained interactivity. These projects all share a clear definition of the problem that should be overcome, in terms of student outcomes and classroom strategies, to enhance these outcomes within the context of the school. Often, the outcomes are clearly specified for one school subject or elements of a school subject, such as comprehensive reading. The content of the projects is a balanced mix of the effectiveness knowledge base and the concepts from school improvement. The projects have detailed designs, both for the implementation of school improvement and for evaluation in terms of empirical research. By means of a research component integrated into the projects right from the start, it is possible to test effectiveness hypotheses, and to evaluate improvement outcomes at the same time. The use of control groups is essential in this respect, and various projects now incorporate control groups or choose to compare

their results to norm groups on the basis of nationwide tests. Also, many projects are longitudinal in their designs. Although most integrated projects have started recently, some of them have been running for almost a decade now, and they have been disseminated to various educational contexts. Therefore, long-term effects and context-specific effects can easily be tracked by means of follow-up measurement.

An additional feature of projects which last for several subsequent years is the possibility of testing the effectiveness of school improvement strategies and changing strategies whenever necessary. The Halton's Effective Schools Project illustrates this feature clearly (Stoll and Fink 1996, Stoll et al. 1996). The project started in Canada in 1986 with the intention of implementing British effectiveness knowledge in Halton district schools. It soon became clear that the effectiveness knowledge base in itself would not automatically lead to changes in educational practice. Over the years, the project paid a lot of attention to questions on the processes of change in schools. It focuses on the planning process in schools, the teaching and learning processes in classrooms, and staff development. Successful changes turned out to be enhanced by a collaborative school culture, a shared vision of what the school will stand for in the future, and a climate in which decisions are made in a transparent way. Based on their Halton experiences, Stoll and Fink (1996) have developed a conceptual model which links school effectiveness and school improvement through the school development planning process. The model blends the school effectiveness knowledge base with knowledge about change processes in schools. The school development planning process is at the center of the model. The process is considered to be multilayered. Two outer layers comprise invitational leadership, and continuing conditions and cultural norms. The inner cycle layer is formed by the ongoing planning cycle of assessment, planning, implementation, and evaluation of educational processes. The two central core layers refer to a strong focus on the teaching–learning processes and the curriculum, and the students in the school. The school development planning process is influenced by the context of the school and foundations such as research findings, and, in turn, influences intermediate outcomes at teacher and school levels, as well as student outcomes. Finally, the planning process is influenced by several partners (external agencies, educational networks).

In the UK, 66 percent of improvement programs now pursue goals which fit into the school effectiveness tradition of student outcomes (Reynolds et al. 1996). However, it is still not clear whether real improvements will always occur. The IQEA project (Improving the Quality of Education for All, Hopkins et al. 1994) started in 1991 as a staff development project. Gradually, a focus on classroom improvement and its effects on student achievement took over. The project does not stop with the implementation of priorities for development, but also pays explicit attention to conditions that will sustain the changes. These are staff development, involvement, leadership, coordination, inquiry and reflection, and collaborative planning (Stoll et al. 1996). In addition, when the classroom became the center of attention, the project specified the classroom-level conditions that are necessary for effective teaching and student achievement. These are authentic relationships, rules and boundaries, teacher's repertoire, reflection on teaching, resources and preparation, and pedagogic partnerships. Other promising projects in the UK are the Lewisham School Improvement Project and the Hammersmith and Fulham LEA Project. Both projects actively try to enhance student achievement by means of school effectiveness knowledge, and both projects are cooperating with a research institute (Reynolds et al. 1996).

Recent theories about school improvement stress the self-regulation of schools. Self-regulation assumes target setting and embodies the behavioral concept of *mechanisms, feedback, and reinforcement*. This self-regulatory approach to school improvement can be combined with the analogous self-regulatory feedback loops in educational effectiveness, which are again further elaborated in the upward spiraling school development planning process (Stoll and Fink 1996, Hopkins 1995).

The analysis of school improvement efforts over a period of time resulted in a distinction of several types of schools (effective vs. ineffective and improving vs. declining). Stoll and Fink (1998) and Hopkins et al. (1999) give descriptions of those schools and the features of the change processes going on. The declining effective school (the 'cruising school') has received particular attention because it points at the difficulties of keeping educational quality at the same level (Fink 1999).

School Learning for Transfer

Most of what is taught in school is expected to affect learning and performance that transcend the mastery of those subjects: one learns addition to prepare the grounds for the study of multiplication, science to understand the surrounding physical and natural world, and history to gain a sense of identity and a deeper understanding of current events. Such expectations concern the transfer of what is learned in school in one domain to other realms of learning and activity, a spillover of learning that functions like a ripple effect. Thus, the study of topic A is supposed to facilitate the study of B, make it easier, faster, or better understood relative to when B is learned without the learning of A preceding it. Two approaches to the study of transfer have dominated the field since the beginning of the twentieth century: transfer as a function of similar elements between A and B, and as a function of the understanding of general principles that are transferable to a variety of situations. The history of research on transfer shows how these two major principles underlie the development of the field, even when other basic assumptions about learning and thinking have recently been challenged.

1. *Two Basic Approaches*

The expectation for transfer has as long a history as institutional learning itself. Plato argued that the study of abstract reasoning assists the solution of daily problems. Similarly, the debates about Talmudic and Biblical texts in ancient times were argued to 'sharpen minds.' The scientific study of transfer has a long history as well; it dates back to the beginning of the twentieth century with the studies by Thorndike and Woodworth (1901) in which the idea that Latin and other taxing school subjects developed one's general 'faculties of mind' was challenged. The expected transfer was not found; mastery of Latin, Greek, or geometry did not facilitate either performance or efficiency in learning other subjects. Thorndike's

findings led to his formulation of the theory of 'identical elements': transfer from A to B is likely to occur the more elements are common to both. It followed that transfer can take place only in the relatively rare case when there is clear and apparent similarity between the constituent elements of the learned topics. Thus, one would have to learn a host of independent issues and procedures as no transfer in the absence of identical elements should be expected.

Thorndike's theory was countered by a more cognitively-oriented and Gestalt-flavored alternative that emphasized the meaningful conceptual understanding of underlying principles which then could be thoughtfully applied to new situations. The more general the learned principle, the farther could it be transferred to new instances. Judd (1908) had his subjects learn to shoot at targets submerged in water after having learned principles of light refraction in water. Having learned these principles, subjects were much better at hitting the targets than those who have only practiced the activity.

As we shall see below, the two approaches—transfer as a matter of common elements and transfer as a matter of higher order cognitive processes of understanding and abstraction—although having undergone profound modifications and developments over the years, continue to this day to dominate the field.

2. *Paucity of Findings*

Research on transfer as well as practitioners' expectations for transfer are characterized by an ongoing pendulum-like oscillation between the two approaches. Such oscillation is not so much the result of evidence that supports both approaches as it is a function of the paucity of findings clearly supporting either one of them. Indeed, one of the hallmarks of the field is the great discrepancy between the expectation for transfer from school learning to the acquisition of new subjects or to the handling of daily events and the findings from controlled transfer studies. The latter often do not yield the transfer findings one would have expected. A typical case is the study by Pea and Kurland (1984) who have found that children learning LOGO programming showed no advantage in their ability to plan over children who did not master LOGO.

Transfer, when at all found in carefully carried out studies, appears to be highly specific, as when a particular procedure or principle is applied in a new situation which bears great and apparent (often analogical) similarity to the learning material, and when the process is accompanied by such facilitation as coaching, specific guidance and cueing (see Bransford and Schwartz (1999, Cox (1997, for detailed reviews). Such findings would seem to support Thorndike's theory and pessimism about transfer, as summarized by Detterman (1993): 'In short, from studies that claim to show transfer and that don't show transfer, there is no evidence to contradict Thorndike's general conclusions: Transfer is rare, and its likelihood of occurrence is directly related to the similarity between the two situations' (p.15).

3. *Transfer on the Rebound*

Whereas Thorndike's pessimism seemed to have won the day for a while, the research tradition of Judd (1908), with its emphasis on comprehension and general (nonspecific) transfer gradually showed its strength. As research of this tradition tended to show, when relevant principles or strategies are mindfully attended to, or better yet—either abstracted by learners and/or metacognitively monitored—transfer to a variety of instances can be obtained even in the absence of apparent common elements. At the same time, other research on the transfer of skills, ostensibly still in a tradition more similar to that originated by Thorndike (Thorndike and Woodworth 1901), has also yielded positive results. Thus, for example, Singley and Anderson (1989) have shown that when training to near automaticity of discrete skill components is carried out, transfer from one task (e.g., a line editor) to another (text editor) can be virtually perfect. Also more field-based research found support for impressive transfer from the study of university-taught disciplines: Nisbett et al. (1993) have shown that the study of psychology, and also to a lesser extent medicine (but not law or chemistry), improve students' abilities to apply statistical and methodological rules of inference to both scientific and daily problems.

4. *The High and the Low Roads to Transfer*

The renewed success of the two lines of research, often addressing higher order cognitions and information processing exercized by multiple activities, suggests that transfer may not be a unitary process as the two approaches differ in important ways. Observing these differences, Salomon and Perkins (1989) have developed a theory to account for the possibility that transfer takes either one of two routes (or a combination thereof), described as the *high road* and the *low road* of transfer. The low road reflects to an extent the Thorndikian line, and more recently that of Anderson's skill-acquisition and transfer theory. It is taken when skills, behaviors, or action tendencies are repeatedly practiced in a variety of situations until they are mastered to near-automaticity and are quite effortlessly applied to situations whose resemblance to the learning situations is apparent and easily perceived. Learning to drive and learning to read are two cases in point as is transfer from one text editor to another as studied by Singely and Anderson (1989). Other candidates for low road transfer are attitudes,

cognitive styles, dispositions, and belief systems the application of which to new situations is rarely a mindful process.

In contrast, the high road to transfer is characterized by the process of mindful abstraction of knowledge elements that afford logical abstraction: principles, rules, concepts, procedures, and the like. It is this mindfully abstracted, decontextualized idea ('ethnic oppression may lead to revolt') that becomes a candidate for transfer from one particular instance (the Austro-Hungarian Empire) to another (Russia and Cechenia). Simon (1980) commented in this respect that 'To secure substantial transfer of skill acquired in the environment of one task, learners need to be made explicitly aware of these skills, *abstracted from their specific task content*' (p. 82, emphasis added).

There is ample evidence to support the role of the high road in obtaining transfer. One of the studies by Gick and Holyoak (1983) illustrates this point. Participants who were given two stories and were asked to write a summary of how the two stories resembled each other (that is, their common moral), showed a 91 percent transfer to the solution of another story, relative to 30 percent transfer of a non-summary group. Bassok (1990), showed that mastering algebraic abstractions (plus examples) allowed students to view physics problems as particular instances to which the more abstract algebraic operations could be applied. Physics, on the other hand, is too particular and thus students do not expect and do not recognize any possible relationship between it and algebraic operations. Research also directs attention to the role played by self-regulation and metacognitions in the process of mindful abstraction and transfer via the high road. Following the studies and review of Campione et al. (1982), Salomon et al. (1989) have shown that students interacting with a semi-intelligent computerized Reading Partner that provides metacognitive-like guidance, tend to internalize that guidance and transfer it to new reading as well as to writing situations.

The high road/low road theory sheds light on the many failures of obtaining transfer in controlled studies. Close examination of such studies suggests that in many cases neither the low road of repeated practice nor the high road of mindful abstraction was taken. Not enough time is allocated for practice for the former, and not enough attention is given for mindful abstraction for the latter. As a consequence, neither near automatic transfer on the basis of easily recognized common elements can be attained, nor farther transfer on the basis of metacognitively guided mindful abstraction.

5. *New Approaches*

Research on transfer, until recently, did not challenge the basic paradigm and conception of transfer as a process involving change of one's performance on a new task as a result of his or her prior performance on a preceding and different task. Such a conception of transfer has recently become challenged on the basis of new theories of learning, the role of activity, and the place of cognitions therein. These challenges can be arranged along a dimension ranging from the least to the more radical, relative to traditional notions of transfer.

Bransford and Schwartz (1999), coming from a mainstream tradition of cognitive science applied to instructional issues, argue that the current ways of demonstrating transfer are more appropriate for studying only full-blown expertise. According to them, 'There are no opportunities for…[students] to demonstrate their abilities to learn to solve new problems by seeking help from other resources such as text or colleagues or by trying things out, receiving feedback, and getting opportunities to revise' (p. 68). They recommend replacing the typical transfer task which they call 'sequestered problem solving' (SPS) by a conception of transfer as 'preparation for future learning' (PFL). Thus, one would measure transfer not by having students apply previously acquired knowledge or skill to new situations, demonstrating either *knowledge how* or *knowledge that* something, but rather by demonstrating *knowledge with*—thinking, perceiving, and judging with whatever knowledge and tools are available even if that knowledge is not consciously recalled. In other words, transfer would be expected to become demonstrated by way of 'people's abilities to learn new information and relate their learning to previous experiences' (Bransford and Schwartz (1999, p. 69).

An illustration of the above can be seen in a study in which college and fifth grade students did not differ in their utilization of previous knowledge and educational experiences for the creation of a statewide plan to recover the bald eagle. This is a typical SPS way of measuring transfer, suggesting in this case that previous educational experiences did not transfer to the handling of the new problem. However, when the students were asked to generate questions that would need to be studied in preparation for the creation of a recovery plan (applying a PFL approach), striking differences were found between the two age groups in favor of the college students. Focusing on different issues, the two groups showed how, knowingly or not, previous learning has facilitated the generation of the list of questions to be asked. The use of tools and information resources would also show how previous learning of skills and knowledge becomes actively involved in the process of solving a new problem.

While Bransford and Schwartz (1999) continue to adhere to the traditional conception of learning as knowledge acquisition and to cognitions as general and transferable tools of the mind, others have developed an alternative, socio-cultural approach according to which neither the mind and its content

(e.g., arithmetic algorithms) should be treated as a neutral toolbox ready for application wherever suitable, nor should knowledge-in-use and social context of activity be taken as two independent entities. Learning is a matter of participation in a community of learners, thus knowledge is not a noun denoting *possession* but rather a verb denoting the active process of *knowing-as-construction within a social context of activity*. One underlying assumption is that learner, activity, and content become united through culturally constructed tools. A second assumption is that learning is highly situated in a particular activity context of participation, and its outcomes are 'becoming better attuned to constraints and affordances of activity systems so that the learner's contribution to the interaction is more successful' (Greeno 1997, p. 12). Seen in this light, the traditional *cognitivist* concern with the transferability of acquired knowledge across tasks becomes, from the newer *situative* perspective, an issue concerned with the task and the 'consistency or inconsistency of patterns of participatory processes across situations' (Greeno (1997, p. 12).

An important practical implication of this approach is that one would need to take into consideration the kinds of participatory activities to which school-based learning might be expected to transfer, rather than expect decontextualized school materials to transfer all on its own to other tasks, situations, and activities. Students are likely to restructure new situations to fit their previous practices and thus make the old available for transfer to the new. Illustrating this approach to learning and cognition, Saxe (1991), showed that Brazilian children's mathematical experience as street vendors affected their math learning when later on they became enrolled in school, and vice versa. '[I]n recurring activities like practices of candy selling and schooling—contexts in which knowledge is well learned and in which similar problems emerge on a repeated basis—transfer is a protracted process. In their repeated efforts to solve practice-linked problems, individuals attempt to structure problem contexts in coherent and more adequate ways' (p. 179).

The new approaches to transfer clearly deviate from the traditional views. They suggest new ways of measuring transfer, and more radically—challenge traditional assumptions by treating knowledge, skill, task, activity, and context as one participatory activity. By so doing, they emphasize the uniqueness of each activity setting. An important aspect of this approach is its ability to incorporate within the idea of participatory activity motivational and dispositional elements also. These elements have so far been neglected by much research on transfer, although they may be crucial for students' choice to treat each situation as different, or as allowing students to exercise familiar patterns of participation. Still, it appears that despite these important novelties, the principles of transfer as a function of similarity between situations (or activities) and of depth of understanding general principles (e.g., of useful participation in a community of learners) have not yet been replaced but only redefined.

School Management

School management is in considerable disarray, if not turmoil, and is likely to remain so in the first decade of the twenty-first century. This is partly a reflection of sweeping transformations in society, mirrored in developments in education generally and in schools in particular. It also reflects failure to effect a powerful link between school management as a field of study and school management as a field of practice, so that each informs and influences the other. More fundamental is the concern that, in each instance, management is not connected to learning as well as it should be.

1. *Definition of School Management*

Disarray is evident in the matter of definition. In some nations, notably the USA, administration is used to describe a range of functions performed by the most senior people in an organization, with management a more limited, sometimes routine set of tasks, often performed by those in supporting roles.

A conceptual difficulty relates to the distinction between leadership and management. The work of Kotter (1990) is helpful in resolving the issue. Leadership is concerned with change and entails the three broad processes of establishing direction, aligning people, and motivating and inspiring. Management is concerned with the achievement of outcomes, and the three broad processes of planning and budgeting, organizing and staffing, and controlling and problem-solving.

These difficulties are reflected in the role ambiguity of those who hold senior positions in schools, notably principals or head teachers. There is a generally held view that their work entails both leadership and management. They should certainly be leaders. In some instances managers will support them. There is concern when they act solely as managers. Kotter (1990) offers a contingent view that is as helpful for schools as it is for organizations in general. He contends that the emphasis and balance in leadership and management are contingent on two variables: the amount of change that is required and the complexity of the operation. Complex schools in a turbulent environment require high levels of leadership and management. Schools that are relatively simple but are faced with major change require leadership more than management. Schools that are complex in stable circumstances require management more than leadership. Simple schools in stable settings may require little of each.

2. *School Management as a Field of Practice*

There are three important developments in school management that are evident in almost every nation (Caldwell and Spinks 1998). Schools and systems of schools vary in the extent to which each has unfolded. The first is the shift of authority and responsibility to schools in systems of public education. Centrally determined frameworks of curriculum, standards, and accountabilities are still in force but schools have a considerable degree of freedom in how they will meet expectations. This development is known as school-based management or local management or self-management, and is frequently accompanied by the creation of school councils, school boards, or other structures for school-based decision-making. Comprehensive reform along these lines is most evident in Australia, the UK, Canada, New Zealand and the USA, but most other nations have begun the process or are planning it.

Reasons for decentralization vary but are generally consistent with the changing view of the role of government that gathered momentum in the final decade of the twentieth century. As applied to education, this view holds that governments should be mainly concerned with setting direction, providing resources, and holding schools to account for outcomes. They should also provide schools with the authority and responsibility to determine the particular ways they will meet the needs of their students, within a centrally determined framework.

The second development arises from higher expectations for schools as governments realise that the knowledge and skill of their people are now the chief resource if nations are to succeed in a global economy. There is recognition of the high social cost of failure and the high economic cost of providing a world-class system of education. As a result, there is unprecedented concern for outcomes, and governments have worked individually and in concert to introduce systems of testing at various stages of primary and secondary schooling to monitor outcomes and provide a basis for target setting in bringing about improvement. In several countries, notably the UK and some parts of the USA, rankings of schools are published in newspapers. Comparisons of national performance are now possible through projects such as the Third International Mathematics and Science Study (Martin and Kelly 1996).

The third development is change in the nature of schooling itself. Driven to a large extent by advances in information and communications technology, much of the learning that in the past could only occur in the classroom can now occur at anytime and anywhere there is access to a networked computer. Students and their teachers have access to a vast amount of information. Interactive multi-media have enriched and individualized learning on a remarkable scale. This development is not uniform across all schools or across all nations, and disparities are a matter of concern.

There is growing anxiety on the part of government that structures for the delivery of public education that

have survived for a century or more may no longer be adequate for the task. Charter schools made their appearance in Canada and the USA in the 1990s, and the number increased very rapidly, even though they are still a small fraction of the total number of schools. Charter schools receive funding from the public purse but are otherwise independent, operating outside the constraints of a school district. A schools-for-profit movement gathered momentum around the same time, with public funding enhanced by private investment through the offering of shares on the stock exchange, as instanced by the pioneering Edison Schools. In the UK, the Blair Government privatized the support services of several local education authorities and established a framework for public–private partnerships in the management of publicly owned schools. The number of private schools is increasing in most countries, reflecting growing affluence and loss of faith in the public sector. A contentious policy, gaining ground in a number of countries, is the provision of public funds (often described as 'vouchers') allowing parents to access private schools when public schools do not meet expectations.

Taken together, these developments have created conditions that call for high levels of leadership and management at the school level. Schools are more complex and are experiencing greater change than ever before. A particular challenge is to prepare, select, place, appraise, and reward those who serve, and there is growing concern in some countries about the quality and quantity of those who seek appointment. Some governments have created or are planning new institutions to address this concern, illustrated by the establishment in England in 2000 of the National College for School Leadership. There is evidence of a loss of faith in the university as an institution to shape and inform approaches to school management, and to prepare those who will serve as leaders and managers in the future.

3. *School Management as a Field of Study*

School management has emerged relatively recently as a sub-field of study within the broader field of educational management (administration). There were few formal programs and little research on the phenomenon until the 1950s. Prior to that, approaches to the management of schools paralleled those in industry. Indeed, it was generally recognized that management in education was largely a mirror image of industry, with the creation of large centralized and bureaucratized systems of public education. The knowledge base was drawn from the industrial sector.

Departments of educational administration made their appearance in universities in the US in the mid-twentieth century and soon proliferated. They were established in the UK soon after, with many other nations following suit, drawing on the US and, to a lesser extent, the UK for their intellectual underpinnings. The first quarter-century, from the early-1950s to about the mid-1970s was characterized by efforts to build theory in educational management, modeling to a large degree the discipline approach of the behavioral sciences. In the USA, *Educational Administration Quarterly* was an attempt to provide for education what *Administrative Science Quarterly* has done for administration (management). In the UK, a seminal work edited by two pioneers in the field had the title *Educational Administration and the Social Sciences* (Baron and Taylor 1969).

Separate sub-disciplines were created in fields such as economics, finance, governance, human relations, industrial relations, law, planning, policy, and politics. Large numbers of students enrolled, and departments of educational administration became a major source of revenue for schools of education.

The theory movement in educational management was the subject of powerful attack in the mid-1970s, notably by Canadian scholar T. B. Greenfield (1975). However, it was not until the late 1980s that a systematic response was mounted by the University Council for Educational Administration in the 1987 report of the National Commission on Excellence in Educational Administration (NCEE 1987). The critique was largely directed at efforts to build a scientific theory of educational management; the separation of management from learning and teaching; and fundamental considerations of context, culture, ethics, meaning, and values. Blueprints for reform were drawn up but the field was still in ferment at the turn of the twenty-first century (see Murphy and Forsyth (1999) for a review of efforts to reform the field). Evers and Lakomski have developed a new conceptual framework ('naturalistic coherentism') in an effort to bring coherence to the fields of educational administration and management. Lakomski (2001) argues that leadership ought to be replaced by better conceptions of organizational learning.

On a more pragmatic level, the critique of educational management as a field of study lies in its failure to impact practice on a large scale, and to assist in a timely manner the implementation of reform and the resolution of concerns. A promising approach to unifying the field is to place learning at the heart of the effort. This means that policy interest in the improvement of student outcomes should be the driver of this 'quest for a center,' as US scholar Joseph Murphy (1999) has described it. Murphy classified the different stages of development in the 'profession' of educational administration, as summarized in Table 1.

Much momentum was gained in the 1990s with the establishment of the International Congress for School Effectiveness and Improvement (ICSEI), which made its mission the bringing together of policy-makers, practitioners, and researchers. The periodical *School*

Table 1
Rethinking the center for the profession of educational administration (Murphy 1999)

Time frame	Center of gravity	Foundation	Engine
1820–1900 Ideology	Philosophy	Religion	Values
1901–1945 Prescription	Management	Administrative functions	Practical knowledge
1946–1985 Behavioral science	Social sciences	Academic disciplines	Theoretical knowledge
1986– Dialectic	School improvement	Education	Applied knowledge

Effectiveness and School Improvement quickly established itself as a leading international journal.

The integration of policy, practice, and research to achieve school improvement is becoming increasingly evident, illustrated in approaches to literacy in the early elementary (primary years). The examples of Australia and the UK are interesting in this regard. Levels of literacy were considered by governments in both nations to be unacceptably low. Implementation of approaches in the Early Literacy Research Project led to dramatic improvement in the state of Victoria, Australia.

Concepts such as 'whole school design' emerged from this integration. Hill and Crévola (1999) formulated a 'general design for improving learning outcomes' that proved helpful in parts of Australia and the United States. It has nine elements: beliefs and understanding; leadership and coordination; standards and targets; monitoring and assessment; classroom teaching strategies; professional learning teams; school and classroom organization; intervention and special assistance; and home, school, and community partnerships. The implications are clear as far as educational management is concerned: there must be high levels of knowledge about learning and teaching and how to create designs and formulate strategies that bring about improvement. This contributes to a particularly demanding role where decentralization has occurred, as is increasingly the case in most nations.

4. *The Future of School Management*

The picture that emerged at the dawn of the twenty-first century is one in which school management does not stand in isolation. Leadership and management, as conceptualized by Kotter (1990) are both important, and their focus must be on learning, integrated in the notion of creating a coherent and comprehensive whole-school design. Those who serve in positions of leadership are operating in a milieu of high community expectations in which knowledge and skill are the chief determinants of a nation's success in a global economy. Rapidly increasing costs of achieving expectations mean a capacity to work in new arrangements, including innovative public–private partnerships. High expectations mean a commitment to core values such as access, equity, and choice. All of this unfolds in an environment in which the nature of schooling is undergoing fundamental change.

There are major implications for universities and other providers of programs for the preparation and professional development of school leaders. An interesting development in Victoria (Australia) and the UK is that governments are turning to the private sector to specify requirements and offer a major part of training programs. Governments in both places commissioned the Hay Group to assist in this regard. The target population in the UK is serving principals, numbering about 25,000. The program has been very highly rated by both principals and employers. The most recent contribution of the Hay Group has been the specification for Victoria of 13 competencies and capabilities for school leaders. The focus is school improvement and there are four components: (a) driving school improvement (passion for teaching and learning, taking initiative, achieving focus); (b) delivering through people (leading the school community, holding people accountable, supporting others, maximizing school capability); (c) building commitment (contextual know-how, management of self, influencing others); and (d) creating an educational vision (analytic thinking, big picture thinking, gathering information).

These developments suggest that training will be a shared responsibility in the future, with a limited role for universities unless they can form effective partnerships with the profession itself and work in association with private providers. Universities will have a crucial role to play, especially in research, but again that is likely to be in a range of strategic alliances if it is to be valued. The role of the university in philosophy and critique of school management will be more highly valued to the extent that the disjunction is minimized (between study and practice and between management and learning).

A fundamental issue that awaits resolution is the extent to which those who work in school management are not weighed down by the high expectations. It was noted at the outset that applications for appointment are declining in quality and quantity. There is even a

concern in well-funded schools in the private sector. Part of the solution is to infuse leadership and management throughout the school and generally build the capacity of all to work in the new environment. The concept of 'knowledge management' is likely to be become more important, so that accounting for the resources of a school will extend beyond financial and social capital to include intellectual capital in the form of the knowledge and skill of staff. This may go only part of the way, given that schools are in many respects still operating with a design for an earlier era. Innovation in design must extend to the creation of a work place that is engaging for all that work within it. What should be retained and what should be abandoned in current designs is the challenge for the first decade of the twenty-first century. Drucker's concept of 'organized abandonment' (Drucker 1999) is as important for schools as it is for other organizations.

School Outcomes: Cognitive Function, Achievements, Social Skills, and Values

Achievement in US schools is as high as it was in the mid-1970s, despite the fact that increasingly more poor and minority students are remaining in schools longer than ever. Unlike in the early 1960s, where researchers debated whether there was any impact of schooling on students' learning, it is now accepted that schools (and especially teachers) impact student achievement.

Classroom learning and school achievement broadly defined continue to grow in important ways (see, for example, Biddle et al. 1997). However, much of the recent scholarship on classroom processes has been conceptual in nature, and the associated empirical research (if any) typically involves only a few classrooms. There is considerable advocacy for certain types of classroom environments—classroom environments that are notably different from traditional instruction—but solid empirical support to show the effects of new instructional models is largely absent.

Here we discuss the need for new school-based research that addresses curriculum and instructional issues in order to advance theoretical understanding of student learning in school settings. We argue that it is no longer possible to discuss 'successful schooling' on the basis of subject-matter outcomes alone. Effective schools research and policy discussions must also include the measurement of non-subject-matter outcomes of schooling.

1. Status of Achievement in Schools

The state of achievement in US schools is widely debated and incorporates at least three major camps. The first contends that current school performance is lower than that of US youth from the mid-1970s and that of international contemporaries. Indeed, several publications supported by the federal government have corroborated the assertion that US schools are failing, including *Nation at Risk* (National Commission for Excellence in Education 1983) and *Prisoners of Time* (National Education Commission on Time and Learning 1994).

A second camp argues that students' performance today is as good as it was in the mid-1970s and that international comparisons are uninterpretable (Berliner and Biddle 1995). These and other researchers note that the stability of achievement has been maintained at a time when US schools are increasingly diverse and serving more minority students and those from poor homes than ever before. This camp also: (a) notes that reports of average school achievement are often highly misleading, because students' performance varies markedly between schools; and (b) has concerns about the performance of minority students.

Importantly, there is documentable evidence not only of the stability of student achievement over time, but also of real progress. For example, in less than a decade, the number of students, including minority students, taking advanced placement tests in high schools for college credit doubled such that one-fifth of US students in 1996 entered college with credits earned from testing (Good and Braden 2000).

A third camp agrees with the second position, but asserts that traditional achievement standards are no longer applicable to a changing society—schools must address different, higher subject-matter standards. Although we accept the premise that some curriculum changes are probably necessary to accommodate the knowledge needs of a changing society, we have two major problems with advocates for new, higher standards. First, there has been no specification of what these new skills are and, typically, if examples are even provided, the rhetoric of higher standards essentially translates into moving content normally taught later (college calculus) to appear sooner (in high school). This position is specious, because it lacks sound theoretical and empirical support. Second, extant data suggest that achievement of students in states with 'higher standards' is lower than that of students in states with purported lower standards (Camilli and Firestone 1999)!

We align our arguments with advocates of the second camp, and we note that there is extensive evidence to support this position—student achievement scores are stable in the face of growing student diversity (Berliner and Biddle 1995, Good and Braden 2000). However, despite strong empirical data to show that student performance has not declined, we believe there is much room for improvement. For example, schools in urban settings need to improve student subject-matter performance, and all schools need to further enhance student non-subject-matter achievement.

The academic accomplishments of students in today's schools are difficult to understand for various reasons. Here, we review several reasons why the achievement of US students is problematic.

2. *Which Test is Appropriate?*

For one example of the difficulty of using extant assessment instruments to compare students within the USA or across cultures, one only need note the discrepancy between the measures. For example, as Bracey and Resnick (1998) report, in 1996 the National Assessment of Educational Progress (NAEP) mathematics performance indicated that only 18 percent of US fourth graders were proficient, only 2 percent were advanced, and 32 percent were below basic. In contrast, US fourth graders performed well above the average scores of the 26 countries that participated in the international TIMSS study at the fourth-grade level. Which test is the best descriptor? Are US students above average in fourth-grade mathematics, or not? This issue of 'which test' is embedded in US testing, as well. For example, in New York state there has been a raging debate about the appropriateness of a state-mandated test (i.e., in relation to other measures, such as advanced placement tests).

3. *Problems with Curriculum, Theory, and Test Alignment*

Other factors also limit efforts to relate the implemented curriculum with student achievement. For example, in mathematics, a current 'theoretical' recommendation is to avoid instruction that is a mile wide and an inch deep (i.e., in terms of the breadth and depth of curriculum concepts covered). Those who advise teachers about this problem apparently do not worry about the opposite problem—creating a curriculum that is four inches wide and a mile deep! Aligning standardized achievement tests with curriculum implementation is vital for meaningful interpretation of student scores. Appropriately, achievement tests should assess the philosophical orientation of the curriculum. Then, other tests and research can be used to assess the utility of a curriculum for various purposes (i.e., do various curricula have different effects on long-term memory of the curriculum taught or on students' ability to transfer ideas learned in a curriculum to solve new problems?).

Finally, curriculum writers often do not understand the learning theory that undergirds particular instructional practices or goals. Some curriculum theorists do not appear to understand that behavioral models are powerful when dealing with factual and conceptual knowledge (and constructivist models are exceedingly weak in this area). Also, they often fail to understand that information-processing models (cognitive science) are more powerful than behavioral or constructivist principles at addressing wide horizontal transfer of academic concepts and authentic problem solving. In addition, in applying constructivist principles, many curriculum experts do not even recognize the differences among constructivist theories.

Despite the difficulties associated with assessment, instruments, and the curricula, and instructional alignment with achievement outcomes, there are data to suggest that teachers and schools can make a difference in student achievement.

4. *Effective Teachers*

The question that was problematic is the mid-1970s—'Do teachers make a difference in student learning?'—can now be answered with a definite '*yes*' (Weinert and Helmke 1995). There are clear data to

illustrate that some teachers notably outperform other teachers in helping similar students to learn the type of material historically measured on standardized achievement tests. It is not only possible to identify effective teachers on this useful but limited measure of student learning (e.g., see Good et al. 1983), but also research has illustrated that the practices of 'successful' teachers could be taught to other teachers.

As one instance of this research base, the Missouri Mathematics Program was successful in improving students' performance in mathematics. However, a series of research studies in this program found that teachers who were involved in the training program implemented the intended program *unevenly*. Also, not surprisingly, higher levels of program implementation were associated with higher levels of student mathematical performance. Importantly, some of the 'resistance' to implementing the Missouri Mathematics Program was due to teachers' beliefs about mathematics and how it should be taught (Good et al. 1983). Teachers' beliefs are a key, but often overlooked, point in school reform. And, as Randi and Corno (1997) found, failure to take teachers' ideas into account lowers the impact of many reform interventions.

Many aspects of teaching and learning are still problematic. Although there are numerous plausible case examples of teachers who impact students' ability to think and to apply knowledge, there is still debate about how teachers obtain these 'higher order' outcomes and whether other teachers can be educated in ways that allow them to achieve comparable effects on their students. Unfortunately, research on teachers' roles in helping students to develop thinking and problem-solving skills has in recent times been limited to case-study research. Further, research that helps teachers to expand—and assess—their capacity for impacting students' thinking abilities has been inert.

5. *Effective Schools*

There is some evidence that schools (serving similar populations of students) have more effect on student achievement (as measured by conventional standardized achievement tests) than do other schools (e.g., Good and Weinstein 1986). However, unlike the correlational and experimental research on teacher effects, the early research base describing 'effective schools' was sparse and questionable. Teddlie and Stringfield's (1993) longitudinal study in Louisiana has provided strong evidence that schools make a difference. They found that schools serving similar populations of students had different 'climates' and that these school differences were associated with differential student achievement. In general, the study confirmed many of the arguments that school effects researchers had made previously. Interestingly, in their eight-year study, about one-half of the schools retained their relative effectiveness during the time period (stability rates were similar for schools that had initially been defined as effective or ineffective). More work on this issue is warranted.

There still have not been successful and replicated studies to show that factors associated with 'effective' schools can be implemented in other schools in ways that enhance student achievement. Although there are notable examples that schools can be transformed, there is comparatively little research to see if this knowledge can be used to improve other schools.

6. *Comprehensive School Programs*

In recent years, intervention using components of previous teacher and school effects research and emerging ideas (e.g., cooperative student groups) have been combined in 'comprehensive school programs' designed to transform all aspects of schooling at the same time (including governance, structure, instruction, home schooling, communication, curriculum, and evaluation!). Although these broad interventions offer potential, it should be noted that the theoretical assumptions and congruence of these programs have not been assessed. Some programs appear to have a serious misalignment between program components. For example, as McCaslin and Good (1992) noted, some schools emphasize a behavioral approach to classroom management ('do as you are told') and a constructivist approach to the curriculum ('think and argue your conception').

Recent school intervention efforts have focused upon the impact of broad programs on student achievement. Typically, research includes no observational data, and thus there is no evidence of what parts of the program are implemented and/or whether the program parts that are presented represent a theoretically integrated program or a 'patchwork quilt' of separate and conflicting program parts. Further, the more complex and comprehensive the intervention model, the more likely teachers will alter program parts (often permanently). These 'teachable' moments go unnoticed by reformers. Perhaps unsurprisingly, there is growing consensus that such programs have not had consistent, demonstrable effects on students' achievement (Slavin 1999).

7. *Little Support for New Research*

In the past decade, policy leaders have tended to agree with advocates of camp one about the effectiveness of schools. Those in camp one (and who believe that schools are failing radically) have been able to convince policymakers to invest widely in charter and voucher plans, even in the absence of any convincing

pilot data. To these advocates, both the problem and solution are evident. Those in the second camp (stable student achievement over time) have been 'represented' by researchers attempting to implement comprehensive school reform. Unfortunately, as noted above, such research attempts fail to show the effects of program implementation. This group of researchers does not question the knowledge base sufficiently and hence fails to develop research designs that could improve its conceptions of 'good practice.'

Those who fall into the third camp (new societal requirements mandating new processes and outcomes of schooling) are prepared to reject extant theory and research on the basis that it is outdated and irrelevant. Indeed, it is not only that monolithic state-mandated standardized tests have gotten in the way of scientific research, but also that there is a growing willingness of professional groups to advocate desirable teaching processes on theoretical grounds alone. Prestigious groups, such as the National Council of Teachers of Mathematics (NCTM), have encouraged curriculum development without advocacy for research on instruction and have encouraged teachers to teach less and to use more student group work. Although it is perhaps the case that at an aggregated level, teachers as a group should teach less, the real issue is about when teachers should teach and when students should explore alone or with other students in small or large groups.

8. *Controllable and Uncontrollable Influences on Student Learning*

It has become better understood in the last 25 years of the twentieth century that schools can influence students' learning independent of home background. However, it is also better understood that the effects of schools are mediated by other factors. Bracey and Resnick (1998) argue that many factors impacting students are within the control of the school district, including: aligning textbooks with standards; aligning the broader curriculum with standards; employing high-quality teachers and providing them with appropriate professional development; and having modern textbooks and laboratory equipment. Although these factors are controllable in theory, it should be noted that some school districts have considerably fewer resources to work with than do other districts. It seems unconscionable that all schools do not receive these controllable resources, which are known to impact achievement.

Bracey and Resnick (1998) have argued that there are various out-of-school factors that can influence student achievement, including: teenage pregnancy rates; percentage of female-headed households; poverty rate; parental and maternal educational levels; the percentage of students for whom English is not their native language; number of violent incidents per year; and number of annual policy visits/disciplinary actions that occur at particular schools. These opportunity-to-learn variables are seen as conditions that impact student achievement but are largely beyond the direct influence of the school system. Accordingly, various groups have noted that achievement problems of students from low-income families need to be addressed by other social agencies. Clearly, poor achievement in schools is often outside the control of individual schools, but not outside the influence of the broader society. If a society chooses to hold individual schools 'accountable' for achievement, it is incumbent on that society to spread its wealth in ways that address factors that individual schools cannot address.

9. *Improving Performance: Aligning Theory and Research*

Massive investments of public funds in student testing have occurred over the last two decades of the twentieth century and, as noted, some policymakers have called for even more testing and for raising extant standards. The research for higher standards has led to the development of tests in some states that are designed, absurdly, so that most students fail them. Oddly, despite this massive investment in testing, no information has been obtained to describe adequately what students learn in schools and how conditions can be changed to further enhance student learning. We believe that school reform efforts need to bring theory and empirical research together. It is time to stop advocacy from prestigious groups that do not support their reform calls in the form of theory and data.

There is a growing sense of the importance of instructional balance in order to scaffold the learning needs of students in complex classroom settings (Good and Brophy 2000, Grouws and Cebulla 2000). However, these assertions demand more research examination in various contexts. In contrast, this advice is currently not echoed by professional groups. These groups continue to overemphasize (in our opinion) problem solving and application without concomitant attention to the development of conceptual knowledge. The ability to solve problems also requires the ability to recognize and find problems as well as the computational and conceptual skills necessary for addressing problems. Simply put, there can be too little or too much attention to concepts, facts, or problem solving.

10. *Non-subject-matter Outcomes of Schooling*

Americans have always argued that their students should not simply be 'academic nerds,' but that students should also be participants in broader society (have jobs, participate in drama or sports, etc.).

Increasingly, parents and citizens have expressed interest in schools being more responsive to the non-subject-matter needs of youth. Often, this argument is expressed only in terms of improving achievement—if children feel secure, they will achieve better. But increasingly, the assertion is made that some outcomes of schooling are important whether or not they impact subject-matter learning.

Despite the considerable advocacy of policy leaders for higher standards, many citizens are pushing hard for students to learn responsibility. For example, when asked what first comes to their minds when Americans think about today's teenagers, 67 percent described them as 'rude, irresponsible, and wild,' and 41 percent reported that they did not think teens had enough to do and that they were not being taught the value of hard work (schools are not doing their 'job') (Farkas et al. 1997). This idea is echoed in the 1999 Phi Delta Kappan/Gallup poll, where 43 percent of parents reported that the main emphasis of schools should be on students' academic skills, and 47 percent of parents said they believe that the main emphasis of schools should be helping students to learn to take responsibility. And earlier in a 1996 Phi Delta Kappan/Gallup poll, parents indicated they would prefer their children to receive bad grades and be active in school activities rather than making an excellent grade and not participating in extracurricular activities (60 percent to 20 percent). It is clear that parents and citizens, reacting to a perception of adolescents' moral decline, believe that schools should play a greater role in teaching non-subject-matter content, such as responsibility and civic behavior.

Although citizens want schools to provide students with more non-subject-matter knowledge, there are problems with the systematic addition of this 'content' to the curriculum. One problematic issue is the difficulty in finding consensus on what a moral curriculum would look like. Subsequently, what assessment criteria should be used to measure the curriculum's effectiveness? Is the curriculum successful if more students vote? Or is it effective if students are able to negotiate conflicts calmly? As we have argued, achievement tests do not always represent adequately the curricula they are supposed to measure. Therefore, it is reasonable to think that appropriate accountability and assessment tools would be difficult to implement for non-subject-matter content—at least without adequate empirical research.

Policymakers, however, are not only supporting past emphases of the impact of schools on achievement, but are pressuring for higher and higher standards. In some instances, the standards have been pushed so high (and artificially high) that in Virginia and in Arizona over 90 percent of students failed exams that presumably represented efforts by state government to improve standards. At some level, increasing standards may be a laudable goal; however, developing standards that only 10 percent of our students pass seems to be a ridiculous and self-defeating effort. Given the exaggerated, negative views of youth, and testing policies designed to guarantee youth's failure, it seems important to explore motivation. Are such practices designed to suggest that youth, especially minority youth, do not deserve resources in their schools?

11. *Educators on Noncognitive Factors*

Rothstein (2000) has noted that, in part, achievement measures are reified in making decisions about the effectiveness of schooling, because there are many of these measures, but few ways to measure noncognitive outcomes. He noted that there are 10 core outcomes that motivate citizens to invest in schools so that students can contribute to society and lead productive adult lives. The dimensions he identifies are literacy, competencies in mathematics, science, and technology, problem solving, foreign languages, history knowledge, responsible democratic citizenship, interest in creative arts, sound wellness practices, teamwork and social ethics, and equity (narrowing the gap between minority and white students in the other nine areas).

Wanlass (2000) has drawn attention to the numerous problems in contemporary society, including the effects of a global economy, increased ethnic diversity, advanced technology, and increasing risk for various problems such as intolerance (hate crimes), overpopulation, and a dramatic depletion of natural resources. In this context, she argued a need to help youth develop the affective dispositions required for the modern world (leadership, tolerance, philanthropic concern). She suggested several strategies, capitalizing on the unique strengths and talents of more students and the need to better develop the unique abilities of nonacademic areas as well as academic concerns (performing arts, social interaction, leadership, civic-mindedness, social advocacy, etc.).

Goodenow (1992) has argued that students who feel more connected to their schools are more likely to be academically and socially successful. Students who felt more personally valued and invested in were more likely to place higher value and have higher expectations for classroom success than were students who did not feel valued. This finding was replicated in a large-scale study (Blum and Rinehart 1996), which surveyed more than 90,000 students nationwide and found that those who felt more connected to their schools were less likely to engage in risky behavior, including: smoking, doing drugs, engaging in sexual activity, and repeated truancy, and they were less likely to drop out of school. In this study, school connectedness was defined as students who: (a) felt they were treated fairly, (b) reported they got along with other teachers and students, and (c) felt close to people at school. Connectedness was also explored in

terms of how schools were perceived by their teachers and administrators. A school that encouraged more connectedness exhibited less student prejudice and had higher daily attendance rates, lower drop out rates, and more teachers employed with masters degrees. Although these data are correlational in nature, it suggests that some factors thought to be uncontrollable, may in fact be controllable.

Researchers have also investigated the role of non-subject-matter variables as they influence students' motivation to achieve. For example, Nichols (1997) examined the nature of the relationship between students' perceptions of fairness and their reported levels of motivation to achieve. Of the four dimensions of fairness identified through factor analytic techniques (personal, rules, punishment, teacher), a *personal* sense of fairness more strongly mediated motivational variables than did other dimensions. Similar to Goodenow (1992), this data set indicated that students who felt more personally valued were more likely to be motivated to achieve in school settings. However, even if students' personal sense of fairness was not linked directly to an achievement motivation, it would seem that this is a desirable outcome of schooling. Students should feel respected and safe, whether or not these variables influence achievement.

12. Conclusion

Clearly, more public debate is called for, if more focused judgments are to be reached concerning those aspects of schools that are defined as most critical. However, given the growing evidence that citizens are concerned about non-subject-matter outcomes of schooling, it seems incumbent on policymakers to 'proxy' these concerns by collecting data on some of the many outcomes that could be measured. There is a need for research and arguments focused on non-subject-matter variables, as well. For example, it seems that high subject-matter specialization and excessively high levels of student obedience (as opposed to student initiatives) are not a prescription for forging a professional community well prepared for engaging in creative work and problem solving.

A recent poll of teenagers found that the three greatest pressures they experience are to get good grades (44 percent), to get into college (32 percent), and to fit in socially. In contrast, fewer teens report feeling pressure to use drugs or alcohol (19 percent) or to be sexually active (13 percent). What modern youth are concerned about varies markedly from the view presented by the media. Unfortunately, policymakers at present seem more intent on blaming youth and holding them accountable than on understanding them. The collection of reliable data on various non-subject-matter outcomes of schooling might help to assure that youth are developing the proactive skills necessary for life in a democracy (e.g., civility, a willingness to examine ideas critically, and ambition).

The historical concern for evidence about subject-matter growth should continue—particularly if these measures are collected in ways that provide a basis for curriculum improvement. However, it is important to recognize that US public schools are about much more than subject-matter acquisition. More research on students and how they mediate social, emotional, and academic contexts might enable educators to design better school programs that recognize students both as academic learners and as social beings (McCaslin and Good 1992).

Schooling: Impact on Cognitive and Motivational Development

Up until the mid-1970s, neither the general public nor the social sciences could agree on whether schooling has a significant impact on cognitive development, how large this impact is or may be, and which variables are responsible for any potential effects it may have. For example, even in 1975, Good et al. asked skeptically, 'Do schools or teachers make a difference? No definite answer exists because little research has been directed on the question in a comprehensive way' (Good et al. 1975, p. 3). Things have changed since then, because the findings from numerous empirical studies have banished any serious doubts concerning whether schooling impacts on both the cognitive and motivational development of students.

This article will report the arguments questioning the importance of school for the mental development of children and adolescents and assess their scientific validity; present the empirical evidence on the strong impact of school on cognitive development, while simultaneously showing the limits to its generalizability; and sketch the findings on the role of school in motivational development. The final section presents some conclusions on the relations between cognitive and motivational development under the influence of school.

1. *Scientific Doubts Regarding the Impact of Schooling on Cognitive Development*

Compared with the impact of social origins and/or stable individual differences in intellectual abilities on cognitive development, that of schooling was long considered marginal. Nonetheless, the Coleman Report (Coleman et al. 1966) was still a great shock to many politicians, educators, and teachers when it concluded, 'that school brings little influence to bear on a child's achievement that is independent of his background and general social context' (p. 325). Just as radically, Jencks et al. (1972) confirmed 'that the character of schools' output depends largely on a single input, namely, the characteristics of the entering children. Everything else—the schools' 'budget, its policies, the characteristics of the teachers—is either secondary or completely irrelevant' (p. 256). According to their findings, elementary school contributed 3 percent or less to the variance in cognitive development, and secondary school 1 percent or less.

Even though both Coleman et al.'s (1966) and Jencks et al.'s (1972) general statements were modified and differentiated slightly in comparisons between private and public schools, between middle-class and lower-class children, and between the effects of different school variables, the final conclusion remains unchanged: 'Nevertheless, the overall effect of elementary school quality on test scores appears rather modest' (Jencks et al. 1972, p. 91). Viewed from the perspective of the beginning of the twenty-first century, such statements and conclusions are, without exception, underestimations of the impact of schooling on cognitive development in childhood and adolescence.

There are various reasons for these underestimations. First, two aspects of cognitive development that should be kept strictly separate are frequently confounded: the growth and acquisition of competencies, knowledge, and skills on the one side compared with the change in interindividual differences in cognitive abilities on the other. We now know that schools are necessary and very influential institutions for the acquisition of that declarative and procedural knowledge that cannot be learned in the child's environment outside school, but that the quantity and quality of schooling has only a limited power to modify individual differences in abilities.

Second, Coleman et al. (1966), Jencks et al. (1972), and many other studies, compared very similar schools in the USA or other industrialized countries. Naturally, such schools reveal more commonalities than

differences due to the similarities in teacher training, curricular goals, educational traditions, the budget of the educational institutions, the state-regulated quantity of teaching, and standardized achievement tests. The methodological problems in such research did not become evident until the publication of findings from cross-cultural studies. These showed that when schools in the Third World—or even achievement measured in ethnic groups with no or very low school education—are taken into account alongside schools in industrialized countries, massive effects of the quantity and quality of instruction can be ascertained (Anderson et al. 1977).

The third reason for underestimating the impact of schools was that scientific interest in educational sociology focused on the role of social class and the family in mental development, whereas developmental psychology was dominated by Jean Piaget's constructivist model. Whereas theories of cognitive development deal with general mechanisms of thought, action, and experience, models of school learning in the strict sense are concerned with the acquisition of specific skills and small bits of knowledge. Piaget and his co-workers emphasized 'that this form of learning is subordinate to the laws of development and development does not consist in the successive accumulation of bits of learning since development follows structuration laws that are both logical and biological' (Inhelder and Sinclair 1969, p. 21).

2. *Empirical Confirmation of the Impact of Schooling on Cognitive Development*

In many social scientists, the skeptical attitude toward the role of schools in recent decades has been overcome to a large extent (although not completely) by the results of numerous empirical studies. This applies not only to the acquisition of specific cognitive competencies but also to the promotion of intelligence.

After reviewing the relevant literature, Rutter (1983, p. 20) came to the conclusion that 'the crucial component of effective teaching includes a clear focus on academic goals, an appropriate degree of structure, an emphasis on active instruction, a task-focused approach, and high achievement expectations.' Although recent years have seen increasingly strong criticism of Rutter's description of the successful classroom, it is broadly confirmed empirically that active teachers, direct instruction, and effective classroom management on the one side accompanied by active, constructive, and purposeful learners on the other side are necessary conditions for the effective acquisition of competencies, knowledge, and skills. Naturally, a major role can also be assigned to intrinsically motivated, self-organized, and cooperative learning (Weinert and Helmke 1995).

Nonetheless, the impact of schools on cognitive development ranges far beyond teaching declarative and procedural knowledge and also includes the promotion of intellectual abilities. For example, Ceci (1991) summarized his state-of-the-art review as follows:

> Of course, schooling is not the complete story in the formation and maintenance of IQ-scores and IQ-related cognitive processes … Children differ in IQ and cognitive processes prior to entering school, and within a given classroom there are sizeable individual differences despite an equivalence of schooling. … Thus, the conclusion seems fairly clear: Even though many factors are responsible for individual and group differences in the intellectual development of children, schooling emerges as an extremely important source of variance, notwithstanding historical and contemporary claims for the contrary. (p. 719)

Looking at the available data from industrialized countries, the Third World, and, above all, cross-cultural studies on the impact of schooling on cognitive development in general and the effectiveness of specific features of schools in particular, substantial effects can be ascertained on intellectual abilities; on metacognitive strategies; on the acquisition of verbal, mathematical, scientific, logical, and technological competencies; and on various forms of domain-specific and cross-domain knowledge. These findings provide unequivocal support for Geary's (1995) hypothesis that schools are necessary cultural conditions for the acquisition of those abilities and skills that cannot be learned in the child's immediate environment: this means almost all the cognitive competencies necessary for a good life and a successful career in our modern scientifically and technologically shaped world.

Up to which level cognitive development is enhanced and which competencies are acquired depends strongly on the quality and quantity of schooling. This is confirmed by findings from a number of large-scale international studies that not only compared school achievement but also assessed important features and variables in the individual national school systems. A current example is the Third International Mathematics and Science Study (TIMSS) carried out by the International Association for the Evaluation of Educational Achievement (IEA; see Baumert et al. 1997).

In association with numerous national and regional studies on educational productivity, school effectiveness, or school improvement, it has been possible to identify a variety of combinations and configurations of variables in the school system, the individual school, the classroom, the teacher, instruction, and the school context that impact on various dimensions and aspects of the cognitive development of students. At the same time, these findings have also led to scientific suggestions for improving school systems.

Alongside mean effect sizes, the long-term effects of exceptional schools and teachers are of particular interest. For example, Pederson et al. (1978) reported

the strong long-term effects of one excellent teacher in a single-case study. Compared with the students of other teachers, the children she had taught in their first two years at school were significantly more successful in their later academic careers as well as in their later jobs. More detailed analyses of this effect revealed that this teacher attained above-average effects on school performance in the first two school grades as well as on her students' attitudes toward work and their initiative, but no great increase in intellectual abilities. Even more important than the direct teacher effects were the indirect effects of a good, successful, and positively experienced start to school on all the children's further cognitive and motivational development.

Although it has to be said that this is only one single-case study, its findings could be replicated as a trend, though not so emphatically, in several representative longitudinal studies (Weinert and Helmke 1997). However, great methodological care is necessary when gathering, analyzing, and interpreting longitudinal data. Only multilevel analyses (that view teacher or instruction variables as being moderated by classroom contexts, and classroom effects as being influenced by features of the school, the school system, and the sociocultural environment) permit valid estimations of the effects of certain clusters of variables on students' cognitive development and growth in knowledge.

Such studies have shown that individual variables make only a very limited contribution to explaining the variance in student outcomes. There are many reasons for this: one of the most important is the complex 'multideterminedness' of students' academic achievement. Haertel et al. (1983) characterize the ensuing theoretical and methodological problems as follows:

> … classroom learning is a multiplicative diminishing-returns function of four essential factors—student ability and motivation, and quality and quantity of instruction … Each of these essential factors appear to be necessary but insufficient by itself to classroom learning; that is, all four of these factors appear to be required at least at minimum levels for the classroom learning to take place. It also appears that the essential factors may substitute, compensate, or trade-off for one another in diminishing rates of return. (p. 75)

3. *The Limited Impact of School on the Modification of Individual Differences in Cognitive Abilities and Competencies*

Of the four essential conditions for classroom learning identified by Haertel et al. (1983), only two (the quantity and quality of instruction) are under the control of the school and the teacher. The other two (ability and motivation) are features of students. Already when entering school, children exhibit large interindividual differences in both their cognitive competencies and their motivational tendencies.

Through genetic factors and through covariations between genotype and environmental influences, interindividual differences in intellectual abilities already become moderately stable early in childhood. Round about the seventh year of life, astonishingly high stability coefficients of 0.5 to 0.7 are already found, despite the relatively low reliability of many tests at this age level. Assuming that more intelligent students learn, on average, more quickly, more easily, and better than less intelligent students under the same conditions of instruction, it can be anticipated that interindividual differences in mental abilities and cognitive development will not diminish under the influence of school but become increasingly more stable. This is also supported by the results of many empirical studies: For example, during the course of elementary schooling, stability coefficients in verbal intelligence tests increase to about 0.8, nonverbal intelligence to 0.7, mathematical competencies to 0.7, reading and writing to 0.7, and the development of positive attitudes toward learning, self-confidence, and test anxiety to 0.6 in each case (Weinert and Helmke 1997). This recognizable trend in elementary school continues in secondary school, with stabilities in IQ scores already attaining values between 0.8 and 0.9 from the age of 12 years onward, thus permitting almost perfect long-term prediction.

These and other empirical findings can be used to draw some theoretical conclusions on classroom learning that may be modified, but not falsified, by variations in school contexts:

(a) Cognitive abilities and competencies develop dramatically in childhood and adolescence—not least under the influence of the school. At the same time, interindividual differences already stabilize at a relatively early age and then remain more or less invariant.

(b) This trend applies not only for intellectual abilities but also for the acquisition of cognitive competencies and domain-specific knowledge. This is particularly apparent when the knowledge acquired is cognitively demanding. In this case, it is necessary to assume a relationship between the level of intelligence and the quality of the knowledge ('intelligent knowledge').

(c) Naturally, the stabilities in individual differences are in no way perfect, so that changes can be observed in students' relative positions in the ranking of abilities and academic achievements. However, very strong changes are often an exception due to idiosyncrasies rather than the rule.

(d) All attempts to level out these individual differences in cognitive abilities and competencies that stabilize during the course of schooling and to make achievements and achievement dispositions equal for all students have generally been unsuccessful. The same applies to the concept of mastery learning when

practiced over a longer period of time and on demanding tasks.

(e) Of course, very significant changes in individual differences result when students are taught for different lengths of time and/or with different achievement aspirations in various subjects or the same subject. Whereas, for example, some students broaden their basic knowledge of the world only slightly through the physics they learn at school, others acquire a high degree of expertise in the subject. Despite the doubtful validity of the claim put forward in the novice–expert research paradigm that intellectual abilities and talents are irrelevant for the acquisition of expertise, the extent of deliberate practice seems to be decisive for the achievement of excellence.

(f) Regardless of the level of individual abilities and regardless of the stability of interindividual differences in ability, it is still necessary for all students to acquire all their cognitive competencies through active learning. Many studies have shown that the quantity and quality of instruction are useful and, in part, even necessary for this.

4. *The Impact of Schooling on Motivational Development*

The available statistical meta-analyses confirm the belief shared by most laypersons that student motivation is an essential personal factor for successful learning at school. However, motivational tendencies and preferences are not just conditions of learning but are also influenced by learning and teaching in the classroom. Their systematic promotion is simultaneously an important goal of school education.

To analyze motivational conditions and consequences of school learning, it is necessary to distinguish strictly between dispositional motives and current motivation. Whereas motives (e.g., achievement motive, affiliation motive, attribution style, test anxiety, self-confidence) are understood as personal traits that are relatively stable and change only slowly, motivation concerns current approach or avoidance tendencies that not only depend on dispositional motives but are also influenced strongly by situational conditions (stimuli, incentives, rewards, threats, etc.). Naturally, the long-term modification of motivational development through the school predominantly involves the students' dispositional motives, attitudes, and value orientations.

School enrollment between the fifth and seventh year of life seems to be a sensitive period of development for this. The cognitive competencies acquired during preschool years enable first graders to compare themselves with others, to make causal interpretations over the differences and changes in achievement they register, and to form anticipations regarding future achievements. At the same time, the school class offers a variety of opportunities for comparisons on the levels of behavior, achievement, evaluation, and ability. Teachers play an important role in this.

Almost all preschool-age children are optimists: They look forward to attending school, most anticipate that they will do well, they have only a low fear of failure, and they believe that they will be able to cope with all the demands of the school. This more-than- optimistic attitude changes during the first two years at school. In general, children become realists, although most of them continue to hold positive expectations regarding their own success. This basic attitude stabilizes during the further course of schooling—naturally, with large interindividual differences due, in part, to personal academic successes and failures, in part to a stable anticipation bias (Weinert and Helmke 1997).

This general developmental trend is modified more or less strongly by specific features of the school, the classroom, the teacher, and the methods of instruction (for overview see Pintrich and Schunk 1996). A few examples of this will be given below. These come either from studies in which the motivational effects of teaching and learning were observed in the classroom, or from studies assessing the effects of planned interventions.

Personal causation (the feeling of being an origin and not a pawn) is an important motivational condition for successful classroom learning. If students are to experience personal causation, they must have opportunities to (a) set themselves demanding but realistic goals, (b) recognize their own strengths and weaknesses, (c) be self-confident about the efficacy of their own actions, (d) evaluate whether they have attained the goals they have set themselves, and (e) assume responsibility not only for their own behavior but also, for example, that of their classroom peers.

Psychological interventions designed to enhance the 'origin atmosphere' in the classroom and increase the 'origin experiences' of the students have led not only to the intended motivational changes but also to broad improvements in average academic achievement. Similarly positive outcomes are reported from studies designed to improve the goal orientation of learning, to strengthen achievement motivation, and to modify the individual patterns of attributions used in intuitive explanations of success and failure. For example, efforts have been made in both classrooms and individual students to modify the typical attribution style for learned helplessness (attributing failure to stable deficits in ability and success to luck or low task difficulty) so that given abilities and varying effort as a function of task difficulty become the dominant personal attribution patterns.

Positive modifications to student motivational development depend decisively on the teacher's attitudes, instructional strategies, and feedback behavior. As a result, many intervention programs for enhancing motivation focus on both students and teachers

simultaneously. For example, a large study of 'self-efficacious schools' is being carried out at the present time in Germany. It is testing the assumption that enhanced self-efficacy beliefs may affect not only teacher behavior (by reducing burnout syndromes and enhancing a proactive attitude) but also student learning (by increasing motivation and achievement).

For several decades, theories of learning motivation have been dominated by the assumption that basic needs are satisfied through achievement, social support, rewards, self-evaluation, and so on. Frequently the motivational mechanisms were those underlying expectancy × value models, cost-benefit calculations, or instrumental behavior models. In comparison, intrinsic motives for learning have played a much smaller role. Intrinsic motivation addresses needs and goals that are satisfied by the process of learning itself and by the possibility of experiencing and enjoying one's own expression of competence and increasing knowledge in a preferred content domain. In this theoretical framework, working and learning are not a means to an end, but are more or less an end in themselves; learning activities and learning goals are not clearly distinguished (e.g., exploratory drive, experience of flow, effectancy motivation, etc.). Underlying these concepts is the assumption '… that intrinsic motivation is based in the innate, organismic needs for competence and self-determination. It energizes a high variety of behaviors and psychological processes for which the primary rewards are the experience of effectance and autonomy' (Deci and Ryan 1985, p. 32).

The reason for a careful consideration of intrinsic motivation is that in educational philosophy intrinsic motivated learning and behavior are regarded as the most important goals of schooling. The worry is that strengthening extrinsic motivation by making external incentives and rewards available is likely to be detrimental to achieving this goal. The ideas underlying such fears come from the results of some studies investigating the 'overjustification effect,' which show that the use of rewards can undermine intrinsic motivation. However, the results of several recent studies indicate that this fear is unjustified. Furthermore, the relation between dispositional motives, actual motivation, and learning activities is not simple and linear but is influenced strongly by interconnections with cognitive processes, metacognitive strategies, and volitional skills.

5. *Conclusions*

Schools are cultural and educational institutions for promoting cognitive development and imparting those competencies that the child cannot acquire within the immediate environment. Throughout the world, schools fulfil this evolutionary, psychological, and cultural function more or less well. The quantity and quality of instruction are a major source of the variance in the genesis of interindividual differences in cognitive competencies. Moreover, the development and promotion of competent, self-regulated learning is an equally important goal of schools in modern societies. The development of intrinsic and extrinsic motives becomes particularly important here in association with metacognitive and volitional competencies. This is why recent decades have seen not only studies examining which relations can be found between the classroom atmosphere, the teacher's behavior, and the subjective experiences of the students on the one side and their motivational and cognitive development on the other side, but also numerous programs designed to promote motivation systematically that have been tried out with, in part, notable success.

The relation between cognitive and motivational development and their interaction are of particular interest in both theory and practice. This is just as true for the influence of academic success on the development of a positive self-concept as for the importance of the self-concept for individual progress in learning (Weinert and Helmke 1997).

Schools, Micropolitics of

'Micropolitics' is a specific perspective in organization theory. It focuses on 'those activities taken within organizations to acquire, develop, and use power and other resources to obtain one's preferred outcomes in a situation in which there is uncertainty or dissent' (Pfeffer 1981, p. 7) because it considers them as most important for the constitution and the workings of organizations.

This article will explore the uses and usefulness of this concept in educational research. It starts by outlining the micropolitical view on educational organizations. Then, it gives some examples of representative micropolitical research in order to illustrate typical topics and research strategies. Finally, it discusses criticisms of micropolitics and indicates areas for development.

1. *The Concept of Micropolitics*

1.1 *Main Elements*

Traditional organizational theories of different origins seem to converge in describing organizations as goal oriented and rationally planned, characterized by stable objective structures, a high degree of integration, and a common purpose of its members. Conflicts between the members of an organization are considered costly and irrational 'pathologies' to be eradicated as soon as possible.

However, conflicts are endemic in organizational life (Ball 1987). Different stakeholders pursue their own interests which are not necessarily identical with the formulated goals. Coalitions are formed, meetings are boycotted, and formal structures are ignored. As such phenomena frequently occur in organizations, it is not helpful to exclude them from organizational theorizing: models which can cope with this 'dark side of organizational life' (Hoyle 1982, p. 87) are needed.

The micropolitical perspective was originally developed in the realm of profit organizations (e.g., Bacharach and Lawler 1980, Pfeffer 1981). In a 1982 seminal paper, Eric Hoyle (1982) put forward arguments for exploring the concept also for education. In 1987 Stephen Ball (1987) published the book *The Micro-Politics of the School* in which he used empirical material to push the development of the concept. In its wake the term 'micropolitics' appeared more frequently in various research papers (see Blase 1991 for a representative collection). What are the main elements of a micropolitical view of schools as presented in this early research?

(a) The micropolitical perspective is based on a specific view of organizations. They are seen as characterized by diverse goals, by interaction and relationships rather than structures, by diffuse borders and unclear areas of influence rather than clear-cut conditions of superordination and delegation, by continuous, unsystematic, reactive change rather than by longer phases of stable performance and limited projects of development. The main focus of micropolitical approaches is not the organization as it aspires to be in mission statements or organizational charts, but the organization-in-action and, in particular, the 'space between structures' (Hoyle 1982, p. 88) which produces enough ambiguity to allow political activities to flourish.

(b) A micropolitical approach is based on a specific image of actors. The members of organizations are seen as pursuing their own interests in their daily work. The actors may do this as individuals, they may coalesce in loosely associated interest sets, or use subdivisions of the organization (e.g., departments, professionals versus administration) as power bases. In order to protect or enhance their organizational room for maneuver, they aim to retain or obtain control of resources, such as the following (see Kelchtermans and Vandenberghe 1996, p. 7, Ball 1987, p. 16):

(i) material resources, such as time, funds, teaching materials, infrastructure, time tabling, etc.

(ii) organizational resources such as procedures, roles, and positions which enable and legitimate specific actions and decisions. They define 'prohibited territories' and relationships of subordination or autonomy. Thereby, they have their bearing on the actors' chances to obtain other resources (e.g., through career, participation, etc.).

(iii) normative or ideological resources, such as values, philosophical commitments, and educational preferences. A particularly important ideological resource is the 'definition of the organization' which indicates what is legitimate and important in the organizational arena.

(iv) informational resources: the members of an organization are interested in obtaining organizationally relevant information and to have their expertise, knowledge, and experience acknowledged.

(v) social resources: affiliation to, support from, and reputation with influential groups within and outside

the school are assets which may be mobilized for one's organizational standing.

(vi) personal resources: also personal characteristics—such as being respected as a person, being grounded in an unchallenged identity as a teacher, etc.—are resources in organizational interactions.

(c) A micropolitical perspective pays special attention to interaction processes in organizations. These are interpreted as strategic and conflictual struggle about the shape of the organization which, in consequence, defines the members' room for maneuver. This has the following implications:

(i) Organizational interaction is power-impregnated. It draws on the resources mentioned above for influencing the workings of an organization. However, these resources have to be mobilized in interaction in order to become 'power.'

(ii) Power is in need of relationship. In order to satisfy his or her interests an actor needs some interaction from other actors. Power builds on dependency, which makes the relationship reciprocal, but, as a rule, asymmetric.

(iii) Power is employed from both ends of the organizational hierarchy. There are advantages of position, however, 'micropolitical skills may be well distributed throughout the organization and position is not always an accurate indicator of influence' (Ball 1994, p. 3824).

(iv) Actors use a multitude of strategies and tactics to interactively mobilize their resources and to prevent others from doing so, such as, for example, setting the agenda of meetings, boycotting and escalating, avoiding visibility, confronting openly or complying, carefully orchestrating scenes behind closed doors or in public arenas, etc.

(v) Organizational interaction is seen as conflictual and competitive. 'Confronted by competition for scarce resources and with ideologies, interests and personalities at variance, bargaining becomes crucial' (Gronn 1986, p. 45). The relationship between control and conflict (or domination and resistance) is conceived 'as the fundamental and contradictory base of organizational life' (Ball 1994, p. 3822).

(vi) Organizational change is nonteleological, pervasive, and value-laden since it advances the position of certain groups at the expense of the relative status of others (see Ball 1987, p. 32). Schools are not organizations easily changed; a 'quick-fix orientation' in innovation will not be appropriate to their cultural complexities (see Corbett et al. 1987, p. 57).

2. *Research in the Micropolitics of Education*

2.1 *Methods and Strategies*

If part of the micropolitical activities which are interesting for the researcher take place in privacy, if these processes are often overlain by routine activities (see Ball 1994, p. 3822), and if experienced actors regularly use strategies such as covering up actions, deceiving about real intentions etc., then researching the micropolitics of schools will have to cope with some methodological problems.

To come to grips with their object of study micropolitical studies focus on critical incidents, persons and phases that disrupt routine, for example, the appointment of a new principal, the introduction of new tasks or programs, instances of structural reorganization (e.g., a school merger), etc. They pay special attention to the processes of (re-)distribution of resources, rewards, and benefits (see Ball 1994, p. 3823) or analyze instances of organizational conflict to find out how new organizational order has been established. These strategies provide a quicker access to indicative processes, but are certainly in danger of inducing an overestimation of the proportion of conflict in organizations. Micropolitical studies try to enhance their credibility through triangulation of methods, collection of multiple perspectives, long-term engagement in the field, critical discourse in a team of researchers, and feedback from participants and external researchers.

Although there have been some attempts to tackle organizational micropolitics with quantitative means (see Blickle 1995), most studies are based on qualitative methods. There have been interview and observation studies, however, the typical strategy is a case study approach mainly based on interviews, field notes from participant or nonparticipant observation, transcripts of meetings, analyses of documents, and cross-case comparison of different sites.

A good example of such a case study is Sparkes' (1990) three-year study of a newly appointed departmental head's attempts at innovation: the head seeks to orientate Physical Education teaching towards a child-centered approach emphasizing mixed-ability grouping and individual self-paced activities which run counter to the then prevalent 'sporting ideology.' In the beginning the new head believes in rational change and democratic participation. The head tries to make other department members understand his own particular teaching approach before introducing changes to the curriculum. However, not all staff can be convinced through dialogue.

In his management position the departmental head can control the agenda of department meetings, time, and procedure of arriving at decisions, etc. He secures the agreement of crucial staff members before the meetings and networks with other influential persons outside his department. His proposals for innovation are nevertheless met with resistance by some staff. However, this resistance cannot prevent the structural changes being introduced. However, these structural changes cannot guarantee teachers' conformity to the head's educational goals within the confines of individual classrooms. Thus, he goes on to consolidate

his domination of the department by careful selection of new staff and exclusion of the unwilling.

Although being successful in that his proposals for curriculum change were implemented within one year, the departmental head ended up in a situation that was characterized by conflict and uncertainty and, thus, in many respects, counteracted his own aspirations of democratic leadership. Sparkes suggests that his findings have some bearing beyond the specific case. He warns that the 'ideology of school-centered innovation … fails to acknowledge the presence and importance of conflict and struggle both within, and between, departments … the commonly held view of teacher participation in the innovative process as 'good' in itself is highly questionable. The findings presented indicate that qualitative differences exist in the forms of participation available to those involved and that, to a large extent, these are intimately linked to the differential access that individuals have to a range of power resources' (Sparkes 1990, p. 177).

2.2 Research Topics

Typical topics of micropolitical studies are the following:

Processes of change: when organizational 'routine games' are disrupted e.g., through educational, curricular, or organizational innovations, through the recruitment of new principals or teachers, through the introduction of quality assurance systems, then intensified processes of micropolitical relevance are to be expected. Some studies investigate how externally mandated reform is dealt with in schools: when Ball and Bowe (1991, p. 23) studied the impact of the 1988 British Educational Reform Act, they found that 'the implementation of externally initiated changes is mediated by the established culture and history of the institution, and that such changes, ''their acceptance and their implementation become sites as well as the stake of internal dispute.'' The reform puts some possible alternative definitions about the meaning and the workings of schools on the agenda which have to be 'processed' in the local environments through disputes over topics such as, for example, 'serving a community versus marketing a product' or 'priority to managerial or professional views of schooling.'

Leadership and the relationships in the organization: traditionally, educational ethnography had a strong classroom orientation. Micropolitics may be understood as a move to apply ethnographic methods to study the interaction of the members of the school outside the classroom. Although parents', pupils' and ancillary staff's voices are included in some studies, most research focuses on the interaction of teachers. Since steering and regulation of schoolwork are at the heart of the micropolitical approach, it is no wonder that issues of leadership have been frequently investigated (see Ball 1987, p. 80). Holders of senior positions must acquire micropolitical skills for their career advancement and they 'have much to lose if organizational control is wrested from them' (Ball 1994, p. 3824) which makes them perfect foci for study. While many of these studies concentrated on sketching vivid images of a 'politics of subordination,' Blase and Anderson (1995) developed a framework for a 'micropolitics of empowerment' through facilitative and democratic leadership.

Socialization and professional development of teachers: the politically impregnated organizational climate in schools is the context in which individual teachers develop their professional identity (Kelchtermans and Vandenberghe 1996). During the first years of their career teachers concentrate on acquiring knowledge and competencies with respect to academic and control aspects of classroom instruction. Later on they build up a 'diplomatic political perspective,' because they feel under 'constant scrutiny' by pupils, parents, fellow teachers, and administrators (see Blase 1991, p. 189, Kelchtermans and Vandenberghe 1996). A pervasive feeling of 'vulnerability' induces many teachers to develop a range of protective strategies such as low risk grading, documentation of assessment and instruction, avoidance of risky topics and extracurricular activities, etc. (see Blase 1991, p. 193). Thus, it is no wonder that some authors claim that the acquisition of political competence is fundamental to teachers' career satisfaction (see Ball 1994, p. 3824). Since micropolitical perceptions and competencies are almost absent in beginning teachers' interpretive frameworks, attention to the induction phase is important (Kelchtermans and Vandenberghe 1996, p. 12).

Understanding schools as organizations: since micropolitics is an approach to organization theory all these studies aim to contribute to our understanding of schools as organizations. There are many studies which prove the intensity of power-impregnated activity in schools and analyze typical causes and process forms. It has been argued that political control strategies are a characteristic part of school life 'precisely because the professional norms of teacher autonomy limit the use of the effectiveness of more overt forms of control' (Ball 1994, p. 3824).

In Iannaconne's (1991) view, the unique contribution a micropolitical approach can offer lies in exploiting the metaphor of 'society' for schools: a typical school is organized like a 'caste society' since a majority of its members are 'subject to its laws without the right to share in making them' (Iannaconne 1991, p. 469). From the characteristics of a 'caste society' some hypotheses about schools may be derived, e.g.:

(a) Such societies are characterized by great tensions between the castes and a fragile balance of power.

(b) They tend to conceal the internal differences of a caste from others. Consequently, critical self-examination of castes and open debate over policy issues is difficult.

(c) They tend to avoid fundamental conflicts and to displace them into petty value conflicts.

'In schools, as in small rural towns, the etiquette of gossip characterizes teacher talk. Faculty meetings wrangle over trivial matters, avoiding philosophic and ethical issues like the plague' (Iannaconne 1991, p. 469).

3. *Criticism and Areas for Development*

The first wave of research and conceptual work in micropolitics at the beginning of the 1990s has triggered some criticism which will be discussed in order to identify possible limitations, but also areas for development.

(a) Many authors of the micropolitical approach revel in examples of illegitimate strategies: secrecy, deception, and crime add much to the thrill of micropolitical studies. Some critics argue that talking about the pervasiveness of 'illegitimate power' produces itself a 'micropoliticization' of practice and will undermine confidence in organizations. This claim implies that a second meaning of 'micropolitics' is introduced: it does not (only) refer to an approach in organization theory (which analyses both legitimate and illegitimate interactions and their effects for the structuration of an organization), but refers to those specific activities and attitudes in organizations which are based on power politics with illegitimate means. This conceptual move, however, produces problems: how should it be possible to draw the line between 'good' and 'bad organizational politics' since it were precisely situations characterized by diverse goals and contested expertise which made a concept like 'micropolitics' necessary?

(b) Although the proponents of micropolitics are right to criticize a presupposition of organizational consensus, it is unsatisfactory to interpret any consensus as a form of domination (see Ball 1987, p. 278, Ball 1994, p. 3822). Many early studies did not include cooperative or consensual interactions (see Blase 1991, p. 9). It will be necessary to develop conceptual devices to account for relationships of co-agency which neither dissolve any cooperation into subtle forms of domination nor gloss over the traces of power which are at the core of collaboration and support (see Altrichter and Salzgeber 2000, p. 104).

(c) In focusing on strategic aspects of action micropolitical approaches are again in danger of overemphasizing the 'rationality' of organizational action. To understand the workings of organizations it may be necessary to consider actions which are mainly influenced by emotions and affect, which have not been carefully planned according to some interests, as well as unintended consequences of otherwise motivated actions.

(d) Although being right to put the spotlight on the potential instability of organizational processes, early micropolitical studies had some difficulty in conceptualizing the relative stability and durability of organizations, which we can observe every day in many organizations. For this purpose, it will be necessary to bring agency and structure in a balanced conceptual relationship: micropolitics will not deal with 'relationships rather than structures' (Ball 1994, p. 3822) but precisely with the interplay between interaction and structure.

(e) The understanding of politics displayed in many early micropolitical studies was quite unsatisfactory, not to say unpolitical. Politics was often seen as the opposite of truth and reason; it was associated with treason, conspiracy and accumulation of influence as if fair and democratic ways of negotiation in organizations were inconceivable. More recent studies, for example, Blase and Anderson (1995), seem to overcome this bias. It was also criticized that in some micropolitical studies the external relationships of the organization were dissolved into the interactions between individual actors. However it must be said that some studies took care to account for the societal embedding of organizational interactions (see Ball and Bowe 1991). In the meantime there is general agreement that this must be a feature of sound micropolitical studies (see Blase 1991, p. 237).

Problems (c) and (e) may be overcome by reference to Giddens' (1992) theory of structuration, to Crozier and Friedberg's (1993) concept of organizational games, and to Ortmann et al.'s (1990) studies of power in organizational innovation. On this conceptual basis, organizational structure may be seen as an outcome of and resource for social actions which enables and restricts actions, but never fully determines them. Organizations are webs woven from concrete interactions of (self-)interested actors. They acquire some spatial-temporal extension through the actors' use and reproduction of 'games.' The 'game' is the point of conceptual intersection in which the analytically divided elements of agency and structure, of individual and organization meet. The game works as an 'indirect integration mechanism which relates the diverging and/or contradictory action of relatively autonomous actors' (Crozier and Friedberg 1993, p. 4). In order to take action and to pursue their own interests members of organizations must at least partly use structural resources of the organization i.e., they are forced to play within the organizational rules, and thereby, they reproduce these rules. The functioning of an organization may be explained as 'result of a series of games articulated among themselves, whose formal and informal rules indirectly integrate the organization members' contradictory power strategies' (Ortmann et al. 1990, p. 56). The interlocked character of the games and the high amount of routine elements in social practices are major reasons for the relative stability of organizations (see Altrichter and Salzgeber 2000, p. 106).

Schumpeter, Joseph A (1883–1950)

Joseph A. Schumpeter is one of the best known and most flamboyant economists of the twentieth century. His main accomplishments are to have introduced the entrepreneur into economic theory through *Theorie der wirtschaftlichen Entwicklung* (1912) and to have produced a magnificent history of economic thought, *History of Economic Analysis* (posthumously published in 1954). Schumpeter's interests were wide ranging, and his writings also include contributions to sociology and political science. His analysis of democracy, which can be found in his most popular work, *Capitalism, Socialism, and Democracy* (1942), is generally regarded as an important addition to the theory of democracy.

1. Early Life and Career

Joseph Alois Schumpeter was born on February 8, 1883 in the small town of Triesch in the Austro-Hungarian Empire (today Trest in Slovakia). His father was a cloth manufacturer and belonged to a family which had been prominent in the town for many generations; and his mother, who was the daughter of a medical doctor, came from a nearby village. Schumpeter's father died when he was four years old, an event that was to have great consequences for the future course of his life. Some time later his mother moved to Graz and then to Vienna, where she got married to a retired officer from a well known, aristocratic family, Sigismund von Kéler. Schumpeter was consequently born into a small-town bourgeois family but raised in an aristocratic one; and his personality as well as his work were to contain a curious mixture of values from both of these worlds.

After having graduated in 1901 from the preparatory school for the children of the elite in the Empire, Theresianum, Schumpeter enrolled at the University of Vienna. His goal from the very start was to become an economist. Around the turn of the century the University of Vienna had one of the best educations in economics in the world, thanks to Carl Menger and his two disciples Eugen von Böhm-Bawerk and Friedrich von Wieser. Schumpeter had the latter two as his teachers, and he also attended lectures in mathematics on his own. When Schumpeter received his doctorate in 1906, he was 23 years old and the youngest person to have earned this degree in the Empire.

After having traveled around for a few years and added to his life experience as well as to his knowledge of economics, Schumpeter returned in 1908 to Vienna to present his *Habilitationsschrift*. Its title was *Das Wesen und der Hauptinhalt der theoretischen Nationalökonomie (*1908; *The Nature and Essence of Theoretical Economics)*, and it can be characterized as a work in economic methodology from an analytical perspective. In 1909 Schumpeter was appointed as-

sistant professor at the University of Czernowitz and thereby became the youngest professor in German-speaking academia. It was also at Czernowitz that Schumpeter produced his second work, the famous *Theorie der wirtschaftlichen Entwicklung* (1912; 2nd edn. from 1926 trans. as *The Theory of Economic Development*). At the University of Graz, to which he moved as a full professor in 1911, Schumpeter produced a third major study, *Epochen der Dogmen- und Methodengeschichte* (1914; trans. in 1954 as *Economic Doctrine and Method*). Over a period of less than ten years Schumpeter had produced three important works, and one understands why he referred to the third decade in a scholar's life as 'the decade of sacred fertility.'

1.1 The Works from the Early Years

Das Wesen is today best known for being the place where the term 'methodological individualism' was coined. In its time, however, this work played an important role in introducing German students to analytical economics, which Gustav von Schmoller and other members of the Historical School had tried to ban from the universities in Germany. *Das Wesen* is well written and well argued, but Schumpeter would later regard it as a youthful error and did not allow a second edition to appear. The reason for Schumpeter's verdict is not known, but it is probably connected to his vigorous argument in the book that economics must sever all links with the other social sciences.

While the emphasis in *Das Wesen* had been exclusively on statics, in his second book, *Theorie der wirtschaflichen Entwicklung*, it was on dynamics. Schumpeter very much admired Walras' theory of general equilibrium, which he had tried to explicate in *Das Wesen*, but he was also disturbed by Walras' failure to handle economic change. What was needed in economics, Schumpeter argued, was a theory according to which economic change grew out of the economic system itself and not, as in Walras, a theoretical scheme in which economic change was simply explained as a reaction to a disturbance from outside the economic system.

Schumpeter starts the argument in *Theorie* by presenting an economy where nothing new ever happens and which therefore can be analyzed with the help of static theory, that is all goods are promptly sold, no new goods are produced or wanted, and profits are zero. Schumpeter then contrasts this situation of a 'circular flow' with a situation in which the activities of the entrepreneur sets the whole economic system in motion, and which can only be explained with the help of a dynamic theory. The model that Schumpeter now presented in *Theorie* would later be repeated and embellished upon in many of his writings: the entrepreneur makes an innovation, which earns him a huge profit, this profit attracts a swarm of other, less innovative entrepreneurs and as a result of all these activities a wave of economic change begins to work its way through the economic system, a business cycle, in brief, has been set in motion. The theory of business cycles that one can find in *Theorie* is fairly rudimentary, and Schumpeter would later spend much time in improving upon it.

Much of Schumpeter's analysis in *Theorie* is today forgotten and few economists are today interested in the way that Schumpeter explains interest, capital and profit by relating these to the activities of the entrepreneur. Some parts of *Theorie*, however, are still very much alive and often referred to in studies of entrepreneurship. In one of these Schumpeter discusses the nature of an innovation, and explains how it differs from an invention; while an invention is something radically new, an innovation consists of an attempt to turn something—for example, an invention—into a money-making enterprise. In another famous passage Schumpeter discusses the five main forms of innovations:

> (1) The introduction of a new good … or of a new quality of a good. (2) The introduction of a new method of production … (3) The opening of a new market … (4) The conquest of a new source of supply of raw materials or half-manufactured goods … (5) The carrying out of the new organization of any industry, like the creation of a monopoly position … or the breaking up of a monopoly position.

Schumpeter's description of what drives an entrepreneur is also often referred to, as is his general definition of entrepreneurship: 'the carrying out of new combinations.'

Schumpeter's third work from these early years is a brief history of economics, commissioned by Max Weber (1914–20) for a handbook in political economy (*Grundriss der Sozialökonomik*). Its main thesis is that economics came into being when analytical precision, of the type that one can find in philosophy, came into contact with an interest in practical affairs, of the type that is common among businessmen; and to Schumpeter this meeting took place in the works of the Physiocrats. *Epochen der Dogmen- und Methodengeschichte* was later overshadowed by the much longer *History of Economic Analysis*, but while the latter work tends to be used exclusively as a reference work, Schumpeter's study from 1914 can be read straight through and is also more easy to appreciate.

1.2 Difficult Mid-Years

By the mid-1910s Schumpeter had established himself as one of the most brilliant economists in his generation, and like other well-known economists in the Austro-Hungarian Empire he hoped for a prominent political position, such as finance minister or economic adviser to the Emperor. During World War I Schumpeter wrote a series of memoranda, which were

circulated among the elite of the Empire, and through which he hoped to establish himself as a candidate for political office. The various measures that Schumpeter suggested in these memoranda are of little interest today, for example, that the Empire must not enter into a customs union with its powerful neighbor, Germany. What is of considerably more interest, however, is that they provide an insight into Schumpeter's political views when he was in his early 30s. Schumpeter's political profile at this time can be described in the following way: he was a royalist, deeply conservative, and an admirer of tory democracy of the British kind.

Schumpeter's attempt during World War I to gain a political position failed, but his fortune changed after the Empire had fallen apart and the state of Austria came into being. In early 1919 Schumpeter was appointed finance minister in a joint Social Democratic and Catholic Conservative government in Austria, led by Karl Renner. Already by the fall of 1919, however, Schumpeter was forced to resign, mainly because the Social Democrats felt that he had betrayed them and could not be trusted. The Social Democrats in particular thought that Schumpeter had gone behind their backs and stopped their attempts to nationalize parts of Austria's industry. Schumpeter always denied this, and in retrospect it is difficult to establish the truth. What is clear, however, is that the Austrian Social Democrats advocated a democratic and peaceful form of socialism, while Schumpeter detested all forms of socialism.

Loath to go back to his position at the University of Graz, Schumpeter spent the early part of the 1920s working for a small bank in Vienna, the Biedermann Bank. Schumpeter did not take part in the everyday activities of the bank but mainly worked as an independent investor. These activities ended badly, however, and by the mid-1920s Schumpeter was forced to leave the Biedermann Bank and had by this time accumulated a considerable personal debt. For many years to come, Schumpeter would give speeches and write articles in order to pay back his debts. Adding to these economic misfortunes was the death in 1926 of his beloved wife Anna ('Annie') Reisinger, a 20 years younger working class girl to whom Schumpeter had only been married for a year. From this time on, Schumpeter's friends would later say, there was a streak of pessimism and resignation in his personality.

In 1925 Schumpeter was appointed professor of public finance at the University of Bonn, and it is clear that he was both pleased and relieved to be back in academia. While his ambition, no doubt, extended to politics and business, he always felt an academic at heart. The great creativity that Schumpeter had shown in the 1910s was, however, not to return in the 1920s, and Annie's death was no doubt an important reason for this. Schumpeter's major project during the 1920s was a book in the theory of money, but this work was never completed to his satisfaction Schumpeter 1970). Schumpeter did, however, write several interesting articles during these years, some of which are still worth reading. One of these is *'The Instability of Capitalism'* (1928), in which Schumpeter suggests that capitalism is undermining itself and will eventually turn into socialism. Another worthwhile article is *'Gustav vs. Schmoller und die Probleme von heute'* (1926), in which Schumpeter argues that economics has to be a broad science, encompassing not only economic theory but also economic history, economic sociology and statistics. Schumpeter's term for this type of general economics is *'Sozialökonomik.'*

To illustrate what economists can accomplish with the help of sociology, Schumpeter wrote an article on social classes (1927), which is still often referred to. Schumpeter starts out by drawing a sharp line between the way that the concept of class is used in economics and in sociology. In economics, Schumpeter says, class is basically used as a category (e.g., wage-earner/non-wage-earner), while in sociology class is seen as a piece of living reality. An attempt was also made by Schumpeter to link his theory of the entrepreneur to the idea of class.

In mentioning Schumpeter's articles on social classes, something must also be said about two of his other famous studies in sociology: *'The Fiscal Crisis of the Tax State'* (1918) and *'The Sociology of Imperialisms'* (1918–19). The former study can be described as a pioneer effort in the sociology of taxation, which focuses on the situation in Austria just after World War I but which also attempts to formulate some general propositions about the relationship between taxation and society. Schumpeter, for example, suggests that if the citizens demand more and more subventions from the state, but are unwilling to pay for these through ever higher taxes, the state will collapse. In the article on imperialism, Schumpeter argues that imperialism grows out of a social situation which is *not* to be found in capitalism; and whatever imperialist forms that still exist represent an atavism and a leftover from feudal society. Schumpeter's famous definition of imperialism is as follows: 'imperialism is the objectless disposition on the part of the state to unlimited forcible expansion.'

2. *The Years in the United States*

By 1930 Schumpeter was still depressed about his life and quite unhappy about his career; he had found no one to replace his wife on an emotional level and he felt that he deserved a better professional position than Bonn. When Werner Sombart's chair at the University of Berlin became vacant, Schumpeter had high hopes that he would get it. When this did not happen, however, he instead accepted an offer from Harvard University; and in 1932 he moved to Cambridge, Massachusetts for good. Schumpeter was slowly to regain his emotional composure, and also his capacity

to work, in the United States. In 1937 he got married to economist Elizabeth Boody, who regarded it as her duty in life to take care of Schumpeter and manage his worldly affairs. With the support of his wife, Schumpeter produced three major works: *Business Cycles* (1939), *Capitalism, Socialism and Democracy* (1942), and *History of Economic Analysis* (published posthumously in 1954).

2.1 The Works from the American Period

Of these three works, the one for which Schumpeter had the highest hopes was definitely *Business Cycles* (1939), which appeared exactly 25 years after his last book in Europe. This work is more than 1100 pages long and it traces business cycles in Great Britain, the United States and Germany during the years 1787–1938. Schumpeter had hoped that *Business Cycles* would get the kind of reception that Keynes' *General Theory* got, and he was deeply disappointed by the lack of interest that his colleagues and other economists showed. The impression one gets from histories of economic thought, however, is that *Business Cycles* is rarely read today, mainly because few people are persuaded by Schumpeter's theory that business cycles are set off by innovations and that their motion can be best described as a giant Kondratieff cycle, modified by Juglar and Kitchin cycles; Schumpeter's handling of statistics is also considered poor. To a large extent this critique is true, although it should also be noted that a number of themes and issues in this and other of Schumpeter's works are increasingly being referred to in evolutionary economics.

After many years of excruciatingly hard work on *Business Cycles*, Schumpeter decided that he needed an easier task to work on than the recasting of economic theory that was on his agenda since the time in Bonn. In the late 1930s Schumpeter therefore began working on what he saw as a minor study of socialism. This minor study, however, quickly grew in size, and when it finally appeared in 1942—under the title *Capitalism, Socialism, and Democracy*—it was nearly 400 pages long. Of all of Schumpeter's works (1942), this book was to become the most popular one, especially in the United States where it is still considered a standard work in political science. *Capitalism, Socialism, and Democracy* has also been translated into more languages than any other work by Schumpeter, and it is still in print.

Capitalism, Socialism, and Democracy contains an interesting history of socialist parties (part V), a fine discussion of the nature of socialism (part III), and an excellent discussion of the work of Karl Marx (part I). What has made this work into a social science classic, however, are its two remaining parts with their discussion of capitalism (part II) and the nature of democracy (part IV). Capitalism, Schumpeter says, can be characterized as a process of continuous economic change, through which new enterprises and industries are continuously being created and old ones continuously being destroyed. Schumpeter's famous term for this process is 'creative destruction.' Perfect competition of the type that economists talk about, he also says, is a myth; and monopolies, contrary to common belief and economists' dogma, are often good for the economy. Without monopolies, for example, very expensive forms of research and investments would seldom be undertaken.

Schumpeter's theory of monopolies has led to a large number of studies of innovation. By 'the Schumpeterian hypothesis' two propositions are meant: that large firms are more innovative than small firms, and that innovation tends to be more frequent in monopolistic industries than in competitive ones. Each of these hypotheses can in their turn be broken down into further hypotheses. Many decades later the results of all of these studies are still inconclusive, and there is no consensus if monopolistic forms of enterprise further or obstruct innovation (for an overview of research on the Schumpeterian hypothesis, see Kamien and Schwartz 1982).

Schumpeter's overall theory in *Capitalism, Socialism, and Democracy*—the idea that capitalism is on its way to disappear and be replaced by socialism—has, on the other hand, led to little concrete research. One reason for this is probably that many readers of Schumpeter's book have felt that his argument is very general in nature and at times also quite idiosyncratic. Schumpeter argues, for example, that capitalism tends to breed intellectuals, and that these are hostile to capitalism; that the bourgeois class is becoming unable to appreciate property; and that the general will of the bourgeoisie is rapidly eroding. 'Can capitalism survive?' Schumpeter asks rhetorically, and then gives the following answer, 'No. I do not think it can.' Schumpeter's conclusion about the inevitable fall of capitalism has often been sharply criticized (e.g., Heertje 1981). His more general attempt to tackle the question of how social and economic institutions are needed for an economic system to work properly has, however, remained unexplored. There also exists a certain tendency to cite catchy phrases from Schumpeter's work without paying attention to their organic place in his arguments.

What has always been much appreciated in *Capitalism, Socialism, and Democracy* is Schumpeter's theory of democracy. Schumpeter starts out by criticizing what he calls 'the classical doctrine of democracy,' which he characterizes in the following way: 'the democratic method is that institutional arrangement for arriving at political decisions which realizes the common good by making the people itself decide issues through the election of individuals who are to assemble in order to carry out its will.' What is wrong with this theory, he argues, is that there is no way of establishing what the common good is. There is also the additional fact that politicians do not have interests

of their own, according to this theory; their function is exclusively to translate the desires of the people into reality.

To the classical type of democracy Schumpeter counterposes his own theory of democracy, which he defines in the following manner: 'the democratic method is that institutional arrangement for arriving at political decisions in which individuals acquire the power to decide by means of a competitive struggle for the people's vote.' Some critics have argued that Schumpeter's theory is elitist in nature, since democracy is reduced to voting for a political leader at regular intervals. This may well be true, and Schumpeter's theory of democracy no doubt coexists in his work with contempt for the masses. Regardless of this critique, however, Schumpeter's theory is generally regarded as being considerably more realistic than the classical doctrine of democracy.

World War II was a very trying time for Schumpeter since he felt emotionally tied to German speaking Europe, even though he by now was a US citizen. Schumpeter did not support the Nazis but like many conservatives felt that Communism constituted a more dangerous enemy than Hitler. Schumpeter's intense hatred of Roosevelt, whom he suspected of being a socialist, also put him on a collision course with the academic community in Cambridge during World War II. In his diary Schumpeter expressed his ambivalence towards Hitler, Jews, Roosevelt and many other things; and in his everyday life he more and more withdrew into solitude and scholarship. The War, in brief, was a very difficult and demoralizing time for Schumpeter.

From the early 1940s Schumpeter started to work feverishly on a giant history of economic thought that was to occupy him till his death some ten years later. He did not succeed in completing *History of Economic Analysis*, which was instead put together by Elizabeth Boody Schumpeter after several years of work. *History of Economic Analysis* is many times longer than Schumpeter's history of economics from 1914, and it is also considerably more sophisticated in its approach. Schumpeter's ambition with this work, it should first of all be noted, was not only to write the history of economic theory, but also to say something about economic sociology, economic history, and economic statistics, the four 'fundamental fields' of economics or *Sozialökonomik*. It should also be mentioned that *History of Economic Analysis* begins with a very interesting methodological discussion of the nature of economics. This is then followed by a brilliant, though occasionally willful discussion of economics from classical Greece to the years after World War I. The section on twentieth century economics was unfortunately never completed, but it is clear that Schumpeter was very discontent with the failure of his contemporaries to create a truly dynamic economic theory.

Schumpeter died in his sleep on January 8, 1950 and the cause was put down as cerebral hemorrhage. Some of his friends thought that the real reason was overwork, while his diary shows that he had been tired of life for a long time. Schumpeter's private notes also show that behind the image of brilliant lecturer and iconoclastic author, which Schumpeter liked to project, there was a person who felt deeply unhappy with the way that his life had evolved and with his failure to produce a theory that would revolutionize economic thought. 'With a fraction of my ideas,' he wrote in dismay a few years before his death, 'a new economics could have been founded.'

Schütz, Alfred (1899–1959)

Alfred Schütz was born in Vienna on April 13, 1899. Here he studied law and social sciences from 1918 to 1921. After receiving his Doctorate of Law he continued his studies in the social sciences until 1923. His teachers included Hans Kelsen, an eminent lawyer, Ludwig von Mises, and Friederich von Wieser, prominent representatives of the Austrian school of economics. Equally important as his university studies was his participation in the informal academic life of Vienna, e.g., his participation in the private seminars of von Mises, where Schütz also cultivated his philosophical interests. In addition to his scholarly activities, Schütz held a full-time job as a bank attorney, a dual life which lasted until 1956. After the annexation of Austria to the Third Reich, Schütz and his family escaped to New York. On his arrival, Schütz got in touch with Talcott Parsons whose *Structure of Social Action* he intended to review. But despite their intense correspondence (Schütz and Parsons 1978), the contact between Schütz and Parsons broke down. Instead, Schütz became affiliated with the Graduate Faculty at the New School for Social Research in New York where he started teaching as Lecturer in 1943, advancing to a full Professor of Sociology in 1952 and also of Philosophy in 1956. He died on May 20, 1959 in New York.

1. Major Aims of Schütz's Theory

Alfred Schütz's social theory focuses on the concept of the life world, which is understood as a social-cultural world as it is perceived and generated by the humans living in it. Schütz identifies everyday interaction and communication as being the main processes in which the constitution of the life world's social reality takes place. In this sense, his approach pursues two major goals: the development of a theory of action which reveals the constitution of social reality with its meaning structure given in the commonly shared typical patterns of knowledge, and a description of the life world with its multiple strata of reality emerging from these constituting processes. These leitmotifs merge in a theory of life world constitution—a project which occupied Schütz during the final years of his life.

2. Main Intellectual Sources of the Schützian Approach

Schütz's conception originated in the intellectual discourse in the social sciences and philosophy of the early decades of this century. Schütz developed his position from within a triangular interdisciplinary field marked by Max Weber's historising interpretative sociology (*verstehende Soziologie*), the Austrian economic approach represented by Ludwig von Mises, and the philosophical theories of the stream of consciousness formulated by H. Bergson and E. Husserl. From the very onset, he adopted Max Weber's view of social reality as a meaningful social-cultural world, as well as his concept of social action as a meaning oriented behavior, and shared Weber's search for an interpretative method in sociology. He also shared the methodological individualism advocated by Weber and by the Austrian economists who denoted individual action as the starting point of social research. At the same time, he accepted the need for a generalizing theory of action, as stressed by his teacher Ludwig von Mises, and criticized Weber for neglecting to develop the basic framework of such a theory and especially for not inquiring into the constitution of meaning attached to social action. But Schütz's criticism also addressed the 'general theory of action' based on an '*a priori*' postulate of *rational choice* put forth by Ludwig von Mises. Schütz rejected this conception since it imposed an abstract framework on actors' orientation of action and ignored their actual stock of knowledge.

In order to analyze how the meaning attached to action is revealed, Schütz referred to the philosophical concepts of Henri Bergons and Edmund Husserl. Both offer insights into the stream of lived experience and into the acts of consciousness in which our world is meaningfully constituted. Schütz adopted the Bergsonian idea of the stream of consciousness in his first scholarly attempts in 1924–28 (Schütz 1982), only to later recognize the difficulties in Bergson's intuitivism

and to turn to Husserl's phenomenology which ultimately gave the name to his approach. Husserl was concerned with the acts of consciousness which establish the meaningful taken-for-grantedness of the world in humans' natural attitude. His term 'life world,' which Schütz later assumes, is aimed at the reality constituted in those acts. Based primarily on this philosophical approach, Schütz wrote his first monograph, *Der sinnhafte Aufbau der sozialen Welt*, in 1932, in which he developed the basic concept of his theory (Schütz 1932). Starting with the criticism on Max Weber mentioned above, he devoted himself to the process in which humans create the social world as a reality that is meaningful and understandable to them.

3. *Theory of the Life World with its Everyday Core*

In order to grasp the constitution of the social world, Schütz (1932) had to transcend the realm of consciousness and perception analyzed by Husserl. He included both acts of consciousness as well as human action and interaction into the constitutive process under scrutiny. Departing from the transcendental philosophical approach, he developed his own *mundane* phenomenology which analyzes the constitution of the meaningful reality within social relationships in the everyday world.

He proceeded in three steps dealing with three problems constitutive for any theory of action which is searching for the construction of social reality.

(a) How does a meaningful orientation of human action emerge?

(b) How can we understand the Other?

(c) How is socially-shared, intersubjective valid knowledge generated?

Following the principle of methodological individualism, Schütz started with the analysis of single individual action. Relying on Bergson's concept of the inner stream of lived experience and on Husserl's investigations on intentionality and temporality of consciousness, Schütz first explored the constitution of meaning in subjects as a temporal process. The meaning attached to a lived experience emerges from successive acts of selective reflection aimed towards it and framing it into a context of other experiences. The schemes of experience on which the primary meaning of action, i.e., its project is based, arise from this basic temporal dynamics and plasticity of consciousness. The temporality of the meaning attached to an action manifests itself in two kinds of motivation attached to its different temporal dimensions: '*in-order-to-motives*' which direct action toward the future, and '*because-motives*' representing the roots of the action in the past. However, the meaning of the project of action changes during the time when the projected action is going on. The final meaning of an action can be found in the experience perceived by the subject when looking at the changes that have emerged in the meaning structure of the action when the action is completed. The meaning attached to an action and consequently the schemes of experience are thus not only affected by the acts of consciousness but also by the action itself.

In his second step, Schütz proceeded to show how the schemes of experience are shaped by interaction and communication. He perceived communication as a process in which two subjective streams of consciousness are coordinated within a social interaction (*Wirkensbeziehung*). Thus, communication signifies an interaction in which the meaning of ego's action consists in the intention to evoke a reaction of the alter. Actions in this sense have the function of signs which are mutually indicated and interpreted. The ultimate meaning of my action is revealed in the reaction of the Other and vice versa, therefore communication generates a *chain of motives* where my *in-order-to-motives* become *because-motives* of the Other and provide a common stock of shared patterns of interpretation which allows for mutual understanding even if each of the actors are always referring to their own schemes of experience. In this concept of understanding, based on interaction, Schütz offers his own solution to the problem of intersubjectivity posed by Husserl.

The constitution and appropriation of shared knowledge primarily takes place in long-lasting face-to-face interaction (we-relations) where the mutual expectations are learned, verified, and sedimented to typical patterns that can be applied to more remote and anonymous strata of the social world. As a result, the meaning structure of the social world is characterized by *typifications* of actions, situations, and persons generated in interaction and communication.

In these three steps, Schütz laid down the main features of his theory of the life world. In his later work, Schütz (1962, 1964, 1966) determined this communicatively created social reality as the world of everyday life, in which typical patterns are taken for granted, and which represents the intersubjective common core of the reality we live in. Later on (Schütz 1962, 1970), he disclosed further structural characteristics of this everyday core of the life world. Since its typical structure greatly depends on action, it is also the pragmatic orientation selecting the areas where typification processes take place. Both typicality and this kind of selection, which Schütz designated as *pragmatic relevance*, represent two generative principles of order in the everyday world. They determine its formal structure and at the same time, when realized in action, they shape this structure into a concrete social–cultural world, which is thus characterized by social distribution and differentiation of knowledge. A third moment structuring the everyday world can be found in the rootedness of its constitution in individual action. Here actors and their bodies represent the

central point of the *everyday world and its temporal, spatial, and social dimensions* that are arranged into spheres of past and future, of within-reach and distant and of intimacy and anonymity, respectively, to the ctors' own position (Schütz and Luckmann 1973).

Everyday reality is nevertheless not identical with the life world on the whole. By suspending their pragmatic interests, actors are able to modify their everyday experiences and perceive them as objects of a game, fantasy, art, science, or, if the conscious attention is completely absent, as a dream. There are areas—even in the realm of everyday action directed by the principal of pragmatic relevance—which are beyond the sphere of actors everyday practice and therefore transcend it. All these modifications represent different provinces of meaning transcending the everyday world and constituting *multiple realities* (Schütz 1962) which make up the life world. Nevertheless, among the different provinces of the life world, the everyday core denotes a *paramount reality* since it is only here that actors, driven by the *fundamental anxiety* when facing the finality of their lives, have to master their living conditions and are engaged in communicative processes producing common knowledge which makes mutual understanding possible.

Schütz (1962) viewed communication as a substantial constitutive mechanism of social reality and stressed the role of *language* in this process. He considered language—including its syntax and semantics—as an objectivation of sedimented, social provided stock of knowledge that preserves relevances and typification inherent to cultures and social groups, and thus as crucial for the constitution of the life world (Schütz and Luckmann 1989). Schütz saw language as delineating an essential case of social objectified systems of appresentation which bridges the transcendence between different areas and meaning provinces of the life world. Another important integrative mechanism in the life world are symbolic structures, which are often based on language, and intermediate between the everyday world and non-everyday realities such as religion, arts, or politics (Schütz 1962).

Schütz did not restrict his study of the structure of the life world solely to theoretical research. He also applied his theory as a general interpretative scheme to several social fields and problems. He explored courses of intercultural communication and the social distribution of knowledge, the social conditions of equality in modern societies as well as the fields of music and literature (Schütz 1964).

4. *Consequences of the Theory of Life World for the Methodology of the Social Sciences*

Schütz considered the construction of ideal types to be the general methodological device in the social sciences since sociology, economy, political science, etc., explain social phenomena by modeling ideal actors and courses of action which they endorse with special features as explanatory variables. However, he did not see ideal types in the Weberian sense, i.e., as a scientific model which does not need to correspond to reality in all respects. For Schütz, the ideal-typical method is legitimized by his findings on the typicality of everyday world which is the object of social research. Social reality can be approached by type-construction on the scientific level because its immanent structure is typified itself. Thus, the Schützian theory of the life world and its structures represents a methodological tool to bridge the gap between sociological theoretical reasoning and its object. The methodological rule which Schütz derived from his theoretical approach consists correspondingly in the *postulate of adequacy* (Schütz 1962, 1964) between everyday and scientific typifications. This postulate holds that ideal types featured by the social sciences have to be constructed in correspondence to the structure of the everyday typifications, so that everyday actors can take the model for granted when they act under the conditions stated in the ideal type. In this sense, social scientists as well as everyday actors have to follow the same frame of reference given by the structure of the life world but their cognitive attitude differ in several respects: scientists neither share the pragmatic interest of everyday actors nor do they share their everyday rationality restricted by their beliefs in the grantedness of typical knowledge. Opposing T. Parson's functionalism and C. G. Hempel's methodologic positivism, Schütz stressed that scientists must not impose their own theoretical concepts and rationality on their object of study—the life world. First, they must discover and then respect its immanent meaning structure.

5. *The Significance of the Schützian Approach for the Social Sciences*

Since the 1960s, Schütz's theory has drawn sociologists' attention to inquiries into everyday interaction, communication as well as to the insight that social reality has to be considered as a construction produced within these processes. Sociologists started to examine the practices of everyday action, communication and interpretation from which social reality emerges. H. Garfinkel's (1967) *Ethnomethology*, which was aimed at finding the formal properties of everyday practices, led to a series of case studies covering a wide range of everyday life in society and its institutions. Continuing this line of research, examinations of everyday communication were provided by E. A. Shegloff and H. Sacks (1995), whose *Conversational Analysis* became a widespread method in qualitative sociological research. A. Cicourel's (1964) *Cognitive Sociology* revealed the constructed character of data in social institutions as well as in science and thus initiated a

series of studies in the sociology of organization and in the sociology sciences. *Milieus* as formations of everyday interaction are the subject of the *Social Phenomenology* R. Grathoff (1986).

P. L. Berger and Th. F. Luckmann's (1966) idea of *the Social Construction of Reality* (as being a general process in which cultural worlds emerge) triggered new impulses in both the sociology of knowledge and the sociology of culture reconceived now in Schützian terms. In this context, Schütz's impact can also be seen in the sociology of language and the sociology of religion. Contemporary Marxian theory saw the way in which Schütz focused on the everyday practice as a possible mediation between social structure and individual consciousness. The term *phenomenological sociology* was coined in the 1970s (G. Psathas 1973) to address the spectrum of approaches oriented and inspired by Schütz's theory. Under this label, Schütz's approach became one of the general paradigms in the interpretative social science and theory of action. The diffusion and empirical application of the Schützian approach enforced the search for qualitative research methods which would reveal data pertaining to the social construction of social reality in everyday life. Aside from ethnomethodology and conversational analysis mentioned above, this quest especially led to a refinement in the techniques of narrative interviews and in biographical research.

Once established in the 1970s, the Schützian paradigm influenced the mainstream of sociological theory which became sensitive not only to the social construction of life world but also to the phenomenological background of the Schützian theory. The 'life world,' in the sense of a basic social reality provided by humans in their 'natural' intercourse, became one of the central terms in social theory (J. Habermas 1981). The everyday construction of social reality was recognized as a crucial mechanism in which society emerges (P. Bourdieu 1972, A. Giddens 1976, Z. Baumann 1991). The phenomenological conception of meaning constitution reformulated as an *autopoiesis* (self-creation) of social and psychic systems influenced the development of the contemporary sociological system theory (N. Luhmann 1996).

Beyond of the scope of sociology, other humanities also gained innovative impulses from the Schützian approach. In philosophy, Schütz's theory led to a critical assessment of the Husserlian view of intersubjectivity and to the conceptions of a *worldly phenomenology* (L. Embree 1988) or of a *philosophy of modern anonymity* (M. Natanson 1986). In the literature, Schütz's constructionism inspired the *esthetics of reception* which pointed out the beholder's participation in co-creating the autonomous reality of literary works (H. R. Jauss 1982). Schütz's concept of the structure of life world also affected theorizing in social geography (B. Werlen 1993), educational theory (K. Meyer-Drawe 1984), and political science (E. Voegelin 1966).

Science and Development

During the past half-century, conventional understandings of science, development, and their relationship have changed radically. Formerly, science was thought to refer to a clear and specific variety of Western knowledge with uniformly positive effects on society. Formerly, development was viewed as a unidirectional process of social change along Western lines. Formerly, science was viewed as a powerful contributor to the developmental process. Each of these ideas has been subjected to insightful criticism. This article will examine science and development, concluding that the relationship between the two is problematic, partly because of the complexity of the concepts themselves. Three major theories of development are considered, together with the main types of research institutions in developing areas.

1. Science

Much of what is termed science in developing areas is far from what would be considered 'pure science' in the developed world. The 'root concept' of science involves *research*, the systematic attempt to acquire new knowledge. In its modern form, this involves experimentation or systematic observation by highly trained specialists in research careers, typically university professors with state-of-the-art laboratory equipment. These scientists seek to contribute to a cumulative body of factual and theoretical knowledge, testing hypotheses by means of experiments and reporting their results to colleagues through publication in peer-reviewed journals.

Yet when a new variety of seed is tested by a national research institute and distributed to farmers in Africa, this is described as the result of 'science.' When the curator of a botanical exhibit has a college degree, he or she may be described as 'the scientist.' When a newspaper column discusses malaria or AIDS, 'scientific treatments' are recommended. Seeds, educated people, and advice are not science in the abstract and lofty sense of the pursuit of knowledge for its own sake or systematically verified facts about the world. But they are science from the standpoint of those who matter—local people who spend scarce resources on their children's education, development experts who determine how and where to spend funds, politicians who decide whether to open a new university, corporate personnel who open a new factory in a developing region.

Perhaps the most important shift in recent thinking about science is a broadening of the scholarly view to include the ideas of science found among ordinary people. These are often *more* extended in developing areas, because of the association of science with 'modern' things and ideas. 'Science' in its extended sense includes technological artifacts, trained expertise, and knowledge of the way the world works. The importance of this point will be clear in the conclusion.

Given the fuzziness of the boundaries that separate science from other institutions, and the dependence of modern research on sophisticated technical equipment, the term 'technoscience' is often used to denote the entire complex of processes, products, and knowledge that flows from modern research activities. Even if we recognize that the term 'science' has extended meanings, it is useful to draw a distinction between (a) the institutions that produce knowledge and artifacts and (b) the knowledge that is produced. That is, on the one hand, there are organizations, people, and activities that are devoted to the acquisition of knowledge and things that can be produced with knowledge. These constitute the modern organization of *research*. On the other hand, there are *claims* involving knowledge and artifacts—often significantly transformed as they leave the confines of the research laboratory. What makes claims and practices 'scientific' is their association with scientific institutions.

Modern research capacity is concentrated in industrialized countries. Indeed, with respect to the global distribution of scientific and technical personnel, scientific organizations, publications, citations to scientific work, patents, equipment, and resources, scientific institutions display extremely high degrees of inequality. The most common indicator of scientific output is publications. In 1995, Western Europe, North America, Japan, and the newly industrialized countries accounted for about 85 percent of the world total. Leaving aside countries and allies of the former Soviet Union, developing areas contributed less than 9 percent of the world total. Much the same applies to technological output measured in patents and expenditures on research and development (UNESCO 1998).

Yet if we shift our focus from the question of inequality to the question of diffusion, an entirely different picture arises. To what extent have the *idea*

and practice of research spread throughout the world? The main issues here involve who conducts research, on what subjects, and what happens to the results. Each of these topics is the subject of analysis and controversy.

Scientific research in developing countries began during the pre-independence era with the establishment of universities and research institutes. Research was conducted on crops and commodities for export as well as conditions (e.g., disease) that affected the profits sought by external agents from their control over the land, labor, and property of colonized peoples. Methodologies and organizational models for research were brought by European colonists to Asia, Africa, and Latin America. During the era of independence and throughout the 1970s, number of types of entities engaged in the generation of knowledge multiplied. The main scientific organizations now fall into five main types, or sectors: academic departments, state research institutes, international agencies, private firms and, to a lesser degree, nongovernmental organizations.

2. *Development*

The concept of development involves several dimensions of transformation, including the creation of wealth (that is, rapid and sustained economic growth) and its distribution in a fashion that benefits a broad spectrum of people rather than a small elite (that is, a reduction in social inequality). Cultural transformation (recognition of and attendant value placed on local traditions and heritage) has also been viewed as an important aspect of the process since the early 1980s. There is general agreement that development in the second half of the twentieth century is not a mere recapitulation of the process of industrialization that characterized Europe and North America in the eighteenth and nineteenth centuries.

Three theoretical perspectives, with many variations, have dominated development studies: modernization, dependency, and institutional. One way of distinguishing these theories is by their position on the ways in which relationships external to a country affect the process of change. Since scientific institutions and knowledge claims are of external origin, each of these perspectives views science and technology as important in the development process, with very different assessments of the costs and benefits.

2.1 *Modernization*

The oldest approach, sometimes called modernization theory, focused on the shift from a traditional, rural, agricultural society to a modern, urban, industrial form. Transformations internal to a country (such as formal education, a market economy, and democratic political structures) are emphasized, while external relationships are de-emphasized. However, science was the exception to this, available to benefit developing nations through *technology transfer* from Western sources. This idea relied on two assumptions. One was the 'hardness' of technological artifacts—their alleged independence from people and culture, their seeming ability to produce certain effects 'no matter what.' The second was the 'linear model' of technology development in which the (a) discoveries of basic science lead to the (b) practical knowledge of applied science and finally to (c) technological applications such as new products. In retrospect, both of these assumptions were simplistic in any context, but in the developing world they were especially problematic.

The assumption of 'hardness' has been replaced by the generalization that the uses, effects, and even the meanings of technological artifacts are affected by the context of use. First, effective technologies, from automobiles to indoor plumbing, do not typically stand alone, but are embedded in *systems* that provide infrastructure (roads, sewage treatment) which is often lacking. Second, the provision of artifacts such as buildings and computers is much easier than their maintenance, which requires both resources and knowledge. Third, introduction of new technology involves a multiplicity of consequences—positive and negative, short term and long term, economic and ecological. Many of these consequences are unpredictable, even in those rare cases where such foresight is attempted.

The case of the Green Revolution is illustrative. In the 1960s, widespread food shortages, population growth, and predicted famine in India prompted major international foundations to invest research and technology transfer efforts towards the goals of increasing agricultural productivity and the modernization of technology. What resulted were new kinds of maize, wheat, and rice. These modern varieties promised higher yields and rapid maturity, but not without other inputs and conditions. They were, rather, part of a 'package' that required fertilizers as well as crop protection inputs such as pesticides, herbicides, and fungicides—sometimes even irrigation and mechanization. Moreover, seed for these varieties had to be purchased anew each year.

The consequences of the Green Revolution are still debated, and there is little doubt that many of them were positive. Famine in India was averted through increased yields, but the benefits of the technology required capital investments that were only possible for wealthier farmers. Not only did the adoption of new technology increase dependence on the suppliers of inputs, but it was claimed to increase inequality by hurting the small farmer—one intended beneficiary of the technology. The actual complexity of the outcomes is revealed by one of the most sophisticated assessments—modern seed varieties do reach small farmers, increase employment, and decrease food prices, but the benefits are less than expected because the poor are

increasingly landless workers or near landless farm laborers (Lipton and Longhurst 1989).

What is important for the question of the relationship between science and development is that the products and practices of the Green Revolution were research-based technology. This technology was often developed in *international* research institutes funded by multilateral agencies such as the World Bank and bilateral donors such as the US Agency for International Development. Since the combined resources of these donors dwarf those of many poor countries, their developmental and research priorities constitute a broad global influence on the nature of science for development. The largest and most visible of these organizations form a global research network, the Consultative Group for International Agricultural Research (CGIAR) which grew from 4 to 13 centers during the 1970s as support by donors quadrupled. The influence of this network of donors and international agencies was clearly evident in the early 1990s when environmental concerns led to an emphasis on 'sustainability' issues. This led to a change in CGIAR priorities, as the older emphasis on agricultural productivity shifted to the relatively more complex issue of natural resource management.

2.2 Dependency

Modernization theory emphasized internal factors while making an exception of science. Dependency theory and its close relative, world system theory, emphasized the role of *external relationships* in the developmental process. Relationships with developed countries and particularly with multinational corporations were viewed as barriers. Economic growth was controlled by forces outside the national economy. Dependency theory focused on individual nations, their role as suppliers of raw materials, cheap labor, and markets for expensive manufactured goods from industrialized countries. The unequal exchange relationship between developed and developing countries was viewed as contributing to poor economic growth. World system theory took a larger perspective, examining the wider network of relationships between the industrialized 'core' countries, impoverished 'peripheral' countries, and a group of 'semiperipheral' countries in order to show how some are disadvantaged by their position in the global system. Because of their overspecialization in a small number of commodities for export, the unchecked economic influence of external organizations, and political power wielded by local agents of capital, countries on the periphery of the global capitalist system continue to be characterized by high levels of economic inequality, low levels of democracy, and stunted economic growth.

What is important about the dependency account is that science is not viewed in benign terms, but rather as one of a group of institutional processes that contribute to underdevelopment. As indicated above, research is highly concentrated in industrialized countries. Dependency theory adds to this the notion that most research is also conducted for their benefit, with problems and technological applications selected to advance the interests of the core. The literature on technology transfer is also viewed in a different light. The development of new technology for profit is associated with the introduction and diffusion of manufactured products that are often unsuited to local needs and conditions, serving to draw scarce resources away from more important developmental projects. The condition of dependency renders technological choice moot.

This concern with choice, associated with the argument that technology from abroad is often *imposed* on developing countries rather than *selected* by them, has resurfaced in many forms. In the 1970s it was behind the movement known as 'intermediate' technology, based on the work of E. F. Schumacher, which promoted the use of small-scale, labor-intensive technologies that were produced locally rather than of complex, imported, manufactured goods. These 'appropriate' technologies might be imported from abroad, but would be older, simpler, less mechanized, and designed with local needs in mind. What these viewpoints had in common was a critical approach to the adoption of technology from abroad.

By the late 1980s and 1990s even more radical positions began to surface, viewing Western science as a mechanism of domination. These arguments were more closely related to ecological and feminist thought than to the Marxist orientation of dependency theory. Writers such as Vandana Shiva proposed that Western science was reductionist and patriarchal in orientation, leading to 'epistemic violence' through the separation of subject and object in the process of observation and experimentation (1991). 'Indigenous knowledge' and 'non-Western science' were proposed as holistic and sustainable alternatives to scientific institutions and knowledge claims. Such views had an organizational base in nongovernmental organizations (NGOs), which received an increasing share of development aid during this period, owing to donor distrust of repressive and authoritarian governments in developing areas. NGOs have been active supporters of local communities in health, community development, and women's employment, even engaging in research in alternative agriculture (Farrington and Bebbington 1993).

2.3 Institutional Theory

Institutional theory seeks to explain why nations are committed to scientific institutions as well as what forms these take. The central theme is that organizational structures developed in industrialized countries are viewed by policy makers, donors, and other states as signals of progress towards modern institutional

development and hence worthy of financial support. Regardless of the positive or negative consequences of their activities, the introduction and maintenance of certain forms in tertiary education and government serves to communicate this commitment. Institutional theory provides an account of the growth and structure of the academic and state research sectors, as successful organizations in industrialized nations operate as models far from their original contexts.

Academic departments consist of researchers grouped by subject, each of whom is relatively free to select research projects. They bear the closest resemblance to the root concept of science introduced at the beginning of this article. But research requires time and resources. In areas such as sub-Saharan Africa, laboratories and fieldwork are poorly funded, if at all, since many institutions can barely afford to pay salaries. Professors teach, consult, and often maintain other jobs. Research is conducted as a secondary activity and professional contacts with other scientists in Europe and the US are few.

Equally important to the scientific establishment are state research institutes. These organizations are agencies of the state, they are charged with performing research with relevance to development, with health and agriculture the two most important content areas. They are linked to ministries, councils, and international agencies as well as systems (such as Extension Services in agriculture) that deliver technology to users—again based on a model from the developed world.

3. *Relationships Between Science and Development*

The popularity of dependency arguments and the resurgence of interest in indigenous forms of knowledge implies continued competition for older views of the uniformly positive effects of science. Institutional theory provides an alternative account of the spread of science and its organizational forms. But two features of current scholarship may prove more significant in the long run.

First, extreme diversity exists among developing areas in terms of their economic, social, and cultural patterns. It makes decreasing sense to speak of 'development' as an area of study. Latin American nations, for example, are generally far better positioned than the nations of sub-Saharan Africa. There is even wide variation within countries, as the case of India makes clear. While much of India qualifies as a developing area, it is among the world's top producers of scientific work, has a technically skilled, English-speaking labor force second only to the US, and is a leading exporter of computer software for corporations.

Second, 'science' is viewed as having many dimensions, many effects, and fuzzy institutional boundaries, but it is always a feature of the modern, industrial, interconnected world. Science cannot be the cause of modernization because, in its diverse institutional articulations and its evolving fit with society, science exemplifies the meaning of modernization itself.

Science and Industry

The premodern industrial craft economy provided the initial intersection of industry with science through scientific instrument making. The development of scientific inquiry through craft-based production, and its effects, can be seen in Galileo and the telescope, chang-

ing the world-picture and the place of humans within it. From as early as Leeuwenhoek's microscope to as late as the making of the Hubble telescope in the 1980s, lens and mirror construction was an uncertain art, not fully amenable to scientific analysis and control.

The invention of moveable type transformed the transfer of knowledge, through storage and retrieval devices, and facilitated the development of modern scientific as well as popular literature. However, it was the development of the steam engine by a scientifically informed inventor, James Watt, which led to a systematization of practice that could be analyzed scientifically, becoming the basis for the next advance. This process gave rise to a new term, technology, to denote an innovation process as well as its results.

Technology is the feedback link between science and industry. Invented in the eighteenth century, this new concept represented, on the one hand, the systematization of craft, through the creation of engineering disciplines, originally to quantify and sytematize the construction of military fortifications (Calvert 1967). On the other hand, technology was also derived from the extension of science. This occurred through the creation of applied sciences such as solid state physics and the invention of semiconductor devices such as the transistor. This article surveys the relationship between science and industry since the 1700s.

1. *Early Science and Industrial Development*

Science originated in the seventeenth century as organized investigation of the natural world according to relatively secure methodological principles. In this era, practical and theoretical concerns each provided between 40–60 percent of the impetus to research, with some overlap (Merton 1938). Well before science was institutionalized in universities and research institutes, individual scientists, loosely connected through scientific societies, provided an occasional basis for industrial development. For example, in the absence of reliable navigational techniques, commerce was impeded by the need for ships to stay close to shorelines. In response to a prize offered by the British government, astronomers used their observational techniques and knowledge base to develop star charts useful to navigators. Their involvement in solving a commercial problem was secured without incurring explicit costs. These were considered to be assumable by the astronomers themselves, with navigational research considered as an offshoot of their government or academic responsibilities that could be carried out at marginal cost.

Clockmakers approached the problem from the opposite stance by adapting a mechanical device to the solution of the navigational problem. Of lower status and with lesser financial resources and institutional backing than the astronomers, a clockmaker who arrived at a mechanical solution to the problem had great difficulty in being taken seriously by the judges of the competition. Moreover, as an independent craftsman he was dependent upon receiving intermediate financial dispensations from government to improve his device. Nevertheless, science and craft intersected to overcome blockages to the flow of trade by providing reliable navigational methods (Sobel 1996).

Science became more directly involved in industrial production in seventeenth century Germany when professors of pharmacy invented medical preparations in the course of their experimentation. With support from some German princely states, and in collaboration with entrepreneurs, firms were formed to commercialize these pharmaceutical discoveries. Thus, the academic spin-off process, with governmental and industrial links, was adumbrated at this time (Gustin 1975).

2. *Incremental Innovation: Learning by Doing*

In an era when most industry was craft based, incremental improvements arose primarily from workers' experience with the process of production. For example, in the course of firing bricks a worker might notice that a brick had attained exceptional strength under high heat and then attempt, through trial and error, to duplicate what the observation of a chance event had brought to light. Eventually, the conditions that produced the original improved brick might be approximately reproduced and a sufficiently high rate of production achieved, with the 'experimenter' knowing more or less how but not really why the useful result had been achieved (Landes 1969).

Scientific advance was also built upon what is now called 'learning by doing' (Lundvall and Borras 1997). By interviewing various practitioners, researchers began to collate and systematize their local knowledge into broader syntheses. Thus, advances in understanding of stratigraphy derived from miners' practical experience in eighteenth-century Italy (Vaccari 2000).

Much, if not most, innovation still takes place through craft-based experience. Indeed, scientific principles and methods such as those developed in operations research have recently been applied to systematize incremental innovation. Incremental innovation itself has been scientized through the application of statistical techniques, pioneered in Japan during the 1930s by the disciples of Edward Deming, the US researcher, who only later gained consulting opportunities and renown in his own country.

3. *The Industrialization of Science*

The connection between academe, science, and industry strengthened with the invention of the chemistry laboratory as a joint teaching and research format

by Justus Liebig at the University of Giessen in the mid-nineteenthth century (Brock 1997). Having achieved reliable analytical methods, Liebig could assign an unsolved problem to a student and expect a solution to arise in due course, with a minimum of supervision from the master or his assistants. The teaching laboratory model then spread to other experimental fields. As an organizational innovation combined with replicable methods of investigation, the laboratory allowed training and original investigation to be coordinated and expanded, creating a larger market for research equipment.

Alexander Von Humboldt theorized the unity of teaching and research as an academic model as well as a practical tenet (Oleson and Voss 1979). The incorporation of science into the university along with methods to revive classical knowledge led to the development of research as an academic practice. The research university model was transferred from Germany to the US in the mid-nineteenth century and eventually became the base for technology transfer and firm formation (Jencks and Riesman 1968).

Liebig, himself, attempted to take the development of technology from academic research a step further by starting businesses based upon his scientific discoveries. His mix of successes and failures foreshadowed the contemporary science-based firm. Nevertheless, this was an unusual combination of roles of researcher and entrepreneur in one person at the time (Jones 1993). More typically, the professor's students made technology arising from scientific research into companies. Thus, the emblem of the Zeiss optical firm incorporates a portrait of the original founders, including professor and student.

4. *The Foundation of Firms Based on Scientific Research*

With the invention of the laboratory, instrument making was internalized within science. As science and the need for research equipment grew, instrument production began to be externalized and made into an industry. Scientific instrument making is an early source of firm formation linked to academic research. For example, scientist-initiated instrument firms grew up around MIT and Harvard in the late nineteenth century, along with consulting firms such as A. D. Little providing a formal overlay of relationships between university and industry, beyond personal ties between teacher and former student.

Until quite recently, scientific instrument making was a specialized niche industry, having more to do with academia than industry. A shift toward dual use industrial and scientific technologies began to occur with the development of electronic instrumentation. Oscilloscopes served as research tools, for example, to record nerve impulses in physiology, but were also utilized to provide quality assurance in industrial production. The formation of the Hewlett Packard and Varian Corporations, based upon innovations in electronics in the physics department at Stanford University in the 1930s, exemplify this transitional phase in the relationship between scientific instrumentation and industry (Lenoir 1997).

Industrialized science is exemplified today by mass-produced scientific equipment such as the sequencing machines crucial to the human genome project. What is new is the breakdown of the distinction between scientific instrumentation and the means of industrial production. This has occurred through the emergence of technologies such as computers that have broad application to science, business, art, and other techniques (Ellul 1964). Indeed, the computer is a machine with such protean implications that it became the basis of a science itself and contributed to the creation of a new class of sciences of the artificial.

5. *The Rise of Science-based Industry*

Although it had its precursors in China, with gunpowder, paper making, and the organizational technology of bureaucracy, the science–industry interface has been rationalized in the West and North and transferred to the East and South in the modern era. Karl Marx, the initiator of the theory of science-based industry, even though he lost confidence and retreated to a labor theory of value, was far seeing. In the late nineteenth century, he had one example on which to base his thesis, the British chemist Perkin's research on aniline-based dyes that was translated into an industry in Germany.

According to a close observer, 'Science and technology may have converged circa 1900' (Wise 1983). The rise of the chemical and electrical industries in the late nineteenth century fulfilled some of the promise of science for industrial development. Nevertheless, even in these industries the translation of science into useful products often had an intervening phase based on 'cut and try methods that only later became rationalized as in the unit method of scaling up chemical production (Servos 1980).

Thomas Alva Edison, the inventor of the electric light, was also the inventor of the systematic production of inventions. His 'idea factory,' staffed by formally trained scientists and craftspersons, provided a support structure for the application of Edison's basket of techniques to a series of technical problems whose solution was the basis for the creation of new industries and firms (Israel 1998).

One of these companies, the General Electric Corporation (GE), took the connection between science and industry one step further in the US by hiring an academic scientist to organize a research laboratory for the firm. GE's hiring of Willis Whitney brought the consulting function of academics to industrial problems within the firm and also created a new source of

product development, the corporate R&D laboratory (Wise 1983).

A reverse relationship between science and engineering exists when corporations have 'first mover' rather than 'follower' business strategies. Siemens, for example, developed new business on the basis of advanced research in semiconductors during the early postwar period while its competitor, AEG, waited to see if a sufficient market developed before entering a field. Indeed, Siemen's confidence in science was so great that it did not employ sufficient engineers to refine and lower the cost of its production (Serchinger 2000).

The function of the corporate R&D lab was at least threefold: (a) maintain contact with the academic world and other external sources of information useful to the firm; (b) assist in solving problems in production processes and product development originating within the firm; and (c) originate new products within and even beyond the existing areas of activity of the firm.

A few corporate labs, typically in 'public' industries such as telecommunications took on a fourth function as quasi-universities, contributing to the advance of science itself (Nelson 1962). Smaller firms typically focused on the first two functions, close to production, while larger firms more often spanned the entire range of activities (Reich 1987).

6. *University–Industry–Government Relations*

Models for close public–private cooperation that were invented before World War II have recently been revived and expanded (Owens 1990). During the early postwar period, an institutional division of labor arose in R&D, with industry supporting applied research; government funding basic research in universities and research institutes; and universities providing knowledge and trained persons to industry (Reingold 1987). This 'virtuous circle' still accurately describes much of the university–industry–government relationship (Kevles 1977)

Socialist countries developed a variant of this format, attempting to create closer connections to research and production through central planning mechanisms. However, by locating the R&D function in so-called branch institutes, socialist practice actually created a distance between research and production that was even greater than in capitalist firms that located their R&D units geographically apart from production while retaining organizational ties.

Recently, socialist and, to some extent, large corporate formats for R&D have been decomposed and recombined in new formats. In the US, where these developments have taken their most advanced form to date, several innovations can be identified including:

(a) Universities extending their functions from research and training into technology development and firm formation through establishment of new organizational mechanisms such as centers, technology transfer offices, and incubator facilities.

(b) The rise of start-up, high-tech firms, whether from universities, large corporate laboratories, or previous failed spin-offs, providing a new dynamic element in the science–industry relationship, both as specialized research organizations and as production units rooted in scientific advance.

(c) A new role for government in encouraging collaboration among various academic and industrial units, large and small, in industrial innovation going beyond the provision of traditional R&D funding, including laws changing 'the rules of the game' and programs to encourage collaboration among firms and between universities and firms.

An industrial penumbra appears around scientific institutions such as universities and research laboratories, creating feedback loops, as well as conflicts of interest and commitment between people involved in the two spheres. Over time, as conflicts are resolved, new hybrid forms of science-based industry and research, as well as new roles such as the industrial and entrepreneurial scientist, are institutionalized (Etzkowitz 2001).

7. *Conclusion*

Economic development is increasingly based on science and technology at the local, regional, national, and multinational levels. The science–industry connection, formerly an ancillary and subsidiary aspect of both science and industry, now moves to the center of the stage of economic development strategy as the university and other knowledge-creating organizations become a source of new industry. Political entities at all of these levels develop policies and programs to enhance the science–industry interface, and especially to encourage high-tech firm formation (Etzkowitz et al. 2000).

The 'endless frontier' model of 'knowledge flows,' transferred to industry through publications and graduates was insufficient to induce industrial innovation in most cases (Brown 1999). Closer connections were required. A series of organizational innovations to enhance technology transfer took place along a continuum: providing training in entrepreneurship, translation of research findings into intellectual property rights, and encouraging the early stages of firm formation.

The potential for participation in knowledge-based economic development revivifies the discredited nineteenth century notion of progress. During the colonial era, technology transfer typically took place in a format that helped maintain political control, and the higher forms of tacit knowledge were kept secret by employing expatriate engineers. Nevertheless, as in India, a steel industry, created by local entrepreneurs, provided an economic base for a political indepen-

dence movement. Moreover, a seemingly over-expanded higher educational system, originally put in place to train lower level bureaucrats and technicians, has become an engine of growth for India's software industry.

The synthesis of science and industry is universalized, as both industrial and natural heritages, such as machine-tool industry in German and biodiversity in Brazil, are integrated into new global configurations, often through local firms in strategic alliance with multinationals. Given the decreasing scale of scientific equipment and the increasing availability of higher education, countries and regions in virtually every part of the world can take advantage of opportunities to develop niches. A trend toward worldwide technological innovation has transformed the previous designations of third and second worlds into the 'emerging world.'

New candidates for science-based economic growth bridge the expected gaps between 'long waves' of economic growth. Heretofore, the technology-based long waves identified by Freeman and his co-workers were made possible by a few key technologies; that is, information technology and biotechnology (Freeman and Soete 1997). The potential for growth from technologies such as solar photovoltaics, multimedia, and the Internet, and new materials arising from nanotechnology are so numerous that there is little or no technical reason, only political, for business cycles with declines as well as rises.

Science and Law

The relationship between law and science has occupied scientists, philosophers, policymakers, and social analysts since the early modern period. Nature, according

to science's early modern practitioners, was governed by law-like regularities—God's laws—and the work of science lay in discerning and revealing these laws of nature. In time, however, human law came to be seen as a fallible institution in need of rationalization, to be made more like a science in order to avoid arbitrariness. For early twentieth-century legal reformers, science provided a model of regularity for law to aspire to. At the same time, law and science were viewed by their practitioners as independent institutions, each with its own organization, practices, objectives, and ethos. Similarities and differences between the two fields were noted by many observers, with frequent commentary on conflicts between the law's desire for justice and science's commitment to the truth.

By the end of the twentieth century, a new preoccupation with the law's instrumental uses of science emerged, which led to divergent schools of thought about the epistemological status of scientific evidence and the ways in which legal and policy institutions should interact with scientific experts. The growth of the state's regulatory powers increased governments' dependence on scientific methods and information, and disputes developed about the extent to which science could reliably answer the questions put to it by legislators, regulators, and litigants. An influx of technically complex disputes caused judicial systems to reassess their handling of scientific and technical evidence. Analysts of these processes grappled with questions about the law's capacity to render justice under conditions of scientific and social uncertainty, as well as the continued relevance of the lay jury and the role of legal proceedings in the production of scientific knowledge.

This article reviews the resulting scholarship on the nature and consequences of the law–science relationship under four major headings. One concerns the role of these two institutions in shaping the authority structures of modernity, particularly in legitimating the exercise of power in democratic societies. A second relates to the law's impact on the objectives, status, and professional practices of scientific disciplines relevant to the resolution of social problems. A third focuses on responses by courts and their critics to the challenges posed by experts in the legal system, including shifts in the rules governing expert testimony. Fourth and finally, an emerging line of research looks at the law as a site for generating scientific and technical knowledge and inquires into the implications of collaboration between law and science for individual and social justice.

1. *Law and Science in the Transition to Modernity*

Since the origins of modern scientific thought, the term 'law' has been used to describe both the regularities discernible in nature and the rules laid down by religious or secular authorities to guide human conduct. Both kinds of laws, it was once popularly assumed, embodied principles that should work always and everywhere in the same fashion, even though Robert Boyle, an early modern founder of experimental science, cautioned against too literal an assimilation of the behavior of matter under natural law to the behavior of human agents under civil law (Shapin 1994, pp. 330–1). As certain facts about human nature and behavior (such as the approximate equality of humans, their vulnerability, and the limits of their resources and altruism) came to be accepted as given, modern legal theorists adopted more synthetic views regarding the relationship between science and law. According to the renowned British scholar of jurisprudence H. L. A. Hart, for example, these natural facts underwrite a 'natural law' which human societies require in order to maintain their salient moral characteristics (Hart 1961). The American legal theorist Lon Fuller took a more sociological tack in his account of the 'morality of law.' Echoing Robert Merton's well-known essay on the *norms of science*, Fuller argued that law and science resemble each other because each institution possesses an internal morality resulting from its distinctive arrangements, practices, and fiduciary demands (Fuller 1964). Later legal scholarship compared the 'cultures' of law and science and likewise called attention to their normative and procedural particularities (Goldberg 1994, Schuck 1993), but these institutional characteristics were now seen as a source of conflict, or culture clash.

As elite institutions, science and law historically have drawn upon each other's practices to build their authority. Thus, early modern experimentalists in the natural sciences enlisted the support of witnesses, both real and 'virtual' (Shapin and Schaffer 1985), as if they were proving a case in a court of law. The Enlightenment of the eighteenth century and the rise of liberal democracies brought science, now prized for its practical utility (Price 1985), into a more openly instrumental partnership with the law. In the USA, Thomas Jefferson drafted the first Patent Act of the fledgling American republic in 1793, thereby implementing the constitutional grant of power to Congress 'to promote the progress of science and useful arts, by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries.' Where Jefferson saw the state as sponsoring science, some modern scholars have seen science's open, self-regulating, nonhierarchical modes of governance as offering a model or prototype for democracy (Polanyi 1962). Others, however, regard the relationship of scientific and political authority as one of mutual dependency. Democratically constituted governments, they argue, need science and technology in order to answer constant public criticism and make positive demonstrations of their worth to citizens. States, therefore, have harnessed science and technology to instrumental projects in both war and peace.

In these legitimation exercises, the public attests to the state's technical performance, much as scientists bore witness to each other's observations in early modern experimental laboratories (Ezrahi 1990). The law's procedural forms in this way have underwritten the credibility of both modern science and the state.

The law's own dependence on science has grown by distinctive pathways in the USA, as could be expected in a society where public decisions are exceptionally transparent and significant policy change commonly proceeds through litigation. By the beginning of the twentieth century, ideological and political shifts fostered the idea that social policies enacted by the state could and should be responsive to findings in the sciences. An icon of the Progressive era, US Supreme Court Justice Louis D. Brandeis, spurred this development through his historic 'Brandeis brief' in *Muller v. Oregon* (1908). Written to defend the state's 10-hour working-day restriction on women's employment, the 100-page brief is widely regarded as the first attempt to bring social science insights into the courts. Brandeis, then a public interest lawyer in Boston, argued successfully that women were sufficiently different from men to justify special legislative protection, thereby distinguishing the Oregon case from the Court's earlier, infamous decision in *Lochner v. New York* (1905), which struck down a similar state law curtailing working hours for (male) bakers.

Social science evidence received a further boost when, in overturning the 'separate but equal' doctrine that was the basis for racial segregation in public schools, the Supreme Court in *Brown v. Board of Education* (1954) relied on psychological studies of segregation's 'detrimental effect upon the colored children.' In later years, students with disabilities would benefit from similar sorts of evidence in claiming rights to special education (Minow 1990). Employment discrimination, racial segregation, antitrust, capital punishment, and environmental liability were among the many litigated subjects that brought social science testimony into the US courts in the latter decades of the twentieth century. These cases kept alive the view that objective scientific information could be invoked in legal proceedings to combat various forms of oppression and social injustice.

If science was allied with the search for justice in US courts, its role in policymaking was primarily as the voice of reason. Government's increasing involvement in welfare policy in the New Deal, intensified by the rise of social regulation in the 1970s, created new demands for rational decisions concerning a host of costly and potentially explosive problems, such as race and the environment. As can be observed in the context of environmental regulation (Jasanoff 1990), federal agencies proved increasingly less able to take refuge in generalized claims of expertise. Much work went into separating science from politics and creating new institutions to deliver putatively independent advice to government, although episodes like the 1995 dissolution of the Office of Technology Assessment, an advisory body to the US Congress, called attention to the fragility of such efforts. New types of scientific expertise also evolved to support governmental decisions with substantial distributive impacts, as discussed in the next section.

The relationship between law and science in modern European states was in some ways more covert than in the USA, but nonetheless pervasive. The crises of industrialization in the nineteenth century and the ensuing rise of the welfare state ushered in a demand for credible public action that states could not satisfy without rapid increases in their capacity to order society through newly accredited social science disciplines (Wagner et al. 1991). In turn, the classifications offered by the human sciences in particular supplied the basis for new forms of self-understanding, normalization, and social control. Whether in medicine, psychology, criminology or studies of intelligence, science offered the means for dividing people into categories of normal and pathological, mainstream and deviant. The scientific study of human characteristics thus enabled members of society to see and discipline each other without the need for constant, formal regulatory oversight by the state (Foucault 1990). Science, on this account, not only provided supports for legal authority but actually replaced some of the ordering functions of positive law.

European institutions at first resisted the pressures that fed attempts to separate science from politics in US legal contexts. Expert advisory bodies were routinely constituted to include political as well as technical expertise, although judgments about the need for lay or nonprofessional expertise varied from country to country. European courts, for their part, dealt with more focused and on the whole less politically salient disputes than in the USA, so that there were fewer reasons to contest expert judgments. By the 1990s, however, a number of developments tried public confidence in European governments' uses of science, chief among them the growing political influence of the European Union's technical bureaucracies and the fallout from the UK government's botched response to the bovine spongiform encephalopathy (BSE) crisis, which cast doubt on the integrity and impartiality of experts. European lawmakers, regulators, and courts began reconsidering the adequacy of their institutional arrangements for science-based decision-making, as the issue of science and governance rose to new prominence on political agendas.

2. *Disciplines, Professions, and the Law*

The interactivity of law and science has spurred new disciplinary formations and helped to change professional norms and practices, especially in the human sciences, which serve both as allies in regulation and

law enforcement and as uneasy subjects of the law's skeptical gaze. This dual relationship with the law has prompted novel lines of scientific research and theorizing, accompanied by periodic legal encroachment upon science's professional autonomy. Developments in the fields of risk analysis and psychology clearly illustrate these patterns.

The scientific study of risk is an outgrowth of state efforts to manage the hazards of industrial production and an extension of modern governments' growing reliance on formal decision-making tools to rationalize difficult political decisions. Uncertainty about technology's risks and benefits rose through the twentieth century along with the size and complexity of systems of production. From village-based economies, in which injured parties presumed they knew the agents as well as the causes of harms inflicted on them, the global economy pulled consumers into webs of relationships that diffused both the knowledge of risks and the responsibility for regulation and compensation. Epitomizing the plight of industrialization's innocent victims, millions of asbestos workers in mines, shipyards, and other industries were unknowingly exposed to severe health hazards, and hundreds of thousands died of consequent illnesses. Resulting lawsuits financially crippled asbestos manufacturers without adequately recompensing injured workers. A 1984 accident at a US subsidiary's chemical plant in Bhopal, India, again produced hundreds of thousands of victims, with massive scientific and legal uncertainties clouding the settlement of claims.

As the pervasiveness of industrial hazards became apparent, legislatures sought to ensure that regulation would not wait for proof in the form of 'body counts': risk, not harm, became the basis for action under new laws safeguarding health, safety, and the environment, and state agencies struggled to develop credible processes for assessing and mitigating risks before anyone was injured. The sciences, for their part, responded with attempts to mobilize existing knowledge and methods to provide more useful tools for analyzing risks and crafting preventive strategies.

From relatively modest beginnings, rooted largely in the engineering and physical sciences (as in assessing the risks of meltdown in nuclear power plants), risk assessment in support of regulatory standards grew into an important, and increasingly contested, branch of the social sciences. Risk studies acquired the indicia of professionalization, with dedicated journals, societies, curricula, and centers at major universities. One focus of research and development in this field, particularly in the USA, was the construction of reliable models for measuring risk, from the use of animal species as surrogates for humans to sophisticated methods of representing uncertainty in risk estates (National Research Council 1994). Risk assessment presented not only methodological difficulties for scientists and engineers, but also institutional challenges for governments needing to persuade industry and the public that their decisions were scientifically sound and politically balanced (Jasanoff 1990). Lawsuits questioning the risk assessment practices of federal agencies were not uncommon and led to several significant judicial decisions, including Supreme Court rulings on the validity of the occupational standard for benzene in 1980 and the air quality standard for ozone and particulates in 2001.

Other researchers meanwhile approached risk from the standpoint of social psychology, asking why lay observers frequently diverged from experts in their judgments concerning the relative significance of different types of risk. This question engendered a sizeable body of experimental and survey work on risk perception (Slovic 2000), as well as theoretical critiques of such work, showing problems in both the framing and characterization of lay attitudes (Irwin and Wynne 1994). While some social scientists occupied themselves with identifying and measuring 'real' risks, or perceptions of them, others treated *risk* itself as a new organizing principle in social life, noting that vulnerability to risk did not map neatly onto earlier divisions of society according to race, class or economic status (Beck 1992). By contrast, the US environmental justice movement generated data suggesting that social inequality still mattered in the distribution of industrial risks, which fell disproportionately on poor and minority populations (Bullard 1990). This strategic, though controversial, research led in 1994 to a presidential executive order demanding that US federal agencies should consider the equity implications of their actions; equity analysis emerged in this way as an offshoot of existing methodologies for assessing risk and offered formal justification for legal claims of environmental *in*justice.

Unlike risk analysis, which is a product of twentieth-century concerns, law and the mental health disciplines have existed in a relationship of close reciprocity at least since 1843, when the British House of Lords laid down the so-called M'Naghten rule for determining whether a criminal defendant is entitled to relief on grounds of insanity. The rule holds that a person may be released from criminal responsibility for actions taken while he or she was unable to distinguish between right and wrong as a result of mental disease or defect.

More recently, the human sciences' ability to sort people's behavior and capacities into seemingly objective, 'natural' categories has served the needs of both democratic and totalitarian states in a growing variety of legal settings. The need to determine people's mental states in civil as well as criminal proceedings was an important driver of the legal system's enrolment of professionals from these fields. In US law, for example, psychiatric evidence was used to determine whether a criminal accused could stand trial, whether conditions for sentencing leniency or parole were met, and whether a convicted criminal posed a sufficient threat of long-term dangerousness to

deserve the death penalty. While these intersections provided new professional opportunities for psychiatry and psychology, spawning a thriving pedagogic specialty of law and mental health (Gutheil and Appelbaum 2000), entanglements with the law also disclosed frequent divisions among experts and undermined disciplinary authority in other ways.

The most visible challenge to professional autonomy occurred in the 1974 US case of *Tarasoff v. Regents of the University of California* (redecided in 1976), in which the California Supreme Court ruled that psychiatrists were required to warn (later changed to a duty to protect) third parties threatened by their patients. Although the decision did not open the floodgates to liability as many therapists had feared, *Tarasoff* was widely seen as influencing therapeutic practice, often in counterproductive ways. In another notable decision affecting the mental health field, the US Supreme Court in *Barefoot v. Estelle* (1983) essentially ignored an *amicus* brief by the American Psychiatric Association stating that psychiatric predictions of dangerousness are wrong in as many as two out of three cases. The Court expressed confidence in juries' capacity to evaluate expert evidence even if it is weak or deficient.

By the end of the twentieth century, the alliance between law and the human sciences—joined, eventually, by the nascent science of genomics—helped to define a host of novel disorders and syndromes that were invoked to extenuate or penalize various types of conduct. Post-traumatic stress disorder (PTSD), for example, along with its specific manifestations such as rape trauma syndrome, entered the *DSM-IV*, the official diagnostic handbook for psychologists. So codified, PTSD became not only an identifiable and presumably treatable medical condition, but also a basis for asserting new legal claims (as in lawsuits for stress-related psychological injury in the workplace) or defending oneself against them (as in murder trials of sexually abused defendants). Possibly the most notorious example of synergy between law and psychology occurred in a rash of so-called recovered memory and child abuse cases, which became especially prevalent in the US in the 1980s (Hacking 1995). Initially gaining credibility from psychiatric experts, who testified to the reliability of recovered childhood memories, these cases caused scandal as witnesses recanted and it became apparent that some experts had more likely instilled than elicited the shocking 'memories.' The profession eventually organized to deny the scientific validity of the claims and repudiate the expertise of the claimants (Loftus and Ketcham 1994).

Research on eyewitness identification, another branch of research dealing with memory and recall, also received its chief impetus from the legal process. Prompted by insupportably high error rates on the part of eyewitnesses, psychologists tested people's ability to recognize persons they had encountered in stressful situations and discovered that many factors, such as race, inhibit accurate identification under these circumstances (Wells 1988). These findings began to have an impact on police procedure by the late 1990s as awareness dawned that relatively simple changes, such as sequential rather than simultaneous presentation of suspects in line-ups, could substantially improve the reliability of eyewitness testimony.

3. *Scientific Evidence and Expert Witnesses*

Whereas civil law systems relegated the production of scientific and technical evidence largely to national forensics labs and court-appointed experts, common law proceedings traditionally left it to the parties themselves to produce evidentiary support for their claims. The adversary process, with its right of cross-examination, was assumed to be equal to the task of testing the evidence, no matter how arcane or technical, thereby permitting the fact-finder—the judge or jury—to ascertain the truth. Although commentators sometimes deplored the practice of treating experts as hired guns, the parties' basic right to present their evidence was not in doubt, and courts rarely used their legally recognized power to appoint independent experts who might offer a more disinterested view (Jasanoff 1995).

By the turn of the century, several factors combined to challenge this hands-off attitude. The sheer volume of cases demanding some degree of technical analysis was one contributing cause, especially in the US, where low entry barriers to litigation and the inadequacy of social safety nets routinely brought into the courts controversies that were resolved by other means in most common law jurisdictions. Highly publicized instances of expertise gone awry, as in the recovered memory cases, shook people's confidence in the power of cross-examination to keep out charlatans presenting themselves as scientists. The economic consequences of successful products liability lawsuits strained the system from yet another direction, especially in a growing number of mass tort actions that threatened industries with bankruptcy. It was tempting to blame many of these developments on the perceived weaknesses of the adversary system: the passivity and low scientific acumen of judges, the technical illiteracy of juries, the gamesmanship of lawyers, the bias or incompetence of experts selected by parties. These deficits led to calls for reforming the process by which expert testimony was admitted into the courtroom.

The initial round of critique marked a turn away from the liberal ideals of the 1970s and proved to be politically powerful, although it was neither methodologically rigorous nor of lasting scholarly value. An early broadside accused courts of deciding cases on the basis of 'junk science,' a rhetorically useful concept that took hold with opponents of the burgeoning tort

system but proved difficult to characterize systematically (Huber 1991). The barely concealed program of this and related writings was to remove as much as possible of the testing of scientific evidence from the adversary system, particularly from the jury's purview, and to decide these issues either in judicially managed pretrial proceedings or with the aid of scientists appointed by the courts. Undergirding this literature was an almost unshakable faith in science's self-corrective ability and a technocratic conviction that truth would eventually win out if only the legal system left scientific fact-finding to scientists (Foster and Huber 1997). These attacks also tacitly presumed that mainstream expert opinion could be identified on any issue relevant to the resolution of legal disputes. These positions would later be thrown into doubt, but not until the spate of polemical work had left its mark on American scientific and social thought.

Studies by practicing scientists, physicians and some legal academics reiterated and amplified the theme of the law's misuse of science. Critics cited as evidence a number of tort cases in which multimillion dollar jury verdicts favorable to plaintiffs conflicted with the opinions of respected scientists who denied any causal connection between the alleged harmful agent, such as a drug or workplace toxin, and the harm suffered. Particularly noteworthy was the litigation involving Bendectin, a medication prescribed to pregnant women for morning sickness and later suspected of causing birth defects in their children. Juries frequently awarded damages despite assertions by epidemiologists that there was no statistically significant evidence linking Bendectin to the claimed injuries. Research on the role of experts in these cases showed suggestive differences in behavior (such as higher rates of repeat witnessing) between plaintiffs' and defendants' experts (Sanders 1998), leading some to question whether judges were adequately screening offers of scientific testimony. Another episode that drew considerable critical commentary was litigation involving silicone gel breast implants. Close to a half-million women surgically implanted with these devices sued the manufacturer, Dow Corning, claiming injuries that ranged from minor discomfort to permanent immune system damage. The company's initial settlement offer broke down under the onslaught of lawsuits, but epidemiological studies, undertaken only after the commencement of legal action, indicated no causal connection between the implants and immune system disorders. Publication of these results in the prominent *New England Journal of Medicine* led its executive editor to join the chorus of accusation against the legal system's apparent misuse of science (Angell 1996).

Rising discontent about the quality of scientific evidence led the US Supreme Court to address the issue for the first time in 1993. In *Daubert v. Merrell Dow Pharmaceuticals*, the Court set aside the so-called *Frye* rule that had governed the admissibility of expert testimony for the preceding 70 years. Instead of simply demanding that scientific evidence should be 'generally accepted' within the relevant peer community, the Court urged judges to screen science in pretrial proceedings, in accordance with standards that scientists themselves would use. The Court offered four sample criteria: (a) was the evidence based on a testable theory or technique, and had it been tested; (b) had it been peer reviewed; (c) did it have a known error rate; and (d) was the underlying science generally accepted? Two more major evidence decisions of the 1990s cemented the high court's message that trial judges should play a vastly more proactive gate-keeping role when confronted by scientific and technical evidence. As judicial involvement on this front increased, new complaints appeared on the horizon: that judges were using the *Daubert* criteria as an inappropriately inflexible checklist rather than as the guidelines they were meant to be; that mechanical application of *Daubert* and its progeny was trumping deserving claims; that judges were usurping the jury's constitutional role; and that misinterpretation of *Daubert* was introducing unscientific biases and impermissibly raising the burden of proof in civil cases.

In most civil law jurisdictions, by contrast, the inquisitorial approach to testing evidence, coupled with the state's near monopoly in generating forensic science, precluded much controversy about the legitimacy of experts or the quality of their testimony. Tremors could be detected, however, arising from such episodes as the discovery of substandard or fabricated evidence in British trials of Irish terrorists and child abuse suspects and the French government's cover-up of the contamination of the blood supply with the HIV-AIDS virus. Ironically, as US courts moved to consolidate their gate-keeping function in the 1990s, constricting the entry routes for experts, a countermove could be discerned in some European legal systems to open the courts, and policy processes more broadly, to a wider diversity of expert opinion (Van Kampen 1998).

4. *Sites of Knowledge-making*

Investigation of the law-science relationship took a considerably more sophisticated turn in the 1990s as it attracted the attention of a new generation of researchers in science and technology studies. From this disciplinary vantage point, the use–misuse framing that dominated popular writing appeared superficial in the extreme when set against the observed richness of interactions between the two institutions. Rather, as this body of work began to document, it was the hybridization of law and science that held greatest interest and significance for science and society. At this active frontier of social problem solving, one could observe in fine-grained detail how important normative and epistemological commitments either reinforced or contradicted each other in contemporary

societies. For example, even within the common law's adversarial environment, the ritualistic character of legal proceedings successfully held the line against certain forms of radical skepticism, leaving untouched traditional hierarchies of expert authority (Wynne 1982), a belief in the ultimate accessibility of the truth (Smith and Wynne 1989), and an abiding faith in technological progress (Jasanoff 1995).

At the same time, the legal process increasingly came to be recognized as a distinctive site for the production of otherwise unavailable knowledge and expertise. Even in cases where litigation arguably produced anomalous results—such as Bendectin and breast implants—resort to the courts demonstrably added to society's aggregate store of information. Other cases were unambiguously progressive. A particularly striking example was the importation of molecular biological techniques into the arenas of criminal identification and paternity testing in the form of 'DNA typing.' Not only did the legal system's needs provide the initial context for the technique's development, but subsequent contestation over the reliability of DNA-based identification had impacts on the field of population genetics and spurred the formation of new testing methods and agencies, as well as the standardization of commonly used tests (Lynch and Jasanoff 1998). As the technique became black-boxed, new market niches for it emerged within the legal process, most spectacularly as a means of exonerating mistakenly convicted persons. The success of DNA as a forensic tool thus helped to destabilize the legal system's longstanding commitment to eyewitness evidence, and even its reliance on the seemingly unassailable authority of fingerprints (Cole 2001), thereby facilitating critiques of a possibly antiquated privileging of visual memory (Wells 1988). But the massive uptake of forensic DNA analysis by the criminal justice system also opened up new areas of social concern, such as privacy and database protection, which called for continued vigilance and ingenuity on the part of the legal system.

The rise of DNA typing, like that of risk analysis and post-traumatic stress disorder, captured the dynamics of an epoch in which the establishment of any form of social order became virtually unthinkable without the mutual engagement of law and science. In such a time, commentary deploring the law's alleged misuse of science appeared increasingly reductionist and out of touch with everyday reality. The emergence of science and law as a special topic within science and technology studies responded to the inadequacies of earlier analyses and showed greater intellectual promise. A major contribution of this work was to abandon once for all the pared down 'clashing cultures' model of the law–science relationship and to put in its place a more nuanced picture of the positive interplay between normative and cognitive authority. By exploring in detail how the law not only 'uses' science, but also questions it and often compensates for its deficiencies, the new scholarship on science and law invited reflection on the intricate balancing of truth and justice in technologically advanced societies.

Science and Religion

Understanding the present relationship between science and religion requires a recognition of broad historical trends. The subject has been most commonly treated in depth by historians of science, though scholars in both pure science and theology have also been active. Several posts in the UK, including a professorship at Oxford, and at least three major journals are devoted to the subject of science and religion (*Zygon*, *Perspectives on Science and Christian Faith*, and *Science and Christian Belief*), and numerous organizations have been formed to promote its study both in the US and UK.

Scholarship has become increasingly sophisticated, and frequent attacks on earlier 'simplistic' views have had the effect of excluding from the debate a great many ordinary people. This is quite unnecessary, though it is true that both 'science' and 'religion' are not eternally unchanging entities and do vary over time and space. In what follows, science is simply the study and systematic observation of the natural world, while religion may be seen generally as humanity's quest after God, a quest taking a variety of different forms. The subject is, of course, an emotive issue for some, from vociferous antagonists of religion (like the geneticist Richard Dawkins) to equally uncompromising supporters (such as the American 'creationists').

In the following account the main emphasis will be on Christianity, not for partisan reasons but because, historically, that religion more than any other has related closely to the emerging sciences.

1. *The Social Relations of Science and Christianity*

This topic has become the subject of a number of well-known statements or theses, five of which will now be considered. Some are about specific periods in history (as the seventeenth century) while others relate to allegedly more timeless issues. Some bear well-known names of their chief proponents.

1.1 *The Merton Thesis*

In 1938, the American sociologist Robert Merton argued that the emergence of science in the seventeenth century was promoted by the ascendancy of Protestant religion. Since then this contentious position has been revisited again and again, and it is hard to resist the conclusion that, in modified form, the thesis has more than an element of truth. Certainly, there is a correlation between visibility in science and religious allegiance. In the French *Académie des Sciences* from 1666 to 1885, the ratio of Protestants to Catholics was 80:18, despite the preponderance of Catholics in the country. Others have shown a similarly high proportion of Puritans (not merely Protestants) in the membership of the early Royal Society in England, and Merton argued that Puritan attitudes did much to encourage its growth.

There have been objections to such 'counting of heads,' not least because of the difficulty of defining a Puritan. If such a person is considered theologically rather than politically some of the difficulties disappear. On this basis a Puritan is one who holds strongly to the teaching of the Bible as opposed to the church or tradition, not necessarily a supporter of the Parliamentary cause in revolutionary England. Yet it may still be argued that such correlations do not prove that Puritan theology encouraged science, for may not both have emerged from a common cause? Could not both have been an expression of new movements of social and economic change and of a libertarian philosophy? This may well be true, but a general correlation in the 1600s between promotion of science and a generally Protestant loyalty to the Bible seems inescapable.

1.2 The Hooykaas Thesis

This goes further than the Merton thesis might suggest, and argues that the origins of modern science do not merely correlate neatly with Protestant beliefs but are directly derived from them. It has been implied by many authors since the 1970s but is particularly associated with the Dutch historian of science Reijer Hooykaas (1906–94) in his epochal *Religion and the Rise of Modern Science*. To make such an assertion is to stand traditional views on their head. It was once customary to see science as a truly Greek inheritance, at last freed from religious shackles at the Renaissance. Hooykaas invites us to view it rather as a product of Biblical theology, freshly released at the Reformation, and subverting much of Greek philosophy which had for 1500 years inhibited any real rise of experimental science.

Serious evidence exists in support of this thesis. There are explicit declarations by many well-known scientific figures from Francis Bacon to Isaac Newton and beyond that their science was inspired theologically. Then there is a remarkable congruity between Biblical and scientific credos. At least five points of intersection can be identified. (a) Most profound of all, perhaps, was what Hooykaas called the 'demythologization of nature,' so that nature was no longer to be seen as divine or even animate, but more like a machine than anything else. It is not God but a creation by him, and therefore a proper object of study and experiment. Such was the theology of the Old and New Testaments, and it was eloquently proclaimed by statements from 'the father of chemistry' Robert Boyle and many others. (b) Moreover, the idea that nature worked by laws is at the very foundation of science, and is also Biblical. Amongst those who wrote of laws impressed by God on nature were Descartes, Boyle, and Newton. Men looked for laws when they recognized the law-giver. (c) But science can only discover these laws by experimentation. Manipulation of nature had been regarded by many Greeks as socially unacceptable (except for slaves) or even impious. Among the most urgent advocates of an experimental method, based on widespread Biblical approval of manual techniques for testing, was Francis Bacon who urged 'men to sell their books, and to build furnaces.' (d) Then again a further religious impetus to science came from the Biblical exhortations to see the heavens and earth as manifesting the glory of their Creator. The astronomer Kepler, it is said, asserted that in his researches he 'was thinking God's thoughts after him.' This religious motivation became a strong emphasis in Calvinistic theology. (e) Finally, the Biblical mandate for humanity to exert 'dominion' over nature opened up possibilities of scientific work 'for the glory of God and the relief of man's estate' (Bacon). As Hooykaas wrote:

> The Biblical conception of nature liberated man from the naturalistic bonds of Greek religiosity and philosophy and gave a religious sanction to the development of technology [Hooykaas, *Religion and the Rise of Modern Science*, 1973, p. 67].

One cannot dismiss the burgeoning literature linking science to Protestantism in the seventeenth century as mere rhetoric. But it can be argued that Hooykaas underestimates the numbers of Roman Catholics who were eminent in science, though even here caution is needed. The oft-quoted counter example of the Catholic Copernicus must not obscure the astronomer's indebtedness to both his Lutheran assistant Rheticus, and the liberal legacies of Erasmus within his own church. Attitudes towards nature varied widely within Catholicism, and there is always the danger of generalising too widely. But in its essence the Hooykaas thesis appears to be substantially correct.

1.3 The Lynn White Thesis

If Christian theology has been one of the formative influences on modern science it does not follow that this has always been in the best interests of the world and its inhabitants. That opinion has been forcibly expressed in a further thesis, first proposed by the American historian Lynn White in 1966/7. He argued that much of the damage to our environment springs from a misuse of science and technology for which 'Christianity bears a huge burden of guilt.' More specifically he locates the problem in the 'realisation of the Christian dogma of man's transcendence of, and rightful mastery over, nature' (White 1967). He urges a return not to the primitive Christianity of the New Testament but to the animistic world of St Francis of Assisi which saw the earth and its inhabitants as brothers rather than instruments. In White's view the Biblical call to 'dominion' must have been understood in terms of exploitation.

However, careful historical examination of the evidence suggests that few, if any, pioneers in science or theology held this particular view. John Calvin explicitly repudiated it, as did the noted eighteenth century writer William Derham. They, and many others, urged an interpretation of dominion as 'responsible stewardship.' In more recent times ideologically driven human conquest of nature has been on the Marxist rather than the Christian agendas. It is now widely acknowledged that, as a historical generalization, the Lynn White thesis stands largely discredited.

1.4 The Conflict Thesis

This thesis is much older than the others we have examined, and much better known. The thesis states that science and religion have been in perpetual conflict and that, eventually, science will vanquish

religion. It was most notoriously promulgated by the Victorian naturalist T. H. Huxley, but has been advocated by many others in the late nineteenth century and is probably best not attributed to any one individual. Two books arguing the point are *History of the Conflict between Religion and Science* by J. W. Draper (first published in 1875), and *A History of the Warfare of Science with Theology in Christendom* by A. D. White (1895). They achieved enormous circulation and are still in print.

The essence of the argument is that where scientific conclusions have been challenged by the church there has usually been an eventual retreat by the ecclesiastical authorities. Two classic cases were those of Galileo in the seventeenth century and of Darwin nearly 250 years later. It was in the aftermath of the latter *imbroglio* that the conflict thesis was formulated. Many more examples were unearthed by Draper and White and an impressive case assembled (especially by the latter).

Manifestly, it is hard to reconcile this thesis with the three previously considered. If science owed so much to religion how could they possibly be in conflict? The thesis flies in the face of massive evidence that points to a powerful alliance between science and Christianity since at least the seventeenth century. A noteworthy feature of the conflict thesis is that it was first proposed at a time when history of science hardly existed and historical scholarship had certainly not explored the nuances perceived by Merton, Hooykaas, and their colleagues. Detailed examination of the relatively minor cases urged by Draper and White reveals that many were badly documented, some plainly apocryphal and others greatly exaggerated. It seems that the authors sometimes saw what they were looking for and built their generalizations on a slender foundation. To be sure, Galileo and Darwin were assailed by organized religion but they seem to have been relatively isolated exceptions to the general rule that Christianity and science coexisted in harmony. Partial explanations for the persecution of Galileo lay in power struggles within the church, while Darwin's problems arose in part from a deeply divided society in industrial Britain.

Today the books of Draper and White are rated not as serious works of historical scholarship but as highly polemical tracts reflecting the tensions existing in the social and cultural environment in which the authors lived. Draper wrote as a man deeply disenchanted with the Roman Catholic church, not least for its recent declaration of papal infallibility. White, on the other hand, was President of one of the first explicitly nonsectarian colleges in the US (Cornell) and had suffered badly at the hands of the religious establishment. Each had his own axe to grind in taunting the organized church. The result was not history but myth.

Yet a conflict thesis is commonly held in the world today, so one needs to asks how such a tendentious myth could have become so entrenched in Western culture. To understand the reason it is necessary to recall the plight of English science in the last 40 years of Victoria's reign. Underfunded by government, inadequately supported by secondary education, unpopular with the general public for a variety of reasons and a poor relation in those citadels of the establishment, the universities of Oxford and Cambridge, English science was crying out for recognition and support. It was falling seriously behind in the race with Continental science (especially German) and had no chance of occupying a leading place in English culture. In search of a weapon with which to acquire some kind of hegemony Thomas Henry Huxley and some close allies determined on a course of action. They would seek by all means within their power to undermine the privileged position of the Anglican church and put science in its place. A detailed strategy was worked out, an important element being the propagation of a conflict thesis in which the church was always portrayed as the vanquished party in its perennial fights with science. The books of Draper and White were at their service, and so was evolution which, as Huxley said, was a good stick with which to beat the church. With all the discipline of a military campaign the attack was launched and the conflict thesis enshrined as a self-evident truth in English culture. It was a demonstrably wrong but it carried the day, at least with the general public (see Russell 1989).

1.5 The Complementarity Thesis

In the 1960s and 1970s the scientist/philosopher Donald MacKay made much of the paradigm of complementarity. Derived from modern physics, where, for instance, wave and particle descriptions of light are complementary, the notion was applied to explanations from science and theology. It was the antithesis of a reductionist view where objects or events were nothing but phenomena of one kind (usually materialist). This view did not preclude traffic from one area to another, and did not deny their mutual influence. Indeed MacKay was committed strongly to the Hooykaas thesis. But it did mean that science and theology could co-exist as complementary enterprises.

We may call this the complementarity thesis. Its merits include the ability to account for several phenomena of modern and recent science. One of these is the large number of scientists who hold to Christian beliefs. In Huxley's day they included many of the most eminent physical scientists as Faraday, Joule, Stokes, and Lord Kelvin. Statistical surveys undertaken since that day have confirmed the same general trend, which is quite the opposite of common expectation. In the early years of the twenty-first century the numbers appear to be increasing. The only reasonable explanation is that such people regard their

scientific and religious activities as complementary and nonthreatening. Membership data and corporate activities of organisations like the American Scientific Affiliation and Christians in Science appear to bear this out.

In modern times an interesting tendency strengthens still further the case for a complementary approach. That is the rebirth of natural theology, in which the natural universe is seen to testify to the power and goodness of God. Such arguments go back to Biblical times, but were advocated with fresh vigour in the late eighteenth and early nineteenth centuries, reaching their peak with *Natural Theology* by William Paley, first appearing in 1802. The argument for a Designer from the apparent design of the natural world received hard blows from the philosophical critique of Hume and the evolutionary theories of Darwin. The proponents of the conflict thesis added their opposition. Yet over 100 years later the disclosures of modern science have caused some cynics to have second thoughts, and have encouraged scientist/theologians like John Polkinghorne to revive a form of natural theology that does justice to a natural world infinitely more complex than that perceived by Paley or even Darwin.

2. *Beyond Traditional Christianity*

It remains to note that orthodox Christianity has no monopoly in engagement with science, though historically it happens to have been the most prominent faith to do so. Much literature on science and religion has focused, therefore, on the Christian faith. A modern variant of Christianity is sufficiently different to justify the term heterodox; that is the so-called process theology that denies omniscience to God and regards natural processes as contributing to his self-fulfillment. It has been extensively used in discussions about indeterminacy in nature, about human free will and about the phenomenon of evil. Though favoured by some philosophers and theologians it cuts little ice with the majority of scientists.

The other great monotheistic religions of Judaism and, to a smaller extent, Islam have encouraged their followers in the study of nature though, operating in very different cultures and with different presuppositions, their effects have been rather unlike those of Christianity. The eastern mystical religions have arguably been less important for the growth of science, though some parallels between atomic physics and Buddhism have been emphasized by Franz Capra. The early promise of Chinese science was not fulfilled because the concept of scientific law was hardly present, reflecting, according to the historian Joseph Needham, the absence of any monotheistic law-giver in ancient Chinese culture.

Finally, the growth of environmental awareness has led some to espouse an almost pantheistic view of the universe as an alternative to the view of it as a machine which can be used or abused at whim. They have been encouraged by the *Gaia* hypothesis of James Lovelock which emphasizes the complexity of earth and its biosphere and its capacity for self-regulation. This had led several (including Lovelock) to posit the earth as in some sense 'alive.' From this it has been but a step to invoke the earth (*Gaia*) as a mother and even a goddess. If taken to extremes this view may lead to a greater sensitivity to the needs for sustainable development and other desirable attitudes to the earth. But it may also lead to a reversion to a prescientific animistic or even divine universe in which the benefits of a thriving science are rejected as minimal. If, however, the values of Christian monotheism are integrated with these views it may be possible for science to prosper, but always in a spirit of responsible stewardship. At present, we seem a long way from either of these positions.

Science and Social Movements

The social movements that are discussed in this article refer to major political processes of popular mobilization that have significant societal significance, and include organized forms of protest as well as broader and more diffuse manifestations of public opinion and debate. In relation to science, social movements conceived in this way can be seen to have served as seedbeds for new modes of practicing science and organizing knowledge more generally, and also as sites for critically challenging and reconstituting the established forms of scientific activity.

1. *Introduction*

Since they fall between different academic specializations and disciplinary concerns, the relations between science and social movements have tended to be a neglected subject in the social sciences. For students of social movements in sociology and political science, the relations to science have been generally of marginal interest and received little systematic attention (Dellaporta and Diani 1999), while in science and technology studies, social movements usually have been regarded more as contextual background than as topics of investigation in their own right. Considering their potential significance as 'missing links,' both in the social production of knowledge and in broader processes of political and social change, however, the relations between science and social movements deserve closer scrutiny. For one thing, new ideas about nature and society have often first emerged outside the world of formal scientific activity, within broader social and political movements. Social movements have also often provided audiences, or new publics, for the spreading and popularization of scientific findings and results. Movements of religious dissent were among the most significant disseminators of the new experimental philosophy in the mid-seventeenth century, for example, while, in the nineteenth and twentieth centuries, new approaches to medicine, social relations, gender roles, and the environment found receptive audiences within social and political movements. Most visibly, social movements and their spokespersons have offered critical perspectives on both the form and content of science, as well as on the uses to which science has been put. In recent decades, a range of so-called new social movements have criticized the dominant biases and perspectives of many scientific and technological fields. This article first presents these different forms of interaction between science and social movements in general, historical terms. It then discusses contemporary relations between science and social movements, and, in particular, the environmental movement.

2. *Historical Perspectives*

A fundamental insight of the sociology of knowledge, as it developed in the 1920s and 1930s, was to suggest that modern science emerged in the seventeenth century out of a more all-encompassing struggle for political freedom and religious reform (Scheler 1980/1924; Merton 1970/1938). What eventually came to be characterized as modern science represented an institutionalized form of knowledge production that, at the outset, had been inspired by more sweeping social and political transformations. The historical project of modernity did not begin as a new scientific method, or a new mechanical worldview, or, for that matter, as a new kind of state support for experimental philosophy in the form of scientific academies. As for the Reformation, it arose as a more deep-seated challenge to traditional ways of thought in social and religious life. It was a protest against the Church (which is why the members of the movement were called protestants), and it was an encompassing social and cultural movement that articulated and practiced alternative, or oppositional forms of religion, politics, and learning as part of its political

Table 1
A schematic representation of the scientific revolution from movement to institution

From movement…	*To institution*
Social reform	Reform of philosophy
Millenarian vision	Experimental program
Connection to radical politics	Rejection of politics
Decentralized structure	Central academy
Democratic/open to all	Elitist/professional
Spiritual (absolute) knowledge	Instrumental (probabalistic) knowledge
Technical-economic improvement	Scientific development
Informal communication pamphlets, correspondence	Formal communication journals, papers

struggle (Mandrou 1978). The teachings of Paracelsus, Giordano Bruno, and Tomaso Campanella, to name some of the better known examples, combined a questioning of established religious and political authority with an interest in scientific observation, mathematics, mechanics, and technical improvements (Merchant 1980). But as the broader movements were replaced by more formalized institutions in the course of the seventeenth century, the political and social experiments came to be transformed into scientific experiments; the political and religious reformation, tinged with mysticism and filled with mistrust of authority, was redefined and reconstituted, at least in part, as a scientific revolution (see Table 1).

In the later seventeenth and early eighteenth centuries, the scientific 'aristocracy' that had emerged in London and Paris at the Royal Society and the *Academie des Sciences* was challenged by dissenting groups and representatives of the emerging middle classes, some of whom fled from Europe to the colonies in North America, and some of whom established scientific societies, often in provincial areas in opposition to the established science of the capital cities. Many of them shared with the academicians and their royal patrons a belief in what Max Weber termed the protestant ethic, that is, an interest in the value of hard work and the virtue of making money, and most had an interest in what Francis Bacon had termed 'useful knowledge.' The social movements of the enlightenment objected, however, to the limited ways in which the Royal Society and the Parisian Academy had organized the scientific spirit and institutionalized the new methods and theories of the experimental philosophy. The various attempts to democratize scientific education in the wake of the French Revolution and to apply the mechanical philosophy to social processes—that is, to view society itself as a topic for scientific research and analysis—indicate how critique and opposition helped bring about new forms of scientific practice. Adam Smith's new science of political economy developed in the Scottish hinterland, and many of the first industrial applications of experimentation and mechanical philosophy took place in the provinces, rather than in the capital cities, where the scientific academies were located (Russell 1983).

Many of the political and cultural trends of the nineteenth century—from romanticism and utopianism to socialism and populism—also began as critical movements that at a later stage, and in different empirical manifestations, came to participate in reconstituting the scientific enterprise. Romanticism, for example, first emerged as a challenge to the promethean ambitions of science, in the guise, for example, of Mary Shelley's mad Doctor Frankenstein, while socialism, in the utopian form promulgated by Robert Owen, was a reaction, among other things, to the problematic ways in which the technological applications of scientific activity were being spread into modern societies. Romantic writers and artists, like William Blake, Johann Goethe, and later Henry David Thoreau, were critical of the reductionism and cultural blindness of science and of the 'dark satanic mills' in which the mechanical worldview was being applied. They sought to mobilize the senses and the resources of myth and history in order to envision and create other ways of knowing (Roszak 1973). Some of their protest was transformed into constructive artistic creation, and later in the century, the romantic revolt of the senses inspired both the first waves of environmentalism in the form of conservation societies and the emergence of a new kind of holistic scientific discipline, to which was given the name ecology: household knowledge.

In the late nineteenth century, the labor movement also sought a deep-going, fundamental political, and cultural transformation of society, but it would see its critical message translated, in the twentieth century, into packages of reforms and a more welfare-oriented capitalism, on the one hand, and into the 'scientific socialism' of Leninand Stalin on the other (Gouldner 1980). Once again, however, science benefited from this institutionalization of the challenge of social movements; the knowledge interests of the labor movement, for example, entered into the new social science disciplines of economics and sociology. A political challenge was once again transformed into programs of scientific research and state policy; but while new forms of scientific expertise were developed, little remained of the broader democratization of knowledge production that the labor movement, in its more radical days, had articulated.

In the early twentieth century, the challenge to established science was mobilized most actively in the colonies of European imperialism, as well as in the defeated imperialist powers of Germany and Italy; the critique was primarily of scientific civilization writ large, and of what Mahatma Gandhi in India called its 'propagation of immorality.' In the name of modernism, science stood for the future and legitimated, in the colonies as well as in Europe, a wholesale destruction of the past and of the 'traditional' knowledges—the other ways of knowing—that had been developed in other civilizations (Tambiah 1990). These social movements had an impact on the development of political ideology on both the right and left, but also inspired new sciences of ethnography and anthropology, as well as the sociology of knowledge. Even more important perhaps were the various attempts to combine the artisanal knowledges of the past and of other peoples with the modern science and technology of the present in new forms of architecture, design, and industrial production. Many of the regional development programs of the 1930s and 1940s, in Europe and North America, can trace their roots back to the cultural critique of modernism that was inspired by the Indian independence movement and by such 'movement intellectuals' as William Morris and

Patrick Geddes in Britain. Both Roosevelt's New Deal and the Swedish model welfare state can be said to have mobilized civilizationally critical perspectives in their projects of social reconstruction.

3. *Science and Contemporary Social Movements*

In recent decades, social movements have also served to challenge and reorient the scientific enterprise. Out of the anti-imperialist and student movements of the 1960s and the environmentalist, feminist, and identity movements of the 1970s and 1980s have emerged a range of alternative ideas about science, in form, content, and meaning, that have given rise to new scientific theories, academic fields, and technological programs (Schiebinger 1993, Harding 1998). Out of critique have grown the seeds of new, and often more participatory, ways of sciencing—from technology and environmental impact assessment to women's studies, queer theory, and postcolonial discourses. What were in the 1960s and 1970s protest movements of radical opposition largely have been emptied of their political content, but they have given rise to new branches of, and approaches to, science and technology. While the more radical, or oppositional, voices have lost much of their influence, the more pragmatic and scientific voices have been given a range of new opportunities. This is not to say that there is no longer a radical environmental opposition or a radical women's liberation movement, but radicals and reformists increasingly have drifted apart from one another, and in most countries now work in different organizations, with little sense of a common oppositional movement identity. There has been a fragmentation of what was a coherent movement into a number of disparate bits and pieces (Melucci 1996).

The new social movements rose to prominence in the downturn of a period of institutional expansion and economic growth. They emerged in opposition to the dominant social order and to its hegemonic scientific technological regime, which had been largely established during and immediately after World War II (Touraine 1988). The war led to a fundamental transformation in the world of science and technology, and to the emergence of a new relation, or contract, between science and politics. Unlike previous phases of industrialization, in which science and engineering had lived parallel but separate identities, World War II ushered in the era of technoscience. The war effort had been based on an unprecedented mobilization of scientists to create new weapons, from radar to the atomic bomb, and to gather and conduct intelligence operations. In the process, 'little' science was transformed into big science, or industrialized science.

Especially important for the social movements that were to develop in the 1960s and beyond was the fact that scientific research was placed at the center of postwar economic development. Many of the economically significant new products—nylon and other synthetic textiles, plastics, home chemicals and appliances, television—were based directly on scientific research, and the new techniques of production were also of a different type: it was the era of chemical fertilizers and insecticides, of artificial petrochemical-based process industries, and food additives. The forms of big science also differed from the ways in which science had been organized in the past. The big science laboratories—both in the public and private sectors—were like industrial factories, and scientific-technical innovation came to be seen as an important concern for business managers and industrial organizers. The use of science in society had become systematized, and, as the consequences of the new order became more visible, new forms of mistrust and criticism developed (Jamison and Eyerman 1994).

One wing of the public reacted to the destruction of the natural environment, what an early postwar writer, Fairfield Osborn, termed 'man's war with nature.' The exploitation of natural resources was increasing and, in the 1940s and 1950s, it began to be recognized that the new science-based products were more dangerous for the natural environment than those that had come before. But it would only be with Rachel Carson, and her book *Silent Spring* in 1962, that an environmental movement began to find its voice and its characteristic style of expression. It was by critically evaluating specific instances of scientific technology, particular cases of what Osborn had called the 'flattery of science' that the environmentalist critique would reach a broader public. Carson singled out the chemical insecticides for detailed scrutiny and assessment, but her point was more general. Carson's achievement was to direct the methods of science against science itself, but also to point to another way of doing things, the biological or ecological way—what she called in her book the road not taken.

Another source of inspiration for the new social movements came from philosophers and social historians who questioned the more general impact of technoscience on the human spirit. It was one-dimensional thinking which critical theorists like Herbert Marcuse reacted against, the dominance of an instrumental rationality over all other forms of knowing. For Lewis Mumford, another major source of inspiration, it was the homogenization of the landscape that was most serious, the destruction of the organic rhythms and flows of life that had followed in the wake of postwar economic growth, as well as the dominance of what he termed the 'megamachine,' the use of technology for authoritarian purposes.

In the 1970s, a range of new social movements, building on these and other sources of inspiration, came to articulate an oppositional, or alternative approach to science and technology (Dickson 1974). The so-called new social movements represented an integrated set of knowledge interests, which combined the critique of Rachel Carson with the liberation

dialectics of Marcuse and the direct democracy of the student movement. The new movements involved a fundamental critique of modern science's exploitative attitude to nature, as well as an alternative organizational ideal—a democratic, or participatory ideal—for the development of knowledge. There were also distinct forms of collective learning in the new social movements of environmentalism and feminism, as well as grass-roots engineering activities that went under the name of appropriate or alternative technology.

4. Social Movements as Cognitive Praxis

On the basis of these historical and contemporary relations between science and social movements, many social movements can be characterized as producers of science (Eyerman and Jamison 1991). The critical ideas and new public arenas that are mobilized by social movements often provide the setting for innovative forms of cognitive praxis,combining alternative worldviews, or cosmological assumptions with alternative organizational and practical–technical criteria. In the case of environmentalism, the cosmology was, to a large extent, the translation of a scientific paradigm into a socioeconomic paradigm; in the 1970s, the holistic concepts of systems ecology were transformed into political programs of social ecology, and an ecological worldview was to govern social and political interactions. Technology was to be developed under the general perspective that 'small is beautiful' (in the influential phrase of E. F. Schumacher), and according to the assumption that large-scale, environmentally destructive projects should be opposed and stopped. At the same time, new contexts for education and experimentation and the diffusion of research were created in the form of movement workshops and, in the Netherlands, for example, in the form of science shops, which allowed activist groups to gain access to the scientific expertise at the universities (Irwin 1995).

In the 1980s, this cognitive praxis was decomposed largely into a disparate cluster of organizations and individuals, through processes of professionalization and fragmentation. The knowledge interests of the environmental movement were transformed into various kinds of professional expertise, which made it possible to incorporate parts of the movement into the established political culture, and to shift at least some of the members of the movement from outsider to insider status. Some of the alternative technical projects proved commercially viable—biological agriculture, wind energy plants, waste recycling—and gave rise to a more institutionalized form of environmental politics, science, and technology (Hajer 1995).

Similar processes can be identified in relation to other social movements of recent decades (Rose 1994). The political struggles for civil rights, women's and sexual liberation, and ethnic and national identity have inspired new approaches to knowledge that have since been institutionalized and transformed into established scientific fields, such as women's studies, gay and lesbian studies, African-American studies, as well as in new areas of medicine and technology.

At the same time, science itself has been reconstituted, partly as a result of the critical perspectives and cognitive challenges posed by social movements. Many of the postmodern theories of the cultural and human sciences have been inspired by the experiences of social and political movements. Out of the alternative public spaces that have been created by social and political movements has emerged a new kind of scientific pluralism, in terms of organization, worldview assumptions, and technical application. In the transformations of movements into institutions, a significant channel of cognitive and cultural change can thus be identified. It may be hoped, in conclusion, that these interactions between science and social movements will receive more substantial academic attention in the future.

Science and Technology, Anthropology of

The anthropology of science and technology is an expanding arena of inquiry and intervention that critically examines the cultural boundary that sets science and technology off from the lives and experiences of people. Most research in this arena draws on ethnographic fieldwork to make visible the significance and force of this boundary, as well as meanings and experiences that cut across it or otherwise get hidden. Key categories of projects include juxtaposing shared systems of cultural meaning, following flows of metaphors back and forth across the boundary, and retheorizing or relocating the boundary itself in ways that reconnect science and technology to people. While advancing understanding of how people position science and technology in both specialized and everyday worlds, the anthropology of science and technology also calls attention to cultural possibilities whose realization might help expand participation in decision-making about science and technology.

1. *Helping STS Fulfill its Dual Objectives*

The unique contribution of this field to science and technology studies (STS) is that it helps revive and refocus questions regarding relations among science, technology, and people. STS research and researchers are held together by their diverse, yet collective, efforts to trouble and transform the dominant, but simplistic, model or image of science and technology in society. According to the dominant model, researchers live in specialized technical communities whose deliberations are essentially opaque and presumably free of cultural content. Knowledge, in the singular, is created by these bright, well-trained people located inside the academy and then diffuses outside into the public arena through mechanisms of education, popularization, policy, and the benefits of new technologies. Its social significance is evaluated exclusively in the public arena, where knowledge is used, abused, or ignored. The outward travel of knowledge preserves the autonomy of creation and establishes a sharp boundary between science and technology on the one side and people on the other, including the actual lives of scientists and technologists.

STS has sought to engage this model in two ways. First, it brings together researchers who analyze the conceptual and the social dimensions of science and technology simultaneously and in historical perspective. Second, by offering new ways of thinking, STS promises to afford society new pathways for confronting and resolving problems that involve science and technology. STS thus offers the dual trajectories of theory and intervention, of proposing new frameworks of interpretation, and participating critically in societal problem solving. These activities complement one another. Good theory defines pathways that make a difference, and successful acts of critical participation depend upon novel theoretical insights.

During the 1980s and early 1990s, a major focus within STS was on a philosophical debate between 'objectivism' and '(social) constructivism.' Constructivism provided a major theoretical advance over 1970s research on the 'public understanding of science' and the 'impacts' of science and technology, which tended to take for granted the internal contents of science and technology (see *Technology Assessment*). One important body of constructivist work was often labeled 'anthropology of science' because it relied on the direct observation of scientists in laboratories to link scientific practices to knowledge development. For more information on this formative strand in the anthropology of science (see *Laboratory Studies: Historical Perspectives*; *Actor Network Theory*). By questioning how science and technology gain internal contents, the philosophical debate between objectivism and constructivism concentrated attention on the science/technology side of the cultural boundary with people. Also, a focus on the emergence and stabilization of either new scientific knowledge or new technological artifacts tended to maintain the more general cultural separation between science and technology (see *Technology, Social Construction of*).

The newer strands in the anthropology of science and technology explicitly foreground the interventionist potential of STS by moving back and forth across the boundary between science/technology and people, investigating its force and making visible meanings and experiences that get hidden when it is taken for granted. In this work, the commitment to ethnographic practices forces attention to alternative pathways for critical participation as an integral part of theoretical innovation (see also *Ethnography*).

2. *Helping Anthropology Rethink Culture*

As recently as 1988, the American Anthropological Association (AAA) rejected proposed panels on the anthropology of science and technology on the grounds such work did not fit under the AAA umbrella. Things had changed by 1992 as a series of

panels on 'cyborg anthropology' and on the work of Donna Haraway attracted standing-room-only audiences in a ballroom setting.

Key to this shift was a growing recognition that anthropological debates over the status of cultural analysis and cultural critique were similar to developments and deliberations in STS. Anthropologists grew hopeful that analyzing and critiquing the dominant model of science and technology in cultural terms might further people's understanding of how sciences and technologies, including anthropology, live in society. Emerging questions included: what are the implications of accounting for science, technology, and people in cultural terms? Might the finding of wider cultural meanings in science and technology improve searches for alternative configurations? To what extent has anthropology itself depended on the dominant model of science and technology in society? How can one participate critically in science and technology through ethnographic work? As it emerged from symbolic anthropology during the 1970s, the concept of culture drew from the predominant model of language as an underlying grammar, structure, or system of symbols and meanings (see *Culture: Contemporary Views*). Beneath surface differences in speech and action among competent participants in a given community lies a more fundamental sharedness, a bounded 'culture.' This concept of cultures as sets of shared assumptions or presuppositions depends on a contrast with the concept of 'nature.' Where nature provides people with base needs and desires, culture provides content and meaning.

Until the 1980s, it appeared difficult to apply the concept of culture to science and technology. While theorizing culture as a bounded system helped in accounting for differences across cultures, this approach offered no means of accounting for differences within cultures. Yet research questions in STS typically focused on the latter. Also, much research in anthropology itself, for example, kinship theory, depended on the nature/culture distinction for its legitimacy. Treating anthropological work itself as a cultural enterprise could have threatened to undermine the discipline.

As Franklin (1995) put it, by the 1990s 'several trajectories coalesce[d] to produce … momentum' for an emerging anthropology of science and technology. Feminist anthropology had made visible the role of biological assumptions in gender and kinship studies (see *Kinship in Anthropology*). Poststructuralism made it possible to think about power–knowledge relationships and to make the conceptual limitations of the 'human' a focal point for social theory (see *Knowledge, Sociology of*; *Postmodernism in Sociology*). Postmodernist critiques of science and technology called attention to the processes of their production, making 'progress' a contingent effect (see *Cultural Studies of Science*). In revealing how anthropologists 'write culture' by turning people into 'others,' postmodernism in anthropology introduced 'cultural critique' as an anthropological practice (see *Cultural Critique: Anthropological*). Cross-cultural comparisons of knowledge systems began to reposition Western science as ethnoscience (see *Knowledge, Anthropology of*; *Indigenous Knowledge: Science and Technology Studies*; *Postcoloniality*). The rise of interdisciplinary cultural studies juxtaposed 'popular' with 'high' cultural forms, revealing power relations between the two and retheorizing culture as a site of active work (see *Cultural Studies of Science*).

Feminist critiques of science demonstrated its saturation with gender metaphors, and feminist critiques of reproductive technologies provided compelling accounts of women's experiences that could not be counted unproblematically as the benefits of innovation (see *Feminist Epistemology*; *Gender and Technology*). Cross-disciplinary interests in emerging transnational forms demanded simultaneous attention to technology, knowledge, and capital (see *Globalization, Anthropology of*; *Postcoloniality*; *Capitalism: Global*). Growing demands for accountability across the academy in general fueled interest in how ethnographic research can make a difference in the arena under study (see *Ethnography*; *Advocacy in Anthropology*).

During the early 1990s, cultural anthropologists studying science and technology actively resisted the label 'anthropology of science and technology' on the grounds it masked these trajectories, confining diverse work to a bounded subdiscipline. The label works only to mark a collection of intellectual activities within which competition exists not to achieve domination but to make a difference and where border crossing is accepted to enhance the life chances of what the dominant model submerges. Ongoing projects fall into roughly three categories, with individual researchers and studies often contributing to more than one.

3. *Juxtaposing Cultural Systems of Meaning*

The publication of Sharon Traweek's *Beamtimes and Lifetimes* in 1988 marked the emergence of projects that identify and juxtapose cultural systems of meaning in science and technology. Rather than focusing solely on theory change in science, Traweek provides 'an account of how high energy physicists see their own world; how they have forged a research community for themselves, how they turn novices into physicists, and how their community works to produce knowledge' (1988, p. 1). Studying the culture of high-energy physicists extends and transforms the anthropological project of cross-cultural comparison by studying people who live in more than one culture at the same time, in this case those of the international physics community, Japan, and the United States.

Demonstrating sharedness among high-energy physicists and then setting physicists off as a community

achieves two key contributions. It repositions the dominant model of science and technology, which physicists both embrace and embody, into one among many possible cultural perspectives without suggesting that all perspectives on physical knowledge are equal. The ethnographic approach also locates the researcher within the power relations that constitute the field of study and makes visible ways in which scientists function as people who live social lives.

The juxtaposition of shared systems of meaning has proven fruitful in analyzing public controversies over science and technology. Articulating subordinate perspectives and locating these alongside dominant ones demonstrates that factual claims gain meaning in terms of more general frameworks of interpretation. Such work also intervenes in power relations in ways that highlight mediation and collaboration as possible pathways for resolution (see also *Scientific Controversies*).

Representative contributions in this category juxtapose Brazilian spiritists, parapsychologists, and proponents of bacterial theories of cancer with 'orthodox' perspectives (David Hess); antinuclear weapons groups with nuclear weapons scientists (Hugh Gusterson); creation science with evolutionary science (Christopher Toumey); antinuclear power with pronuclear power groups (Gary Downey); artificial intelligence researchers with expert system users (Diana Forsythe); advocates of midwifery with obstetrics (Robbie Davis-Floyd); Marfan scientists with technicians and activists (Deborah Heath); a unified Europe with separate nation–states seeking space travel (Stacia Zabusky); nuclear power plant operators with plant designers (Constance Perin); and competing workgroups in industry (Frank Dubinskas). Recent work questions the culture/people relationship by understanding cultures as, for example, shifting discourses (Gusterson) or recursive, cross-cutting perspectives in a social arena (Hess). Future work will likely review the notion of sharedness, no longer asserting it as a condition of anthropological analysis but exploring what gets accomplished when it can be demonstrated empirically.

4. *Following Flows of Metaphors Across the Boundary*

The publication of Emily Martin's *The Woman in the Body* in 1987 marked the emergence of projects that follow flows of metaphors from general cultural life into science and technology and back again into people's lives and experiences. Writing a cultural history of the present, Martin demonstrates how medical conceptions of menstruation and menopause draw upon metaphors of production in portraying these as breakdown, the failure to produce. In addition to contrasting descriptions from medical textbooks with an ethnographic account of the actual experiences of women, Martin also experiments with re-imagining menstruation and menopause as positive processes of production.

Following flows of metaphors brings a new approach to the study of public understanding and of what the dominant model of science and technology characterizes as impacts. It calls direct attention to the existence and life of the cultural boundary that separates science and technology from people. How do people import scientific facts and technological artifacts into their lives and worlds? How does the dominant model of science and technology live alongside and inform other cultural meanings?

Like the strategy of juxtaposition, following metaphors focuses attention on how people involve themselves with science and technology, making visible those meanings and experiences that do not have a place within the dominant model alongside those that do. What sorts of effects do scientific facts have in people's bodies and lives? How do experiences with technologies go beyond the simply positive, negative, or neutral? How do emerging sciences and technologies contribute to the fashioning of selves? Such work makes visible patterns and forms of difference that may not correlate with demographic categories of race, gender, and class.

Finally, following metaphors introduces the possibility of speculating on alternative cultural possibilities, including narrative experiments with counterfactual scenarios. While sharing with readers an anthropological method of critical thinking, such speculation also forces more explicit attention to how anthropological accounts participate critically within their fields of study. How, for example, might choices of theory and method combine with aspects of researchers' identities to shape pathways of intervention?

Work along these lines follows how sonography and amniocentesis accelerate the introduction of medical expertise into pregnancies (Rayna Rapp); the cultural origins of Western science and its shifts over time (David Hess); how people calculate in diverse settings (Jean Lave); the cultural meanings of medicine in everyday life (Margaret Lock); the narrative construction of scientists' autobiographies (Michael Fischer); creative adjustments when medical expertise fails to account for pregnancy loss (Linda Layne); the flows of meanings that constituted the reproductive sciences as sciences (Adele Clarke); what living with gender assumptions means for women scientists (Margaret Eisenhart); how Bhopal lives as fact and image in different enunciatory communities (Kim Fortun); and how patents travel around the world (Marianne De Laet).

Future work is likely to elaborate questions of scale and identity. How do metaphors gain effects at different scales and how do meanings that live at different scales combine in people's lives and selves? How do people respond to meanings that summon

and challenge them, positioning themselves in searches for identities that work (see also *Identity in Anthropology*).

5. *Retheorizing the Boundary between Science/Technology and People*

The publication of Donna Haraway's *Simians, Cyborgs, and Women* in 1991 marked the emergence of projects that retheorize the boundary itself. Moving through the project of following flows of metaphors to reimagine categories that 'implode' on one another, Haraway calls for 'pleasure in the confusion of boundaries and … responsibility in their construction' (1991, p. 150). Claiming the cyborg (see *Cyborg*) as a feminist icon and key marker of what she calls the 'New World Order,' Haraway forges attention to the contemporary dissolution of boundaries between human and animal, human and machine, and physical and nonphysical. Challenging the 'god-trick' of universalism, she poses 'situated knowledges' (see *Situated Knowledge: Feminist and Science and Technology Studies Perspectives*) as a means of holding simultaneously to a radical historical contingency and a no-nonsense commitment to faithful accounts of a 'real' world.

This project calls attention to burgeoning collections of activities involving science and technology that live across the purported separation between them or across their boundary with people. It includes the exploration of emerging fields that do not fit conventional disciplinary categories, such as biotechnology, biomedicine, and bioengineering, and documents the decline and loss of a distinction between basic and applied science. Following novel activities in research and production motivates the invention of new labels for the anthropological object of study, including, for example, 'technoscience' and 'technoculture.'

The project of retheorizing the boundary between science/technology and people highlights the presence of the nature/culture distinction in anthropology of science and technology as well as in other areas of STS inquiry and intervention. Pressing questions include: through what sorts of processes do analytic findings and interpretations become naturalized as facts in everyday, or popular, modes of theorizing? In what ways might analytic accounts, including claims about culture, depend upon facts from popular theorizing? How might new modes of theorizing about analysis contribute to rethinking the nature/culture distinction itself?

Finally, by calling attention to the difficulty of living within existing categories while attempting to theorize and embody new ones, retheorizing the boundary sharpens the question of intervention. Locating experiences that live across categories invites researchers to examine how emergent categories impact and inflect old ones. Through what sorts of pathways might reformulations actually intervene and achieve change in specific cases? How might it be possible to assess the extent to which reformulations and refigurations prove, in fact, to be helpful, and to whom?

Contributions to this diverse project explore how ideas of the natural help constitute cultural ways of knowing (Marilyn Strathern); the situatedness of practices in machine design and machine use (Lucy Suchman); opportunities for a 'cyborg anthropology' that studies people without starting with the 'human' (Gary Downey, Joseph Dumit, Sarah Williams); how reproductive technologies blur the facts of life (Sarah Franklin); emerging refigurations to constitute and categorize artificial life (Stefan Helmreich); the activities of biotechnology scientists who move outside the academy to gain academic freedom (Paul Rabinow); the importance of 'good hands' and 'mindful bodies' in laboratory work (Deborah Heath); how practices of tissue engineering materialize new life forms (Linda Hogle); experiences with PET scanning that escape the nature/culture distinction (Joseph Dumit); the contemporary production of 'cyborg babies' (Robbie Davis-Floyd and Joseph Dumit); experiences of computer engineers that belie the separation of human and machine (Gary Downey); possibilities for reinvigorating general anthropology by locating technology and humans in the unified frame of cyborg (David Hakken); and how African fractal geometry escapes classification in either cultural or natural terms alone (Ron Eglash) (See also *Actor Network Theory* for an approach that defines both humans and nonhumans as 'actants'.)

Future work is likely to forge novel alliances among theoretical perspectives previously separated by the nature/culture distinction. Actively locating academic theorizing in the midst of popular theorizing will likely force modalities of intervention into focus. Finally, to the extent that the anthropology of science and technology succeeds in challenging and replacing the simplistic dominant model by blurring and refiguring the boundary between science/technology and people, wholly new projects of inquiry and intervention will have to emerge to take account of the changing context. Science and Technology: Internationalization

Science is predominantly done in national scientific communities, but scientific information regularly crosses boundaries. Various conditions influence this flow, which means that it is not symmetric in all directions. Internationalization is the uneven process wherein cross-border linkages of communication and collaboration in science and technology among countries multiply and expand. Linkages involve individual scientists and their institutions, but also, increasingly, governments through treaties and conventions that include strong science and technology components. The growing density of interconnections between large industrial corporations regarding research in the precompetitive phase as well as technological alliances is also relevant.

1. Some Distinctions

1.1 Scientific Internationalism

Scientific internationalism emerged with the development of national academies of science (Crawford et al. 1993). Later, correspondence and interchange between individual scientists channeled through international scientific unions and congresses appearing in the nineteenth century (Elzinga and Landström 1996). The flare-up of nationalism and World War I caused a temporary rupture in this internationalism, both in mode of organization and spirit. After the war, transnational scientific relations were gradually repaired, even with Germany, but at the cost of promoting a strict neutralist ideology, nurturing an image of science disembodied from and standing above society.

1.2 Scientific Internationalization and Economic Globalization

The multiplier effect of interconnections between transnational corporations (TNCs) and financial institutions that shape trade related agreements and intellectual property regimes influences, but must not be confused with, scientific internationalization. It is a 'globalization' process in the economic sphere, driven by for-profit motives, facilitated by a combination of neoliberal politics, privatization and information-technological developments. Internationalization of science, by contrast, is ultimately predicated on trust and solidarity among intellectual peers, even though it is interpenetrating increasingly with economic globalization.

A further distinction is between quantitative and qualitative aspects of internationalization. Quantitative studies deal with numbers and patterns of cross-border linkages, and multinational interconnectivity or collaboration and cooperation. They provide indications of changing trends, but for deeper insights need complementation by studies of qualitative changes, e.g., emergence of new institutional arrangements and incentive systems that facilitate international exchange, reorientation of local research agendas, or harmonization of approaches to policy and priorities, like foresight methodologies, at national and regional levels.

Internationalization of industrial research and development (R&D) is now recognized as an important research topic. Statistical surveys and empirical case studies confirm increases in the numbers of multi-country patents held by individual firms, as well as a proliferation of technological alliances within and between a triad of trading blocks (NAFTA; North American Free Trade Agreement, EU; European Union, and Developing Asian Economies plus Japan). In this respect it is actually more appropriate to speak of a 'triadization' than economic globalization.

Pertinent literature on internationalization of technology also refers to other types of interaction between TNCs, and it deals with various R&D management strategies in this context. But in this respect also, extant overviews are limited largely to providing taxonomies and typologies of discernible patterns (*Research Policy* 1999); (for further details, see *National Innovation Systems* and *Technological Innovation*).

Qualitative aspects of internationalization also include epistemic change: i.e., in the intellectual contents of scientific fields, namely, dominant perspectives, methodologies and theories. Thematic integration appears along research fronts, as well as sectoral lines where problems transcend national boundaries (acid rain, global climate change, AIDS), or are too costly for a single nation to handle alone (e.g., CERN). In these instances, and more generally, when international research programs foster coordination of national contributions they also force standardization of data formats, preferred instrumentation and experimental practices.

In what follows, transformations of interconnectivity consonant with internationalism is probed in cartographic, institutional and epistemic dimensions, with political aspects also thrown in relief.

2. *Tracing the Span and Patterns of International Networks*

At the time of writing, the volume of science, national outputs per monies allocated per gross national product (GNP), and the distribution of research efforts and patenting across the globe are mapped regularly. This is done with the help of publication counts (of papers) and reviews of who cites whom (Price 1986) to trace citation patterns and coauthorship linkages (see *Scientometrics*). Visibility of scientists from different countries or in regions is compared. Evaluations of research performance use science and technology indicators as proxies for effectivity, quality and international standing of research groups and their institutions.

The span of global networks increased during the last decades of the twentieth century. Coauthorship patterns reveal growing contacts of scientists across national borders during the 1970s and 1980s (Hicks and Katz 1996), with a certain slackening in the 1990s (UNESCO 1998). Leading scientific producers such as the USA engage less in international co-authorships than do smaller countries—the larger the national or regional scientific community, the greater is 'self-reliance.' Generally, internationalism is only played up in large countries when scientific leadership is in decline, or other countries possess desired specialty knowledge. An interesting anomaly is that India and China also figure lower on polls of cross-border co-authorships than might be expected. Latin America has remained constant, while Africa, especially its sub-Saharan part, stands out as most disadvantaged.

Concentration of resources, prestige, authority and recognition thus display regional variations, with densities following continental contours dominated by an Anglophone region. The predominance of English as the main language of scientific communication, as evidenced in the Science Citation Index (SCI), is also increasing. International coauthorship furthermore reveals subclusters (e.g., the Scandinavian countries) influenced by geographical vicinity, historical traditions, and linguistic as well as cultural affinities. The number of Third World countries now participating in world science has increased, but the vast majority still belong to the scientific periphery (Schott 1998). The share of liberal democracies in world science 1986 was nearly five times their share of world population, while the poorer countries' share in scientific production counted for only one-tenth of their share of the world population. With a few remarkable exceptions (India, Brazil, China) this global gap became even more exaggerated during the 1990s (Schott 1993).

Increased connectivity, scope and participation in scientific communication across national borders, in other words, cannot be equated with decreasing hierarchization. Rather, 'globalization' of institutional models and participation in science is accompanied by a deglobalization in dispersion of science. This contrasts sharply with the notion of science as a public good. Scientific knowledge remains highly concentrated where it is first created, namely among OECD countries. The scientific centers in advanced industrial nations, by virtue of prestige and scientific achievement (often measured by relative density of Nobel laureates in specific fields) also exercise influence over work done in peripheral countries. A Eurocentric skew persists in power, resources, problem selection, and overriding perspectives on the content and function of science and technology.

The end of the Cold War opened a new era of pluricentrism, primarily around three large regional blocks: North America, the European Union, plus Japan and developing economies in Asia. These cleavages are reflected in transnational citation impact and coauthorship clusters, and they coincide with current density patterns in international trade and technology alliances (EC 1997, pp. 10–11, 93).

3. *Driving Factors*

Public spending on R&D is more intense in the USA than in the EU, while in terms of patenting, Japan has caught up with the USA, and the EU rates third (EC 1997a, pp. 53, 93). Economic globalization is a second driving force to reckon with, also uneven. With R&D investments concentrated in a few high-technology industries in the world, these lead strategic reconfigurations in S&T landscapes. Rapid advances in information and communication technologies interlock with economic development, providing new vehicles for rapid interaction (e.g., the Internet), and spurring further alliances and integration of knowledge in pre-competitive phases. Simultaneously, science is being drawn more deeply into the economic globalization process by policy responses, as countries

and whole regions (e.g., the EC through its Framework Programs) facilitate technological development for highly competitive world markets. The EC's mobility schemes for graduate students and post docs must be seen in this light, and so also—by extension—events like the turn of the millennium announcement of a cooperative bilateral university-level agreement between two of the world's most prestigious institutions, MIT (Massachussetts Institute of Technology, USA) and Cambridge University (UK), and the EC's a new integrative policy for 'the European Research Area.' Such events herald a new phase in the intermeshing of the two processes, scientific internationalism and economic globalization.

An ideological driving factor is the traditional cosmopolitan ethos inherent to academe. Associated with modernity, it incorporates the idea of progress, with a history parallel to the emergence of the nation state, democracy and secularization. This means it is in fact culturally bound, as are its CUDOS components enunciated by Robert Merton as the social glue of modern scientific institutions: intellectual Communism, Universalism, Disinterestedness, and Organized Skepticism (see *Norms in Science*). Recent deconstruction of such norms, standards and models of science by scholars in the newer sociology of science highlights the role of particularism, drawing attention to social mechanisms of negotiation between various actors, and how these shape or 'stabilize' scientific consensus that can never be final. This captures the cultural diversity of scientific practices, but not the basic ideological import of universalism as an ideal in scientific internationalism.

A recent factor of internationalization resides in the global nature of environmental problems and the demand for concerted political action on a global scale to address them. Increasing numbers of treaties and conventions with strong science and technology components have been drawn up in this vein. On a converging track one finds pressures of escalating costs of large-scale facilities and calls to share budgetary burdens in newer as well as more traditional fields. The end of the Cold War was also a triggering factor. In its wake appear programs to aid Eastern and Central European scientists in their transition to capitalism and market-driven incentives, and new forms of international science and technology cooperation.

Finally, there are the local pressures in smaller nations that push scientists in settings of relative isolation in all parts of the world to integrate their work more closely with research fronts. Here the benefits of internationalization and the added intellectual stimulation it entails sometimes has the makings of a self-fulfilling prophecy. Pressures to increase local visibility and gain international recognition by exposure to wider peer control of scientific quality get entrenched in procedures and new funding opportunities at national research councils and universities, affecting the behavior of individuals and groups of researchers, and success in getting grants.

4. *Explanatory Models*

Traditional literature on the history of international scientific organizations usually distinguishes two types of fora, scientific non and intergovernmental organizations (scientific NGOs and scientific IGOs). These are taken to represent two different institutional mechanisms for fostering internationalization. In the innovation literature, on the other hand, the focus has mostly been on firms and their role in international diffusion of technologies.

In general, there are two broad strands of theorizing about international organizations. One is rooted in the assumption that networks and more stable forms of organization arise in response to considerations of efficiency and rational goal-oriented behavior, in the course of which less viable alternative forms of interaction are circumvented. An economistic variant of this approach is implicit in an evolutionary theory of technological advance and diffusion. Here 'market' is taken as the selection mechanism that filters out a set of particular technologies from many potentially possible ones, and these get diffused across the globe (Nelson and Winter 1982).

Explicitly or implicitly, the market is regarded as being determined by the tastes, preferences and purchasing power of potential technology users, who are treated as exogenous. Internationalization, in turn, becomes largely a unidirectional product of technological regimes or trajectories which cross and are taken up in socially constituted selective environments. Depending on similarities in the selection mechanisms, or 'learning' between national innovation systems, the transfer of ideas and technologies may be harmonized successively at a global level.

Theoretical assumptions in the historiography of scientific organizations, or alternatively in regime-theory within the study of international relations, run somewhat parallel to this. Instead of the prominence attributed to an economic imperative, in these literatures ideological or political imperatives, and even communities of experts, may be foregrounded. One therefore gets the picture of internationalization primarily as the product of ideologically driven self-direction by the scientific community (in the case of scientific NGOs) or of governments' guiding hands, plus rules and experts (in the case of scientific IGOs).

In all these accounts, the organizations in question are regarded more or less as mechanisms through which other agencies act. They are not depicted as purposive actors with an autonomy, power or culture of their own, even if regime-theory has been criticized for giving too much prominence to experts while

obfuscating the role of the nation states that invest them with authority.

In contrast to this, a sociological strand of theorizing takes its point of departure in Weber's view of bureaucracies and focuses squarely on issues of legitimacy and power. Its advocates seek to explain a much broader range of impacts organizations can have, among others by virtue of their role in constructing actors, interests and social purpose. Emphasized are complexity, multiplicity and flexibility, with actors incorporated as endogenous to the processes of change. In this perspective it becomes interesting to consider how fora for international interaction, once they are created, take on a life of their own, exercising power autonomously in ways unintended and unanticipated by scientific associations or governments at the outset. The same can be said about conventions or regimes introduced to regulate and standardize intercourse between firms internationally in the fields of trade or intellectual property rights; norms are taken to have significant repercussions on the character of the interface between science and industry, and on the use of expertise in other realms.

The constructivist approach associated with sociological institutionalism thus explains the emergence of the relatively autonomous powers of new international fora, in terms of the rational-legal authority they embody, emphasizing the new interests for the parties involved, and the concomitant learning process in which certain organizational models become diffused across the globe. New bureaucracies as they develop are seen to provide a generic cultural form that shapes the various forums in specific ways in their respective domains (firms, scientific NGOs, and scientific IGOs). New actors are seen to be created, responsibilities specified, and authority delineated, defining and binding the roles of both old and new actors, giving them meaning and normative values. In this model, culture, imagery, and rhetoric are held to be forceful ingredients in the life of international organizations, especially in the way these play out their roles in constructing social worlds with a global reach (Finnemore 1993, Barnett and Finnemore 1999).

With the foregoing in mind, the next section highlights some empirical facets, with particular regard to the two most obvious institutional mechanisms (and associated with them, a few typically prominent actors and programs) pertinent to internationalization of—mostly academic, but also governmentally directed—science (as distinct from internationalization of R&D in industrial enterprise—for this see *National Innovation Systems*).

5. *Two Institutional Mechanisms: Scientific NGOs and IGOs*

The numbers and influence of scientific NGOs and IGOs have grown tremendously since the 1980s. Now they not only find themselves interacting, but also pulled in different directions by lobbies of both transnational corporations (TNCs) driven by the profit motive, and nongovernmental civic society organizations (social movement NGOs). The latter are frequently fired by an ethic of equality and justice. Truth, politics, money, and human equality or justice, then, are the four 'logics' that meet in international forums, when strategies to tackle global problems are negotiated, e.g., Rio 1992; in the process new international groups of experts join the scene. This is an important field for future studies (Rayner and Malone 1998).

Analytically, it is useful to draw a distinction between autoletic and heteroletic organizations, especially between ones meant to serve science as an end in itself, and ones that are created and sustained by governmental action (Elzinga and Landström 1996). This is parallel to the distinction between policy for science, and science for policy, serving to mark institutional separation of science from politics, an aspect central to arguments regarding the integrity and objectivity of expert knowledge under strain (see *Scientific Controversies*).

5.1 *Scientific NGOs*

In general, nongovernmental mechanisms operate directly between research communities of different countries, without the intervening medium of governments. They are autoletic, the premise being that communities of scientists are best be left to themselves to organize their transnational contacts for common goals. A unique example is the International Council of Scientific Unions (ICSU), the umbrella organization that in 1931 sprang from an older cosmopolitan ideal (Greenaway 1991). It coordinated the Second International Polar Year (1932–3), the forerunner of a series of programs of global, often multidisciplinary studies that began in 1952 with the plan for the International Geophysical Year (1957). Present-day successors are the International Geosphere-Biosphere Program (IGBP) and the World Climate Research Program (WCRP). These cut across disciplines pertinent to research into global environmental problems. Each has several subprograms dealing with specific themes and aspects of global climate change.

Other major programs cover biodiversity (DIVERSITAS) and the International Human Dimensions of Global Environmental Change program (IHDP), cosponsored with the International Social Science Council (ISSC), ICSU's smaller sister organization for the social sciences, created in 1952. A milestone event is the World Conference on Science in Budapest (ICSU 1999), sponsored jointly with the United Nations Educational, Scientific and Cultural Organization (UNESCO), one of the world's most wide-ranging intergovernmental organizations. Since

its foundation in 1945 UNESCO has worked constantly to link the peripheries to the centers of science.

5.2 Scientific IGOs

Scientific IGOs typify the second (heteroletic) type of mechanism for internationalization. They promote scientific interchange via governmental channels. The point of departure is not scientific knowledge production as such, but the use of science for a particular purpose that form the basis for concerted action. In such contexts science is made a vehicle for the promotion of cultural, economic, political, and other goals at regional and global levels. UNESCO has already been mentioned. The World Meteorological Organization (WMO) and the World Health Organization (WHO) are two of many others within the UN family; in the domain of technology too there are many IGOs, some of which set and regulate standards. The World Bank is another significant actor. A recent addition is the Intergovernmental Panel on Climate Change (IPCC), which follows up on the science produced under the auspices of IGBP and WCRP, harmonizing research-based statements in advice to governments. This has important repercussions for scientific and technological pursuits.

Some IGOs serve stakeholder interests in specific regions of the world, OECD being an example. Since 1963 it has been a pacesetter in developing R&D statistics, and science and technology policy doctrines, contributing to some harmonization between countries. A recent innovation was the creation of the Forum for Megascience (1992), renamed the Global Science Forum. It is responsible for periodical reviews of very large-scale projects so costly (in the order of billions of US dollars per year) and complex that they require multinational collaboration. Thence science and international diplomacy must meet to produce unique management cultures (Watkins 1997). Megaprojects can be concentrated at one site (e.g., CERN) or distributive (e.g., the Human Genome Project). Deep ocean drilling, climate change, thermonuclear fusion experimentation, as well as Antarctic research are further examples. Antarctica is a continent shaped by science as key vehicle in an international regime outside the UN (Elzinga, in Crawford et al. 1993).

6. Intermesh and Thematic Integration

Proliferation and interpenetration of scientific NGOs and IGOs over past decades has gone hand-in-hand with a corresponding growth in numbers of civic NGOs and corporate lobbies. These also interact with scientific bodies, adding to the hybrid criss-cross of connections in which scientific and political agendas converge and blend. Leading scientists respond to the strain by constantly reemphasizing the need to protect the objectivity and integrity of scientific knowledge claims (Greenaway 1991). Conflicts have emerged around attempts to commercialize and privatize national databases, with both ICSU and IGOs, like the WMO, coming out strongly in favor of a policy for open access to information that is invaluable for world research on global problems. Similar tensions have evolved over intellectual property in biotechnology, where scientists are more apt to be of two minds (see *Intellectual Property*, *Concepts of*).

In the wake of globalization, in Third World countries in particular, both scientists and politicians have reacted against the design of Trade Related Intellectual Property Rights (TRIPS) as negotiated within the World Trade Organization (WTO). Around these and other issues, new tensions arise to pull scientists in several directions along the four different 'logics' (delineated at the beginning of Sect. 4).

Thematic integration of research agendas is a second qualitative dimension needing further study. How problems are framed, data, as well as concept formation involves interpretation and epistemological imperatives (see *Situated Knowledge: Feminist and Science and Technology Studies Perspectives*). This is apparent in research on global climate change, where large international scientific programs (IGBP and WCRP) work hand-in-hand with IPCC to orchestrate problem sets, preferred methodologies and modeling criteria. Core sets of concepts spun in the world's leading scientific countries with epistemic communities of climatologists around General Circulation Models (GMCs) have a bearing on the type of data field workers should look for, and the format in which the data are cast; special funding programs exist that enroll scientists from the scientific peripheries.

Creating global consensus around a core of scientifically accepted knowledge and streamlining homogeneous accounts to spur concerted political action have epistemological implications beyond science. As activities, they contribute to the formation of common world views. Concepts such as 'global warming potential' (of greenhouse gases) help to build bridges between science and political decision-making. The very notion of 'global climate,' as well as 'Earth system science' are other examples where conceptual work facilitate cognitive integration, both over disciplinary boundaries in science and in interfaces with citizens at large (Jasanoff and Wynne, in Rayner and Malone 1998). They change our world picture in a reimagining of humankind in its encounters with nature (e.g., ideas like anthropogenic 'fingerprints'). Representations of local climates, the atmosphere, and circulations systems in the oceans are linked up with representations of human ecology (e.g., land use), which in turn are linked to conceptions of risk and truth (see *Risk, Sociology and Politics of*). Internationalization of science resonates with gradual reorientation of perspectives and scientific practices in unitary fashion. To what extent alternatives to expertise as avenues of

knowledge production are foreclosed remains a contentious issue.

Science and Technology, Social Study of: Computers and Information Technology

Roots and origins being elusive and often illusory, I will date this article from about 1980, when some key collaborations between sociotechnical systems (STS) scholars and maverick computer scientists began. This passes lightly over some early important work critiquing automation, such as that of J. D. Bernal, the early days of the STS movement in Europe, particularly in England, Germany, and Scandinavia, and the neo Marxian analyses of labor process, many of which came to inform later STS work described below.

The nexus of work that currently links STS with computer and information science is a very complex one, with roots in all the areas described below, and held together by a strong, invisible college. This group shares a common concern with how computers shape, and are shaped by, human action, at varying levels of scale. The links with STS include concerns about computer design within the social construction of technology; computers as an agent of social or organizational change; ethics and/or computing (Introna and Nissenbaum 2000); critical studies of computers and computer/information science; applied, activist, and policy research on issues such as the 'digital divide,' or the unequal distribution of computing and information technology across socioeconomic strata and regions of the world.

Some contributions from this part of STS that have been used by scholars in many other parts of the field are Suchman's 'situated action' perspective; Star's 'boundary objects' (Star and Griesemer 1989); Forsythe's methodological questions about 'studying up' and the politics of the anthropology of computing (1993); Henderson's work on engineering drawings as 'conscription devices' (1999); Edwards' work on computing and the Cold War, and its model of 'closed and green' worlds (1996); Berg's critique of rationalization in medicine via computing (1997); Heath and Luff's study of 'centers of control' via the technologies and interactions of the London Underground work force (2000); Woolgar's program building and analytic work—much of it concerning the World Wide Web—from the Virtual Society? Program based at Brunel University (Grint and Woolgar 1997); Bowker's concept of 'infrastructural inversion,' taken from information management at Schlumberger Corporation (1994); and Yates' historical examination of information control techniques in American business (1989, 1996, 1999); Hanseth et al.'s work on standards and ethics in information technology (1996); and Bowker and Star's work on large-scale classification schemes (1999).

1. Automation and the Impact of Computerization

Many early studies of computers and society, or computers and organizations, concerned computing

as an automation of human work. This included two major analytical concerns: the replacement of humans by machines in the workplace, and the 'deskilling' of existing functional jobs (Braverman 1998). Later, the analytic picture became much richer, as researchers realized that automation and deskilling were just two dimensions of the picture. An early breakthrough article by two social-computer scientists defined this territory as 'the web of computing' (Kling and Scacchi 1982), a term which became a touchstone for the next generation. It refers to the co-construction of human work and machine work, in the context of complex organizations and their politics. Much of this research took place in business schools; some in departments of sociology or industrial psychology. In Scandinavia and other regions with strong labor unions, partnerships between the unions and researchers were important, at first focused on job replacement and deskilling, and later, on design created through partnerships with users, social scientists, and computer designers (discussed below).

The social impact of computing remains a strong research strain worldwide, despite the anthropological fact that finding 'untouched tribes' is increasingly difficult. Thus the problematics of interest to STS have shifted from *initial impact* on a group or institution, to understanding *ongoing dynamics* such as usage, local tailoring of systems, shifts in design approaches, understanding the role of infrastructure in helping to form impacts, and the ecology of computers, paper, telephones, fax machines, face-to-face communication, and so forth commonly found in most offices, and increasingly in homes and schools.

2. *The Emulation of Human Cognition and Action (Artificial Intelligence and Robotics)*

The early program of artificial intelligence (AI) work, beginning in an organized way during World War II, was to create a machine that would emulate human thinking (classic AI) and action (robotics). Some of the emulation work came in the form of intelligent tutoring systems and expert systems (Wenger 1987) meant to replace or supplement human decision making. The decision-making side of the research continues to be strong in management schools and in government agencies; it is often critiqued by STS researchers, although some do use these tools (Gilbert and Heath 1985, Byrd et al. 1992). The discussion about whether emulation of human thinking would be possible dates far back; it came to the attention of many STS researchers with the work of philosopher Hubert Dreyfus (1979, 1992), who argued for the irreducibility of human thought and therefore its impossibility in computers. Later STS researchers (including Forsythe, Star, and Suchman) formed direct collaborations with AI researchers. These partnerships took both critical and system-building forms; in both cases, the social science researchers acted as informants about the nature of the 'real world' as opposed to the emulated world of AI. AI changed during the late 1980s and early 1990s—some computer scientists spoke of the 'AI winter,' referring to funding problems unknown in the 1970–88 period. As personal computing and e-mail spread, and later, the Web (1994→), and the early promises of AI seemed not to be paying off, AI began to lose its prestige within computer science. Many AI researchers changed to problems in information science, software engineering, or cognitive science. A branch of AI, distributed artificial intelligence, continued to interact with the STS community (Huhns 1987, Huhns and Gasser 1989). Their interests were in modeling and supporting spatially and temporally distributed work and decision practices, often in applied settings. This reflected and bridged to STS concerns with community problem-solving, communication and translation issues, and the division of labor in large scientific projects.

3. *The Enterprise of Computing, Its Military Roots and the Role of Activism*

In 1983 US President Ronald Reagan introduced his (in)famous 'Star Wars' (officially known as the Strategic Defense Initiative, or SDI) military defense program, a massively expensive attempt to create a distributed laser and missile-based system in space that would protect the USA from foreign attack. The proposal put computer scientists, and especially software engineers, at the center of the design effort.

An immediate outcry was raised by the computing community as well as by alarmed STS scholars close to it. There were concerns that a system of that magnitude was untestable; tools were lacking even to emulate the testing. There were concerns about its viability on other grounds. There were also concerns about its ecological impact on the field of computer science (akin to those raised by organismal biologists about the Human Genome Project)—that the lion's share of research funds would be funneled into this project, orphaning others.

A new group, Computer Scientists for Social Responsibility (CPSR) (www.cpsr.org), was formed in Silicon Valley as a focus for these concerns. The group quickly found common ground in many areas, including activist, ethical, policy and intellectual questions. It has flourished and now sponsors or co-sponsors three conferences a year in which STS scholars often participate: Computers, Freedom and Privacy (policy); Directions in Advanced Computing (DIAC) (intellectual and design directions, and their political and ethical bases and outcomes); and the Participatory Design Conference (PDC) (brings together users, community organizers, computer and social scientists to work on issues of co-design and

appropriate technology) (Kyng and Mathiassen 1997). It, like its counterparts in the UK (Computers and Social Responsibility) and elsewhere, became an important meeting ground between STS and computer/information science. This was especially true of those critical of military sponsorship of computing agendas (at one point in the US some 98 percent of all funding of computer science came from the military, especially ARPA (formerly DARPA)—the Advanced Research Projects of the Army, arguably the critical actor in the creation of the internet (Abbate 1999).

Beginning in the 1980s, a grassroots movement sometimes called 'community computing' arose, and linked with CPSR and other similar organizations. It attempted to increase access to computing for poor people and those disenfranchised from computing for a variety of reasons (Bishop 2000). This often involved the establishment of 'freenets,' or publicly available free computing. Terminals were placed in venues such as public libraries, churches, and after-school clubs; some were distributed directly to people in need. This general problematic has come to be called the 'digital divide,' and forms an active nexus of research across many areas of interest to STS.

An important part of the attempt to enfranchise everyone arose in the world of feminist activism and scholarship, as early computer hackers were nearly all male, and there were sexist and structural barriers to women as both users and professionals. Another meeting place between STS and computer/information science was formed by numerous conferences on women in computer science, gender and computing, and feminist analyses of the problem choice and ethics of computer science. An excellent series of conferences, whose proceedings are published in book form every four years, is sponsored by IFIPS (the International Federation of Information Processing Societies, Working Group 9.1, entitled Women, Work and Computing). See, for example, Grundy et al. (1997). There is a resurgence of interest in this topic with the advent of the Web (see, e.g., Wakeford 1999).

4. *Design*

Beginning in the early 1980s, but reaching full strength in the late 1980s, a number of STS and STS-linked scholars began studying information technology design. This took two forms: studying the work of doing design, and doing design as part of a multidisciplinary team. Henderson's work (cited above) on the visual design practices of engineers is a good example of the former; other important works in the area include Kunda (1992); and a special issue on Design of the journal *Computer Supported Collaborative Work* (Volume 5:4, 1996). STS scholars participating directly in design did so in a number of ways. Anthropologists (such as Nardi 1993, Nardi and O'Day 1999) and Orr (1996) looked at issues such as the culture of programming, its practices, and the role of technicians (Barley and Orr 1997). Some, such as Nardi, conducted usability tests for prototypes of systems. Sociologists examined work practices, organizational processes, and informed the computer scientists about the ways in which these issues could shape or block design (Star and Ruhleder 1996).

5. *From 'The Unnamable' to Social Informatics: Shaping an Invisible College Linked to STS*

An invisible college of social scientists, including STS researchers, who do–study–critique computer and information science has steadily grown since the early 1980s. A brief overview of some of the 'sister travelers' now growing in strength in STS itself includes the following.

5.1 *Organization Theory and Analysis*

People who study organizations have for some time been concerned with the use and impact of computing within them. During the 1990s, STS has become an increasingly important theoretical resource for this field, and has resulted in a number of organization science conferences inviting keynote addresses by STS scholars; reading STS work and attempting to apply it in organizational design and studies. The work of Latour and actor network theory has been especially important (Orlikowski et al. 1995). The policy area of STS has also become increasingly important where issues of privacy, employee rights, intellectual property, and risk are related to computer and information systems (regular updated reports and references can be found on Phil Agre's 'Red Rock Eater' electronic news service: http://dlis.gseis.ucla.edu/people/pagre/rre.html).

5.2 *Computer-supported Cooperative Work (CSCW) and the Participatory Design Movement (PD)*

Cognitive and experimental psychologists have been involved with the design of computer and information systems since at least the 1950s. They formed a field that came to be known as Human–Computer Interaction (HCI). This field focused originally on very small-scale actions, such as measuring keyboard strokes, attention and interface design, ergonomics of workstations, and usability at the level of the individual user. In the late 1980s, part of this field began to stretch out to more organizational and cultural issues (Grudin 1990, Bannon 1990). The impact of the

personal computer and the consequent decentralization of computing, and the rapid spread of networked computing to non-computer specialists were important factors. This wing of HCI began to draw together computer scientists, sociologists, anthropologists, and systems analysts of like mind. In 1986 there was a search to put a name to this. Two of the major competitors were 'office information systems' (to replace the old 'office automation'), and 'computer-supported cooperative work (CSCW),' which won out. CSCW is an interdisciplinary and international group that studies a range of issues including the nature of cooperation, critiques of computer science, building systems to support cooperative work (both local and high distributed). STS scholars have been part of this field since the beginning; Star was a founding co-editor of the journal. Her work and that of Suchman's have been widely used in CSCW.

Closely linked with CSCW is PD, the practice of designing computer systems with user communities and social informaticians. Annual conferences are held in tandem with CSCW. They have picked up and actively use STS approaches. The roots of PD have been reviewed recently by Asarco (2000); they include corporate initiatives, community development, social movements, and the Scandinavian School, discussed in the next section.

5.3 *The 'Scandinavian School'*

In the 1950s the (powerful) trade unions in Scandinavia helped to pass the 'codetermination legislation.' This law stated that unions must be involved in technological design—originally motivated by concerns about deskilling and job loss through automation. A form of sociotechnical systems analysis evolved into a set of techniques for studying work places and processes. As computers arrived in the workplace, this came to include progressive computer scientists and social scientists, many of whom now participate in STS publishing and conferences, as well as CSCW and PD (Greenbaum and Kyng 1991, Bjerknes et al. 1987, Bødker 1991, Neumann and Star 1996).

5.4 *Computers and Education*

The use of computers for science education began in the 1960s. The study of this, based in schools of education and science departments, has had both critical components and basic research. In recent years, the addition of distance education via computers, internet classes, and the ubiquity of computers in college classes has become a critical component of this community. One branch is called Computer-Supported Cooperative Learning (CSCL), and has a lively relationship with both STS and CSCW (Koschmann 1996). STS concepts are beginning to be used across all areas of science education, and recent STS conferences reflect the links strengthening between science education and STS.

5.5 *Former Library Schools as an Emergent Nexus for STS Work*

Since the 1980s, schools of library science have experienced massive closures, due to a complex of corporatization, declining public sphere funding for public libraries, and a general move to close professional schools whose faculty and students are mostly women (social work and physical therapy schools have met similar fates). In the USA, a few of the surviving library schools have reinvented themselves as new 'Schools of Information,' most dropping the word 'library' from the title. Sites include the University of Michigan, University of Illinois at Urbana-Champaign, University of North Carolina, and Indiana University. Their faculty now includes social scientists, computer and information scientists, and library scientists. STS work is central to many of the programs, and several faculty members from the STS world who work with information technology or information itself have found positions there. The structural shape of the programs differs in countries with different forms of funding, and different configurations of the public sphere. Kling's 'Social Informatics' page is an excellent resource (http://www.slis.indiana.edu/SI/), as is Myers' 'Qualitative Research in Information Science' (http://www.auckland.ac.nz/msis/isworld/) (see also Kling 2000). However, STS work is still very influential, for example, at the Royal School of Librarianship in Copenhagen.

6. *The Web: Cultural Studies, Economic Impact, Social Practices, and Ethics*

The public availability of the World Wide Web from 1994 and the commercialization of the Internet–Web, combined with falling prices for computers with good graphics and cheap memory, has changed the face of computing dramatically. Many STS scholars have been involved in different facets of studying the Web. Cultural studies of chat rooms, home pages, MOOs and MUDs, and social inequities in distribution and use have exploded (see e.g., Turkle 1995). Some of this is adapted by STS scholars as studying the use and development of technology; some as a lens through which technology mediates culture. E-commerce, including scientific publishing, has come to overlap with STS work (e.g., Knorr-Cetina and Preda 1998). Ethical areas, such as privacy, electronic stalking and harassment, hate speech sites, and identification of

minors on the Web (which are protected by human subjects regulations, but impossible to identify in many e-venues) are among these issues (Friedman and Nissenbaum 1996).

7. *Challenges and Future Directions*

One of the difficult things for STS scholars who work in this area is the process of tacking back and forth between sympathetic communities housed in information and computer science, STS itself, and one's home discipline. This appears at many levels: job openings, publications, choosing conferences to attend, and the growing call from within industry and computer science for ethnographers, social science evaluators, and co-designers. Sometimes this latter call takes the form of guest talks to technical groups, keynote addresses at technical meetings, consulting, or being asked for free advice about complex social problems within an organization. As with STS itself, there are a growing number of PhD programs within social informatics, broadly speaking, and the field is both spreading and converging. This may, in the long run, ease the juggling problem. At present, most researchers in the area pursue a double career, publishing and participating in both computer/IS and STS communities, with some bridge-building back to the home disciplines.

Another challenge lies in the area of methods. Many social informatics/STS researchers inherited methodological practices from their home disciplines, and some of these make an uneasy fit with current technological directions. For example, there is now a great deal of survey research and of 'ethnography' being done on the Web, including intense study of chat rooms, e-discussion lists, and other forms of online behavior. On the survey side, sampling and validity problems loom large, although they are old problems with venerable methods literatures addressing their solution. The question of sampling only from those with e-mail hookups is similar to the old question of sampling only those who have telephones. Every sample has limits. However, the validity issue, such as the practices of filling out e-mail forms, how the survey appears in the context of many other e-mail messages, and the impact of the genre itself on the content is only now beginning to be explored. Similarly, for ethnographers, it is clear that e-mail messages are not the ready-made fieldnotes that many early studies (i.e., from the early 1990s) delighted in. Forms of triangulation between online and offline research are now coming to the fore in sophisticated methods discussions; another contribution lies in the socially little-known interaction between the built information environment and the phenomenology of users (Wakeford and Lyman 1999).

In conclusion, growing overlaps between complex computer/information science groups, STS, and the other social worlds listed above means new opportunities for STS. STS students are finding employment in corporate research and development (R&D) settings, new information schools, government policy employers concerned about information technology, and in the non-profit sector concerned with issues such as the digital divide.

A note on access: much of this sort of material exists in the proceedings of conferences and is indexed by corporate or organizational authors. It is, in libraries, usually held in special Computer Science libraries on campus, and is, by social science standards, badly indexed. Seek help from the reference librarian to find this material. Working groups or special interest groups (SIGs in computer science terminology) can be powerful loci of change, with thousands of members, both professional and academic. Some are of direct interest to STS scholars, such as SIGSOC, the Special Interest Group on Computers and Society run by the ACM (Association for Computer Machinery, the dominant professional organization for computer scientists in the USA) or ACM- SIGCHI (SIG on Computers and Human Interaction), which has grown so large it is now functionally its own professional organization. Although all professions have jargon and acronyms, computer and information science is highly dense with them. Scholars seeking to build bridges to the computer/information science community can consult many online 'acronym servers' such as Free On-Line Dictionary of Computing at http://foldoc.doc.ic.ac.uk/foldoc/index.html; acronym finder at http://www.acronymfinder.com/.

Science and Technology Studies: Ethnomethodology

Ethnomethodology is a sociological approach to the study of practical actions which has influenced the development of constructionist, discourse analytic, and related approaches in science and technology studies (S&TS). Early ethnomethodological studies of ordinary activities and social scientific research practices developed an orientation to local practices, situated knowledge, and concrete discourse which later became prominent in science and technology studies. In addition to being a precursor to S&TS, ethnomethodology continues to offer a distinctive approach to practical actions in science and mathematics which rivals more familiar versions of social constructionism.

1. *Ethnomethodological Research Policies*

In the 1960s, Harold Garfinkel coined the term ethnomethodology as a name for a unique sociological approach to practical actions and practical reasoning (Garfinkel 1974, Heritage 1984, p. 45, Lynch 1993, pp. 3–10). Garfinkel was influenced by existential phenomenology (especially Schutz 1962) and sociological theories of action (especially Parsons 1937). As usually defined, ethnomethodology is the investigation of 'folk methods' for producing the innumerable practical and communicative actions which constitute a society's form of life.

1.1 *Ethnomethodological Indifference*

Unlike methodologists in the philosophy of science who accord special status to scientific methods, ethnomethodologists examine methods for composing and coordinating ordinary as well as scientific activities. Garfinkel deemed all methods to be worthy of detailed study. This research policy is known as ethnomethodological indifference (Garfinkel and Sacks 1970, pp. 345–6, Lynch 1993, pp. 141–2). According to this policy, any method is worthy of study, regardless of its professional status, relative importance, adequacy, credibility, value, and necessity. This does not mean that ethnomethodologists treat all methods as equally 'good'; instead, it means that they do not believe that preconceptions about the importance and validity of particular methods should determine a choice of research topic.

Ethnomethodological indifference is similar in some respects to the more familiar policies of symmetry and impartiality in the Strong Programme in the sociology of scientific knowledge (Bloor 1976, pp. 4–5). However, there is a significant difference between the two, which has to do with a less obvious implication of the term 'ethnomethodology.' In addition to being a name for an academic field that studies 'folk methods,' the term refers to 'methodologies'—systematic inquiries and knowledge about methods—which are internal to the practices studied. Many social scientists (including many in S&TS) assume that the persons they study perform their activities unreflexively or even unconsciously, and that the intervention of an outside analyst is necessary for explicating, explaining, and criticizing the tacit epistemologies that underlie such activities. In contrast, ethnomethodological indifference extends to the privileges ascribed to social scientific analysis and criticism:

> Persons doing ethnomethodological studies can 'care' no more or less about professional sociological reasoning than they can 'care' about the practices of legal reasoning, conversational reasoning, divinational reasoning, psychiatric reasoning, and the rest. (Garfinkel and Sacks 1970, p. 142)

Perhaps more obviously than other domains of practice, scientific research involves extensive methodological inquiry and debate. Science is not alone in this respect. In modern (and also many ancient) societies, large bodies of literature articulate, discuss, and debate the practical, epistemic, and ethical character of a broad array of activities, including legal procedures,

food preparation, dining, sexuality, child rearing, gardening, and fly fishing. Any effort to explain such practices sociologically must first come to terms with the fact that explanations of many kinds (including social explanations) are embedded reflexively in the history, production, and teaching of the activities themselves.

1.2 Ethnomethodological Reflexivity

Garfinkel (1967, p. 1) spoke of the 'reflexive' or 'incarnate' character of accounting practices and accounts. By this he meant that social activities include endogenous practices for displaying, observing, recording, and certifying their regular, normative, and 'rational' properties. In other words, social agents do not just act in orderly ways, they examine, record, and reflexively monitor their practices. This particular sense of 'reflexivity' goes beyond the humanistic idea that individuals 'reflect' on their own situations when they act, because it emphasizes collective, and often highly organized, accounting practices. The fact that the persons and organized groups that social scientists study already observe, describe, and interpret their own methodic practices can provoke challenges to the authority of social science methods when the latter conflict with native accounts. Whether or not a social scientist agrees with, for example, official accounts of scientific method given by the subjects of an ethnographic or historical investigation, it is necessary to pay attention to the more pervasive way in which methodic understandings, and understandings of method, play a constitutive role in the practices under study. For ethnomethodologists, the research question is not just 'How do a society's (or scientific field's) members formulate *accounts* of their social world?,' but 'How do members perform actions so as to make them account-*able*; that is, observable and reportable in a public domain of practice?' Accordingly, accounts are not simply interpretations made after actions take place; instead, actions display their accountability for others who are in a position to witness, interpret, and record them.

1.3 Topic and Resource

The idea that explanations, explanatory concepts, and, more generally, natural language resources are common to professional sociology and the activities sociologists study is a source of long-standing consternation and confusion in the social sciences (Winch 1990, [1958]). As Garfinkel and Sacks (1970, p. 337) noted:

> The fact that natural language serves persons doing sociology, laymen or professionals, as circumstances, as topics, and as resources of their inquiries furnishes to the technology of their inquiries and to their practical sociological reasoning *its* circumstances, *its* topics, and *its* resources.

An injunction developed by ethnomethodologists (Zimmerman and Pollner 1970), and adopted by proponents of discourse analysis (Gilbert and Mulkay 1984) is that social analysts should not confuse topic and resource. That is, they should not confuse the common sense explanations given by participants in the social activities studied with the analytic resources for studying those same activities. A variant of this injunction in social studies of science warns the analyst not to adopt, for polemical purposes, the very vocabulary of scientific authority that social studies of science make problematic (Woolgar 1981, Ashmore 1989). While this may be good advice in particular cases, when taken as a general policy the injunction not to confuse topic and resource may seem to encourage a retreat from the very possibility of describing or explaining, let alone criticizing, the practices in question. If every possible analytic resource is already found in the social world as a problematic social phenomenon, then what would a sociologist have to say that is not already incorporated into the practices and disputes studied? While acknowledging that this is a problem for any sociological explanation of science, Latour (1986) recommends a 'semiotic turn' which would examine the terms of the (scientific) tribe from the vantage point provided by an abstract theoretical vocabulary. But, unless one grants special epistemic status to semiotics, this 'turn' simply reiterates the problem.

2. Ethnomethodology and the Problem of Description

Ethnomethodologists do not agree upon a single solution to the problem of reflexivity, and contradictory ways of handling it are evident in the field, but some ethnomethodologists believe that sociological descriptions do not require special theoretical or analytical auspices in order to overcome reflexivity. As Sharrock and Anderson (1991, p. 51) argue, under most circumstances in which descriptions are made and accepted as adequate, there is no need to overcome epistemological scepticism. Ethnomethodologists treat reflexivity as ubiquitous, unavoidable, and thus 'irremediable.' Consequently, reflexivity is not a 'methodological horror' (Woolgar 1988, p. 32) that makes description or explanation impossible or essentially problematic, because an ethnomethodologist is in no worse (or better) shape than anyone else who aims to write intelligible, cogent, and insightful descriptions of particular states of affairs. Even so, there still remains the question of the scientific, or other, grounds of ethnomethodological descriptions.

2.1 The Possibility of 'Scientific' Descriptions of Human Behavior

A possible basis for ethnomethodological descriptions is presented in an early argument written by Sacks (1992, pp. 802–5), the founder of a field that later came to be called conversation analysis. This was a brief, but intriguing, argument about the possibility of developing a science that produces stable, reproducible, naturalistic accounts of human behavior. Sacks observed that natural scientists already produce accounts of human behavior when they write natural language descriptions of methods for reproducing observations and experiments. Social scientists who attempt to describe 'methods' in a broad range of professional and non-professional activities are in no worse position than natural scientists who attempt to describe their own particular methods. In other words, Sacks conceived of the replication of experiments as a particular (but not necessarily special) case of the reproduction of social structures. While social scientists do not aim to produce 'how to' manuals, they can write accounts of social actions which are 'true' in a praxiological sense: adequate to the production and reproduction of the relevant practices.

2.2 Replication and the Reproduction of Social Structure

It is well established in the sociology of science that replication is problematic. Instead of being a methodological foundation for establishing natural facts, particular instances of experimental replication often beg further questions about the detailed conditions and competencies they involve (Collins 1985). To say that replication is problematic does not imply that it is impossible, but it does raise the question of how scientists manage to secure assent to the adequacy of their experiments. The phenomenon of just how scientists conduct experiments, and how they establish particular results in the relevant communities, has become a major topic for socio-historians and ethnographers of science (Gooding et al. 1989). Consequently, in the more general case of the reproduction of social structure, it seems reasonable to conclude that Sacks identifies a topic for ethnomethodological research, but not a grounding for a possible sociological research program (Lynch and Bogen 1994).

Ethnomethodological studies of the reproduction of order in science, other professions, and daily life, address the topic of the production of instructed actions. Instructed actions include an open-ended variety of actions performed in accordance with rules, plans, recipes, methods, programs, guidelines, maps, models, sets of instructions, and other formal structures. In addition to examining efforts to reproduce initial observations, ethnomethodologists have studied a series of topics: deriving mathematical proofs, following instructions for photocopying, and reproducing standard laboratory protocols (Garfinkel 1986, 1991, Garfinkel et al. 1981, Livingston 1986, Suchman 1987).

2.3 Ethnomethodology and Social Constructionism

Ethnomethodology has an ambivalent relation to social constructionism. Early laboratory studies (Latour and Woolgar 1979, Knorr 1981) integrated selected themes from ethnomethodology into constructionist arguments, but many ethnomethodologists prefer to speak of the 'production' rather than the 'construction' of social orders (Lynch 1993, Button and Sharrock 1993). While it may be so that no fact is ever free of 'construction' in the broadest sense of the word, local uses of the term in empirical science (though not in mathematics and certain branches of theory) refer to research artifacts which are distinguished from a field of natural objects (Lynch 1985). Ethnomethodologists prefer not to speak indiscriminately of the construction or manufacture of knowledge, in order to preserve an 'indifferent' orientation to the way distinctions between constructed and unconstructed realities are employed in practical action and situated argument.

2.4 Normative and Ethical Considerations

Ethnomethodology has been criticized for treating normative aspects of the activities studied as 'mere phenomena' (Habermas 1984, p. 106). For example, when studying a contentious court case (Goodwin 1994) or jury deliberation (Maynard and Manzo 1993), an ethnomethodologist does not assess the discursive practices by reference to ideal standards of validity, rationality, or justice. This does not suppose that normative considerations are 'mere' phenomena. Instead, it supposes that peoples' methods (the phenomena studied by ethnomethodologists) are just that: situated actions that, for better or worse, incorporate normative judgments and ethical claims.

Instead of recasting such judgments and claims in terms of one or another transcendent framework, ethnomethodologists attempt to explicate the way normative judgments are produced, addressed, and fought over in specific circumstances. When ethnomethodologists investigate highly charged uses of, and appeals to, normative judgment, they enable readers to examine specific configurations of action and reasoning that do not neatly fall under recipe versions of norms and values. Consequently, rather than invoking or developing a normative theory, ethnomethodologists invite their readers to consider intricate situations of practice and contestation that no single general framework can possibly forecast or resolve.

Practical and ethical dilemmas are no less salient for ethnomethodologists than for cultural anthropologists,

lawyers, and other participant-investigators. The policy of ethnomethodological indifference does not relieve an investigator of ethical choices and responsibilities. Like other investigators, ethnomethodologists may in some circumstances find it advisable to respect norms of privacy and propriety, while in others they may feel compelled to expose wrongdoing. However, as a body of doctrines, research policies, and exemplary studies, ethnomethodology does not supply a set of rules or ethical guidelines for making such difficult choices. This does not mean that ethnomethodologists proceed without ethics, but that their ethical judgments, like many of their other judgments, have a basis in communal life that is not encapsulated by any academic school, theory, or method.

Science and Technology Studies: Experts and Expertise

1. Introduction

Science is a social activity to construct, justify, and critique cognitive claims based on widely accepted methodologies and theories within relevant communi-

ties. The term science is used here to include claims of true statements about any phenomenon, be it natural, anthropological, social, or even metaphysical. Methods or procedures are clearly distinct among the various domains of science, but the main assertion here is that the overall goal of claiming truthful statements remains the essence of scientific inquiry throughout all disciplines (similar attempts in Campbell 1921, pp. 27–30). Using scientific expertise, however, is not identical with generating scientific statements (Lindblom and Cohen 1979, p. 7ff.).

In a policy arena, scientific experts are expected to use their skills and knowledge as a means of producing arguments and insights for identifying, selecting, and evaluating different courses of collective action. Since such advice includes the prediction of likely consequences of political actions in the future, experts are also in demand to give advice on how to cope with uncertain events and how to make a prudent selection among policy options, even if the policy-maker faces uncertain outcomes and heterogeneous preferences (Cadiou 2001, p. 27). Many policy-makers expect scientific experts to help construct strategies that promise to prevent or mitigate the negative and promote the positive impacts of collective actions. In addition, scientific expertise is demanded as an important input to design and facilitate communication among the different stakeholders in debates about technology and risk.

Based on these expectations, scientific expertise can assist policy-makers to meet five major functions (similar in Renn 1995):

(a) providing factual insights that help policy-makers to identify and frame problems and to understand the situation (*enlightenment function*);

(b) providing instrumental knowledge that allows policy-makers to assess and evaluate the likely consequences of each policy option (*pragmatic or instrumental function*);

(c) providing arguments, associations, and contextual knowledge that helps policy-makers to reflect on their situation and to improve and sharpen their judgment (*reflexive function*);

(d) providing procedural knowledge that helps policy-makers to design and implement procedures for conflict resolution and rational decision making (*catalytic function*); and

(e) providing guidelines or designing policy options that assist decision-makers in their effort to communicate with the various target audiences (*communicative function*).

These five functions touch on crucial aspects of policy-makers' needs. First, insights offered by experts help policy-makers to understand the issues and constraints of different policy options when designing and articulating policies. Policy-makers need background information to develop standards, to ground economic or environmental policies on factual knowledge, and to provide information about the success or failure of policies. Second, scientific methods and their applications are needed to construct instrumental knowledge in the format of 'if–then' statements and empirically tested theories; this knowledge leads to the articulation of means-ends oriented policies and problem solving activities. Third, scientific reasoning and understanding help policy-makers to reflect on their activities and to acknowledge social, cultural, institutional, and psychological constraints as well as opportunities that are not easily grasped by common sense or instrumental reasoning. However, scientific statements may also restrict policy-makers as they are directed towards adopting a single perspective in analyzing and framing a problem. Fourth, policy-makers may use scientists to design procedures of policy formulation and decision making in accordance with normative rules of reasoning and fairness. These procedures should not interfere with the preferences of those who are involved in the decision-making process, but provide tools for making these preferences the guiding principle of policy selection. To meet this function, scientists need to play a role similar to a chemical catalyst by speeding up (or if necessary slowing down) a process of building consensus among those who are entitled to participate in the policy-making process (Fishkin 1991). Lastly, scientific experts can help to design appropriate communication programs for the purpose of legitimizing public policies as well as preparing target audiences for their specific function or role in the task of risk management.

This article focuses predominantly on the influence of scientific and technical expertise, in particular the results of technology assessments, on public policy-making. The second section deals with the risks and challenges of technical experts providing input to policy design and implementation. The third section addresses the influence of systematic knowledge for policy-making. The fourth section provides some theoretical background for the role of expertise in deliberative processes. The fifth section focuses on cultural differences in the use of expertise for policy-making. The last section summarizes the main points of this article.

2. *Using Scientific Expertise for Policy-making: Risks and Challenges*

The interaction between experts and policy-makers is a major issue in technology management today and is likely to become even more important in the future. This is due in the first instance to the increased interactions between human interventions and natural responses and, secondarily, to the increased complexity of the necessary knowledge for coping with economic, social, and environmental problems. Population growth and migration, global trade, inter-

national market structures, transboundary pollution, and many other conditions of modern life have increased the sensitivity to external disturbances and diminished the capability of social and natural systems to tolerate even small interventions. Although contested by some (Simon 1992), most analysts agree that ecological systems have become more vulnerable as the impact of human intervention has reached and exceeded thresholds of self-repair (Vitousek et al. 1986).

Given this critical situation, what are the potential contributions of expertise to the policy process? In principle, experts can provide knowledge that can help to meet the five functions mentioned above and to anticipate potential risks before they materialize. But they can do this only to the degree that the state of the art in the respective field of knowledge can provide reliable information pertaining to the policy options. Many policy-makers share assumptions about expertise that turn out to be wishful thinking or illusions (Funtowicz and Ravetz 1990, Jasanoff 1990, 1991, Rip 1992, Beck 1992). Most prominent among these are:

(a) *illusion of certainty:* making policy-makers more confident about knowing the future than is justified;

(b) *illusion of transferability:* making policy-makers overconfident that certainty in one aspect of the problem applies to all other aspects as well;

(c) *illusion of 'absolute' truth:* making policy-makers overconfident with respect to the truthfulness of evidence;

(d) *illusion of ubiquitous applicability:* making policy-makers overconfident in generalizing results from one context to another.

These illusions are often reinforced by the experts themselves. Many experts feel honored to be asked by powerful agents of society for advice. Acting under the expectation of providing unbiased, comprehensive, and unambiguous advice, they often fall prey to the temptation to oversell their expertise and provide recommendations far beyond their realm of knowledge. This overconfidence in one's own expertise gains further momentum if policy-maker and advisor share similar values or political orientations. As a result policy-makers and consultants are prone to cultivate these illusions and act upon them.

In addition to these four types of illusions, experts and policy-makers tend to overemphasize the role of systematic knowledge in making decisions. As much as political instinct and common sense are poor guides for decision making without scientific expertise, the belief that scientific knowledge is sufficient to select the correct option is just as short sighted. Most policy questions involve both systematic as well as anecdotal and idiosyncratic knowledge (Wynne 1989). Systematic knowledge often provides little insight into designing policies for concrete issues. For example, planning highways, supporting special industries, promoting health care for a community and many other issues demand local knowledge on the social context and the specific history of the issue within this context (Wynne 1992, Jasanoff 1991). Knowledge based on local perspectives can be provided only by those actors who share common experiences of the issue in question. The role of systematic versus particularistic knowledge is discussed in more detajobil in the next section.

3. *The Relevance of Systematic Expertise for Policy-making*

There is little debate in the literature that the inclusion of expertise is essential as a major resource for designing and legitimizing technological policies (Jasanoff 1990). A major debate has evolved, however, on the status of scientific and technical expertise for representing all or most of the knowledge that is relevant to these policies. This debate includes two related controversies: the first deals with the problem of objectivity and realism; the second one with the role of subjective and experiential knowledge that non-experts have accumulated over time. This is not the place to review these two controversies in detail (see Bradbury 1989, Shrader-Frechette 1991). Depending on which side one stands on in this debate, scientific evidence is either regarded as one input to fact-finding among others or as the central or even only legitimate input for providing and resolving knowledge claims. There is agreement, however, among all camps in this debate that systematic knowledge is instrumental for understanding phenomena and resolving problems. Most analysts also agree that systematic knowledge should be generated and evaluated according to the established rules or conventions of the respective discipline (Jaeger 1998, p. 145). Methodological rigor aiming to accomplish a high degree of validity, reliability and relevance remains the most important yardstick for judging the quality of scientific insights. Constructivist scholars in science and technology studies do not question the importance of methodological rules in securing credible knowledge but are skeptical whether the results of scientific inquiries represent objective or unambiguous descriptions of reality (Latour and Woolgar 1979, Knorr-Cetina 1981). Rather, they see scientific results as products of specific processes or routines that an elite group of knowledge producers has framed as 'objective' and 'real.' The 'reality' of these products is determined by the availability of research routines and instruments, prior knowledge and judgments, and social interests (see also Beck 1992, although he regards himself as a moderate realist).

For the analysis of scientific input to policy-making, the divide between the constructivists and the realists matters only in the degree to which scientific input is used as a genuine knowledge base or as a final arbiter for reconciling knowledge conflicts. A knowledge

discourse deals with different, sometimes competing claims that obtain validity only through compatibility checks with acknowledged procedures of data collection and interpretation, proof of theoretical compatibility and conclusiveness, and the provision of intersubjective opportunities for reproduction (Shrader-Frechette 1991, pp. 46ff.). Obviously many research results do not reach the maturity of proven facts, but even intermediary products of knowledge, ranging from plain hypotheses, via plausible deductions to empirically proven relationships, strive for further perfection (cf. the pedigree scheme of Functowicz and Ravetz 1990). On the other hand, even the most ardent proponent of a realist perspective will admit that only intermediary types of knowledge are often available when it comes to assess and evaluate risks.

What does this mean for the status and function of scientific expertise in policy contexts? First, scientific input has become a major element of technological decision-making in all technologically developed countries. The degree to which the results of scientific inquiry are taken as ultimate evidence to judge the appropriateness and validity of competing knowledge claims is contested in the literature and also contested among policy-makers and different social groups. Frequently, the status of scientific evidence becomes one of the discussion points during social or political deliberation depending on the context and the maturity of scientific knowledge in the technological policy arena under question. For example, if the issue is the effect of a specific toxic substance on human health, subjective experience may serve as a heuristic tool for further inquiry and may call attention to deficits in existing knowledge, although toxicological and epidemiological investigations are unlikely to be replaced with intuitions from the general public. If the issue, by contrast, is siting of an incinerator, local knowledge about sensitive ecosystems or traffic flows may be more relevant than systematic knowledge about these impacts in general (a good example for the relevance of such particularistic knowledge can be found in Wynne 1989). Second, the resolution of competing claims of scientific knowledge usually are governed by the established rules within the relevant disciplines. These rules may not be perfect and even contested within the community. Yet they are regarded as superior to any other alternative (Shrader-Frechette 1991, pp. 190ff.). Third, many technological decision options require systematic knowledge that is either not available or still in its infancy or in an intermediary status. Analytic procedures are then demanded by policy-makers as a means to assess the relative validity of each of the intermediary knowledge claims, to display their underlying assumptions and problems, and to demarcate the limits of 'reasonable' claims, that is, to identify the range of those claims that are still compatible with the state of the art in this knowledge domain (Shrader-Frechette 1991). Fourth, knowledge claims can be systematic and scientific as well as idiosyncratic and anecdotal. Both forms of knowledge have a legitimate place in technological decision-making. How they are used depends on the context and the type of knowledge required for the issue in question (Wynne 1992). All four points show the importance of knowledge for technology policy and decision making, but also make clear that choosing the right management options requires more than looking at the scientific evidence alone.

4. *Scientific Evidence in Deliberative Processes*

Given the delicate balance between anecdotal, experiential, and systematic knowledge claims, policy-making depends on deliberative processes in which competing claims are generated or ignored, sorted, selected, and highlighted. The first objective is to define the relevance of different knowledge claims for making legitimate and defendable choices. The second objective is to cope with issues of uncertainty and to assign trade-offs between those who will benefit and those who will suffer from different policy options. The third objective is to take into account the wider concerns of the affected groups and the public at large. These three elets of deliberation are related to coping with the problems of complexity, uncertainty, and ambiguity.

How can deliberative processes deal with the problems of complexity, uncertainty, and ambiguity? To respond to this question, it is necessary to introduce the different theoretical concepts underlying deliberative processes. The potential of deliberation has been discussed primarily in three schools of thought:

(a) The utility-based theory of rational action (basics in Fisher and Ury 1981, Raiffa 1994; review of pros and cons in Friedman 1995): in this concept, deliberation is framed as a process of finding one or more option(s) that optimize the payoffs to each participating stakeholder. The objective is to convert positions into statements of underlying interests. If all participants articulate their interest, it is either possible to find a new win-win option that is in the interest of all or at least does not violate anybody's interest (Pareto optimal solution) or to find a compensation that the winner pays to the losers to the effect that both sides are at least indifferent between the situation without the preferred policy option and no compensation and the implementation of this option plus compensation (Kaldor–Hicks solution). In this context systematic knowledge is required to inform all participants of the likely consequences of each decision option. The evaluation of desirability of each option is a matter of individual preferences and in this perspective outside of the deliberation process.

(b) Theory of communicative action (Habermas 1987, Webler 1995): this concept focuses on the communicative process of generating preferences,

values, and normative standards. Normative standards are those prescriptions that do not apply only to the participants of the discourse but also to society as a whole or at least a large segment of the external population. Normative standards in technological arenas include, for example, exposure limits or performance standards for technologies. They apply to all potential emitters or users regardless whether they were represented at the discourse table or not. The objective here is to find consensus among moral agents (not just utility maximizers) about shared meaning of actions based on the knowledge about consequences and an agreement on basic human values and moral standards. Systematic knowledge in this context helps the participants to provide insights into the potential effects of collective decision options and help them to reorganize their preferences according to mutually desirable outcomes.

(c) Theory of social systems (Luhmann 1986, Eder 1992): the (neo)functional school of sociology pursues a different approach to deliberation. It is based on the assumption that each stakeholder group has a separate reservoir of knowledge claims, values, and interpretative frames. Each group-specific reservoir is incompatible with the reservoir of the other groups. This implies that deliberative actions do not resolve anything. They represent autistic self-expressions of stakeholders. In its cynical and deconstructivist version, deliberation serves as an empty but important ritual to give all actors the illusion of taking part in the decision process. In its constructive version deliberation leads to the enlightenment of decision-makers and participants. Far from resolving or even reconciling conflicts, deliberation in this viewpoint has the potential to decrease the pressure of conflict, provide a platform for making and challenging claims, and assist policy-makers in making them cognizant of different interpretative frames (Luhmann 1993). Deliberations help to reframe the decision context, to make policy-makers aware of public demands, and enhance legitimacy of collective decisions through reliance on formal procedures (Skillington 1997). In this understanding of deliberation, reaching a consensual conclusion is neither necessary nor desirable. The process of talking to each other, exchanging arguments, and widening one's horizon is all what deliberation is able to accomplish. It is an experience of mutual learning without a substantive message. Systematic knowledge in this context is never free of context and prescriptive assumptions. Hence, each group will make knowledge claims according to its interests and strategic goals. Integration of knowledge is based on rhetoric, persuasion skills, and power rather than established rules of 'discovering the truth.'

These three understandings of deliberation are not mutually exclusive although many proponents of each school argue otherwise. Based on the previous arguments, it is quite obvious that the rational actor approach provides a theoretical framework to understand how actors in deliberative processes deal with complexity and partially uncertainty. The communicative action approach provides a theoretical structure for understanding and organizing discourses on ambiguities and moral positions. In particular, this concept can highlight those elements of deliberation that help participants to deal competently with moral and normative issues beyond personal interests. The system–analytic school introduces some skepticism towards the claim of the other schools with respect to the outcomes of deliberation. Instead it emphasizes the importance of procedures, routines, and learning experiences for creating links or networks between the major systems of society. Deliberation is the lubricant that helps each of the collective social actors to move mostly independently in society without bumping into the domains of the other actors.

Deliberative processes aimed at integrating experts, stakeholders, policy-makers, and the public at large can be organized in many different forms. Practical experiences have been made with advisory committees, citizen panels, public forums, consensus conferences, formal hearings, and others (see Rowe and Frewer 2000). A hybrid model of citizen participation (Renn et al. 1993) has been applied to studies on energy policies and waste disposal issues in West Germany, for waste-disposal facilities in Switzerland, and to sludge-disposal strategies in the United States (Renn 1999).

5. *Cultural Styles in Using Scientific Expertise*

The way that knowledge and expertise are included in policy processes depends on many factors. Comparative research on the influence of systematic knowledge in policy processes emphasizes the importance of cultural context and historic developments (Solingen 1993). In addition, state structures and institutional arrangements significantly influence the type of inclusion of expertise into the decision-making processes. There has been a major shift in modern states to an organized and institutionalized exchange of science organizations with policy-making bodies (Mukerji 1989, Jasanoff 1990). Although science has become a universal enterprise, the specific meaning of what science can offer to policy-makers differs among cultures and nations (Solingen 1993). The situation is even more diverse when one investigates the use of science in different countries for advising policy-makers. Scientific and political organizations partially determine what aspects of life are framed as questions of knowledge and what of "subjective" values. In addition, national culture, political traditions, and social norms influence the mechanisms and institutions for integrating expertise in the policy arenas (Wynne 1992).

In one line of work, policy scholars have developed a classification of governmental styles that highlight

four different approaches to integrating expert knowledge into public decisions (Brickman et al. 1985, Jasanoff 1986, O'Riordan and Wynne 1987, Renn 1995). These styles have been labeled inconsistently in the literature, but they refer to common procedures in different nations. The 'adversarial' approach is characterized by an open forum in which different actors compete for social and political influence in the respective policy arena. The actors in such an arena need and use scientific evidence to support their position. Policy-makers pay specific attention to formal proofs of evidence because policy decisions can be challenged on the basis of insufficient use or neglect of scientific knowledge. Scientific advisory boards play an important role as they help policy-makers to evaluate competing claims of evidence and to justify the final policy selection (Jasanoff 1990).

A sharp contrast to the adversarial approach is provided by the fiduciary style (Renn 1995). The decision-making process is confined to a group of patrons who are obliged to make the 'common good' the guiding principle of their action. Public scrutiny or involvement is alien to this approach. The public can provide input to and arguments for the patrons but is not allowed to be part of the negotiation or policy formulation process. Scientists outside the policy-making circles are used as consultants at the discretion of the patrons and are selected according to prestige or personal affiliations. Their role is to provide enlightenment and information. Patrons' staff generate instrumental knowledge. This system relies on producing faith in the competence and the fairness of the patrons involved in the decision-making process.

Two additional styles are similar in their structure but not identical. The consensual approach is based on a closed circle of influential actors who negotiate behind closed doors. Representatives of important social organizations or groups and scientists work together to reach a predefined goal. Controversy is not visible and conflicts are often reconciled before formal negotiations take place. The goal of the negotiation is to combine the best available evidence with the various social interests that the different actors represent. The corporatist style is similar to the consensual approach, but is far more formalized. Well-known experts are invited to join a group of carefully selected policy-makers representing major forces in society (such as employers, unions, churches, professional associations, and environmentalists). Invited experts are asked to offer their professional judgment, but they often do not need to present formal evidence for their claims. This approach is based on trust in the expertise of scientists.

These four styles are helpful in characterizing and analyzing different national approaches to policy-making. The American system is oriented toward the adversarial style and the Japanese system toward the consensual. The policy style of northern Europe comes closest to the corporatist approach, whereas most southern European countries display a fiduciary approach. All these systems, however, are in transition. Interestingly the United States has tried to incorporate more consensual policies into its adversarial system, while Japan is faced with increasing demands for more public involvement in the policy process. These movements towards hybrid systems have contributed to the genesis of a new regulatory style, which may be called 'mediative.' There has been a trend in all technologically developed societies to experiment with opening expert deliberations to more varied forms of stakeholder or public participation. In the United States, it has taken the form of negotiated or mediated rule making, in Europe it has evolved as an opening of corporatist clubs to new groups such as the environmental movement. It is too early to say whether this new style will lead to more convergence among the countries or to a new set of cultural differentiations (Renn 1995).

6. *Conclusions*

The economic and political structures of modern societies underwent rapid transitions in the late twentieth century. This transition was accompanied by globalization of information, trade, and cultural lifestyles, an increased pluralism of positions, values, and claims, the erosion of trust and confidence in governing bodies, an increased public pressure for participation, and growing polarization between fundamentalist groups and agents of progressive change. The resulting conflicts put pressure on political systems to integrate different outlooks and visions of the future and to provide justifications of governmental decisions on the basis of both facts and values. In this situation, policy-making institutions discovered an urgent need for policy advice, as well as new modes of integrating expertise with values and preferences. Research on advisory processes indicates that the following points will need to be addressed.

(a) Using scientific expertise in the policy arena is one element in the quest of modern societies to replace or amend the collective learning process of trial and error by more humane methods of anticipation, in which the possibility of errors is reduced. This process is socially desired, though it cannot reduce the uncertainties of change to zero. Anticipation both necessitates and places new demands on expertise in the service of policy-making.

(b) Scientific expertise can serve five functions: enlightenment; pragmatic or instrumental; reflexive; catalytic; and communicative. All five are in demand by policy-makers, but expertise may also distort their perspective on the issue or prescribe a specific framing of the problem. That is why many policy analysts demand that scientific input be controlled by democratic institutions and be open to public scrutiny.

(c) Scientific expertise is also used for legitimizing

decisions and justifying policies that may face resistance or opposition. Expertise can, therefore, conflict with public preferences or interests. In addition, policy-makers and experts pursue different goals and priorities. Expertise should be regarded as one crucial element of policy-making among others. Scientific advice is often mandated by law, but its potential contributions may vary from one policy arena to another. In particular, scientific expertise cannot replace public input in the form of locally relevant knowledge, historical insights, and social values.

(d) The influence of expertise depends on the cultural meaning of expertise in different social and political arenas. If systematic expertise is regarded as the outcome of a socially constructed knowledge system, its authority can be trumped by processes that are seen to be more democratic. If, however, systematic expertise is seen as an approximation of reality or truth, it gains a privileged status among different sources of knowledge and inputs, even if it is the product of a democratically imperfect process. The degree to which these different understandings of expertise are accepted or acknowledged within a political arena will affect the practical influence and power of experts in collective decision-making.

(e) Scientific expertise is absorbed and utilized by the various policy systems in different styles. One can distinguish four styles: adversarial, fiduciary, consensual, and corporatist. A new mediative style seems to be evolving from the transitions toward more open procedures in decision-making. This style seems to be specifically adjusted to postmodern societies. Scientific expertise in this style pursues a 'system and problem oriented' approach to policy-making, in which science, politics, and economics are linked by strategic networks.

(f) Organizing and structuring discourses on the selection of policy options is essential for the democratic, fair, and competent management of public affairs. The mere desire to initiate a two-way-communication process and the willingness to listen to public concerns are not sufficient. Deliberative processes are based on a structure that assures the integration of technical expertise, regulatory requirements, and public values. Co-operative discourse is one model among others that has been designed to meet that challenge.

No one questions the need to initiate a common discourse or dialogue among experts, policy-makers, stakeholders and representatives of affected publics. This is particularly necessary if highly controversial subjects are at stake. The main challenge of deliberative processes will continue to be how to integrate scientific expertise, rational decision-making, and public values in a coherent form.

Science and the Media

The phrase 'science and the media' as a single concept encompasses two major social institutions. Science is both a system of reliable knowledge about the natural world and a complex social system for developing and maintaining that knowledge. Similarly, the media comprise a variegated system for collecting and presenting information as well as being an institution with significant economic, political, and social impact. Though long perceived as separate realms, recent scholarship has highlighted their mutual dependence. Increasing episodes of tension and conflict in the late twentieth century led scholars, scientists, media producers, and social critics to explore the interactions of science and the media. Working scientists and media producers sought guidance on how to use each others' resources more effectively, while analysts asked how such issues as political and economic interests, rhetorical conventions, and audience responses shed light on the roles of science and media in shaping each other. One effect of recent scholarship has been to elide the difference between 'media' (all forms of media) and 'the media' (particularly the major institutions of newspapers, magazines, television, and radio), an elision that will be evident throughout this article.

1. *Science and the Media: A Brief History*

The history of science and the media is the history of a growing mesh: increasing use of media by science, increasing attention to scientific ideas by media institutions, and increasing tensions caused by the rising interaction.

Through the middle of the twentieth century, science and media were largely seen as separate realms. Science had emerged in the nineteenth century from natural philosophy as a systematic approach to understanding the natural world. With the advent of research-based industries such as chemical dyes and electronic communication, science began to attract the attention of capitalists and government leaders who understood the value of controlling scientific knowledge. By the end of World War II, the emergence of 'big science' had made science a powerful institutional force as well as a system of accredited knowledge with increasingly far-reaching applications. The media had also evolved in the nineteenth century from small, local organizations into nationally and internationally-circulated publications that served as tools of merchant capitalism and political control, full of advertising, business and political news, and the ideology of the industrial revolution. By the early twentieth century, new electronic media such as movies and radio provided the means for newly-developed forms of 'publicity' and propaganda to help produce modern mass society, as well as to increase public access to new forms of cultural entertainment.

Since the late seventeenth century, natural philosophers had relied on print media, particularly professional journals such as the *Philosophical Transactions* and books such as Isaac Newton's *Principia*, as tools for disseminating the results of their investigations. These publications were not only records of experiments or philosophical investigations, but also served as active carriers of the rhetorical structures that enabled natural philosophers to convince people outside their immediate vicinity of the truth of their claims (Shapin and Schaffer 1985).

Early in the nineteenth century, new forms of science media emerged, particularly a genre known variously as 'popularization,' *vulgarisation* [French], or *divulgacion* [Spanish]. These books and magazines provided entrée into the knowledge of the natural world for non-scientist readers. They ranged from textbooks for young women through to new mass-circulation magazines filled with instruction on the latest achievements

of a rapidly industrializing society. The so-called 'great men' of late nineteenth century England (most notably Thomas Huxley and John Tyndall) became evangelists for science, lecturing widely to enlist public support for the enterprise of rational understanding of the natural world; they converted their lectures into articles and books to spread their reach even further. At the same time, scientists' use of media for disseminating knowledge among the scientific community grew dramatically, with the growth of new journals and the founding of publishing houses committed to scientific information.

The growth of both science and media in the twentieth century forced specialization into the fields, leading to a distinction between what some scientists have called 'communication in science' and 'communication about science.' For scientists in their daily work, broad synthetic journals such as *Science* and *Nature* (published respectively in the USA and the UK) were joined by topical journals in chemistry, physics, biology, and their many sub-disciplines. For non-scientists, magazines and other media (such as radio and new 'wire services' for newspapers) increasingly focused on particular audiences, such as teachers, inventors, 'high culture' readers, general media users, and so on. Although scientific ideas appeared in some entertainment media, science in most non-technical media became a component of news coverage for different audiences. In the 1920s and 1930s, a small group of professional journalists began to write almost exclusively about science. (These developments were clearest in the highly developed countries of Europe and North America. The patterns in the rest of the world have been little studied and so cannot be described.)

By the second half of the twentieth century, the interaction of science and media had become a complex web, in which new scientific research appeared in abstracts, journals, press reports, and online, while other forms of science–not necessarily derivative of the research reports–appeared regularly in media outlets such as newspapers, televisions, websites, radio programs, puppet shows, traveling circuses, and museums. Moreover, as science became central to modern culture, the presence of science in media such as poetry, sculpture, fine art, entertainment films, and so on, became more evident. In the journalistic media, many reports circulated internationally, through cooperative agreements between public broadcasting systems and worldwide news services. The rise of the World Wide Web in the 1990s provided further opportunities for information about science to circulate more fully between the developed and developing world.

However, from about the mid-century onward, no matter what media were involved, many working scientists perceived presentations in non-technical media to be incorrect, oversimplified, or sensationalized. Thus, tensions developed between the institutions of science and those of the media. Those tensions led eventually to the development of an analytic field of science and media, populated largely by media sociologists, communication content scholars, and sociologists of science.

2. *Understanding Science and Media*

Analysis of science and media has led to a deeper understanding of the essential role of media in creating scientific knowledge, the ways that media presentations shape understandings of nature, and the role of public debate in constituting scientific issues.

The earliest attempts to understand the relationship of science and media came from two directions: the overwhelming growth of scientific information, leading to attempts by scientists and scientific institutions to learn how to manage scientific publications, and emerging tensions between scientists and journalists, as specialized reporting developed in the 1930s. Research and publications before and after World War II led by the 1970s to two common understandings.

First, sociologists of science had come to understand the fundamental role of communication in the production of reliable knowledge about the natural world. Scientists do not work in isolation, but must constantly present their ideas to colleagues for acknowledgement, testing, modification, and approbation. The process of communication, occurring in various media, is the 'essence of science' (Garvey 1979), leading to science becoming 'public knowledge' (Ziman 1968). At the same time, the apparent differences between the goals of science (methodical, tentative, but nonetheless relatively certain statements about the natural world) and the needs of public media (rapid, attention-getting narratives about issues directly related to readers and viewers, regardless of certainty) had also been explicated (Krieghbaum 1967), leading to practical attempts to 'bridge the gap' between science and the media but also to recurring fears that the gap was unbridgeable.

Beginning in the 1970s, new developments in the sociology of scientific knowledge opened up new ways of conceiving of the relationship between science and media (Barnes 1974, Latour and Woolgar 1979). In particular, attention to the rhetorical goals of scientists in their use of media suggested that a distinction between communication in science and communication about science could not be maintained. Instead, some researchers began to discuss the 'expository' nature of science, showing how scientists tailored their communication to meet the needs of specific media and specific communication contexts (Bazerman 1988, Shinn and Whitley 1985). These researchers highlighted the interaction of the idealized intellectual goals of science (for the production of reliable knowledge about the natural world) with the social and institutional goals of scientists and their employers or

patrons (for priority, status in the community, ownership of ideas and thus patents, and so on).

In this conception of science and media, scientific knowledge itself might differ in different presentations—in some cases, appearing as a 'narrative of science' (focusing on the methodological and theoretical structures leading to particular knowledge of the natural world), in other cases as a 'narrative of nature' (focusing on the relationships between organisms or entities, with emphasis on the 'story' linking different aspects of those organisms and entities) (Myers 1990). The very boundary between 'science' and 'non-science' (or 'mere' popularization), between communication in science and communication about science, was shown to be highly mutable, itself an object of rhetorical construction used for political purposes by participants in scientific controversies to establish control over elements of a debate (Hilgartner 1990).

A second new line of inquiry highlighted the institutional interdependence of science and the media. Pointing to the growing post-World War II need for scientific institutions to generate public and political support, and to the media's need to draw on scientific developments for constant infusions of drama and 'newness,' the new research identified 'selling science' as a major element of the political economy linking science and the media (Nelkin 1987).

Finally, work on the images of science that appeared over time helped show the ways that social concerns interacted with scientific developments to create cultural representations of science (Weart 1988, LaFollette 1990, Nelkin and Lindee 1995).

At the same time that these developments were occurring in the understanding of science communication, new approaches were developing in understanding the relationship between science and the public. Spurred by concerns in the scientific community about lack of 'scientific literacy,' the studies ultimately questioned the idea that the public has a 'deficit' of knowledge that needs to be 'improved' (Irwin and Wynne 1996). Instead, the new approach focused on the possibility of engaging the public in discussions about scientific issues, recognizing the contingent nature of understanding of scientific issues and thus the alternative meanings that might emerge in democratic discussions instead of authoritarian pronouncements (Sclove 1995). Much of the new work looked at issues of uncertainty and risk, highlighting the social negotiations required to make personal and policy decisions in a context of incomplete information (Friedman et al. 1999). The new work clearly implied that science and the media cannot be perceived as separate institutions with separate goals. Instead, better understanding comes from analyzing science and media across audiences, looking at the political and economic interests of media producers, at the rhetorical meanings of media conventions, and at the audience responses to media content (especially in terms of meaning-making).

3. *Approaches to Studying Science and Media*

3.1 *Political and Economic Interests of Media Producers*

The most detailed and well-developed understandings of science and the media point to the political and economic interests that motivate the producers of media representations of science. In many countries, the media depend on government subsidies or at least on political tolerance. Moreover, media are expensive to produce. While the presence of the media in democratic societies is often seen as fundamental to political liberty, the economic need to appeal to broad audiences (even for government-controlled media) often leads to editorial decisions that emphasize broad coverage and sensationalism over depth and sobriety. Science media are no different, and even the most prestigious scientific journals such as *Science* and *Nature* have been criticized for highlighting the most 'newsworthy' research, for hyping scientific reports beyond their value, for engaging in 'selling science.' Newspaper and television coverage of science is routinely criticized for its sensationalism, particularly in the coverage of controversial issues such as food contamination (e.g., the BSE or 'mad cow' epidemic in Britain in the 1980s and 1990s), genetic modification of food, and global climate change. Journalists (and their employers) routinely defend their practices on the basis of 'what readers/viewers want,' which is often judged by sales success. Entertainment media are criticized even more heavily for creating movie plots that involve impossible science or focus on highly unlikely scenarios; producers disclaim any responsibility for accuracy, claiming only to be providing (profitable) escapism. These recurring disputes between the scientific community and media producers highlight the irreconcilable tension between the goals of science and the goals of the media.

3.2 *Rhetorical Meanings of Media Conventions*

An emerging area of understanding is the way that media conventions shape the rhetorical meaning of science communication. Scientific papers reporting original experimental research, for example, have developed a standardized format (called 'IMRAD,' for introduction, methods, results, analysis, discussion). The IMRAD format, conventionally written in an impersonal tone, with passive grammatical constructions, hides the presence of the researcher in the research, highlighting the objective character of scientific knowledge that is claimed to exist independently of its observer. In journalistic reports of scientific controversies, the conventions of objective reporting require 'balance'—the presentation of both sides of a controversy (Bazerman 1988). Though 99.9 percent of all researchers may hold that a new claim

(such as the eventually discredited 1989 announcement of a new form of 'cold nuclear fusion') is scientifically untenable, the journalistic norm of balance may lead to approximately equal attention to all claims. Similarly, journalistic goals of story telling often lead to emphasis on the human, narrative dimensions of an issue over the theoretical or mathematical components of the science. New research is exploring the meaning of visual representations of science, at every level from the technical outputs of genome analyzers to mass media manipulations of false-color images produced by orbiting astronomical telescopes (Lynch and Woolgar 1990).

3.3 Audience Responses to Media Content

One of the most difficult areas to investigate is the audience response to particular media presentations. Virtually no work, for example, has been done on how scientists respond to specialized science media, despite anecdotal stories suggesting that changes in information presentation (such as World Wide Web access to scientific databases) may have dramatic impacts on how scientists conceive of the natural world and frame their hypotheses and theories. Some work has been done at broader public levels, such as responses to media presentations of risk information. But, although the psychology of risk perceptions, for example, has been extensively investigated, the factors affecting individual responses to media coverage of specific risky incidents are so varied as to defy measurement. Though the complexity leads some researchers to reject the possibility of quantitative analysis, others insist that social scientists can learn to isolate appropriate variables. Certainly some areas of audience response could be investigated more carefully; audience reaction to images of science in entertainment films, for example, has never been systematically tested, despite frequent statements that 'the image of scientists in the movies is bad.'

The shift away from separate analysis of 'science' and 'media' to an integrated understanding of 'science and media' has led in recent years to the possibility of cross-cutting analyses, such as those of producers, rhetorical structures, and audience reception. These analyses will ultimately yield a much richer understanding of the interaction of science and media. Less clear is how such improved understanding will contribute to the practical concerns of those in the scientific community and elsewhere, who worry about possible linkages among science literacy, the image of science, and public support for science.

Science and the State

1. Introduction

Since the sixteenth century, the 'scientific revolution' has generated a host of new, intellectual, rhetorical, and institutional strategies for undermining traditional political authorities and constructing alternative ones. Science became a vital resource in the modern attempt to discredit traditional political hierarchies and spiritual transcendental sources of authority in

the context of public affairs. By providing new rationales for order compatible with the novel modern commitments to the values of individualism, voluntarism, and egalitarianism, science and technology paradoxically also provided new grounds for novel modern forms of hierarchy and authority committed to the use of knowledge in the reconstruction of society. The widely shared notion that science goes along with progress appeared to suggest that knowledge, when applied to public affairs, can in fact depoliticize public discourse and action. This faith produced wide mandates for large-scale social and political engineering and monumental state-sponsored technological projects in both authoritarian and democratic states.

While such ideals and projects were from the very beginning criticized by observers such as Edmund Burke (1729–97), throughout the twentieth century the record of the relations between science and politics turned out to be sufficiently mixed to discard earlier hopes. The controversial role of scientists in the production and military deployment of means of mass destruction, the role of scientists in the Nazi experiments on human beings and the endorsement of racism, and their involvement in the industrial pollution of the environment, diminished the public trust in science fostered by such developments as medical breakthroughs and spectacular space flights.

Since the closing decades of the twentieth century, an increasing number of social scientists and historians have been pointing out that new uncertainties in the sphere of politics have been converging with newly recognized uncertainties of science and risks of technology to form novel postmodern configurations of state, science, and society (Eisenstadt 1999, Beck 1992). It has become increasingly recognized that, in ethnically and religiously heterogeneous and multicultural societies, science and technology can no longer be attached to uncontroversial comprehensive values that privilege claims of neutrality, objectivity, and rationality; nor can the earlier belief that knowledge can depoliticize public discourse and action be sustained any longer.

2. *The Authorities of Science and the State*

The belief that science can provide a secular version of the synoptic divine view of human affairs was politically most significant. Until its erosion towards the end of the twentieth century, the modernist configuration of science and the state was formed over the course of at least four centuries. The secularization of political power in the modern state has put the dilemma of arbitrary rule at the center of modern political theory and practice. Whereas legal and constitutional constraints appeared to be the most appropriate remedy to this problem, the rise of modern science and technology encouraged faith in the possibility of restraint and moderation through public enlightenment and by means of scientific and technical advice. Not surprisingly, the redemptive drive behind the integration of science and politics had its origins in premodern religious visions and values (Manuel 1974). In both its authoritarian and democratic versions, this modernist program rested on the belief that the modern state can remedy the defects of the present sociopolitical order and realize an ideal order. Science contributed to this modernist outlook the faith in the power of secular knowledge to control nature and reconstruct society. In his dedication to Lorenzo di Medici of Florence in *The Prince* (1513), Niccolo Machiavelli implies that the holder of the God's-eye view of the entire state is neither the King, who looks down at the people from the top of the hierarchy, nor the people, who see the King at the top from their lower state. It is a person like himself, a man of knowledge. The King, to be sure, has knowledge of the people, and the people have knowledge of the King but, because of his intellectual perspective, 'a man of humble and obscure condition' like Machiavelli can claim to see both the King and his subjects and understand the nature of their interactions.

Political theory and political science thus claimed to have inherited the God's-eye view of the whole polity and evolved a secular vision of the state as an object of knowledge. In turn, the nation-state has often found it useful to adopt the frame, if not always the content, of the inclusive scientific outlook in order to legitimate its interventions in the name of the general common good and its expressions in public goals such as security, health, and economic welfare. If, from the inclusive perspective of the state, all citizens, social groups, or institutions appeared as parts which the supreme power had the capacity to fit together or harmonize, science in its various forms often provided the technical means to rationalize, and the rhetorical strategies to depoliticize, such applications of power.

The potential of science not only as a source of knowledge but also as a politically useable authority was already recognized by Thomas Hobbes. This founder of modern political theory was in contact with Francis Bacon, admired William Harvey's findings about the circulation of the blood, and criticized Robert Boyle's position on the vacuum (Shapin and Schaffer 1985). In his influential works on the state, Hobbes tried to buttress his claims by appealing to the authority of scientific, especially mathematical, certainties, hoping to enlist the special force of a language, which claims to generate proofs as distinct from mere opinions (Skinner 1996). Although he was suspicious of the experimental science of Boyle, Hobbes followed Machiavelli in describing politics in the language of causes rather than motives. Thomas Sprat, the historian of the Royal Society (1667), claimed that when compared to the contentious languages of religions, the temperate discourse of science can advance con-

sensus across diverse social groups. In both the experimental and mathematical scientific traditions, however, knowledge, whether based on inferences or observations (or on their combination), was expected to end disputes.

The association between science and consensus was regarded as deeply significant in a society which had begun to view authority and order as constructed from the bottom up rather than coming from above (Dumont 1986). Reinforced by the growing image of science as a cooperative, nonhierarchical, and international enterprise in which free individuals come to uncoerced agreements on the nature of the universe, scientific modes of reasoning and thinking appeared to suggest a model for evolving discipline and order among equals (Polanyi 1958, 1962).

Deeply compatible with the notion that legitimate power and authority are constituted by social contracts, the rise of modern scientific knowledge appeared to accompany and reinforce the rise of the modern individual and his or her ability to challenge hierarchical forms of knowledge and politics. From Hobbes and Descarte, through Kant, J. S. Mill, and late-modern democratic thinkers such as Popper, Dewey, and Habermas, the commitment to the centrality of individual agency becomes inseparable from a growing faith in the possibility of expanding public enlightenment backed up by the demonstrated success of scientific modes of reasoning and acting.

3. *Power and the Social Sciences*

In succeeding centuries, one of the most persistent ambitions of Western society has been to make conclusions touching the 'things' of society, law, and politics appear as compelling and impervious to the fluctuations of mere opinion as conclusions touching the operation of heaven and earth. The faith that natural scientists are bound by the 'plain' language of numbers to speak with an authority which cannot be corrupted by fragile human judgment was gradually extended to the fields of engineering and the social sciences (Porter 1986). The notion that experts who are disciplined by respect for objective facts are a symbol of integrity and can therefore serve as guardians of public virtues against the villains of politics and business was widely interpreted to include, beyond natural scientists, other categories of experts who speak the language of numbers. Social science disciplines like economics, social statistics, sociology, political science, and psychology adopted modes of observing, inferring, and arguing which appeared to deploy in the sphere of social experience notions of objective facts and discernible laws similar to those that the natural sciences had developed in relation to physical nature. The social sciences discovered that the language of quantification is not only a powerful tool in the production of knowledge of society but also a valuable political and bureaucratic resource for depersonalizing, and thus legitimizing, the exercise of power (Porter 1995). In the context of social and political life the separation, facilitated by expert languages, between facts and values, causal chains and motives, appeared profoundly consequential. Until effectively challenged, mostly since the 1960s, such scientific and technical orientations to human affairs appeared to produce the belief that economic, social, political, and even moral 'facts' can be used to distinguish subjective or partisan from professional and apolitical arguments or actions. The apparent authority of science in the social and political context motivated the principal founders of modern ideologies like socialism, fascism, and liberalism to enlist science to their views of history, society, and the future.

While theoretical and mathematified scientific knowledge remained esoteric, as religious knowledge was for centuries in the premodern state, the ethos of general enlightenment and the conception of scientific knowledge as essentially public made scientific claims appear agreeable to democratic publics even when these claims remained, in fact, elusive and removed from their understanding. In fields such as physics, chemistry, and medicine, machines, instruments, and drugs could often validate in the eyes of the lay public claims of knowledge which theories alone could not substantiate. The belief that science depoliticizes the grounds of state policies and actions, and subordinates them to objective and, at least in the eyes of some, transparent, professional standards, has been highly consequential for the uses of science in the modern state.

Political leaders and public servants discovered that the appearance of transparency and objectivity can make even centralized political power seem publicly accountable (Price 1965, Ezrahi 1990). Moreover, the realization that the authority of science could in various contexts be detached from substantive scientific knowledge and deployed without the latter's constraint often enhanced the political usefulness of both natural and social scientists independently of the value actually accorded to their professional judgments. Still, the uses of expert scientific authority in the legitimization of state politics and programs has often empowered scientists to actually exercise influence on the substance of government actions or to effectively criticize them from institutional bases outside the government (Jasanoff 1990). The actual uses of scientific expertise could often be just the consequence of a political demand for expert authority.

4. *Science in Democratic and Authoritarian States*

In democratic societies, the integration of scientific authority, and sometimes also of scientific knowledge and technology, into the operations of the modern

state encouraged the development of a scientifically informed public criticism of the government. This process was greatly augmented by the rise of the modern mass media and the ability of scientists to call public attention to governmental failures traceable to nonuse or misuse of scientific expertise. The role of scientists in empowering public criticism of the uses of nuclear weapons and nuclear energy (Balough 1991), in grounding public criticism of the operation of such agencies as the National Aeronautics and Space Administration (NASA) and the Food and Drugs Administration (FDA), and in the criticism of public and private agencies for polluting the environment, illustrates the point. In authoritarian states like the Soviet Union, such cooperation between scientists, the mass media, and the public in criticizing government policies and actually holding the government accountable was, of course, usually repressed. In the authoritarian modernist version of science and the state, science was used mostly to justify, and partly to direct, comprehensive planning and control. Here, the force of scientific knowledge and authority rarely constrained the rationalization of centralization or warranted public skepticism towards the government or criticism of its actions (Scott 1998).

Even in democratic states, however, science and technology were massively used to promote the goals of reconstruction, coordination, mass production, and uniformity. The redemptive role assumed by the political leadership in the name of equality, public welfare, and uniformity was no less effective in rationalizing state interventions than the totalistic utopianism enlisted to justify the direction and manipulation of society in authoritarian regimes. In all the variants of the modern state, bodies of expert knowledge such as statistics, demography, geography, macroeconomics, city planning, public medicine, mental health, applied physics, psychology, geology, and others were used to rationalize the creation of government organizations and semipublic regulatory bodies which had the mandate to shift at least part of the discretion held formerly by political, legal, and bureaucratic agents to experts (Price 1965, Wagner et al. 1991).

In many democratic states, the receptiveness to experts within the state bureaucracy was manifest in the introduction of merit-based, selective, personnel recruitment procedures and a widening use of examinations. The cases of the former USSR and Communist China suggest, by contrast, the ease with which experts and their expertise could be controlled by political loyalists. Even where it was facilitated, however, the welding of bureaucrats and professionals was bound to be conflict-ridden. The hierarchical authority structure of bureaucratic organizations has inevitably come to both challenge and be challenged by the more horizontal structure of professional peer controls (Wilson 1989, Larson 1977). Nevertheless, the professionalization of fields of public policy and regulation boosted the deployment of more strictly instrumental frames of public actions in large areas. The synoptic gazes of power and science could thus converge in supporting such projects as holistic social engineering, city planning, and industrial scientific agriculture (Scott 1998).

5. *Science, War, and Politics*

The most dramatic and consequential collaboration between science and the modern state took place during wars. Such collaboration was usually facilitated by the atmosphere of general mobilization, defining the war effort as the top goal of the nation. In a state of emergency, even democratic states have suspended, or at least limited, the competitive political process. Under such conditions, democracies have temporarily, albeit voluntarily, experienced the usual conditions of the authoritarian state: centralized command and control and a nationally coordinated effort. In the aftermath of such wars, politicians and experts often tried to persist in perpetuating the optimal conditions of their collaboration, regarding the resumption of usual political processes as disruptive of orderly rational procedures. In authoritarian nationalist or socialist states, open competitive politics was repressed as a matter of routine along with the freedom of scientific research, and the liberty of scientists to diffuse their findings and interpret them to students and the public at large (Mosse 1966). In such countries, the political elite usually faced the dilemma of how to exploit the resources of science for the war effort and for advancing its domestic goals without becoming vulnerable to the revolutionary potential of science as the expression of free reason, criticism, and what Robert K. Merton called 'organized skepticism' (1973). In the democratic state, the special affinities between the participatory ethos of citizens, free to judge and evaluate their government, and the values of scientific knowledge and criticism did not usually allow the coherences and the clarities of the war period to survive for long, and the relations between science and the state had to readjust to conditions of open political contests and the tensions between scientific advice to, or scientific criticism of, the state. Limitations imposed by open political contests were mitigated, however, in political cultures which encouraged citizens to evaluate and judge the government with reference to the adequacy of its performance in promoting public goals. The links between instrumental success and political legitimation preserved in such contexts the value of the interplay between expert advice to the government and to its public critics in the dynamic making of public policy and the construction of political authority. Political motives for appealing to the authority of science could of course be compatible with the readiness to ignore knowledge and

adequate performance, although it did not need to contradict the willingness to actually use scientific knowledge to improve performance. Discrepancies between the uses of scientific authority and scientific knowledge became widespread, however, because of the growing gaps between the timeframes of science and politics in democratic societies. In fields such as public health, economic development, security, and general welfare, instrumentally effective policies and programs must usually be measured over a period of years, and sometimes even decades. But the politicians whose status has come to be mediated by the modern mass media need to demonstrate their achievements within the timeframe of months or even days or weeks. In contemporary politics, one month is a long time, and the life expectancy of issues on the public agenda is usually much shorter. Such a state of affairs means that political actors often lack the political incentives to invest in the costly resources that are required for instrumental success whose payoffs are likely to appear only during the incumbency of their political successors.

6. *Science and the Transformation of the Modern Democratic State*

These conditions have encouraged leaders in democratic states increasingly to replace policy decisions and elaborate programs with grand political gestures (Ezrahi 1990). Where instant rewards can be obtained by well-advertised commitment to a particular goal or policy, the political motive to invest in substantive moves to change reality and improve governmental performance over the longer run may easily decline.

Besides the tendency of democratic politics to privilege the present over the future in the allocation of public resources, the position of science in substantiating long-term instrumental approach to public policy was further destabilized by the fragmentation of the normative mandates of state policies. Roughly since the 1960s, the publics of most Western democracies have become increasingly aware of the inherent constraints on the determination and ordering of values for the purpose of guiding public choices. Besides the influence of ethnic, religious, linguistic, or cultural differences on this process, such developments as the feminist movement reflect even deeper pressures to reorder basic values. Feminist spokespersons demanded, for example, that financial and scientific resources directed to control diseases be redistributed to redress gender discrimination against the treatment of specifically female diseases. In part, the feminist critique has been but one aspect of wider processes of individuation, which, towards the later part of the twentieth century, have increased the diversity of identities, tastes, lifestyles, and patterns of association in modern societies. This new pluralism implied the necessity of continually renegotiating the uses of science and technology in the social context and locally adapting it to the diverse balances of values and interests in different communities. In the course of the twentieth century, leading scientific voices like J. B. S. Haldane, J. B. Bernal, and Jacques Monod tended to treat almost any resistance to the application of advanced scientific knowledge in human affairs as an 'abuse of science' resulting from irrationalism, ignorance, or prejudice. These and many other scientists failed to anticipate the changes in social and political values which complicated the relations of science and politics during the twentieth century and the constraints imposed by the inherently competitive value environment of science and policy making in all modern states.

The constant, often unpredictable, changes in the value orientations of democratic publics and other related developments have clearly undermined confidence in the earlier separation between facts and values, science and politics, technological and political structures of action. Such a central element of policy making as risk assessment, for example, which for a long time was regarded as a matter best left to scientists, was gradually understood as actually a hybrid process combining science and policy judgments (Jasanoff 1990, Beck 1992). In contemporary society, in which the respective authorities of science and the state were demystified, knowledge has come to be regarded as too complex to directly check power, and power as too diffused to direct or repress the production and diffusion of knowledge.

Historically, one of the most important latent functions of science in the sociocultural construction of the democratic political universe was to warrant the faith in an objective world of publicly certifiable facts which can function as standards for the resolution or assessment of conflicts of opinions. To the extent that scientists and technologists could be regarded as having the authority to state the valid relations between causes and effects, they were believed to be vital to the attribution of responsibility for the desirable or undesirable consequences of public actions. Policies were regarded within this model of science and politics as hypotheses, which are subject to tests of experience before a witnessing public (Ezrahi 1990). Elements of this conception have corresponded to the modern political experience. Although the public gaze has always been mediated, and to some extent manipulated, by hegemonic elites, publics could usually see when a war effort failed to achieve the stated objectives, when a major technology like a nuclear reactor failed and endangered millions of citizens, or when economic policy succeeded in producing affluence and stability. The expansion of this conception of government responsibility and accountability to regions outside the West even made it possible to redescribe fatal hunger in wide areas in India, for instance, as the consequence of policy rather

than natural disaster (Sen 1981). Still, in large areas, the cultural and normative presuppositions of the neutral public realm as a shared frame for the nonpartisan or nonideological description and evaluation of reality have not survived the proliferation of the modern mass media and the spread of political and cultural pluralism. In contemporary democracies, the pervasive mediating role of largely commercialized electronic communication systems has diminished the power of the state to influence public perceptions of politics and accentuated the weight of emotional and esthetic factors relative to knowledge or information in the representation and construction of political reality. Influenced by diverse specialized and individualized electronic media, the proliferation of partly insulated micro-sociocultural universes within the larger society has generated a corresponding proliferation of incommensurable notions of reality, causality, and factuality.

7. *Transformations of the Institutional Structure and Intellectual Orientations of Science*

Changes in the political and institutional environment of science in the modern state have been accompanied by changes in the internal institutional and intellectual life of science itself. In the modern democratic state, the status of science as a distinct source of certified knowledge and authority was related to its institutional autonomy vis-à-vis the structure of the state and its independence from private economic institutions. Freedom of research and academic freedom were regarded as necessary conditions for the production and diffusion of scientific knowledge and, therefore, also for its powers to ground apolitical advice and criticism in the context of public affairs. Such institutional autonomy was, of course, never complete. The very conditions of independence and freedom had to be negotiated in each society and reflected at least a tacit balance between the needs of science and the state as perceived by the government. But the international universalistic ethos of science tended to ignore or underplay such local variations (Solingen 1994).

The institutional arrangements that secured a degree of autonomy and freedom to scientists seemed to warrant the distinction between basic and applied research, between pure research directed to the advancement of knowledge and research and development directed to advance specific industrial, medical, or other practical goals. An important function of this distinction was to balance the adaptation of science to the needs of the modern state and the preservation of the internal intellectual traditions and practices of scientific research and academic institutions. In practice, the relations between science and the state were more symbiotic than the public ethos of science would have suggested. Scientific institutions, in order to function, almost always required public and political support and often also financial assistance. On the other hand, the state could not remain indifferent to the potential uses of scientific knowledge and authority to both secure adequate responses to problems and facilitate the legitimation of its actions by reference to apolitical expert authority. Thus, while the separation between truth and power and the respect for the boundaries between pure and applied sciences, as well as between politics and administration, were considered for a long time as the appropriate way to think about the relation between science and politics (Price 1965), the relations between science and the state, as well as between scientists and politicians, turned out to be much more interactive and conflict-ridden. Since scientists and politicians respectively controlled assets useful for each other's work, they were bound to be more active in trying to pressure each other to cooperate and engage in mutually useful exchanges (Gibbons et al. 1994).

Not all these exchanges were useful to either science or the state in the long run. The mobilization of scientists to the war efforts of the modern nation-state, while it boosted the status of scientists domestically in the short run, had deleterious effects on the international network of scientific cooperation, as well as on the independence of science in the long run. Especially in cases of internally controversial wars, like the American involvement in Vietnam, the mobilization of science inevitably split the scientific community and politicized the status of science. Nevertheless, the unprecedented outlays of public money made available to science in the name of national defense allowed many research institutions to acquire expansive advanced facilities and instruments that permitted the boosting of pure science in addition to militarily related research and development. But the gains in size and in potential scientific advance were obtained at the cost of eroding the glorious insulation of scientific research and exposing its delicate internal navigational mechanisms to the impact of external political values and institutions (Leslie 1993). Yielding to the pressures of the modern nation-state to make science more relevant and useful to more immediate social goals inevitably reduced the influence of internal scientific considerations and the priorities of scientific research (Guston 2000). Following such developments, the university, the laboratory, and the scientific community at large could often appear less elitist and more patriotic, but also more detached from their earlier affinities to humanistic culture and liberal values.

Like the partnership between science and the state, the partnership between science and the market often facilitated by their collaboration during the war effort and postwar privatization of projects and services has undermined the autonomy of science and the ethos of basic research in many late modern states. But, whereas the interpenetration between science and the

state subjected the internal intellectual values of science to the pressures of public goals and pressing political needs, the links between science and the private sector subordinated scientific norms to the private values of profit making. The conversion of scientific expertise into capital opened the way for substantial private support for the intellectual pursuits of science. But the linkages between science, industry, and capital only reinforced the decline of science and its institutions as a bastion of enlightenment culture, progress, and universal intellectual values. Thus, while scientific and technical knowledge and skills were increasingly integrated into a wider spectrum of industrial productions and commercial services, science as a whole became more amorphous, less recognizable or representable as a set of distinct institutions, and a community with a shared ethos (Gibbons et al. 1994).

An instructive illustration of these processes is the pressure exerted by both the state and private business firms on scientists to compromise the cherished professional norm of publicity. In the context of science, the transparency of methodology and the publicity of research results have for a long time been reinforced by both ethical commitment and practical needs. The methodologies and findings of any research effort are the building blocks, the raw materials, with which scientists in discrete places produce more knowledge. Transparency and publicity are necessary for the orderly flow of the research process and the operation of science as a cooperative enterprise (Merton 1973). In addition, publicity has been a necessary element of the special status of science as public knowledge. From the very beginning, pioneering scientists such as Bacon, Boyle, and Lavoisier distinguished scientific claims from the claims of magic, alchemy, cabala, and other esoteric practices by the commitment to transparency. Transparency was also what rendered claims of scientific knowledge appear publicly acceptable by democratic citizens (Tocqueville 1945). Turning scientific research into a state secret in order to gain an advantage in war or into an economic (commercial) secret in order to gain an advantage in the market was not congenial to sustaining the cooperative system of science or the early luster of science as an embodiment of noble knowledge and virtues which transcended national loyalties and sectoral interests. In the aftermath of such developments, the virtues of objectivity, distinterestedness, universality, and rationality which were associated with earlier configurations of science (Polanyi 1958, 1962, Merton 1973) appeared unsustainable. Moreover, the fact that the resources of science and technology could be enlisted not only by liberal and democratic but also by fascist, communist, and other authoritarian regimes accentuated the image of science as an instrument insufficiently constrained by internal norms and flexible enough to serve contradictory, unprogressive, and extremely controversial causes.

8. *The Postmodern Condition and the Reconfiguration of Science and the State*

These developments had a profoundly paradoxical impact on the status of science in the late-modern state. Especially since the closing decades of the twentieth century, while such projects as the decoding of the human genome indicate that scientific knowledge has advanced beyond even the most optimistic predictions, the authority of science in society and in the context of public affairs has suffered a sharp decline. In order to consider this state of affairs as reversible, one needs to believe that the insular autonomy of science can be restored and that the political and economic environments of science can become more congenial for sustaining this condition. Such expectations seem unwarranted. On the other hand, an apparent decline in the distinct social and political value of scientific authority may not necessarily undermine the impact of scientific knowledge on the ways states and governments act. What appears against the past as the decline of scientific authority in the larger social and political context may even be redescribed as a reconfiguration of the authority of expertise in the postmodern state. The earlier distinctions between science, politics, law, ethics, economy, and the like may have become irrelevant in complex contemporary societies, in which the use of scientific knowledge requires finer, more intricate, and continual adjustments and readjustments between science and other expressions of truth or power.

In the absence of hegemonic ideological or national frames, the macropolitical sphere of the state divides into a multitude of—often just temporary and amorphous—subgroups, each organized around a particular order of values and interests. In each of these particular universes scientific knowledge and expertise can occupy a privileged authority as a means to advance shared goals. When these groups clash or compete in the wider political arena, their experts tend to take sides and function as advocates. The state and its regulatory institutions enlist their own experts to back up their particular perspectives. Within this new, more open-ended and dynamic system, science is more explicitly and reflexively integrated into social economic and political values. In the context of the new pluralist polity, the authority and knowledge of science may therefore be less distinctly visible and less relevant to the symbolic, ideological, or cultural aspects of politics. At the same time, it is no less present in the organization, management, and the normative constitution of social order.

Science, Economics of

Determining the principles governing the allocation of resources to science as well as the management and consequences of the use of these resources are the central issues of the economics of science. Studies in this field began with the assumption that science was a distinct category of public spending that required rationalization. They have moved towards the view that science is a social system with distinct rules and norms. As the systems view has developed, the focus of the economics of science has moved from the effects of science on the economy to the influence of incentives and opportunities on scientists and research organizations.

There is a productive tension between viewing science as a social instrument and as a social purpose. In the first view, science is a social investment in the production and dissemination of knowledge that is expected to generate economic returns as this knowledge is commercially developed and exploited. This approach has the apparent advantage that the standard tools of economic analysis might be directly employed in choosing how to allocate resources to science and manage their use. In the second approach, science is assumed to be a social institution whose norms and practices are distinct from, and only partially reconcilable with, the institutions of markets. While this second approach greatly complicates the analysis of resource allocation and management, it may better represent the actual social organization of science and the behavior of scientists, and it may therefore ultimately produce more effective rules for resource allocation and better principles for management. Both approaches are examined in this article, although it is the first that accounts for the majority of the economics of science literature (Stephan 1996).

1. *The Economic Analysis of Science as a Social Instrument*

In arguing for a continuing high rate of public funding of science following World War II, US Presidential

Science Advisor Vannevar Bush (1945) crafted the view that science is linked intrinsically to technological and economic progress as well as being essential to national defense. The aim of 'directing' science to social purposes was already well recognized, and had been most clearly articulated before the war by John D. Bernal (1939). What distinguished Bush's argument was the claim that science had to be curiosity-driven and that, in companies, such research would be displaced by the commercial priorities of more applied research. The view that science is the wellspring of economic growth became well established within the following generation, giving rise to statements like 'Basic research provides most of the original discoveries from which all other progress flows' (United Kingdom Council for Scientific Policy 1967).

The concept of science as a source of knowledge that would be progressively developed and eventually commercialized became known as the 'linear model.' In the linear model, technology is science reduced to practical application. The 'linear model' is an oversimplified representation that ignores the evidence that technological change is often built upon experience and ingenuity divorced from scientific theory or method, the role of technological developments in motivating scientific explanation, and the technological sources of instruments for scientific investigation (Rosenberg 1982). Nonetheless, it provides a pragmatic scheme for distinguishing the role of science in commercial society.

If science is instrumental in technological progress and ultimately economic growth and prosperity, it follows that the economic theory of resource allocation should be applicable to science. Nelson (1959) and Arrow (1962) demonstrated why market forces could not be expected to generate the appropriate amount of such investment from a social perspective. Both Arrow and Nelson noted that in making investments in scientific knowledge, private investors would be unable to capture all of the returns to their investment because they could not charge others for the use of new scientific discoveries, particularly when those discoveries involved fundamental understanding of the natural world. Investment in scientific knowledge therefore had the characteristics of a 'public good', like publicly accessible roads. This approach established a basis for justifying science as a public investment. It did not, however, provide a means for determining what the level of that investment should be.

Investments in public goods are undertaken, in principle, subject to the criterion that benefits exceed costs by an amount that is attractive relative to other investments of public funds. To employ this criterion, a method for determining the prospective returns or benefits from scientific knowledge is required. The uncertainty of scientific outcomes is not, in principle, a fundamental barrier to employing this method. In practice, it is often true that the returns from investments in public good projects are uncertain, and prospective returns often involve attributing to new projects the returns from historical projects. Griliches (1958) pioneered a methodology for retrospectively assessing the economic returns on research investment, estimating that social returns of 700 percent had been realized in the period 1933–55 from the $2 million of public and private investments on the development of hybrid corn from 1910–55. Other studies of agricultural innovation as well as a limited number of studies of industrial innovation replicated Griliches' findings of a high social rate of return (see Steinmueller 1994 for references). Mansfield (1991) provides a fruitful approach for continuing to advance this approach. Mansfield asked R&D executives to estimate the proportion of their company's products and processes commercialized in 1975–85 that could not have been developed, or would have been substantially delayed, without academic research carried out in the preceding 15 years. He also asked them to estimate the 1985 sales of the new products and cost savings from the new processes. Extrapolating the results from this survey to the total investment in academic research and the total returns from new products and processes, Mansfield concluded that this investment had produced the (substantial) social rate of return of 28 percent.

The preceding discussion could lead one to conclude that the development of a comprehensive methodology for assessing the rate of return based on scientific research was only a matter of greater expenditure on economic research. This conclusion would be unwarranted. Efforts to trace the returns from specific government research efforts (other than in medicine and agriculture) have been less successful. The effort by the US Department of Defense Project Hindsight to compute the returns from defense research expenditures not only failed to reveal a positive rate of return, but also rejected the view that 'any simple or linear relationship exists between cost of research and value received' (Office of the Director of Defense Research and Engineering 1969). Similar problems were experienced when the US National Science Foundation sought to trace the basic research contributions underlying several major industrial innovations (National Science Foundation 1969). In sum, retrospective studies based on the very specific circumstances of 'science enabled' innovation or upon much broader claims that science as a whole contributes a resource for commercial innovation seem to be sustainable. When these conditions do not apply, as in the cases of specific research programs with uncertain application or efforts to direct basic research to industrial needs, the applicability of retrospective assessment, and therefore its value for resource allocation policy, is less clear.

More fundamentally, imputing a return to investments in scientific research requires assumptions about the 'counter-factual' course of developments that

would have transpired in the absence of specific and identified contributions of science. In examples like hybrid corn or the poliomyelitis vaccine, a reasonable assumption about the 'counter-factual' state of the world is a continuation of historical experience. Such assumptions are less reasonable in cases where scientific contributions enable a particular line of development but compete with alternative possibilities or where scientific research results are 'enabling' but are accompanied by substantial development expenditures (David et al. 1992, Mowery and Rosenberg 1989, Pavitt 1993).

For science to be analyzed as a social instrument, scientific activities must be interpreted as the production of information and knowledge. As the results of this production are taken up and used, they are combined with other types of knowledge in complex ways for which the 'linear model' is only a crude approximation. The result is arguably, and in some cases measurably, an improvement in economic output and productivity. The robustness and reliability of efforts to assess the returns to science fall short of standards that are employed in allocating public investment resources. Nonetheless, virtually every systematic study of the contribution of science to economy has found appreciable returns to this social investment. The goals of improving standards for resource allocation and management may be better served, however, by analyzing science as a social institution.

2. *Science as a Social Institution*

The economic analysis of science as a social system begins by identifying the incentives and constraints that govern the individual choices of scientists and this may reflect persistent historical features of science or contemporaneous policies. Incentives may include tangible rewards such as monetary awards, intangible, but observable, rewards such as status, and less observable rewards such as personal satisfaction. Similarly, constraints should be interpreted broadly, including not only financial limitations but also constraints stemming from institutional rules, norms, and standards of practice. The following simplified account suggests one of several ways of assembling these elements into a useful analytical framework.

Becoming a scientist requires substantial discipline and persistence in educational preparation as well as skills and talents that are very difficult to assess. Scientific training may be seen as a filter for selecting from prospective scientists those who have the ability and drive to engage in a scientific career. In addition, the original work produced during research training demonstrates the capacity of the researcher and provides a means for employers to assess the talents of the researcher (David 1994). Analyzing science education as an employment filter is a complement to more traditional studies of the scientific labor market such as those reviewed by Stephan (1996). The employment filter approach may also waste human resources by making schooling success the only indicator of potential for scientific contribution. If, for example, the social environment of the school discourages the participation or devalues the achievement of women or individuals from particular ethnic groups, the filter system will not perform as a meritocracy.

The distinctive features of science as a social system emerge when considering the incentives and constraints facing employed scientists. Although there is a real prospect of monetary reward for outstanding scientific work (Zuckerman 1992), many of the incentives governing scientific careers are related to the accumulation of professional reputation (Merton 1973). While Merton represented science as 'universalist' (open to claims from any quarter), the ability to make meaningful claims requires participation in scientific research networks, participation that is constrained by all of the social processes that exclude individuals from such social networks or fail to recognize their contribution. The incentive structure of seeking the rewards from professional recognition, and the social organization arising from it, is central to the 'new economics of science' (Dasgupta and David 1994).

The new economics of science builds upon sociological analyses (Cole and Cole 1973, Merton 1973, Price 1963) of the mechanisms of cumulative reinforcement and social reward within science. From an economic perspective, the incentive structure governing science is the result of the interactions between the requirement of public disclosure and the quest for recognition of scientific 'priority', the first discovery of a scientific result. Priority assures the alignment of individual incentives with the social goal of maximizing the scientific knowledge base (Dasgupta and David 1987). Without the link between public disclosure and the reward of priority, it seems likely that scientists would have an incentive to withhold key information necessary for the further application of their discoveries (David et al. 1999).

As Stephan (1996) observes, the specific contribution of the new economics of science is in linking this incentive and reward system to resource allocation issues. Priority not only brings a specific reward of scientific prestige and status but also increases the likelihood of greater research support. Cumulative advantage therefore not only carries the consequence of attracting attention, it also enables the recruitment of able associates and students and provides the means to support their research. These effects are described by both sociologists of science and economists as the Matthew effect after Matthew 25:29, 'For to every one who has will more be given, and he will have abundance; but from him who has not, even what he has will be taken away.' As in the original parable, it

may be argued that this allocation is appropriate since it concentrates resources in hands of those who have demonstrated the capacity to produce results.

The race to achieve priority and hence to collect the rewards offered by priority may, however, lead to inappropriate social outcomes because priority is a 'winner take all' contest. Too many resources may be applied to specific races to achieve priority and too few resources may be devoted to disseminating and adapting scientific research results (Dasgupta and David 1987, David and Foray 1995), a result that mirrors earlier literature on patent and technology discovery races (Kamien and Schwartz 1975). Moreover, the mechanisms of cumulative advantage resulting from achieving priority may reduce diversity in the conduct of scientific research. This system has the peculiarity that the researchers who have the greatest resources and freedom to depart from existing research approaches are the same ones who are responsible for creating the status quo.

The principal challenges to the view that science is a distinct social system are the growing number of scientific publications by scientists employed in private industry (Katz and Hicks 1996) and the argument that scientific knowledge is tightly bound to social networks (Callon 1994). Private investments in scientific research would appear to question the continuing validity of the 'public good' argument. For example, Callon (1994) contends that scientific results are, and have always been, strongly 'embedded' within networks of researchers and that 'public disclosure' is therefore relatively useless as a means of transfer for scientific knowledge. Gibbons et al. (1994) argue that research techniques of modern science have become so well distributed that public scientific institutions are no longer central to scientific activity.

While the arguments of both Callon and Gibbons et al. suggest that private scientific research is a direct substitute for publicly funded research, other motives for funding and publication such as gaining access to scientific networks suggest that public and private research are complementary (David et al. 1999). The growing reliance of industry on science provides a justification for investing in science to improve the 'absorption' of scientific results (Cohen and Levinthal 1989, Rosenberg 1990). Employed scientists need to be connected with other scientific research colleagues who identify 'membership' in the scientific community with publication, and labor force mobility for employed scientists requires scientific publication. Thus, it is premature to conclude that the growing performance of scientific research in industry or publication of scientific results by industrial authors heralds the end of the need for public support of science.

The growing significance of private funding of scientific research does, however, indicate the need to improve the socioeconomic analysis of the incentive and governance structures of science. Empirical work on the strategic and tactical behavior of individual scientists, research groups, and organizations is urgently needed to trace the implications of the changing environment in which the social institutions of science are evolving. Ultimately, these studies should be able to meet the goal of developing better rules for allocating and managing the resources devoted to science.

Science Education

The launch of Sputnik in 1957 almost single-handedly conferred on science education the status of an Olympic sport. A series of international comparison studies along with the increasing importance of science and technology in the global economy have nurtured this image (e.g., Schmidt et al. 1997). Stakeholders, including policy makers, natural scientists, textbook publishers, test designers, classroom teachers, business leaders, and pedagogical researchers, have responded with competing strategies for improving science education. In some countries, most notably the United States, powerful groups have mandated untested policies and unachievable educational goals—often driven by a single aspect of the problem such as textbooks, assessments, curriculum frameworks, peer learning, or technological innovation.

Experience with failed policy initiatives and ambiguous research findings has highlighted the systemic, intricate, complex, interconnected nature of science education. Innovations succeed under some circumstances, but not others. Students regularly fail to learn what they are taught, prefer ideas developed from personal experiences, and make inferences based on incomplete information. Curriculum designers often neglect these aspects of learners and expect students to absorb all the information in a textbook or learn to criticize research on ecology by studying logic puzzles (Linn and Hsi 2000, Pfundt and Duit 1991).

International studies of science learning in over 50 countries raise questions about the complex relationships between achievement and curriculum, or between interest in science and science learning, or between teachers' science knowledge and student success that many have previously taken for granted. This systemic character of science education demands a more nuanced and contextual understanding of the development of scientific understanding and the design of science instruction, as well as new research methods, referred to as design studies, to investigate the impact of innovations.

1. Developing Scientific Understanding

1.1 Knowledge Integration

Most researchers would agree that science learners engage in a process of knowledge integration, making sense of diverse information by looking for patterns and building on their own ideas (Bransford et al. 1999, Bruer 1993). Knowledge integration involves linking and connecting information, seeking and evaluating new ideas, as well as revising and reorganizing scientific ideas to make them more comprehensive and cohesive.

Designing curriculum materials to support and guide the process of knowledge integration has proven difficult. Most textbooks and even hands-on activities reflect a view of learners as absorbing information rather than attempting to integrate new ideas with their existing knowledge. Recent research provides guidance to curriculum designers by describing the interpretive, cultural, and deliberate dimensions of knowledge integration. Learners interpret new material in light of their own ideas and experiences, frequently relying on personal perspectives rather than instructed ideas. For example, science learners often believe that objects in motion come to rest, based on their extensive observations of the natural world. Learning happens in a cultural context where group norms, expectations, and supports shape learner activity. For example, when confronted with the Newtonian view that objects in motion remain in motion, many learners conclude that objects come to rest on the playground but remain in motion in science class, invoking separate norms for these distinct contexts. Individuals make deliberate decisions about their science learning, develop commitments about reusing what they learn, pay attention to some science debates

but not others, and select or avoid science as a career. For example, some students desire a cohesive account of topics like motion and seek to explain new phenomena such as the role of friction in nanotechnology, while others report with pride that they have 'forgotten everything taught in science class.' The interpretive, cultural, and deliberate dimensions of science learning apply equally to pre-college students, preservice and in-service science teachers, research partnerships, and lifelong science learners. These perspectives help clarify the nature of knowledge integration and suggest directions for design of science instruction.

1.2 Interpretive Nature of Science Learning

Learners develop scientific expertise by interpreting the facts, processes, and inquiry skills they encounter in terms of their own experiences and ideas. Experts in science develop richly connected ideas, patterns, and representations over the years and regularly test their views by interpreting complex situations, looking for anomalies, and incorporating new findings. For example, expert physicists use free body diagrams to represent mechanics problems while novices rely on the formulas they learn in class.

Piaget (1971) drew attention to the ideas that students bring to science class such as the notion that the earth is round like a pancake, or that heavier objects displace more volume. Piaget offered assimilation and accommodation as mechanisms to account for the process of knowledge integration. Vygotsky (1962) distinguished spontaneous ideas developed from personal experience such as the view that heat and temperature are the same from the instructed distinction between heat and temperature. Recent research calls for a more nuanced view of knowledge integration by showing that few learners develop a coherent perspective on scientific phenomena: most students develop 'knowledge in pieces' and retain incohesive ideas in their repertoire (diSessa 2000). Even experts may give incohesive views of phenomena when asked to explain at varied levels of granularity. For example, scientists may have difficulty designing a picnic container to keep food safe even when they have expert knowledge of molecular kinetic theory (Linn and Hsi 2000).

Science textbooks, lectures, films, and laboratory experiments often reinforce students' incoherent views of science; they offer disconnected, inaccessible ideas, and avoid complex personally-relevant problems. For example, many texts expect students to gain understanding of friction by analyzing driving on icy roads. But non-drivers and those living in warm climates find this example unfamiliar and inaccessible. Similarly, research on heat and temperature reveals that difficulties in understanding the particulate nature of matter stand in the way of interpreting the molecular-kinetic model. The engineering-based heat flow model offers a more descriptive and accessible account of many important aspects of heat and temperature such as wilderness survival or home insulation or thermal equilibrium.

Designing instruction to stimulate the interpretive process means carefully selecting new, compelling ideas to add to the views held by students and supporting students as they organize, prioritize, and compare these various ideas. This process of weighing alternative accounts of scientific phenomena can clash with student ideas about the nature of science and of science learning. Many students view science knowledge as established and science learning as memorization. To promote knowledge integration, students need to interpret dynamic examples of science in the making and they need to develop norms for their own scientific reasoning.

Students need a nuanced view of scientific investigation that contrasts methodologies and issues in each discipline. General reasoning skills and critical thinking are not sufficient. Instead, students need to distinguish the epistemological underpinnings of methodologies for exploring the fossil record, for example, from those required for study of genetic engineering. They need to recognize pertinent questions for research on earthquake-resistant housing, DNA replication, and molecular modeling. Effective knowledge integration must include an understanding of the ethical and moral dilemmas involved in diverse scientific areas, as well as the nature of scientific advances.

Research on how students make sense of science suggests some mechanisms to promote the interpretive process of knowledge integration. Clement (1991) calls for designing bridging analogies to help students make effective connections. For example, to help students understand the forces between a book and a table, Clement recommends comparing the experience of placing the book on a spring, a sponge, a mattress, and possibly, releasing it on air. Linn and Hsi (2000) call on designers to create pivotal cases that enable learners to make subtle connections and reconsider their views. For example, a pivotal scientific visualization of the relative rates of heat flow in different materials helped students interpret their personal observations that, at room temperature, metals feel colder than wood. To help students sort out alternative experiences, observations, school ideas, and intuitions, research shows the benefit of encouraging students to organize their knowledge into larger patterns, motivating students to critique alternative ideas, and establishing a taste for cohesive ideas.

1.3 Cultural Context of Science Learning

All learning occurs in a cultural context where communities respond to competing perspectives, confer status on research methods, and establish group norms and expectations. Students benefit from the cultural

context of science, for example, when they find explanations provided by peers more comprehensible than those in textbooks or when peers debate alternative views. Expert scientists have well established mechanisms for peer review, norms for publications, and standards for inquiry practices. Group norms are often institutionalized in grant guidelines, promotion policies, and journal publication standards. The cultural context of the classroom has its own characteristics that may or may not support and encourage the development of cohesive, sustained inquiry about science. Students may enact cultural norms that exclude those from groups underrepresented in science from the discourse (Wellesley College Center for Research on Women 1992, Keller 1983) or limit opportunities for students to learn from each other. Textbooks and standardized tests may privilege recall of information over sustained investigation. Images of science in curriculum materials and professional development programs may neglect societal or policy issues.

Contemporary scientific controversies, such as the current international debate about genetically modified foods, rarely become topics for science classes. As a result, students may develop flawed images of science in the making and lack ability to make a critical evaluation of news accounts of personally-relevant issues. For example, to make decisions about the cultivation and consumption of genetically-modified foods, students would ideally compare the risks from traditional agricultural practices such as hybridization to the risks from genetic modification. They would also weigh issues of economics, world hunger, and individual health. In addition, students studying this controversy would learn to distinguish comments from scientists supported by the agricultural industry, environmental protection groups, and government grants. Examining knowledge integration from a cultural perspective helps to clarify the universality of controversy in science and the advantages of creating classroom learning communities that illustrate the role of values and beliefs in scientific work (Brown 1992, Bransford and Brown 1999).

1.4 Deliberative Perspective on Science Learning

Students make deliberate decisions about science learning, their own progress, and their careers. Lifelong science learners deliberately reflect on their views, consider new accounts of scientific problems, and continuously improve their scientific understanding; they seek a robust and cohesive account of scientific phenomena. Designing instruction that develops student responsibility for science learning creates a paradox. In schools, science curriculum frameworks, standards, texts, and even recipe-driven hands-on experiences leave little opportunity for independence. Yet, the curriculum cannot possibly provide all the necessary information about science; instead, students need supervised practice in analyzing their own progress in order to guide their own learning.

Many instructional frameworks offer mechanisms leading to self-guided, intentional learning (Linn and Hsi 2000, White and Frederiksen 1998). Vygotsky (1962) drew attention to creating a 'zone of proximal development' by designing accessible challenges so that students, supported by instruction and peers, could continue to engage in knowledge integration. Vygotsky argued that, when students encounter new ideas within their zone of proximal development and have appropriate supports, they can compare and analyze spontaneous and instructed ideas, achieve more cohesive understandings, and expand their zone of proximal development. With proper support students can even invent and refine representations of their experimental findings (diSessa 2000). Others have shown that engaging students in guided reflection, analysis of their own progress, and critical review of their own or others, arguments establishes a more deliberative stance towards science learning (Linn and Hsi 2000, White and Frederikson 1998).

2. Designing Science Instruction

Design of science instruction occurs at the level of state and national standards, curriculum frameworks for science courses, materials such as textbooks or software, and activities carried out by both students and teachers. In many countries, a tension has emerged between standards that mandate fleeting coverage of a list of important scientific topics and concerns of classroom teachers that students lack opportunity to develop a disposition towards knowledge integration and lifelong science learning. As science knowledge explodes, citizens face increasingly complex science-related decisions, and individuals need to regularly update their workplace skills. To make decisions about personal health, environmental stewardship, or career advancement, students need a firm foundation in scientific understanding, as well as experience interpreting complex problems. To lead satisfying lives, students need to develop lifelong learning skills that enable them to revisit and refine their ideas and to guide their own science learning in new topic areas.

Recent research demonstrates the need to design and test materials to be sure they are promoting knowledge integration and setting learners on a path towards lifelong learning. Frameworks for design of science instruction for knowledge integration call for materials and activities that feature accessible ideas, make thinking visible, help students learn from others, and encourage self-monitoring (Bransford et al. 2000, Linn and Hsi 2000, White and Frederiksen 1998).

2.1 Designing Accessible Ideas

To promote knowledge integration, students need a designed curriculum that includes pivotal cases and

bridging analogies to help them learn. Rather than asking experts to identify the most sophisticated ideas, designers need to select the most accessible and generative ideas to add to the mix of student views. College physics courses generally start with Newton rather than Einstein; in pre-college courses one might start with everyday examples from the playground rather than the more elegant but less understandable frictionless problems.

To make the process of lifelong knowledge integration accessible, students need some experience with sustained, complex inquiry. Carrying out projects such as developing a recycling plan for a school or researching possible remedies for the worldwide threat of malaria, engage students in the process of scientific inquiry and can establish lifelong learning skills. Often, however, science courses neglect projects or provide less knowledge integration intensive experiences such as a general introduction of critical thinking or hands-on recipes for solving unambiguous problems. By using computer learning environments to help guide students as the carry out complex projects curriculum designers can foster a robust understanding of inquiry (Driver et al. 1996).

Projects take instructional time, require guidance for individual students, bring the complexities of science to life, and depend on well-designed questions. Students often confuse variables such as food and appetite, rely on flawed arguments from advertisements or other sources, and flounder because they lack criteria for critiquing their own progress. For example, when students critique projects, they may comment on neatness and spelling, rather than looking for flaws in an argument. Many teachers avoid projects because they have not developed the pedagogical skills necessary to mentor students, deal with the uncertainties of contemporary science dilemmas, or design researchable questions. Research shows that computer learning environments can make complex projects more successful by scaffolding inquiry, providing help and hints, and freeing teachers to interact with students about complex science issues (Feurzeig and Roberts 1999, Linn and Hsi 2000, White and Frederiksen 1998).

2.2 Making Thinking Visible

Students, teachers, and technological tools can make thinking visible to model the process of knowledge integration, illustrate complex ideas, and motivate critical analysis of complex situations. Learning environments, such as WorldWatcher (http://www.worldwatcher.nwu.edu/), Scientists in Action (http://peabody.Vanderbilt.edu), and the Web-Based Integrated Science Environment (WISE—http://wise.berkeley.edu) guide students in complex inquiry and make thinking visible with scientific visualizations. In these projects, students successfully debate the causes of frog deformities, evaluate the water quality in local streams, and design houses for desert climates. Research demonstrates benefits of asking students to make their thinking visible in predictions, reflections, assessments of their progress, and collaborative debate.

Technological learning environments also make student ideas visible with embedded performance assessments that capture ability to critique arguments, make predictions, and reach conclusions. Such assessments help teachers and researchers identify how best to improve innovations and provide an alternative to high stakes assessments (Heubert and Hauser 1998, Bransford et al. 1999).

2.3 Helping Students Learn from Others

When students collaboratively investigate science problems, they can prompt each other to reflect, provide explanations in the language of their peers, negotiate norms for critiques of arguments, and specialize in specific aspects of the problem. Several programs, including Kids as Global Scientists (http://www.onesky.umich.edu/) and Project Globe (http://www.globe.gov/), orchestrate contributions from students around the world to track and compare extreme weather.

Technological learning environments support global collaborations as well as collaborative debate and equitable discussion. In collaborative debate (see Science Controversies On-Line: Partnerships in Education, SCOPE, http://scope.educ.washington.edu/), students research contemporary controversies on the Internet with guidance from a learning environment, prepare their arguments often using visual argument representations, and participate in a classroom debate where every student composes a question for each presenter. Teachers have a rich sample of student work to use for assessment. Online scientific discussions engage many more students than do class discussions and also elicit more thoughtful contributions (Linn and Hsi 2000).

2.4 Promoting Autonomy and Lifelong Learning

New pedagogical practices often implemented in computer learning environments can nudge students towards deliberate, self-guided learning. Projects with personally-relevant themes capitalize on the intentions of students and motivate students to revisit ideas after science class is over. For example, students who studied deformed frogs brought news articles to their teacher years after the unit was completed. Projects can offer students a rich context, such as the rescue of an endangered animal or the analysis of the earthquake safety of their school, that raises investment in science learning.

Students need to monitor their own learning to deal with new sources of science information, such as the Internet, where persuasive messages regularly appear along with public service announcements. Helping students jointly form partnerships where multiple forms of expertise are represented, develop common norms and criteria for evaluating arguments, and deliberately review their progress prepares for situations likely to occur later in life.

3. Research Methods

Researchers have responded to the intricate complexities in science education with new research methods informed by practices in other design sciences, including medicine and engineering. In the design sciences, researchers create innovations like science curricula, drugs, or machines and study these innovations in complex settings. In education, these innovations, such as technology enhanced science projects, build on increased understanding of science learning.

Research in a design science is typically directed by a multi-disciplinary partnership. In education, partners bring expertise in a broad range of aspects of learning and instruction, including technology, pedagogy, the science disciplines, professional development, classroom activity structures, and educational policy; collaborators often have to overcome perceptions of status differences among the fields represented. By working in partnership, individuals with diverse forms of expertise can jointly contribute to each others' professional development.

Practices for design studies come from design experiments and Japanese lesson study (Brown 1992, diSessa 2000, Lewis 1995). Design studies typically start when the partnership creates an innovation, such as a new learning environment, curriculum, or assessment and have as their goal the continuous improvement of the innovation. The inspiration for innovative designs can come from laboratory investigations, prior successes, spontaneous ideas, or new technologies. Many technology-enhanced innovations have incorporated elements that have been successful in laboratory studies, like one-on-one tutoring or collaborative learning. Other innovations start with scientific technologies such as real time data collection (Bransford et al. 1999).

In design studies, partners co-design innovations and evaluations following the same philosophy so that assessments are sensitive to the goals of instruction. Partners often complain that standardized, multiple choice tests fail to tap progress in knowledge integration and complex scientific understanding. Results from assessment allow the partnership to engage in principled refinement of science instruction and can also inform future designers. Often, innovations become more flexible and adaptive as they are refined, making it easier for new teachers to tailor instruction to their students and curricular goals. Design studies may also be conducted by small groups of teachers engaging in continuous improvement of their instruction, inspired by the Japanese lesson study model. When teachers collaborate to observe each other, provide feedback, and jointly improve their practice, they develop group norms for design reviews.

Methodologies for testing innovations in complex settings and interpreting results include an eclectic mix of approaches from a broad range of fields, including classroom observations, video case studies, embedded assessments of student learning, student performance on design reviews, classroom tests, and standardized assessments, as well as longitudinal studies of students and teachers. When partnerships design rubrics for interpreting student work they develop a common perspective.

Design study research has just begun to address the complexities of science education. For example, current investigations reveal wide variation among teachers implementing science projects. In classrooms, some teachers spend up to five minutes with each group of students, while others spend less than one minute per group. In addition, some teachers, after speaking to a few small groups, recognize a common issue and communicate it to their whole class. This practice, while demanding for teachers, has substantial benefits. Developing sensitivity to student dilemmas when complex projects are underway requires the same process of knowledge integration described above and may only emerge in the second and subsequent uses of the project. The design study approach to science instruction succeeds when teachers and schools commit to multiple refinements of the same instructional activities, rather than reassigning teachers and selecting new curriculum materials annually.

4. Emerging Research Topics and Next Steps

Emerging areas for science education research include professional development and policy studies. The interpretive, cultural, and deliberate character of learning applies equally to these fields. Teachers may value lifelong science learning but have little experience connecting the science in the curriculum to their own spontaneous ideas and few insights into how to support this process in students.

Teachers taking a knowledge integration approach to instruction face complex questions such as whether to introduce genetics by emphasizing genotypes, phenotypes, the human genome, or a treatment perspective. They may discover that some students come to class believing that two unrelated people who look alike could be twins. Effective professional development should help teachers with these sorts of specific questions rather than providing general

grounding in the science discipline or glitzy experiments that confuse rather than inform students. Inspired by the Japanese lesson study approach, more and more research groups are convening and studying collaborative groups of science teachers who face similar instructional decisions. Like science students, science teachers need opportunities and encouragement to build on their spontaneous ideas about learning, instruction, and the nature of science to become proficient in guiding their own professional development.

Science policy-makers may also be viewed through this lens of interpretive, cultural, and deliberate science learning. Policy-makers frequently hold ideas about science learning that might be at odds with those held by teachers. The status differences between policy-makers, natural scientists, and classroom teachers can interfere with open and effective communication. Building a cohesive perspective on pedagogy, science teaching, and science learning has proven very difficult in almost every country. The popularity of high-stakes assessments that might be insensitive to innovation underscores the dilemma. Recent news reports that high-stakes assessments are motivating absenteeism, cheating, and unpromising teaching practices increases the problem (Heubert and Hauser 1998).

Science educators face many complex, pressing problems including the connection between science and technology literacy; the dual goals of excellence and equitable access to science careers; the tradeoffs between a focus on public understanding of science and career preparation; the role and interpretation of high stakes tests; and the challenges of balancing the number of topics in the curriculum with the advantages of science project work. If we form a global partnership for science education and jointly develop a cohesive research program on lifelong learning, we have an unprecedented opportunity to collaboratively design and continuously improve teaching, instruction, and learning.

M. C. Linn

Science Funding: Asia

Science funding refers to national expenditure, from both public and private sources, for the institutionalization and promotion of a variety of scientific activities conventionally termed research and development (R&D). These may take the form of basic, applied, and development research undertaken or sponsored across a range of science and technology (S&T) institutions in national S&T innovation systems. In the postwar era, the concept of science funding assumed considerable importance in the national policies of Asian countries. The government, both as a patron and as a powerful mediator, played a significant part in shaping the structure and direction of science funding.

In the latter half of the twentieth century, the belief in science as a symbol of 'progress' was transformed into an established policy doctrine in the Asian region.

Creating wealth from knowledge and achieving social, political, and military objectives came to be closely associated with deliberately fostering S&T activities through funding scientific research. In the mid 1990s, the Asian region accounted for 26.9 percent of the world's gross expenditure on research and development (GERD), which was US$470 billions in 1994. While Japan and newly industrializing countries (NICs) accounted for 18.6 percent, South East Asia, China, India, and other South Asian countries accounted for 0.9 percent, 4.9 percent, 2.2 percent, and 0.3 percent respectively. Within the Asian region, whereas Japan and NICs accounted for about 69 percent, other countries accounted for 31 percent of total science funding.

Three main interrelated approaches underlie the concept of science funding in Asian countries. The first approach underlines the importance and essential nature of public or government funding of R&D as a 'public good' that improves the general interest and welfare of the society or nation as a whole. The public good approach emphasizes the funding and generation of knowledge that is non-competitive, open for public access, and non-exclusive. As private firms and the market are unable to capture all of the benefits of scientific research, they often tend to under-invest in R&D, which is also a key component of the process of innovation. It is in this context that public funding becomes important by bearing the social costs of generating scientific knowledge or information. Further, numerous studies have shown that public funding of scientific research as a public good yields several social and economic benefits (see Arrow 1962, Pavitt 1991). In contrast to institutionalized and 'codified' forms of knowledge, scientific capacity in the form of 'tacit knowledge' is seen to be embodied in research personnel trained over a period of time. Thus, publicly supported training in higher educational settings and networks of professional associations and academies forms an important component of science funding.

A closely related second approach to science funding is state sponsorship of military and defense related strategic R&D. Even though there is considerable spinoff from military R&D to the non-military sectors of economy, the main rationale for the importance given to such research is national security. Most countries in the world, including those in the Asian region, spend more money on military and defense-related scientific research activities than in the civilian R&D domain.

The third approach essentially recognizes the importance of private sources of funding for scientific research. Although private patrons have always played an important part in supporting S&T-related research activities, the postwar decades, particularly the 1980s and 1990s, witnessed a remarkable shift from public to private sources of funding of science. The significance of private science funding has grown since the 1980s, as the 'linear model,' which was based on the perceived primacy of basic research, began to lose its credibility. Insights from studies on the economics of innovation came to substantiate the view that it is 'downstream' development spending in the spectrum of R&D 'that plays a crucial role in determining who gets to capture the potential rents generated by scientific research' (Rosenberg 1991, p. 345). Private industrial firms, rather than government funding, dominate this segment of R&D in Asia as in other regions. Second the importance of private industry as a source of science funding attracted considerable attention from the mid 1980s, as the success of Japan and other East Asian NICs came to be analyzed from the perspective of how these countries transferred the burden of science funding from public to private sources.

Table 1
GERD by source of funding from the late 1970s (A) to the mid-1990s (B)

	Govt		Private industry		Other nat. sources	
	A	B	A	B	A	B
Japan	30	22	70	67	—	10
NICs	43	33	52	63	3	4
SE Asia	86	58	14	27	—	15
India	89	82	12	16	—	1
China	100	82	—	15	—	3
OSA	85	78	6	8	7	14

Source: World Science Report, Unesco, Paris, 1998; CAST ASIA II, 22–30 March 1982.
OSA: Other South Asian Countries include Bangladesh, Nepal, Myanmar, Pakistan, Sri Lanka, and Mongolia.
NICS include South Korea, Taiwan, Singapore, Hong Kong.
South East Asia includes Thailand, Philippines, Malaysia, Indonesia, and Vietnam.

As the expenditure on military R&D is largely met by governments, the pattern of GERD in the Asian region can be explored in terms of public and private sources. As Table 1 shows, three broad subregions are discernible in the Asian region insofar as the source of science funding is concerned. While private industry accounts for approximately two-thirds, government accounts for one-third of the total R&D expenditure in the case of Japan and NICs. There has been a significant transformation in the increase of private funding of science in South Korea. Private sources accounted for about 2.3 percent of GDP, that is, 80 percent of total R&D funds, which is one of the highest levels in the world. In Japan, Singapore, and Taiwan, over 65 percent of total R&D spending is financed by private industry. Much of this transformation is the result of state mediation and institutional mechanisms which offer appropriate incentives for the private sector to invest in R&D.

In the second subregion of South East Asia, there has been a perceptible change in private industry's share of total R&D, which increased from 14 percent to 27 percent, whereas the government's share witness-

Table 2
GERD and military expenditure as a percentage of GDP

	GERD 1994	Military expenditure 1985	1995
Japan	3.02	1.00	1.00
NICs	1.60	5.45	4.05
SE Asia	0.50	2.95	2.20
India	0.80	3.50	2.40
China	0.50	4.90	2.30
Other Asian countries	0.38	4.60	3.50

Source: World Science Report, Unesco, Paris, 1998; World Development Reports 1998/1999; and 1999/2000.

ed a decline from 86 percent to 58 percent between the late 1970s and the mid-1990s. In Southern Asia, which comprises China, India, and other South Asian countries, the government continues to be the main patron for science funding. The private sector accounts for less than 16.5 percent. In China and India, while the proportion of private funding of R&D increased to 15 percent and 4.4 percent respectively during the late 1970s and the mid-1990s, the private sector is likely to play a more dominant role in the 2000s. This is because these countries are witnessing considerable foreign direct investment and economic restructuring which are fostering liberalization and privatization. Except in the case of the Philippines and Sri Lanka, where about a quarter of total R&D funding is met by foreign sources, foreign funding hardly plays a significant role in the Asian region as whole.

Although there is no established correlation between GERD as a percentage of GDP and economic growth rates, this indicator has assumed great significance in S&T policy discourse in the 1990s. Whereas the industrially advanced countries spend between 2 percent to 3 percent of GDP on R&D activities, middle-income countries such as the NICs and some others in the South East Asian region spend over 1.5 percent. The poorer developing countries spend less than 1 percent and the countries falling at the bottom of economic and human development rank index spend even less than 0.5 percent. This general trend is also largely borne out in Asia, as shown in Table 2. However, the relation between different types or forms of R&D and economic growth has also come into sharper focus.

Even though the of share private industry in overall R&D effort is emerging as one of the determinants of economic dynamism, some studies draw attention to various national technological activities (in relation to the national science base) which have a direct bearing on national economic performance measured in terms of productivity and export growth (see Pavitt 1998, p. 800). For instance, as shown in Table 3, the most economically dynamic NICs such as Taiwan and South Korea began with relatively weak scientific strength, as did India in the early 1980s. Nevertheless, they outperformed India by the early 1990s in terms of the change in their share of world publications, as well as in the share of registered patents in USA. Taiwan and South Korea not only spent a much higher proportion on R&D as a percentage of GDP, but the privately dominated R&D structure was such that it gave high priority to patenting. In actual terms, while Japan and South Korea filed 335,061 and 68,446 patents in their respective countries, India filed only 1545 patents in 1995–6. Further, whereas high technology exports as a proportion of total manufacturing exports in Japan, South Korea, Hong Kong, and Singapore registered 39 percent, 39 percent, 27 percent, and 71 percent respectively, India registered hardly 10 percent in 1996, which is much lower than the figure for China (21 percent) for the same year.

As indicated in Table 2, there is a good deal of military burden in most of the Asian countries. Even though there was drastic reduction in military expenditure as a percentage of GDP between 1985 and 1995 in the region, all the Asian countries and subregions still spend three to four times more on military activities than on civilian R&D. While Pakistan maintained over 6 percent, Sri Lanka increased its military expenditure as a percentage of GDP from 2.9 percent to 4.6 percent between 1985 and 1995. Japan is the only country in the Asian region that limited its military expenditure to 1 percent of GDP while spending over three times this figure on civilian R&D (3.1 percent) during the same period.

Table 3
Trends in scientific and technological performance in selected Asian countries

County	Change in share of world publications, 1993/1982	Change in share of US patents, 1993/1983	Publications per million population, 1980–84
Taiwan	5.97	12.81	23.3
South Korea	5.45	29.79	8.00
Singapore	3.53	03.20	71.6
Hong Kong	2.37	02.42	45.90
India	0.83	02.45	18.10

Source: As given in Pavitt (1998, p. 800).

In terms of the sectoral focus of R&D funding in the Asian region, a contrasting picture emerged. Japan and NICs directed their science funding to high technologies, capital, exports of engineering goods, advanced materials, modern biology, and basic research in information and communication technologies. In the 1990s, Japan, South Korea, and Singapore registered greater proportions of private sector funding than even Germany and the USA. Japan's R&D expenditures have increased eightfold over the 20 year period from 1971 to 1993, which is the highest rate of increase among the industrially developed nations.

At the other extreme are the Southern Asian countries, including China, India, Pakistan, Bangladesh, Nepal, Myanmar, and Sri Lanka, where R&D funding related to agriculture and to the manufacturing sector assumed equal importance, as over 60 percent of their populations was dependent on agriculture. Another revealing feature about countries such as China, India, and Pakistan was the importance given to military and strategic R&D, which consumed 45 to 55 percent of the total R&D budget.

In most of the South East Asian countries, the contribution of agriculture to the GDP witnessed a considerable decline in contrast to Southern Asian countries. In terms of sectoral contribution to the GDP, none of the South East Asian countries accounted for more than 26 percent (the figure for Vietnam) for agriculture in 1998. The manufacturing and service sectors witnessed unprecedented growth rates between 1980 and 1998. Though these countries spend no more than 0.5 percent of GDP on R&D, the thrust of science funding is directed to manufacturing, industrial, and service-related activities. Agricultural research consumes only 5–10 percent of the total R&D funding, much less than in the Southern Asian countries.

Science Funding: Europe

European governments invest considerable sums of money in science. This article examines the reasons why they do this, covering briefly the historical context of European science funding and highlighting current issues of concern. The focus is on government funding of science, rather than funding by industry or charities, since government has historically been the largest funder of 'science' as opposed to 'technology.' As an approximate starting point, 'science' refers to research that is undertaken to extend and deepen knowledge rather than to produce specific technological results, although the usefulness of this distinction will be questioned below. By 'science policy' what is meant is the set of objectives, institutions, and mechanisms for allocating funds to scientific research and for using the results of science for general social and political objectives (Salomon 1977). 'Europe' here only refers to Western Europe within the European Union, excluding the Eastern European countries.

1. Background

Government funding of science in Europe started in a form that would be recognizable today only after World War II, although relations between science and the state can be traced back at least as far as the Scientific Revolution in the seventeenth century (Elzinga and Jamison 1995). The history of science funding in Europe can be summarized broadly as a movement from a period of relative autonomy for scientists in the postwar period, through stages of increasing pressures for accountability and relevance, resulting in the situation today, where the majority of scientists are encouraged to direct their research towards areas that will have some socially or industrially relevant outcome.

However, this account is too simplistic. Many current concerns about science funding are based on the idea that 'pure' or 'basic' science (autonomous research concerned with questions internal to the discipline) is being sacrificed in place of 'applied' research (directed research concerned with a practical outcome), incorrectly assuming that there is an unproblematic distinction between the two (see Stokes 1997). Looking back, it can be seen that even in the late 1950s there were expectations that science should provide practical outcomes in terms of economic and social benefits, and the work that scientists were doing

at this time was not completely 'pure,' because much of it was driven by Cold War objectives. This is a demonstration of the broader point that in science policy, the categories used to describe different types of research are problematic, and one must be careful when using the traditional terminology. With these caveats in place, it is possible to trace the major influences on European science funding.

In the 1950s and 1960s, much of the technologically oriented funding of research was driven by military objectives and attempts to develop nuclear energy. In terms of science funding, this was a period of institutional development and expansion in science policy (Salomon 1977). The autonomy that scientists enjoyed at this time was based on the assumption that good science would spontaneously generate benefits. Polanyi (1962) laid out the classic argument to support this position, describing a self-governing 'Republic of Science.' He argued that because of the essential unpredictability of scientific research, government attempts to direct science would be counterproductive because they would suppress the benefits that might otherwise arise from undirected research. This influential piece can be seen as a response to Bernal's work (1939), which was partly influenced by the Soviet system and which argued that science should be centrally planned for the social good.

Another important concept of the time was the 'linear model' propounded by US science adviser Vannevar Bush (1945). In this model for justifying the funding of science, a one-way conceptual line was drawn leading from basic research to applied research to technological innovation, implying that the funding of basic research would ultimately result in benefits that would be useful to society.

But pressures on science from the rest of society were increasing. In the 1970s, there was a growing awareness of environmental problems (often themselves the results of scientific and technological developments), and European countries experienced the oil crises, with accompanying fiscal restrictions. There were increasing pressures on scientists to be accountable for the money they were spending on research. Also at this time the social sciences, especially economics, provided new methods for understanding the role of scientific research in industrial innovation and economic growth (see Freeman 1974).

In the 1980s Europe realized it had to respond to the technological and economic challenges of Japan and the US, and because of the ending of the Cold War, military incentives for funding science were no longer so pressing. Technology, industrial innovation, and competitiveness were now the main reasons for governments to fund science. Academic studies of innovation also began to question the linear model of the relationship between science and technology, described above, arguing that the process was actually more complicated (e.g., Mowery and Rosenberg 1989). This led to pressures on the previous 'contract' between government and scientists (Guston and Keniston 1994), which had been based on the assumptions of the linear model. Rather than presuming that science would provide unspecified benefits at some unspecified future time, there were greater and more specific expectations of scientists in return for public funding. This was accompanied by reductions in the growth of science budgets, producing a 'steady state' climate for scientific research, where funding was not keeping up with the rapid pace at which research was growing (see Ziman 1994).

Science policy work at this time produced tools and data for measuring and assessing science. Various techniques were developed, such as technology assessment, research evaluation, technology management, indicator-based analysis, and foresight (Irvine and Martin 1984).

In the 1990s, there was greater recognition of the importance of scientific research for innovation, with the development of new hi-tech industries that relied on fundamental scientific developments (such as biotechnology), in conjunction with other advanced technologies. There were also growing pressures for research to be relevant to social needs. Gibbons et al. (1994) argued that the 1990s have witnessed an increasing emphasis on problem-oriented, multidisciplinary research, with knowledge production having spread out to many diverse locations, and that distinctions between basic and applied science, and between science and technology, are becoming much more difficult to make.

2. *The Influence of the European Union*

Moving from a general historical context to look more specifically at the European level shows that research funding from the European Union (EU), in the form that it currently takes, did not start until 1984 with the first 'Framework Programme.' This funded pre-competitive research (i.e., research that is still some way from market commercialization) following an agenda influenced by industrial needs (Sharp 1997). From the 1960s onward, the Organization for Economic Cooperation and Development (OECD) had been a more influential multinational organization than the EU in terms of national science policies (Salomon 1977). In particular, the OECD enabled countries to compare their research activities with those of other countries, and encouraged greater uniformity across nations.

Currently EU research funding only comprises a few percent of the total research funding of all the member states (European Commission 1994), although it has been more important in the 'less favored' regions of Europe (Peterson and Sharp 1998). Consequently, in terms of science funding, the national sources are more important than the EU. However, EU programs do have an influence on the funding priorities of national governments. In theory, the EU

does not fund research that is better funded by nation states (according to the 'principle of subsidiarity,' see Sharp 1997), so it does not fund much basic research, but is primarily involved in funding research that is directed towards social or industrial needs.

The most important impact of the EU has been in stimulating international collaboration and helping to form new networks, encouraging the spread of skills. One of the requirements of EU funded projects is that they must involve researchers from at least two countries (Sharp 1997). This could be seen as part of a wider political project that is helping to bind Europe together. It is possible that many of these collaborations might have happened without European encouragement because of a steady rise in all international collaborations (Narin et al. 1991). However, it is likely that through its collaborative programs and their influence, the EU will play an increasingly important role in the future of research funding in the member countries (Senker 1999).

3. *Individual Countries in Europe*

Since it is the individual countries in Europe that are responsible for the majority of science funding, the organization of their research systems deserves attention.

All the countries have shown the general trends outlined above, but the historical and cultural differences among the European nations lead to considerable diversity in science funding arrangements. It is possible to compare the different countries by looking at the reasons why they fund science and the ways in which research is organized.

European nations, like those elsewhere, have traditionally funded science to encourage economic development, although most countries also attach importance to advancing knowledge for its own sake. Some countries such as Sweden and Germany have emphasized the advancement of knowledge, and other countries, such as Ireland, have put more emphasis on economic development (Senker 1999). Since the 1980s, the economically important role of science has been emphasized in every country. This has often been reflected at an organizational level with the integration of ministerial responsibilities for science funding with those for technology and higher education.

We can compare individual countries in terms of differences in the motivations behind funding research. Governments in France and Italy have traditionally promoted 'prestige' research, and have funded large technology projects, such as nuclear energy. These reasons for funding research, even though they are less significant in the present climate, have had long-lasting effects on the organization of the national research systems. The UK is notable in that the importance of science for economic competitiveness is emphasized more than in other European countries, and industrial concerns have played a larger role (Rip 1996).

Organizational differences between countries can tell us something about the way research funding is conceptualized and can reflect national attitudes toward the autonomy and accountability of researchers. In the different European countries, the locus of scientific research varies. In some countries, the universities are most important (e.g., Scandinavia, Netherlands, UK), and funds are competed for from research councils (institutions that mediate between scientists and the state, see Rip 1996). In this type of system there will usually be some additional university funding that provides the infrastructure, and some of the salaries. The level of this funding varies between countries, which results in differences in scientists' dependence on securing research council funds and has implications for researcher autonomy. In other countries, a great deal of scientific research is carried out in institutions that are separate from the universities (e.g., France and Italy).

The situation is not static, and scientific research in the university sector has been growing in importance across the whole of Europe (Senker 1999). For example, in France, the science funding system has traditionally been centralized with most research carried out in the laboratories of the Centre National de la Recherche Scientifique (CNRS). Now the situation is changing and universities are becoming more involved in the running of CNRS labs, because universities are perceived to be more flexible and responsive to user needs (Senker 1999). Germany is an interesting case because there is a diversity of institutions involved in the funding of science. There is a division of responsibility between the federal state and the Länder, which are responsible for the universities. There are also several other types of research institute, including the Max Planck institutes, which do basic research, and the more technologically-oriented Fraunhofer institutes. Resulting institutional distinctions between different types of research may lead to rigidities in the system (Rip 1996). In all countries in Europe, there is an attempt to increase coordination between different parts of the national research system (Senker 1999).

4. *Current Trends*

As has been emphasized throughout, European governments have demanded increasing relevance of scientific results and accountability from scientists in return for funding research. Although the situation is complex, it is clear that these pressures, and especially the rhetoric surrounding them, increased significantly during the 1990s. This has led to worries about the place for serendipitous research in a 'utilitarian–instrumental' climate (Nowotny 1997, p. 87).

These pressures on science to be useful are not the only notable feature of the current funding situation. The views of the public are also becoming more important in decisions concerning the funding of science.

The risks and detrimental effects of science are of particular concern to the public, possibly because the legitimacy of the authority of politicians and scientists is being gradually eroded (Irwin and Wynne 1996). Throughout Europe, there has been a growth in public distrust in technological developments, which has led to pressures for wider participation in the scientific process. This is related to the current (and somewhat desperate) emphasis on the 'public understanding of science,' which is no longer simply about educating the public in scientific matters, but has moved towards increasing participation in the scientific process (see Gregory and Miller 1998). Concerns about the environmental effects of scientific developments can be traced back to the 1960s, but recent incidents in the 1980s and 1990s have led to a more radical diminution of public faith in scientific experts (with issues such as climate change, Chernobyl, and genetically modified foods).

The public distrust of science may also be due to the fact that scientists, by linking their work more closely either to industrial needs or to priorities set by government, are losing their previously autonomous and potentially critical vantage point in relation to both industry and government.

Certain European countries, especially the Netherlands and Scandinavia, which have a tradition of public participation, are involving the public more in debates and priority setting on scientific and technological issues. This has been described as a 'post-modern' research system (Rip 1996). As the distinction between science and technology becomes less clear, in this type of research system there is also a blurring of boundaries between science and society.

5. *Implications*

An implication of these changes in science funding is that the growing importance of accountability and of the role of the public in scientific decisions may have epistemological effects on the science itself, since scientific standards will be determined not only by the scientific community but by a wider body of actors often with divergent interests (Funtowicz and Ravetz 1993).

If norms are linked to institutions, and if institutions are changing because of the greater involvement of external actors in science, and of science in other arenas, then the norms may be changing too (Elzinga 1997). This is an issue that was touched on in the 1970s and 1980s by the proponents of the 'finalization thesis' who argued that, as scientific disciplines become more mature, they become more amenable to external steering (Böhme et al. 1983). The importance of external influences leads to worries about threats to traditional values of what constitutes 'good' science (Elzinga 1997, see also Guston and Keniston 1994 for US parallels). There may be an emergence of new standards of evaluation of scientific research.

European science funding has changed considerably since it was institutionalized, partly because of its success in generating new technologies and partly because of its failures and their social consequences. It is becoming more difficult to categorize science, technology, and society as separate entities (Jasanoff et al. 1995), or to think of pure scientists as different from those doing applied research. Wider society has become inextricably linked with the progress of science and the demands placed on scientists and science-funding mechanisms are starting to reflect this restructuring. This tendency is likely to continue into the future.

Science Funding: United States

The pursuit of knowledge has historically been shaped by patronage relationships. The earliest scientists were astronomers and mathematicians supported at ancient courts in the Middle East and China. In Renaissance Europe, observers of and experimenters with nature had patrons in the aristocracy or royal families. In nineteenth century America, industrial philanthropists took up their cause.

Since World War II, research in the United States has received its support largely from government, with help from industry and private foundations. This article focuses on the postwar history of government funding for research in the United States. That history has been characterized by a creative tension between autonomy and accountability, embodied in successive waves of invention of new institutional arrangements. Should science set its own agenda, or should it answer to the public? Could the two goals be reconciled? These issues have echoed through five decades of research policy.

1. Autonomy for Prosperity

In the eighteenth and nineteenth centuries, the US federal government funded research only if it was applied directly to practical goals. The earliest federal efforts were in surveying and geological exploration, activities that contributed both to nation-building and to the search for mineral wealth. A second major wave of federal effort in the latter half of the nineteenth century took up agricultural research in partnership with the States, through land grant colleges and agricultural experiment stations. Scientists were also brought in to solve the immediate problems of wartime. World War I was known as 'the chemists' war,' because of the use of chemical warfare agents. World War II became 'the physicists' war,' with the invention of the atomic bomb. And in the 1930s, a small federal laboratory for health research was established, which later became the National Institutes of Health, the nation's research arm for biomedical sciences (Dupree 1964, Kevles 1978, Strickland 1989).

By the time of World War II, these efforts had grown into a set of research programs in mission agencies, focused on food, health, and defense. These activities were carried out largely in government laboratories, and were focused on immediate, practical goals. In later decades, two other agencies joined this group. The National Aeronautics and Space Administration (NASA) was formed in response to the launching of a Russian satellite, the Sputnik, in 1957 (Logsdon 2000). And the Department of Energy, when it was established in the 1970s, incorporated major research elements, including the high-energy physics laboratories. This array of government research efforts continues to anchor the mission-oriented portion of a pluralistic system of funding for US research.

The other dimension of that system is fundamental research. It is anchored in universities, and interwoven with graduate education and the preparation of new generations of researchers. This second dimension has its origins in moments of national crisis, when government research efforts were expanded temporarily through the cooptation of university researchers. After such an interlude in World War I, influential US scientists tried to convince the federal government to keep the research relationship with universities going, but to no avail. It was only after the success of the crucial atomic bomb project that the achievements of science carried enough weight to make credible proposals for permanent, across-the-board government support for research (Kevles 1978).

The spokesperson for this plan was Vannevar Bush, a university scientist who had been active in the government projects around the war. He called for the formation of a National Research Foundation, to provide basic support for research, without the specific targets that had been imposed during the war. He argued that unfettered research, carried out largely in

Figure 1
US basic research spending, 1953–1998, total and Federal

universities, would build a base of human and knowledge resources that would help solve problems across the range of challenges in health, defense, and the economy (Bush 1990 [1945]).

But to make these contributions, researchers needed freedom—both freedom in the laboratory to choose and pursue research problems, and organizational freedom at the level of government agencies, to set the larger research agenda in directions that were free from political control. Bush's model of the relationship between science and society has been called the 'autonomy for prosperity' model (Cozzens 2001). Most of the experimentation over the next few decades with ways to maintain autonomy while being useful took the form of add-ons to this model.

Bush's model built a protective shell of organizational autonomy around the agencies that provided funds for basic research. The National Science Foundation (NSF) and the National Institutes of Health (NIH), both of which grew very fast in the postwar period, developed strategies that insulated direct decisions around research from the political context. One funding mechanism that embodied the essence of the autonomy-for-prosperity model in its early days was the science development program. Under these programs in the 1950s and 1960s, federal block grants allowed universities to build their educational and research capacities, with very few strings attached (Drew 1985). The second strategy was the project grant/peer review system of funding. Under this mechanism, the government hands over choice of research topics as well as the judgment of what is to count as quality into the hands of researchers. 'Peer review' for project selection became both the major form of quality control in the federal funding system and an important symbol of scientific freedom (Chubin and Hackett 1990).

Ironically, the autonomy-protecting institutional shell that Bush and his successors designed undermined the practical effectiveness that had won credibility for his plan to start with. As government funding for research grew rapidly in the 1950s, beyond the scale of Vannevar Bush's wildest dreams, the institutional shell unintentionally created a protected space where new researchers could do their work without any grounding in the practical problems of the world. As soon as the practical grounding was lost, a gap was created between science and society that needed to be bridged if autonomy was really going to be turned into prosperity.

2. Knowledge Transfer and Knowledge Mandating

Among the first set of funding methods developed to bridge this gap were knowledge transfer mechanisms. Knowledge transfer mechanisms do not threaten either laboratory or organizational autonomy, because they leave the protective shell in place while focusing on diffusing or disseminating research-based knowledge. For example, in the 1960s and 1970s, many federal programs addressed the 'information explosion' with 'science information services,' under the rubric of 'information policy.' The government encouraged first journals, then abstracting and indexing services, to provide access to the exploding journal literature, and later added extension services. The emphasis was on providing infrastructure for communication, not shaping its content; science was to speak to the public, not with it. These mechanisms protect research autonomy by segmenting knowledge processes over time.

As the size of the research enterprise continued to grow, however, the pendulum swung back and the accountability issue inevitably arose. Elected representatives of the public asked 'What are we getting for all this spending?' In the absence of specific answers, a backlash eventually appeared. Policymakers began to demand that research solve societal problems directly, rather than through the diffuse claim of 'autonomy for prosperity.' In 1969, for example, Congress passed 'the Mansfield amendment,' limiting support from the Department of Defense to goal-directed research. The Nixon administration phased out science development programs. And in the 1970s, several 'knowledge mandating' programs appeared. At NSF, for example, the Program of Research Applied to National Needs (RANN) grew out of a Presidential concern about 'too much research being done for the sake of research.' (Mogee 1973). At NIH, the 'War on Cancer' emerged during the same period (Strickland 1989, Rettig 1977).

In their more programmed forms, such programs threatened both individual and organizational autonomy. But even in softer forms, in which money was only redirected from one priority to another, they still threatened organizational autonomy, since external forces were dictating research directions. There is an important lesson in the history of these programs: over time, organizational autonomy won out over societal knowledge mandating. RANN was abolished, and over the years, both NSF and NIH have found ways to look programmatic without doing central planning.

3. Knowledge Sharing

By the mid-1970s, a third approach began to be developed in the United States to bridge the gap between the science produced inside the protective institutional shell and the problems of the world surrounding it. This new form threatened neither the individual autonomy of researchers nor the organizational autonomy of funding organizations. This new form can be called 'knowledge-sharing.'

This approach first took the form of an emphasis on partnerships, and within that emphasis, an early focus on partnerships with industry. New centers involved industry partners in setting strategic plans. The interchange of people and information became the rule. The critical element in these was a two-way dialog, which replaced the one-way science-to-society diffusion of information of knowledge transfer and the one-way society-to-science mechanism of knowledge mandating. In the two-way dialog, scientists became strategic thinkers, able to formulate their own problems creatively, but steeped again, as in the 1950s, in the problems articulated by some external set of partners. Another new element was the explicit link to education, at both graduate and undergraduate levels. The Engineering Research Centers of the NFS, for example, were intended to produce a 'new breed' of engineers, better prepared than previous generations to participate in R&D in industry because they understood the needs and culture of industry.

This new partnership model raised questions: Was knowledge mandating being changed from a public function to a private one under this scheme? A change in the law that allowed universities to hold intellectual property rights in results produced under government grants further heightened these concerns. Public knowledge seemed to be on a path to privatization. At the same time, several well-publicized instances of accusations of fraud in science seemed to undermine the trusting relationships among citizens, government, and science (Guston 1999).

In the late 1980s, however, a second crucial step in the development of the partnership model took place. This was a step back toward the public. Centers were urged to form partnerships, not only with industry, but also with State and local governments, citizen groups, and schools. The benefits that industry gained from earlier collaborations were now available to other parts of society, in a new pattern that has been called 'partner pluralism' (Cozzens 2001). Strategic plans began to be shaped by two-way dialog across many sectors, and the education of a new breed of researcher able to bridge the cultures of university, school, and public service sector began.

Another manifestation of knowledge-sharing and an attempt to restore public trust arrived with a round of attention among researchers to public awareness of science and science education. The 1990s heard a new note in the discussions of the public among science leaders. Research leaders stressed that scientists need to learn more about the public, as well as the public learning more about science. Even the venerable National Academy of Sciences recommended that the institutions of science open their doors to the public,

urging, for example, that NIH take more advice from the public in priority-setting. These were signs of the beginning of a two-way dialog.

4. The Knowledge Society

As US research entered the twenty-first century, many believed that knowledge is the key resource in the new economy. For a society to be innovative, however, its creative capacity must be widely shared. This goal will not be achieved unless its scientists become strategic thinkers steeped in society's problems and issues, and government funding agencies remain public through partner pluralism. Accountability for research in the knowledge society is achieved through the engagement of many societal actors in the research enterprise. By placing many actors on an equal footing and encouraging two-way dialog, research policy in the twenty-first century will help stimulate shared creativity, and open a new path to prosperity.

Science, New Forms of

In recent times, there has been a growing sense that 'science' is not merely expanding in its grasp of the natural world, but that the activity itself is changing significantly. For this we use the term 'new forms of science,' understanding both the practice and the reflection on it. Since science is now a central cultural symbol, changes in the image of science rank in importance with those in the practice itself. Our situation now is one of the differentiation of a practice that hitherto seemed unified, and of conflict replacing consensus on many issues, some of which had been settled centuries ago. The prospect for the immediate future is for a social activity of science that no longer has a unified core for its self-consciousness and its public image.

The main baseline for this 'novelty' is roughly the century preceding World War II, when the 'academic' mode of scientific activity became dominant. This was characterized by the displacement of invention and diffusion by disciplinary research, and of amateurs (with private means or patronage) by research professionals (perhaps with a partial sinecure in advanced teaching). In the latter part of this period, the mathematical–experimental sciences took the highest prestige away from the descriptive field sciences. The social sciences were increasingly pressured to conform to the dominant image. And throughout, the consciousness of the activity, reflected in scholarly history and philosophy as well as in popularization, was triumphalist and complacent. There could be no way to doubt that the idealistic scientists, exploring nature for its own sake, inevitably make discoveries that eventually enrich all humanity both culturally and materially.

Of course, any 'period' in a social activity is an intellectual construct. Closer analyses will always reveal change and diversity within it; and it contains both relics of the deeper past and germs of the future. But occasionally there occurs a transforming event, so that with all the continuities in practice there is a discontinuity in consciousness. In the case of recent science, this was the Manhattan Project, in which the first atomic bombs were designed and constructed in a

gigantic scientific engineering enterprise. It was of particular symbolic significance that the project was conceived and managed, not by humble 'applied scientists' or engineers, but by the elite theoretical physicists. It was science itself that was implicated in the moral ambiguities and political machinations that ensued in the new age of nuclear terror.

After the Bomb, it was no longer possible to build scholarly analyses on assumptions of the essential innocence of science and the beneficence of scientists. Prewar studies in the sociology of science, such as those of Merton (with his 'four norms'), which assumed a purity in the endeavor and its adherents, could later find echoes only in those of the amateur philosopher Polanyi (1951), himself embattled against J. D. Bernal and the Marxist 'planners' of science (1939). But it took about a decade for a critical consciousness to start to take shape. Those scientists who shared the guilt and fear about atomic weapons still saw the cure in educating society, as through the *Bulletin of the Atomic Scientists*, rather than wondering whether science itself had taken a wrong turning somewhere. Leo Szilard (1961) imagined an institute run by wise scientists that would solve the world's problems; and Jacob Bronowski (1961) faced the problem of the responsibility of science for the Bomb, only to deny it absolutely. The vision of Vannevar Bush (1945), of science as a new and endless frontier for America, continued the prewar perspective into postwar funding.

The first significant novelty in the study of science was accomplished in the 1950s by Derek J. de Solla Price (1963). Although his quantitative method seemed at times to be a caricature of science itself, he was submitting scientific production to an objective scrutiny that had hitherto seemed irrelevant or verging on irreverent. And he produced the first 'limits to growth' result; with a doubling time (steady over three centuries!) of 15 years, compared to some 70 in the economy, sooner or later society would refuse to foot the bill. Since the prevailing attitude among scientists was that society's sole contribution to science should be a blank check, Price's bleak forecast, however vague in its timing, was not well received. He went on to give the first characterization of the new age of science; but he only called it 'big,' as opposed to the 'little' of bygone ages.

A more serious disenchantment motivated Thomas S. Kuhn. He had imbibed the naive progressive image of science, whereby truths were piled on truths, and scientists erred only through bad methods or bad attitudes. Then it all cracked, and he wrote his seminal work on *Scientific Revolutions* (1962), all the more powerful because of its confusions and unconscious ironies. Whether he actually approved of routinized puzzle-solving 'normal science' was not clear for many years; to idealists like Popper, Kuhn's flat vision of science represented a threat to science and to civilization (1970).

Through the turbulent 1960s, more systematically radical social critiques began to emerge. Of these, the most cautious was that of John Ziman's *Public Knowledge* (1968), and the most ambiguous that of Jerome Ravetz (combining *Gemeinschaft* craftsmen's science, Nuclear Disarmament, and the Counterculture, but ending his book with a prayer by Francis Bacon) (1996, [1971]). An attempt at a coherent Marxist perspective was mounted by Steven and Hilary Rose (1976). This was enlivened by their internal tension between Old and New Left, but with the complete discrediting of Soviet socialism, it was soon relegated to purely historical significance. A serious attempt at an objective social study of science was made by N. D. Ellis (*The Scientific Worker* 1969) but there was then no audience for such an approach. Another premature social analysis of science came to light around then. This was the work of Ludwik Fleck (1979 [1935]) on the 'genesis and development of a scientific fact'; at the time of its publication and for long after, the very title smacked of heresy.

At the same time, the new dominant social practice of science, either 'industrialized' (Ravetz) or 'incorporated' (the Roses) took shape. The prophetic words of President Eisenhower on the corrupting influence of state sponsorship were little heeded; and an American science that was both 'pure' and 'big' produced its first muckraker, in Dan Greenberg (1967), a Washington correspondent for *Science* magazine. There was a short but sharp protest at the militarization of science in the Vietnam War (Allen 1970), out of which came various attempts at organizing for 'social responsibility in science.'

On the ideological front, there was a collapse of attempts to preserve science as the embodiment of the Good and the True. Somewhat too late for the 1960s but revolutionary nonetheless, Paul Feyerabend published *Against Method*, in which even the rearguard defenses of Popper (1963) and Lakatos (1970) were demolished. Then came the tongue-in-cheek naive anthropology of *Laboratory Life* (Latour and Woolgar 1977), considering scientists as a special tribe producing 'inscriptions' which were intended to gain respect and to rebut hostile criticism. A radically skeptical theory of scientific knowledge was elaborated in sociological studies called 'constructivism.'

As prewar science receded in time and relevance, scholars could settle down to the analysis of this new form of social practice of science in its own terms. Early in the postwar period there had been a conception that scientists in the public arena should be 'on tap but not on top,' a sort of 'drip' theory of their function. But more sophisticated analyses began to emerge. Among these was 'mandated science' (Salter 1988), in which the pitfalls of well-intentioned involvement were chronicled. The special uses and adaptations of science in the regulatory process and in the advisory function were analyzed (Jasanoff 1990). In such studies, it became clear that neither 'science'

nor 'scientist' can be left as elements outside the process; indeed, the old Latin motto 'who guards the guardians?' reminds us of the essentially recursive nature of the regulatory process. For (as Jasanoff showed) those who regulate or advise act by certain criteria and are also selected for their position; and who sets the criteria, and who chooses the agents, can determine the whole process before the scientist-advisors even get to work.

Meanwhile the existing trends in the social practice of science were intensified. Physics lost the preeminence it had gained through winning the war with the Atomic Bomb. Civil nuclear power (which was really engineering anyway) failed to live up to its early promise, producing not only disasters (near and actual) in practice but also intractable problems in waste management. The core of basic physics research, high-energy studies, was caught in a cul-de-sac of ever more expensive machines hunting ever more esoteric particles. It may also have suffered from its overwhelming reliance, not covert but not widely advertised either, on the US military for its funding. Then physics was caught up in the debate over 'Star Wars,' which was controversial not merely on its possible political consequences, but even on the question of whether it could ever work as claimed. In this case, it appeared that the technical criteria of quality were totally outweighed by the political and fiscal.

The focus of leading-edge research shifted to biology, initiated by the epochal discovery of the structure of the genetic material DNA, the 'double helix.' There was a steady growth in the depth of knowledge and in the power of tools in molecular biology. This was punctuated in the 1970s by an episode of discovery of, and reaction to, possible hazards of research. In an unprecedented move, the 'recombinant DNA' research community declared a moratorium on certain experiments, until the hazards had been identified and regulated. Critics of the research interpreted this as an admission that the hazards were real rather than merely hypothetical. There was a brief period (1976–7) of confrontation in the USA, complicated by some traditional town–gown antagonisms and by relics of Vietnam activism. But it soon died down, having served partly to stimulate interest in the research but also planting the seeds of future disputes.

Another novelty in this period was the emergence of ethics as a systematic concern of science. Qualms about the uses of science in warfare go back a long way (Descartes 1638 has a significant statement), as well as disputes over priority and honesty. But with the Bomb, the possibility of science being turned to evil ends became very real; and with the loss of innocence in this respect, other sorts of complaints could get a hearing. Medical research is the most vulnerable to criticism, since the subjects are humans (or other sentient beings) and there must be a balance between their personal interests and those of the research (and hence of the broader community). But some cases went too far, as that of the African-American men who (in the 1930s) were not given treatment for syphilis, so that their degeneration could be recorded for science. Also, there were revelations of some of the more bizarre episodes of military science at the height of the Cold War, such as subjecting unwitting human subjects either to nuclear radiation or to psychotropic drugs. Since some universities shared responsibility with the military for such outrages, the whole of science could not but be tarnished. Out of all this came a problem of the sort that could not have been imagined in the days of little science: activism, to the point of terror tactics, against scientists and labs accused of cruelty to animals.

A further loss of innocence was incurred in the realization of the Marxist vision of science as 'the second derivative of production,' albeit under conditions that Marxists did not anticipate. Now 'curiosity-driven,' or even 'investigator-initiated' research, forms a dwindling minority within the whole enterprise. The days when the (British) Medical Research Council could simply 'back promising chaps' are long since gone. Increasingly, research is mission oriented, with the missions being defined by the large institutions, public and private, possessing the means and legitimacy to do so. Again, it is in biology, or rather bioengineering, where the change is most remarked. With genetic engineering, science is increasingly caught up in the globalization, or rather commodification, of everything that can be manipulated, be it life-forms or even human personality. When firms are accused of bio-piracy (appropriating plants or genetic materials from local people, and then patenting them), this is not exactly new, since it was also practiced by the illustrious Kew Gardens in Victorian times. But such practices are no longer acceptable in the world community (a useful survey of these issues is to be found in Proctor 1991, Chap. 17).

The social organization of science has changed in order to accommodate to these new tasks and circumstances. The rather vague term 'mode 2' has been coined to describe this novel situation (Gibbons et al. 1994). In the terms of this analysis of a condition which is still developing, scientists are reduced to proletarians, neither having control over the intellectual property in the products of their work (since it is done largely on contracts with various restrictions on publication), nor even the definable skills of disciplinary science (since most projects fall between traditional boundaries). The discussion in the book provides a useful term for this sort of science: 'fungible.' For the research workers become a convertible resource, being shipped from project to project, to be reassigned or discarded as convenient. There are all sorts of tensions within such a new dispensation, perhaps most notably the contradictory position of the educational institutions, whose particular sort of excellence may not be compatible with

the demands of the new labor market and research regime.

With the fragmentation and globalization of politics, other new sorts of scientific practice are emerging, not continuous with the evolving mainstream institutions but either independent of, or in opposition to, them. The leading environmental organizations have their own scientific staff who debate regularly with those promoting controversial projects. Increasingly, 'the public' (or representatives of the more aware and critical sections of it) is drawn into deliberative processes for the evaluation and planning of developments in technology and medicine. In some respects a 'stakeholder society' in science is emerging, engaged in debate on issues that had hitherto been left for the experts and politicians to decide. Movements for 'community research' are emerging in the USA (with a focus in the Loka Foundation) and elsewhere.

This development can be seen as an appropriate response to an emerging new major task for science. In the process of succeeding so brilliantly in both discovery and invention, science has thrown up problems that can be loosely defined as risk. The tasks here have significant differences from those of the traditional scientific or technical problems. For one, problems of risk and safety are inherently complex, involving the natural world, technical systems, people, institutions, values, uncertainties, and ignorance. Isolated, reductionist studies of the 'normal science' sort may be an essential component, but cannot determine a policy. Further, 'safety' can never be conclusively established, not merely because it is impossible to prove impossibility, but more because the evidence of causation is either only suggestive (as from toxicological experiments with acute doses on non-human species) or indirect (as from epidemiological studies).

In the debates on managing risk, methodology becomes politicized, as it is realized that the assignment of burden of proof (reflected in the design of statistical studies and of experiments) can be critical in determining the result that goes forward into the policy process. Conflict of interest becomes difficult to avoid, since most opportunities for achieving expertise are gained through work with the interests promoting, rather than with those criticizing, new developments. Also, the debates take place in public forums, such as the media, activist campaigning, or the courts, each of which produces its characteristic distortions on the process.

One response to this increased public involvement has been a variety of recommendations, from respected and even official sources, for greater openness and transparency in the science policy process. In some respects, this is only prudence. In the UK, the controversy over 'mad cow disease' (or the BSE catastrophe) could fester for a decade only because of official control of knowledge and ignorance. In its aftermath, the development of genetically engineered food crops was threatened by 'consumer power' in Europe and beyond. Expressed negatively, we can be said to be living in a 'risk society' (Beck 1992), where new forms of political activity are fostered by the consequences of an inadequately controlled science–technology system (Sclove 1995, Raffensperger 1999). The assumption of beneficence of that system is now wearing thin; thus the mainstream British journal *New Scientist* made this comment on the mapping of the human genome: 'For all our nascent genetic knowledge, if we end up with our genes owned by rich corporations and [with] a genetic underclass, will we really have advanced that much?' (2000)

There is no doubt that a significantly modified practice and image of science will be necessary for these new tasks of managing risks in the current social and political context. If nothing else, traditional science assumed that values were irrelevant to its work (this was, paradoxically, one of its great claims to value), and that uncertainties could be managed by technical routines (such as statistics). This was the methodological basis for the restriction of legitimacy to experts and researchers whose 'normal science' training had rigorously excluded such considerations. With uncertainty (extending even to salient ignorance) and value loading involved in any study of risk or safety, we are firmly in a period where a 'post-normal' conception of science is appropriate (Funtowicz and Ravetz 1993).

The core of this new conception is 'quality,' since 'truth' is a luxury in contexts where, typically, facts are uncertain, values in dispute, stakes high, and decisions urgent. Under these circumstances, there is a need for an 'extended peer community' for the assurance of the quality of the scientific inputs, supplementing the existing communities of subject specialists and clients. And this new body of peers will have its own 'extended facts.' The materials for this new sort of science involve not only the operations of the natural world, but also the behavior of technical systems and the social systems of control. Therefore, information of new sorts becomes relevant, including local knowledge and commitments, investigative journalism, and published confidential reports. Although 'post-normal science' has its political aspects, this proposed extension of legitimacy of participation in a scientific process is not based on political objectives. It is a general conception of the appropriate methodological response to this new predicament of science, where the tasks of managing risks and ensuring safety cannot be left to the community of accredited scientific experts alone.

This account of new forms of science would be incomplete without mention of a tendency which was thought to have been laid to rest long ago, as superstition unworthy of a civilized society. Coming in through East Asian practices of medicine and South Asian practices of consciousness, enriched cosmologies, involving 'vibrations' and 'energies' have become popular, even chic. The reduction of reality to its

mathematical dimensions, which was the metaphysical core of the Scientific Revolution, is now being eroded in the practice of unconventional medicine. Although this has not yet touched the core of either research or the policy sciences, it is a presence, alien to our inherited scientific culture, which cannot be ignored.

We are coming to the end of a period lasting several centuries, when in spite of all the major developments and internal divisions and conflicts, it made sense to speak of 'science' as an activity on which there was little disagreement on fundamentals. The very successes of that science have led to new challenges, from which significantly novel forms of science are emerging, characterized by equally novel forms of engagement with society.

Science, Social Organization of

The sociology of science has been divided since about 1980 between those contending that science gains sociological significance because of its organizational location and forms, and those arguing that it should be understood for its knowledge-building practices. The two groups have tended to treat social organization in completely different ways, and have consciously developed their ideas in opposition to the others. However, both have used some notion of the social organization of science to explain the constitution of facts about nature and the development of ways of reworking nature for strategic advantage.

The tensions between the schools have been productive of new approaches to organizations and the operation of power. A scholar like Jasanoff, interested in political process and expertise, has used constructivist theories of scientific knowledge to show how central science has become to the legal system and regulatory structures (Jasanoff 1990). In contrast, a researcher like Bruno Latour, interested in the social struggles involved in making science 'real,' has demonstrated how the laboratory has become productive of powers that shape contemporary life (Latour 1993). This work, and much more like it, has begun to suggest

the fundamental ways that contemporary political systems and other major institutions depend on science and technology for their forms, operations, and legitimacy.

It would have been hard for sociologists to entirely avoid the correlation between the growth of modern States and the so-called scientific revolution, and the questions it raises about power and control of the natural world. Courts in the fifteenth and sixteenth centuries used scientists to help design military technology, do political astrology, and make the earth into a showplace of power (Grafton 1999, Masters 1998). Even members of the Royal Society in the seventeenth century (often depicted as a politically independent organization for science) dedicated much effort to addressing public problems with their research (Webster 1976). Practical as well as conceptual arts like cartography gained importance in Italy, France, and England as a tool for trade and territorial control. Double entry bookkeeping provided a way of legitimating both commerce and governmental actions through the management of 'facts' (Poovey 1998). Botany and the plant trade, particularly in Spain, The Netherlands, and France, enriched the food supply and increased the stock of medicinal herbs. Italian engineers tried to tame rivers, the Dutch and French built canals (Masters 1998), the English deployed medical police to ensure public health (Carroll 1998), and the French, English, and Germans worked on forestry (Scott 1998). Military engineering throughout Europe was revolutionized with a combination of classical architectural principles, and new uses of cannon fire and other weapons (Mukerji 1997). As Patrick Carroll argues, technoscience was not a product of the twentieth century, but already part of the culture of science (the engine science) of the seventeenth century (Carroll 1998). The point of science and engineering in this period was human efficacy, the demonstration of human capacities to know the world and transform it for effect. One manifestation of this was the cultivation of personal genius and individual curiosity, yielding a dispassionate science, but another was the constitution of political territories that were engineered for economic development and political legibility, and managed (in part) to maintain the strength and health of the population (Mukerji 1997, Scott 1998).

1. *Functionalist Foundations of the Sociology of Science*

The early sociologists of science, such as Merton and Ben-David, took for granted both historical and contemporary links between science and state power. They were steeped in the sociological literature on organizations that defined technology, at least, as central to the organization of major institutions—from the military to industry. Merton in his dissertation recognized the historical interest of courts and States in scientists and engineers, but traced the development of a disinterested culture of science, emanating from the places where thought was at least nominally insulated from political pollution: universities, scientific societies, and professional journals (Merton 1973, Crane 1972). Looking more directly at politics and science, Ben-David (1971), still interested in how social organization could promote excellence in science, considered differences in the organization of national science systems and their effects on thought. He assumed a kind of Mannheimian sociology of knowledge to argue that systems of research impact the progress of science. If location in the social system shaped what people could know, then the social organization of science was necessarily consequential for progress in science and engineering (Ben-David 1971).

These approaches to the organization of science were grounded in their historical moment—the Cold War period. Science and engineering were essential to the power struggle of East and West. It was commonly held that WWII had been won through the successful effort to dominate science and technology. Policymakers in the US and Europe wanted to gain permanent political advantages for their countries by constructing a system of research in science and engineering that would continue to dominate both thought and uses of natural resources. Western ideology touted the freedom of thought allowed in the non-Communist world as the route to the future. According to the Mertonians, history seemed to support this posture. England with its Royal Society independent of the government was the one which produced Newton—not France and Italy with their systems of direct state patronage (Crane 1972, Merton 1973). The result was a clear victory for the open society, and reason to be confident about American science, which was being institutionalized inside universities rather than (in most cases) national laboratories.

2. *The Sociology of Scientific Knowledge*

For all that the sociology of scientific knowledge (SSK) first presented itself as a radical subfield at odds with the functionalist tradition, it continued Merton's impulse to associate science less with politics than philosophy (Barnes et al. 1996). Taking the laboratory (rather than the Department of Defense), as the center of calculation for science (and science studies) was an effective way to imagine that power was not at stake in science—even in the US. Moreover, SSK presented good reasons to look more closely at scientific knowledge. In the Mertonian tradition, sociologists had discussed the relationship of organizational structures to scientific progress—as though sociologists could

and would know when science was flourishing. Sociologists of scientific knowledge were not prepared to make such judgments about scientific efficacy, nor passively willing to accept the word of scientists as informants on this. For SSK researchers, what was at stake was the philosophical problem of knowledge—how you know when an assertion about nature is a fact (Barnes et al. 1996, Collins 1985). This was precisely what Merton (1973) had declared outside the purview of sociology, but SSK proponents now transformed into a research question. How did insiders to the world of science make these kinds of determinations for themselves?

The implications for studying the organization of science were profound. Laboratories were the sites where facts were made, so they were the organizational focus of inquiry (Knorr-Cetina 1981, Latour and Woolgar 1979, Lynch 1985). Making a scientific fact was, by these accounts, a collective accomplishment, requiring the coordination of the cognitive practices both within and across laboratories. Laboratories had their own social structures—some temporary and some more stable. In most cases laboratory members distinguished between principal investigators and laboratory technicians, who had different roles in the constitution of knowledge. The significance of research results depended on the social credibility of the researchers. Science was work for gentlemen whose word could be trusted—not tradesmen or women even if they did the work (Shapin and Schaffer 1985). There were alliances across laboratories forged with ideas and techniques that were shared by researchers and were dedicated to common problems or ways of solving them (Pickering 1984). To make scientific truths required more than just an experiment that would confirm or disconfirm an hypothesis. The results had to be witnessed and circulated within scientific communities to make the 'facts' known (Shapin and Schaffer 1985). Scientific paradigms needed proponents to defend and promote them. Creating a scientific fact was much like a military campaign; it required a high degree of coordination of both people and things. It was a matter of gaining the moral stature in the scientific community to have a scientist's ideas taken as truthful. The tools accomplishing these ends were both social and cognitive (Shapin and Schaffer 1985).

Members of these two schools (Mertonian and SSK) may have envisioned the task of articulating a sociology of science differently, but they shared a basic interest in socially patterned ways of thinking about, mobilizing, and describing nature (or the nature of things). Now that the dust has settled on their struggle for dominance in sociology the epistemological break assumed to exist between them has come to seem less profound. Power circulates through laboratories, and scientific experts circulate through the halls of power (Haraway 1989, Jasanoff 1990, 1994, Mukerji 1989). Ways of organizing research affect both the constitution of knowledge and ways of life (Rabinow 1996). The world we know is defined and engineered through patterns of cognition that include manipulation of nature—in the laboratory and beyond.

3. *The Politics of Knowledge-making and Knowledge Claims*

Contemporary research in the sociology of science has shed new light on organizations that sociologists thought they understood before, but never examined for their cognitive processes and relations to nature. Jasanoff's work on the regulatory system in the US, for example, does not simply argue that concern about pollution and scientific regulation of other aspects of life has stimulated new research and yielded new information for policymakers—although that is true. She has shown how the legitimacy of the State has come to depend (to a surprising extent) on its claims to provide at least a minimal level of well-being for the population. Safe air, a healthy food supply, and good drinking water have become taken-for-granted aspects of political legitimacy that depend not only on manipulations of nature but also on the development of new strategies of reassurance. Regulators have not been able simply to ask scientists to use existing expertise to assess and ameliorate problems. They have had to cultivate sciences pertinent to the problems, and face the controversies about the results of new lines of research. The result is a new set of cognitive tools for science honed for policy purposes, and new pressures on political actors to understand and work with at least some of these measurements (Jasanoff 1990, 1994).

Similarly, political legitimacy in rich countries also rests on the government's ability to confront and address medical problems. As Steven Epstein pointed out in his study of AIDS research, the population now generally expects doctors, scientists, and policymakers to solve problems and keep the population healthy. Any fundamental disruption of this faith in expertise leads to anger and (in the US case he studied) political activism. Government officials (like public health workers) in these instances need not only to advocate and support research but also to make the government's health system seem responsive to public needs. This means that the dispassionate pursuit of scientific truths cannot dictate the practice of research, or the dispersement of drugs. Research protocols cannot be entirely determined by experts, but require debate with the activists as well as professional politicians for whom the problem is an issue (Epstein 1996).

Science is therefore used to manage public health (the body politic), and for creating a healthful environment for the citizenry. It is also used to design and manage infrastructures for the society as a whole. Computers are used to design roads, and manage toll systems.

They are employed by hospitals to define illnesses, codify medical practices, and determine courses of treatment for individuals. The military has not only used scientists and engineers (in Cold War style) to develop new weapons and create new modes for their delivery, but has mobilized these groups to develop national communication infrastructures—from road systems to airports to the Internet (Edwards 1996). This engineering is oddly an outgrowth of territorial politics—in this period when States are supposed (by theories from post-modernist to Marxist) to be dying due to globalization (Castells 1996). However, responsibility for health and well- being are circumscribed by national boundaries, and legal responsibility for them is kept within territorial boundaries and remains largely a problem for States.

4. *Post-colonial Studies of Science and Technology*

The territorial dimensions of legitimacy and public health are particularly apparent in the burgeoning post-colonial literature on science, technology, and medicine, showing the export to poor countries of research involving dangerous materials or medical risks (Rafael 1995). The export of risk was perhaps most dramatically illustrated by the US use of an atoll in the Pacific Ocean for bomb tests, but there have been numerous less dramatic instances of this. Manufacturers using dangerous materials have been encouraged to set up factories in Third World countries where economic growth has been considered a higher priority than environmental safety (Jasanoff 1994). Medical researchers in need of subjects have frequently turned to colonial populations for them (Rafael 1995). These practices make it obvious that dangerous research and manufacture are not necessarily abandoned because of the risks. They are simply done in those less powerful places within a state's sphere of influence where legitimacy is not at stake. In these instances, political regulation at home has not necessarily created a moral revolution in science, but a physical dissociation of practices and responsibility. Outside the social world of Western gentlemen, there has often been little concern on the part of researchers about their moral stature. Governments have not systematically worried about the normative consequences of technological development. Instead, poor people have been treated (like prisoners at home) as a disposable population of test subjects—just what AIDS patients refused to be (Epstein 1996, Jasanoff 1994, Rafael 1995).

This pattern is both paralleled by, and connected to, the export of high technology into post-colonial areas of the world. The growth of manufacturing in Third World countries, using computerized production systems, and the growth of computing itself in both India and Africa for example, testify to another pattern of export of science and technology (Jasanoff 1994, Jules-Rosette 1990). These practices are usually presented as ways that corporations avoid local union rules, and deploy an educated workforce at low cost (Castells 1996). However, they are also ways large corporations have found to limit in-migration of labor from post-colonial regions, and to avoid political responsibility for the health of laboring people from poorer parts of the world. Less a case of exporting risk, it is a way of exporting responsibility for it (Jasanoff 1994).

5. *Commercial Stakes in Scientific Thought*

It would be easy to think that while politics is driving some areas of research, there remains a core of pure science like the one desired by Merton. However, commercial as well as political forces work against this end (Martin 1991). Even the publishing system that was supposed to buffer science from the workings of power has turned out to be corruptible. It is not simply that scientific texts (the immutable mobiles of Latour and Woolgar (1979) have found political uses; texts have not been stabilized by being put in print. As Adrian Johns (1998) has shown, simply because printing technology could fix ideas and stabilize authorship has not meant that the publishing industry would use it this way. In seventeenth-century England—the heyday of the scientific revolution—publications were often pirated, changed for commercial purposes, or reattributed. Scientific authorship never did unambiguously extend empiricism and accurate beliefs about nature, or give scientific researchers appropriate recognition for their work. Publishing in science was just another part of the book trade, and was managed for profit. To this day, commercial pressures as well as peer review shapes the public record in science. The purpose of the science section in newspapers is to sell copies, not promote scientific truth. However, scientists still frequently use the popular press to promote their research and advance their careers in science (Epstein 1996).

The practices of science and engineering themselves are not so clearly detached either. Commercial interests in biotechnology and computing have powerful effects on the organization of research, and relations between the university and industry (Rabinow 1996). Even though the Cold War is over, scientists still often cannot publish what they learn from DOD research (which includes work in computing). They rely on external funding, and so must study what is of interest to the government. They are under careful supervision of administrators when they export engineering practices from the laboratory into the world (Mukerji 1989). Dreams of democracy served by science and technology seem hard to sustain.

6. Beyond Power/Knowledge

The broad range of contemporary studies of the politics of science and engineering do not just manifest a revival of interest in the political dimensions/connections of science and engineering in the post-Foucaultian world of power/knowledge, but they manifest new understandings of how power operates through multiple organizational forms. Scientists have (both historically and in the present) aided in the articulation of a system of power based on the principles familiar to the Frankfurt School—the domination of nature for the domination of people. Researchers in science studies who focus on the political mobilization of research for organizational advantage are now making clearer how strategic scientific management of the natural world works and does not work. It seems that governments and industry historically have not so much attained the ideas about nature they needed or paid for, but that scientists, in pursuing knowledge, have also produced means of dominating nature that have been used (and to some extent contained) by those institutions (Mukerji 1989). Modern states, in funding the cultivation of cognitive systems for learning about and managing natural resources, nuclear power, chemical pollutants, and viruses, have generated new patterns of domination but have also opened themselves up to new questions of legitimacy and, in some cases (Epstein 1996), to a redistribution of expertise. The system of scientific and engineering research is not just productive of ideas, but also transportation systems, research animals, laboratories themselves, and new technologies (like the Internet) (Edwards 1996, Kohler 1994, Rabinow 1996). The result is not just a brains trust of scientists, but an entire sociotechnical environment built for strategic effect (Cronon 1991). The cognitive systems of science and engineering are not just ways of coordinating thought through language to reach the truth, but ways of making the world again to reflect and carry human intelligence (and stupidity) about nature.

Science, Sociology of

To make science the object of sociological analysis directs attention to the production and consumption of scientific knowledge in diverse cultural contexts, institutional structures, local organizations, and immediate settings. The sociology of science divides into three broad lines of inquiry, each distinguished by a particular mix of theories and methods. The earliest systematic studies (mostly from the 1950s to the early 1970s) focus on the structural contexts of scientists' behavior: what rules govern the pursuit of scientific knowledge, how are scientists judged and rewarded, how is scientific research broken up into dense networks of specialists? In the 1980s, sociologists shift their attention to the practices through which scientific knowledge is constructed—at the laboratory bench or in the rhetoric of professional papers. Starting in the 1990s, science is put in more encompassing societal contexts, as sociologists examine scientists as purveyors of cognitive authority, and explore their linkages to power, politics, and the economy.

1. Precursors

It is remarkable how much the literature in sociology of science is bunched into the last third of the twentieth century. Perhaps only after the deployment of nuclear weapons, or only after genetic engineering raised eugenic nightmares, could sociologists begin to think about science as a social problem rather than as a consistent solution; or maybe earlier generations of sociologists were guided by epistemological assumptions that rendered true scientific knowledge immune from social causes—thus putting it outside the orbit of sociological explanation.

1.1 Classical Anticipations

'Science' is nowhere indexed in Max Weber's encyclopedic *Economy and Society*, a measure of his unwillingness or inability to see it as a consequential factor in human behavior or social change. Weber's interest in science was largely methodological and political. Could the causal models employed so effectively in the natural sciences be used as well to study social action? Does the objectivity and neutrality of the social scientist preclude involvement in political activity?

Emile Durkheim also sought to institutionalize sociology by making its methods appear scientifically precise, but at the same time considered scientific knowledge as an object of sociological study. Durkheim suggested that basic categories of thought and logic (such as time and space) are social in origin, in that they correspond to fundamental social categories (such as the division of a society by family or gender). However, as human societies grew in size and as their institutions became functionally differentiated, a distinctively scientific pursuit of knowledge was gradually insulated from such social causes. The observable facts of modern science, Durkheim concluded, were in accord with the reality of the physical world—a position that forestalled examinations of how observable facts are also shaped by the culture and communities in which they arise.

Karl Marx's materialism would seem to commit him to the idea that all beliefs arise amid historically specific conditions of production, as they are shaped by the goals and interests of a ruling class. The rise of science in seventeenth-century Europe is intimately bound with the rise of industrial capitalism and, for Marx, can be explained in terms of the utilities of science-based technologies for improving productivity and enlarging surplus value. But although the rate of scientific growth may be explained by its congruence with the interests of the bourgeoisie, Marx seems to suggest that the content of scientific claims inside professionalized research networks is nonideological—that is, an objective account of natural reality.

1.2 Science in the Sociology of Knowledge

Even more surprising is the failure of systematic sociological studies of science to emerge from a blossoming sociology of knowledge in the 1920s and 1930s. Neither Max Scheler nor Karl Mannheim, authors of foundational treatises on the social determinants of knowledge, inspired sustained inquiry into the social determinants of science—probably because both distinguished scientific knowledge from other kinds in a way that truncated what sociology could say about it. Scheler isolated the content of scientific knowledge—and the criteria for ascertaining validity—by describing these as absolute and timeless essences, not shaped by social interests. The effects of social structure (specifically, the power of ruling elites) is limited to selections of problems and beliefs from that self-contained and essential realm of ideas.

Mannheim sustained the neo-Kantian distinction between formal knowledge of the exact sciences and socio-historical knowledge of culture. Phenomena of the natural world are invariant, Mannheim suggests, and so therefore are criteria for deciding truth (i.e., impartial observations based on accurate measurements). In contrast, cultural phenomena become meaningful only as they are constructed through interest-laden judgments of significance, which are neither impartial nor invariant, and thus they are amenable to sociological explanation.

Robert K. Merton's 1938 classic *Science, Technology and Society in Seventeenth-century England* (see Merton 1973) tackles a fundamental problem:

why did modern science emerge with a flourish in seventeenth-century England? His answer has become known as the 'Merton Thesis:' an ethos of Puritanism that provided both the motivating force and legitimating authority for the pursuit of scientific inquiry. Certain religious values—e.g., God is glorified by an appreciation of his handiwork in Nature, or Blessed Reason separates human from beast—created a cultural context fertile for the rise of science. Merton also explains shifts in the foci of research attention among the early modern 'natural philosophers' by connecting empirical inquiry to the search for technological solutions to practical problems in mining, navigation, and ballistics.

2. *Social Organization of the Scientific Community*

When concerted sociological studies of science began in the late 1950s and 1960s, research centered on the institutions or social structures of science—with relatively less attention given to the routine practices involved in making knowledge or to the wider settings in which science was conducted. This work was largely inspired by theories of structural-functional analysis, which ask how the community of scientists is organized in order to satisfy modern society's need for certified, reliable knowledge. One distinctive feature of this first phase is a reliance on quantitative methods of analysis. With statistical data drawn from surveys of scientists and from the *Science Citation Index* (and other bibliometric sources), sociologists developed causal models to explain individual variations in research productivity and used topographical techniques such as multidimensional scaling to map the dense networks of scientists working at a research front.

2.1 *Norms of Science*

The shift from analyzing science in society to analyzing its internal social organization was effected in Merton's 1942 paper on the normative structure of science (in Merton 1973). Written under the shadow of Nazism, Merton argues that the success of scientists in extending certified knowledge depends, at once, on a salutary political context (namely democracy, which allows science a measure of autonomy from political intrusions and whose values are said to be congruent with those of science—quite unlike fascism) and on an internal institutionalized ethos of values held to be binding upon the behavior of scientists. This ethos comprised the famous norms of science: scientists should evaluate claims impersonally (universalism), share all findings (communism), never sacrifice truth for personal gain (disinterestedness) and always question authority (organized skepticism). Behavior consonant with these moral expectations is functional for the growth of reliable knowledge, and for that reason young scientists learn through precept how they are expected to behave, conformity is rewarded, and transgressions are met with outrage.

Subsequent work ignored Merton's conjectures about science and democracy, as sociologists instead pursued implications of the four social norms. Studies of behavioral departures from these norms—ethnocentrism, secrecy, fraud, plagiarism, dogmatism—precipitated debates over whether such deviance is best explained by idiosyncratic characteristics of a few bad apples or changing structural circumstances (such as commercialization of research) that might trigger increases in such behavior. Sociologists continue to debate the possibility that Merton's norms are better explained as useful ideological justifications of scientists' autonomy and cognitive authority. Other research suggests that the norms guiding scientific conduct vary historically, vary among disciplines, vary among organizational contexts (university research vs. military or corporate research), and vary even in their situational interpretation, negotiation and deployment—raising questions about whether the norms identified by Merton are functionally necessary for enlarging scientific knowledge.

2.2 *Stratification and Scientific Careers*

The norm of universalism in particular has elicited much empirical research, perhaps because it raises questions of generic sociological interest: how is scientific performance judged, and how are inequalities in the allocation of rewards and resources best described and explained? With effective quantitative measures of individual productivity (number of publications or citations to one's work), resources (grant dollars), and rewards (prizes, like the Nobel), sociologists have examined with considerable precision the determinants of individual career success or failure. Competition among scientists is intense, and the extent of inequality high: the distribution of resources and rewards in science is highly skewed. A small proportion of scientists publish most research papers (and those papers collect most citations), compete successfully for research grants and prestigious teaching posts, achieve international visibility and recognition, and win cherished prizes.

Debate centers on whether these observed inequalities in the reward system of science are compatible with the norm of universalism—which demands that contributions to knowledge be judged on their scientific merit, with resources and opportunities meted out in accordance with those judgments. The apparent elitism of science may result from an 'accumulation of advantage': work by relatively more eminent or well-positioned scientists is simply noticed

more and thus tends to receive disproportional credit—which (over time) enlarges the gap between the few very successful scientists and everybody else. Such a process may still be universalistic because it is functional for the institutional goal of science: giving greater attention to research of those with accomplished track-records may be an efficient triage of the overwhelming number of new candidate theories or findings. Others suggest that particularism contributes to the stratification of scientists—old boy networks that protect turf and career reputations by rewarding sycophants. The underrepresentation of women in the higher echelons of science has called attention to sometimes subtle sexism that occurs early in the scientific career (restricted access to well-connected mentors, or essential research equipment, or opportunities to collaborate and assignment to trivial problems or mind-numbing tasks).

2.3 *Institutionalization of the Scientific Role*

A separate line of sociological inquiry (exemplified in work by Joseph Ben-David 1991 and Edward Shils) seeks an explanation for how science first became a remunerable occupation—and later, a profession. How did the role of the scientist emerge from historically antecedent patterns of amateurs who explored nature part-time and generally at their own expense? The arrival of the 'scientist' as an occupational self-identification with distinctive obligations and prerogatives is inseparable from the institutionalization of the modern university (itself dependent upon government patronage). Universities provided the organizational form in which the practice of science could become a full-time career—by fusing research with teaching, by allowing (ironically) the historic prestige of universities as centers of theology and scholasticism to valorize the new science, and by providing a bureaucratic means of paying wages and advancing careers.

The scientific role has also been institutionalized in corporate and government labs. The difficulties of transporting a 'pure science' ideal of university-based research into these very different organizational settings have been the object of considerable sociological attention. Scientists in industry or government face a variety of competing demands: their research is often directed to projects linked to potential profits or policy issues rather than steered by the agenda of their discipline or specialty; the need to maintain trade secrets or national security hampers the ability of scientists in these settings to publicize their work and receive recognition for it. And, as Jerome Ravetz (1971) suggests, the intrusion of 'bureaucratic rationality' into corporate and state science compromises the craft character of scientific work: largely implicit understandings and skills shared by the community of scientists and vital for the sustained accumulation of scientific wisdom have little place in accountabilities driven by the bottom-line or policy-relevance.

2.4 *Disciplines and Specialties*

Sociologists use a variety of empirical indicators to measure the social and cognitive connections among scientists: self-reports of those with whom a scientist exchanges ideas or preprints, subject-classifications of publications in topical indexes or abstract journals, lineages of mentor–student relationshships or collaborations, patterns of who cites whom or is cited with whom ('co-citation'). The networks formed by such linkages show occasional dense clusters of small numbers of scientists whose informal communications are frequent, who typically cite each other's very recent papers, and whose research focusses on some new theory, innovative method, or breakthrough problem. Emergence of these clusters—for example, the birth of radio astronomy in England after WWII, as described by David Edge and Michael Mulkay (1976)—is a signal that science has changed, both cognitively and socially: new beliefs and practices are ensconced in new centers for training or research with different leaders and rafts of graduate students. Over time, these specialties evolve in a patterned way: the number of scientists in the network becomes much larger and connections among them more diffuse, the field gets institutionalized with the creation of its own journals and professional associations, shattering innovations become less common as scientists work more on filling in details or adding precision to the now-aging research framework. As one specialty matures, another dense cluster of scientists emerges elsewhere, as the research front or cutting edge moves on.

3. *Sociology of Scientific Knowledge*

A sea-change in sociological studies of science began in the 1970s with a growing awareness that studies of the institutional and organizational contexts shaping scientists' behavior could not illuminate sufficiently the processes that make science science: experimental tinkering, sifting of evidence, negotiation of claims, replacement of old beliefs about nature with new ones, achievement of consensus over the truth. All of these processes—observation, getting instruments and research materials (e.g., mice) to work, logic, criteria for justifying a finding as worthy of assent, choices among theories, putting arguments into words or pictures, persuading other scientists that you are correct—are uncompromisingly social, cultural, and historical phenomena, and so sociologists set about to explain and interpret the content of scientific knowledge by studying the routine practices of scientific work.

This research is guided by constructivist theories (and, less often, ethnomethodology), which center attention on the practically accomplished character of social life. Rather than allow *a priori* nature or given social structures to explain behavior or belief, constructivist sociologists examine how actors incessantly make and remake the structural conditions in which they work. Such research relies methodologically on historical case studies of scientific debate, up-close ethnographic observations of scientific practices, and on interpretative analysis of scientific texts.

3.1 Sociology of Discovery

Diverse studies of scientific discovery illustrate the range of sociological perspectives brought to bear on these consequential events. An early line of inquiry focusses on the social and cognitive contexts that cause the timing and placing of discoveries: why did these scientists achieve a breakthrough then and there? Historical evidence points to a pattern of simultaneous, multiple and independent discoveries—that is, it is rare for a discovery to be made by a scientist (or a local team) who are the only ones in the world doing research on that specific question. Because honor and recognition are greatest for solutions to the perceivedly 'hottest' problems in a discipline, the best scientists are encouraged by the reward system of science to tackle similar lines of research. But these same social structures can also forestall discovery or engender resistance to novel claims. Cognitive commitments to a long-established way of seeing the natural world (reinforced by reputations and resources dependent upon those traditional perspectives) can make it difficult for scientists to see the worthiness of a new paradigm. Resistance to new ideas seems to be greatest among older scientists, and in cases where the proposed discovery comes from scientists with little visibility or stature within the specialty or discipline that would be transformed.

More recent sociological research considers the very idea of 'discovery' as a practical accomplishment of scientists. Studies inspired by ethnomethodology offer detailed descriptions of scientific work 'first-time-through,' taking note of how scientists at the lab bench decide whether a particular observation (among the myriad observations) constitutes a discovery. Other sociologists locate the 'moment' of discovery in downstream interpretative work, as scientists narrate first-time-through research work with labels such as 'breakthrough.' Such discovery accounts are often sites of dissensus, as scientists dispute the timing or implications of an alleged discovery amid ongoing judgments of its significance for subsequent research initiatives or allocations of resources. These themes—interests, changing beliefs, ordinary scientific work, post-hoc accountings, dissent, persuasion—have become hallmarks of the sociology of scientific knowledge.

3.2 Interests and Knowledge-change

In the mid-1970s to the 1980s, sociology of science took root at the Science Studies Unit in Edinburgh, as philosopher David Bloor developed the 'strong programme,' while Barry Barnes, Steven Shapin, Donald MacKenzie, and Andrew Pickering developed its sociological analog—the 'interest model.' The goal is to provide causal explanations for changes in knowledge—say, the shift from one scientific understanding of nature to a different one. Scientists themselves might account for such changes in terms of greater evidence, coherence, robustness, promise, parsimony, predictive power, or utility of the new framework. Sociologists, in turn, account for those judgments in terms of social interests of scientists that are either extended or compromised by a decision to shift to the new perspective. What becomes knowledge is thus contingent upon the criteria used by a particular community of inquirers to judge competing understandings of nature, and also upon the goals and interests that shape their interpretation and deployment of those criteria. Several caveats are noted: interests are not connected to social positions (class, for example, or nationality, discipline, specialty) in a rigidly deterministic way; social interests may change along with changes in knowledge; choices among candidate knowledge-claims are not merely strategic—that is, calculations of material or symbolic gains are bounded by considerable uncertainty and by a shared culture of inquiry that provides standards for logical or evidential adequacy and for the proper use of an apparatus or concept.

Drawing on historical case studies of theoretical disputes in science—nineteenth-century debates over phrenology and statistical theory, twentieth-century debates among high-energy physicists over quarks—two different kinds of interests are causally connected to knowledge-change. Political or ideological commitments can shape scientists' judgments about candidate knowledge claims: the development of statistical theories of correlation and regression by Francis Galton, Karl Pearson and R. A. Fisher depended vitally on the utility of such measures for eugenic objectives. Different social interests arise from the accumulated expertise in working with certain instruments or procedures, which incline scientists to prefer theories or models that allow them to capitalize on those skills.

3.3 Laboratory Practices and Scientific Discourse

As sociologists moved ever closer to the actual processes of 'doing science,' their research divided into

two lines of inquiry: some went directly to the laboratory bench seeking ethnographic observations of scientists' practices *in situ*; others examined scientists' discourse in talk and texts—that is, their accounting practices. These studies together point to an inescapable conclusion: there is nothing not-social about science. From the step-by-step procedures of an experiment to writing up discovered facts for journal publication, what scientists do is describable and explicable only as social action—meaningful choices contingent on technical, cognitive, cultural, and material circumstances that are immediate, transient, and largely of the scientists' own making.

Laboratory ethnographies by Karin Knorr-Cetina (1999), Michael Lynch (1993), and Bruno Latour and Steve Woolgar (1986) reveal a science whose order is not to be found in transcendent timeless rules of 'scientific method' or 'good lab procedures,' but in the circumstantial, pragmatic, revisable, and iterative choices and projects that constitute scientific work. These naturalistic studies emphasize the local character of scientific practice, the idea that knowledge-making is a process situated in particular places with only these pieces of equipment or research materials or colleagues immediately available. Never sure about how things will turn out in the end, scientists incessantly revise the tasks at hand as they try to get machines to perform properly, control wild nature, interpret results, placate doubting collaborators, and rationalize failures. Even methodical procedures widely assumed to be responsible for the objective, definitive, and impersonal character of scientific claims—experimental replication, for instance—are found to be shot-through with negotiated, often implicit, and potentially endless judgments about the competence of other experimentalists and the fidelity of their replication-attempts to the original (as Harry Collins (1992) has suggested).

Ethnographic studies of how scientists construct knowledge in laboratories compelled sociologists then to figure out how the outcomes of those mundane contextual practices (hard facts, established theories) could paradoxically appear so unconstructed—as if they were given in nature all along, and now just found (not made). Attention turned to the succession of 'inscriptions' through which observations become knowledge—from machine-output to lab notebook to draft manuscript to published report. Scientists' sequenced accounts of their fact-making rhetorically erase the messy indeterminacy and opportunism that sociologists have observed at the lab bench, and substitute a story of logic, method, and inevitability in which nature is externalized as waiting to be discovered. Such studies of scientific discourse have opened up an enduring debate among constructivist sociologists of science: those seeking causal explanations for scientists' beliefs treat interests as definitively describable by the analyst, while others (Gilbert and Mulkay 1984, Woolgar 1988) suggest that sociologists must respect the diversity of participants' discursive accounts of their interests, actions, or beliefs—and thus treat actors' talk and text not as mediating the phenomena of study but as constituting them.

3.4 *Actor-networks and Social Worlds*

After sociologists worked to show how science is a thoroughly social thing, Bruno Latour (1988) and Michel Callon (1986) then retrieve and reinsert the material: science is not only about facts, theories, interests, rhetoric, and power but also about nature and machines. Scientists accomplish facts and theories by building 'heterogenous networks' consisting of experimental devices, research materials, images and descriptive statistics, abstract concepts and theories, the findings of other scientists, persuasive texts—and, importantly, none of these are reducible to any one of them, nor to social interests. Things, machines, humans, and interests are, in the practices of scientists, unendingly interdefined in and through these networks. They take on meanings via their linkages to other 'actants' (a semiotic term for anything that has 'force' or consequence, regardless of substance or form). In reporting their results, scientists buttress claims by connecting them to as many different actants as they can, in hopes of defending the putative fact or theory against the assault of real or potential dissenters. From this perspective, length makes strength, that is, the more allies enrolled and aligned into a network—especially if that network is then stabilized or 'black boxed'—the less likely it is that dissenters will succeed in disentangling the actants and thereby weaken or kill the claim. Importantly for this sociology of science, the human and the social are decentered, in an ontology that also ascribes agency to objects of nature or experimental apparatuses.

Actor-network theory moved the sociological study of science back outside the laboratory and professional journal—or, rather, reframed the very idea of inside and outside. Scientists and their allies 'change the world' in the course of making secure their claims about nature, and in the same manner. In Latourian vernacular, not only are other scientists, bits of nature or empirical data enlisted and regimented, but also political bodies, protest movements, the media, laws and *hoi polloi*. When Louis Pasteur transformed French society by linking together microbes, anthrax, microscopes, laboratories, sick livestock, angry farmers, nervous Parisian milk-drinkers, public health officials, lawmakers, and journalists into what becomes a 'momentous discovery,' the boundary between science and the rest of society is impossible to locate. Scientists are able to work autonomously at their benches precisely because so many others outside the lab are also 'doing science,' providing the life

support (money, epistemic acquiescence) on which science depends.

The boundaries of science also emerge as theoretically interesting in related studies derived from the brand of symbolic interactionism developed by Everett Hughes, Herbert Blumer, Anselm Strauss, and Howard Becker (and extended into research on science by Adele Clarke 1990, Joan Fujimura, and Susan Leigh Star). On this score, science is work—and, instructively, not unlike work of any other kind. Scientists (like plumbers) pursue doable problems, where 'doability' involves the articulation of tasks across various levels of work organization: the experiment (disciplining research subjects), the laboratory (dividing labor among lab technicians, grad students, and postdocs), and 'social worlds' (the wider discipline, funding agencies, or maybe animal-rights activists). Scientific problems become increasingly doable if 'boundary objects' allow for cooperative intersections of those working on discrete projects in different social worlds. For example, success in building California's Museum of Vertebrate Zoology in the early twentieth century depended upon the standardization of collection and preparation practices (here, the specimens themselves become boundary objects) that enabled biologists to align their work with trappers, farmers, and amateur naturalists in different social worlds. As in actor-network theory, sociologists working in the 'social worlds' tradition make no assumption about where science leaves off and the rest of society begins—those boundaries get settled only provisionally, and remain open to challenge from those inside and out.

4. *Science as Cultural Authority*

It is less easy to discern exactly what the sociology of science is just now, and where it is headed. Much research centers on the position of science, scientists, and scientific knowledge in the wider society and culture. Science is often examined as a cognitive or epistemic authority; scientists are said to have the legitimate power to define facts and assess claims to truth. This authority is not treated as an inevitable result of the character or virtue of those who become scientists, the institutional organization of science (norms, for example) or of the 'scientific method.' It is, rather, an accomplished resource pursued strategically by a profession committed not only to extending knowledge but also to the preservation and expansion of its power, patronage, prestige, and autonomy.

No single theoretical orientation or methodological program now prevails. Constructivism remains appealing as a means to render contingent and negotiable (rather than 'essential') those features of scientific practice said to justify its epistemic authority. But as the agenda in the sociology of science shifts from epistemological issues (how is knowledge made?) to political issues (whose knowledge counts, and for what purposes?), constructivism has yielded to a variety of critical theories (Marxism, feminism and postmodernism) that connect science to structures of domination, hierarchy, and hegemony. A popular research site among sociologists of science is the set of occasions where scientists find their authority challenged by those whose claims to knowledge lack institutional legitimacy.

4.1 *Credibility and Expertise*

Steven Shapin (1994) (among others) has identified credibility as a constitutive problem for the sociology of science. Whose knowledge-claims are accepted as believable, trustworthy, true or reliably useful—and on what grounds? Plainly, contingent judgments of the validity of claims depend upon judgments of the credibility of the claimants—which has focussed sociological attention on how people use (as they define) qualities such as objectivity, expertise, competence, personal familiarity, propriety, and sincerity to decide which candidate universe becomes provisionally 'real.' A long-established line of sociological research examines those public controversies that hinge, in part, on 'technical' issues. Case studies of disputes over environmental and health risks find a profound ambivalence: the desire for public policy to be decided by appropriate legislative or judicial bodies in a way that is both understandable and accountable to the populace runs up against the need for expert skills and knowledge monopolized by scientific, medical or engineering professionals. Especially when interested publics are mobilized, such disputes often become 'credibility struggles' (as Steven Epstein (1998) calls them). In his study of AIDS politics, Epstein traces out a shift from activists' denunciation of scientists doing research on the disease to their gaining a 'seat at the table' by learning enough about clinical trials and drug development to participate alongside scientists in policy decisions. In this controversy, as in many others, the cultural boundaries of science are redrawn to assign (or, alternatively, to deny) epistemic authority to scientists, would-be scientists, citizens, legislators, jurists, and journalists.

4.2 *Critique of Science*

Recent sociological studies have themselves blurred the boundaries between social science and politics by examining the diverse costs and benefits of science. Whose agenda does science serve—its own? global capital? political and military elites? colonialism? patriarchy? the Earth's? Studies of molecular biology and biotechnology show how the topics chosen for

scientific research—and the pace at which they are pursued—are driven by corporate ambitions for patents, profits, and market-share. Related studies of the Green Revolution in agricultural research connect science to imperialist efforts to replace indigenous practices in less developed countries with 'advanced technologies' more consonant with the demands of global food markets. Feminist researchers are equally interested in the kinds of knowledge that science brings into being—and, even more, the potential knowledges not sought or valorized. In the nineteenth century, when social and natural science offered logic and evidence to legitimate patriarchal structures, other styles of inquiry and learning practiced among women (Parisian salons, home economics, midwifery, and cookery) are denounced as unscientific and, thus, suspect. Other feminists challenge the hegemony of scientific method, as a way of knowing incapable of seeing its own inevitable situatedness and partiality; some suggest that women's position in a gender-stratified society offers distinctive epistemic resources that enable fuller and richer understandings of nature and culture.

These critical studies share an interest in exposing another side of science: its historical complicity with projects judged to be inimical to goals of equality, human rights, participatory democracy, community and sustainable ecologies. They seek to fashion a restructured 'science' (or some successor knowledge-maker) that would be more inclusive in its practitioners, more diverse in its methods, and less tightly coupled to power.

Science, Technology, and the Military

Technology has changed warfare since time immemorial. The invention of gunpowder, artillery, and rifles revolutionized warfare. Individual scientists, for cen-

turies, have advised the military on specific problems: Archimedes reportedly helped the tyrant of Syracuse in devising new weaponry against the Romans in 212 BC; Leonardo da Vinci supplied us with a variety of drawings of new armaments; and, since the emergence of 'modern' science in the sixteenth and seventeenth centuries, many prominent scientists, including Tartaglia, Galileo, Newton, Descartes, Bernouilli, and Euler, have devoted some of their time and intellect to helping solve military problems.

This article first argues that World War II and the subsequent Cold War produced a dramatic change in the way scientists became involved in the weapons innovation process. Next, it shows that concerns about the resulting 'arms race' brought about a new type of studies—defense technology assessment studies—that dealt with the impact of new weapons systems on national and international security. Many of the newly developed weapons were perceived to have a negative impact, which raised the question of whether and how the weapons innovation process could be influenced. The article discusses a variety of analytical approaches aimed at understanding the dynamics of the weapons innovation process. It argues that a sociotechnical network approach is the most promising one to provide valuable insights for influencing this innovation process. This approach also provides a suitable framework for investigating the relationship between civil and military technological innovation, a subject of growing interest that is discussed in the final section.

1. *Weapons Innovation Becomes Organized*

World War II produced a dramatic change in the way scientists became involved in military matters. Science and scientists in great numbers were mobilized for weapons innovation in a highly organized and concentrated effort. In the USA these scientists contributed, mainly under the auspices of the newly established Office of Scientific Research and Development, to the development of a variety of new technologies, including the atomic bomb, radar, the proximity fuse, and also penicillin. The decisive contribution of scientists to these war efforts implied a fundamental shift in the role of science and technology in future military affairs.

Immediately after the war, US science policy pioneer Vannevar Bush (1945), drawing on the war experience, advised the President:

> [t]here must be more—and more adequate—military research in peacetime. It is essential that the civilian scientists continue in peacetime some portion of those contributions to national security which they have made so effectively during the war.

His advice stood in sharp contrast to Thomas Alva Edison's suggestion, many years before, during World War I, to the Navy, that it should bring into the war effort at least *one* physicist in case it became necessary to 'calculate something' (Gilpin 1962, p. 10).

For the first time in history military research and development (R&D) became a large-scale institutionalized process even in peacetime, indeed on a scale not seen before; it was legitimized as well as fueled by the climate of the Cold War. In the decades following the war, weapons were replaced in a rapid process of 'planned obsolescence.' The R&D was carried out in national laboratories, the defense industry, laboratories of the military services, and at universities to varying degrees in different countries. A United Nations study of 1981 estimated that annually some $100 billion, that is, some 20–25 percent of all R&D expenditures, were devoted to military R&D.

The resulting 'qualitative' arms race in nuclear, conventional, and biological and chemical weapons between the NATO and Warsaw Pact countries during the Cold War raised the question of whether national and international security actually decreased, rather than increased, as a result of 'destabilizing' weapons innovations. A related question was whether military technological developments could be steered or directed so as not to undermine international arms control agreements. After the end of the Cold War in 1990, observers wondered why, particularly in the Western industrialized countries, military R&D efforts continued nearly unabated, while the original threat had disappeared.

The systematic and organized involvement of science and technology in developing new armaments raised more questions of both societal and social-scientific interest. For instance, to what extent have military R&D and defense relations influenced academic research (mainly a concern in the USA) and the course—or even the content—of scientific and technological developments more generally? What is the relationship between (developments in) civil and military technology: are these separate developments or do they, on the contrary, profit from each other through processes of diffusion and spin-off?

Addressing these questions has become an interdisciplinary task, drawing on and integrating insights from many fields. This challenge has been taken up, though still on a limited scale, within the framework of the science and technology (S&T) studies that have emerged since the 1970s.

This article focuses on the origin and nature of 'defense technology assessment studies' and the related research on possibilities for influencing the weapons innovation process.

2. *Defense Technology Assessment Studies*

The declared purpose of weapons innovation is enhancing national security (often broadly interpreted as

including intervention and power projection). However, during the Cold War many argued that the ever-continuing weapons innovation process was actually counter-productive. The issue was not only that the huge amounts spent on armament might be a waste of resources, but also that the huge military R&D effort and the resulting new weapons caused a rapid decrease rather than an increase of national security (e.g., York 1971, p. 228).

Since the 1960s, many studies, often carried out by scientists who had become concerned about the escalating arms race, have dealt with the impact of new weapons systems and new military technologies on national and international security. These studies pointed out, for instance, that the anti-ballistic missile (ABM) systems, consisting of many land-based anti-missile missiles, as proposed by the USA in the 1960s, would actually stimulate the Soviet Union to deploy even more nuclear missiles. Also, a similar ABM system by the Soviet Union would trigger the USA to deploy multi-warhead missiles (MIRVs—Multiple Independently Targetable Re-entry Vehicles). These missiles, carrying up to twelve nuclear warheads, could thus saturate the capabilities of the Soviet ABM interception missiles. Actually, the development and deployment of MIRVed missiles by the USA even preceded a possible Soviet ABM system. As the then US Defense Secretary, Robert McNamara, wrote (quoted in Allison and Morris 1975, p. 118):

> Because the Soviet Union *might* [emphasis in original] deploy extensive ABM defenses, we are making some very important changes in our strategic missile forces. Instead of a single large warhead our missiles are now being designed to carry several small warheads … . Deployment by the Soviets of a ballistic missile defense of their cities will not improve their situation. We have *already* [emphasis added] taken the necessary steps to guarantee that our strategic offensive forces will be able to overcome such a defense.

This weapons innovation 'dynamics' was aptly encapsulated by Jerome Wiesner, former science adviser to President John F. Kennedy, as 'we are in an arms race with ourselves—and we are winning.' In the 1990s, when the USA continued its efforts to develop anti-satellite (ASAT) technology capable of destroying an adversary's satellites, Wiesner's words might rightly have been paraphrased as 'we are in an arms race with ourselves—and we are losing.' For the irony here is that it is the US military system that, more than any other country's defense system, is dependent on satellites (for communication, reconnaissance, eavesdropping, and so on), which would be highly vulnerable to a hostile ASAT system. The most likely route, however, for hostile countries to obtain the advanced ASAT technology would not be through their own R&D, but through the *proliferation*, that is, diffusion of US ASAT technology, once it had been developed. Again, the USA would very likely decrease rather than increase its own security by developing ASAT technology.

Many of the early and later 'impact assessments' of weapons innovations assessed their potential of circumventing and undermining existing international agreements that aimed to halt the arms race, like the Anti-Ballistic Missile (ABM) Treaty (1972) and the accompanying Strategic Arms Limitation Agreements (SALT, 1972), the SALT II Treaty (1979), and a Comprehensive Test Ban Treaty (CTBT, 1996). In addition, assessments were made, both by independent scientists and governmental agencies, of the potential of civil technologies to spill over into military applications: for in such cases, countries could, under the guise of developing civil technologies make all preparations needed for developing nuclear, chemical, or biological weapons.

Through these 'dual-use' technologies, a proliferation of weapons could occur, or at least the threshold lowered for obtaining those weapons, without formally violating the Non Proliferation Treaty (1971), the Comprehensive Test Ban Treaty (1996), the Biological Weapons Convention (1972), or the Chemical Weapons Convention (1993). The *Arms Control* readings (York 1973) from the Magazine *Scientific American* provide an instructive sample of early defense technology assessments.

In the 1980s, both the USA and NATO emphasized the importance of a stronger conventional defense, which was then believed to be feasible because of new 'emerging technologies,' including sensor and guidance technologies, C^3I (Command, Control, Communications and Intelligence) technologies (like real time data processing), electronic warfare, and a variety of new missiles and munitions. The emphasis on high technology in the conventional weapons area, in its turn, triggered a great variety of studies (pro and con) by academic and other defense analysts, not only in the USA, but also in Europe. These included analyses of the technical feasibility of the proposed systems, the affordability of acquiring sufficient numbers of ever more costly weapons, and the associated consequences for national defense and international security.

The results of these defense technology assessments were fed into the public discussion, with the aim of containing the arms race and reaching international arms control agreements, or preventing their erosion.

The impact of these assessments on the weapons innovation process and its accompanying military R&D was often limited. Many, therefore, considered the weapons innovation process to be 'out of control,' providing another topic of S&T studies on military technology.

3. *Influencing the Weapons Innovation Process*

What does it mean to 'bring weapons innovation under political control'? The concept seems obvious at

one level but it is actually not trivial and needs elaboration.

In national politics there is often no consensus on the kinds of armament that are desirable or necessary. Those who say that politics is not in control may actually mean that developments are not in accordance with their political preferences, whereas those who are quite content with current developments may be inclined to say that politics is in control. Neither position is analytically satisfactory. But neither is it satisfactory to say that politics is in control simply because actual weapons innovations are the outcome of the political process, which includes lobbying of defense contractors, interservice rivalry, bureaucratic politics, arguments over ideology and strategic concepts, and so forth, as Greenwood (1990) has suggested. Rather than speaking of control, one should ask whether it would be possible to influence the innovation process in a systematic way, or to steer it according to some guiding principle (Smit 1989). This implies that the basic issue of 'control,' even for those who are content with current developments, concerns whether it would be possible to change their course if this was desired.

A plethora of studies have appeared on what has been called the technological arms race (see e.g. Gleditsch and Njolstad 1990). Many of them deal with what President Eisenhower in his much-cited farewell address called the military-industrial complex, later extended to include the bureaucracy as well. These studies belong to what has been called the bureaucratic-politics school or domestic structure model (Buzan 1987, Chap. 7), in contrast to the action-reaction models (Buzan 1987, Chap. 6), which focus on interstate interactions as an explanation of the dynamics of the arms race. A third approach, the technological imperative model (Buzan 1987, Chap. 8) sees technological change as an independent factor in the arms race, causing an unavoidable advance in military technology, if only for its links with civil technological progress—though a link whose importance is under debate (see also the last section of this article). By contrast, Ellis (1987), in his social history of the machine gun, has shown the intricate interweaving of weapons innovation with social, military, cultural, and political factors. To some extent, these studies might be considered complementary, focusing on different elements in a complex pattern of weapons development and procurement. For instance, the 'reaction' behavior in the interstate model might be translated into the 'legitimation' process of domestically driven weapons developments.

Many of these studies are of a descriptive nature. Some (Allison and Morris 1975, Brooks 1975, Kaldor 1983) are more analytical and try to identify important determinants in the arms race. These factors are predominantly *internal* to each nation and partly linked up with the lengthy process—10 to 15 years—of the development of new weapons systems. Other studies (Rosen 1991, Demchak 1991) relate military innovation, including military technology, to institutional and organizational military factors and to the role of civilians. There are quite a number of case studies on the development of specific weapons systems, and empirical studies on the structure of defense industries (Ball and Leitenberg 1983, Kolodziej 1987, Gansler 1980, 1987) or arms procurement processes (Cowen 1986, Long and Reppy 1980).

However, hardly any of these studies focus on the question of how the (direction) of the weapons innovation process and the course of military R&D might be influenced. One task for future S&T studies, therefore, would be to combine insights from this great variety of studies for a better understanding of these innovation processes. Some steps have already been taken. The lengthy road of developing new weapons systems implies that it will be hard to halt or even redirect a system at the end when much investment has been made. Influencing weapons innovations, therefore, implies a continuous process of assessment, evaluation, and (re-)directing, starting at the early stages of the R&D process (see also *Technology Assessment*). Just striving for 'technological superiority,' one of the traditional guiding principles in weapons development, will lead to what is seemingly an autonomous process. Seemingly, because technology development is never truly autonomous. The appearance of autonomy results from the fact that many actors (i.e., organizations) are involved in developing technology, and no single actor on its own is able to steer the entire development. Rather, all actors involved are connected within a network—we may call it a sociotechnical network—working together and realizing collectively a certain direction in the weapons innovation process.

Network approaches, appearing in several areas of science and technology studies since the mid 1980s, in which the positions, views, interests, and cultures of the actors involved are analyzed, as well as their mutual links and the institutional settings in which the actors operate, open up an interesting road for dealing with the question of influencing military technological developments (Elzen et al. 1996). Such approaches emphasize the interdependencies between the actors and focus on the nature of their mutual interactions (see also *Actor Network Theory*).

From a network approach it is evident why one single organization by itself cannot determine technological developments. At the same time, network approaches have the power to analyze the way these developments may be *influenced* by actors in a network. Networks both enable and constrain the possibilities of influencing technology developments. Analyzing them may provide clues as to how to influence them.

Weapons innovation and its associated military R&D differ in one respect from nearly all other technologies, in that there is virtually only one

customer of the end product—that is, the state. (Some civil industries, like nuclear power and telecommunications in the past, also show considerable similarities in market structure—monopolies or oligopolies coupled with one, or at most a few dominant purchasers. They are also highly regulated, and markedly different from the competitive consumer goods sectors (see Gummett 1990). Moreover, only a specific set of actors comprises the sociotechnical networks of military technological developments, including the defense industry, the military, the defense ministry, and the government. The defense ministry, as the sole buyer on the monopsonistic armament market, has a crucial position. In addition, the defense ministry is heavily involved in the whole R&D process by providing, or refunding to industry, much of the necessary funds. Yet the defense ministry, in its turn, is dependent on the other actors, like the defense industry and military laboratories, which provide the technological options from which the defense ministry may choose. S&T studies of this interlocked behavior offer a promising approach for making progress on the issue of regulatory regimes. Not steering from a central position, but adopting instead an approach of 'decentralized regulation' in which most actors participate then seems the viable option for influencing military technological developments. In this connection various 'guiding principles' could play a role in a regulatory regime for military technological innovation (see also Enserink et al. 1992). Such guiding principles could include the 'proportionality principle,' 'humanitarian principles,' and 'limiting weapons effects to the duration of conflict' (contrary, for instance, to the use of current anti-personnel mines).

Additional phenomena that should in any event be taken into account in such network approaches are the increasing international cooperation and amalgamation of the defense industry, the possibly increasing integration of civil and military technology, and the constraining role of international arms control agreements. The intricate relation between civil and military technology will briefly be discussed in the final section.

4. *Integration of Civil and Military Technology*

Sociotechnical network approaches seem particularly useful for studying the relation between civil and military technology. This issue has assumed increasing interest because of the desire to integrate civil and military technological developments. Technologies that have both civil and military applications are called dual-use technologies. The desire for integration originates (a) from the need for lower priced defense products because of reductions in procurement budgets, and (b) from the new situation that in a number of technological sectors innovation in the civil sector has outstripped that in the military sector. Examples of such sectors are computers and information and communication technology, where such integration already emerges. Such integration, of course, could be at odds with a policy of preventing weapons proliferation as discussed before.

Research on the transformations needed to apply civil technologies in the military sector and vice versa have only just begun. The extent to which civil and military technologies diverge depends not only on the diverging needs and requirements, but also on the different institutional, organizational, and cultural contexts in which these developments occur.

Several case studies illustrate how intricately interwoven the characteristics of technology may be with the social context in which it is being developed or in which it functions. MacKenzie (1990) conducted a very detailed study of the development of missile guidance technologies in relation to their social context, and the technological choices made for improving accuracy, not only for missiles but also for aircraft navigation. He showed how different emphases in requirements for missile accuracy and for civil (and military) air navigation resulted in alternative forms of technological change: the former focusing on accuracy, the latter on reliability, producibility, and economy.

A number of historical studies have addressed the question of the *relation* between civil and military technology. Some of them have shown that in a number of cases in the past, the military successfully guided technological developments in specific directions that also penetrated the civil sector. Smith (1985), for instance, showed that the manufacturing methods based on 'uniformity' and 'standardization' that emerged in the USA in the nineteenth century, were more or less imposed (though not without difficulties and setbacks) by the Army Ordnance Department's wish for interchangeable parts. Noble (1985) investigated, from a more normative perspective, three technical changes in which the military have played a crucial role—namely, interchangeable parts manufacture, containerization, and numerical control—arguing that different or additional developments would have been preferable from a different value system. Studies going back to the nineteenth or early twentieth centuries, though interesting from a historical perspective, may not always be relevant for modern R&D and current technological innovation processes. Systematic studies of the interrelation between *current* military and civil technological developments are only of recent date (see Gummett and Reppy 1988). They point out that it may be useful to distinguish not only between different levels of technology, such as generic technologies and materials, components, and systems (Walker et al. 1988), but also between products and manufacturing or processing technologies (Alic et al. 1992). In certain technological areas the distinguishing features between civil and military technology may be found at the level

of system integration, rather than at the component level. In conclusion one may say that military technology, for many reasons, is a fascinating field for future science and technology studies: its links with a broad scope of societal institutions, its vital role in international security issues, the need for influencing its development, and its increasing integration with civil technology, particularly in the sector of information and communication technologies, which may revolutionize military affairs.

Scientific Academies, History of

Scientific academies are associations of scientific practitioners like the *Academie Royale des Sciences* of Paris, the Royal Society of London, the Berlin Academy, the Russian Academy of Science, or the US National Academy of Science. Since their inception in seventeenth-century Europe, the distinctive feature of scientific academies has been the regulation of their membership and activities according to corporate protocols, statutes, and bylaws (which, nevertheless, may be developed in accordance with the policies of the state authorities that sometimes sponsor them). Typical activities of scientific academies include: the publication of journals, monographs, and the collected work of famous scientists, the award of prizes and medals (the Nobel Prize being the most famous example), the organization of scientific meetings and, more rarely, of research projects (sometimes in collaboration with other academies). They may also take an advising role in matters of science policy, and may be called upon to advise governments on scientific and technological projects.

The sociological and historical significance of scientific academies is tied to their crucial role in the development of science as a peer-based system, in constituting the 'scientist' as a distinct socio-professional role, in establishing networks of communication and collaboration, and, more generally, in fostering the so-called internationalism of science (Crawford 1992). Historically, scientific academies have functioned as institutions demarcating the elite of scientific practitioners from other socioprofessional groups (which may have included other scientific practitioners pursuing different methodological programs or more practical subjects). By doing so, they have created the conditions of possibility for corporate authority in science (though, historically, different academies have taken different stances with respect to their role as judges of scientific and technical claims). They have also constituted themselves as crucial 'lobbying' entities in negotiations between corporate science and the state.

But while academies are seen as a cornerstone in the development of science as a peer-based and peer-regulated system, the very notion of peer has undergone important changes since the seventeenth century and remains contested even today. There is a circular relationship between the definition of peer and academy. Academies are constituted by peers, but they also constitute what peer means. A peer is not only someone who has specific technical competencies in a given scientific field, but also a person who, through a process of training and professional socialization, has developed (and has been given the opportunity to develop) a specific corporate sociability and set of values. The ingredients of such a sociability are rooted in the historical, disciplinary, and socio-political context in which a given academy developed, but there are some features that have cut across these various contexts. One of them is gender. A historically conspicuous feature of scientific academies is their distinctly male corporate culture which, until the beginning of the twentieth century, led to the exclusion of women from their membership—an exclusion that was less marked in other less corporate sites of science (Schiebinger 1989).

Another theme that runs through the literature on academies is their relative 'independence.' Some have seen academies as providing an institutional boundary between science and society, thereby shielding the allegedly ever-threatened 'purity' of science (Ben-David 1971). Others, instead, have taken the empirically more defensible view that academies are institutions constituted within specific socio-political ecologies—ecologies to whose development they contribute from within. The former view sees science as in need of being or becoming as independent as possible from the social nomos, while the latter treats it as a set of practices that have articulated increasingly finer and more pervasive relationships with the socio-political order precisely by developing more specialized and professionalized institutional forms. In one case, institutionalization means separation; in the other it means integration within an increasingly articulated interplay of social institutions.

These considerations bear directly on the problem of defining 'scientific academy.' It is easy to compile a long and inclusive list of past or present academies, but it would be much harder, perhaps impossible, to categorize them as a long-standing institutional type like, say, the university. Depending on historical and national contexts, 'scientific academy' refers to different types of associations with different structures, functions, methodological orientations, membership requirements, notions of intellectual property and authorship, funding arrangements, and affiliations with private patrons or state governments and bureaucracies. Since their inception in seventeenth-century Europe, scientific academies have dealt with the production, reward, and dissemination of scientific knowledge, the training of practitioners, the evaluation of patent applications, and the advising of state and political authorities on scientific and techical matters. Some academies have been established by practitioners themselves and tend to be independently funded. Others are state-sponsored and tend to function as a body of scientific experts for the state that

supports them. Certain academies have a distinctly international membership, while others draw it from a specific country (though they may also extend limited forms of membership to a few foreign practitioners). Some select their members from one specific discipline, others gather practitioners from different fields. Some promote and fund the production of new knowledge, others concerns themselves with its dissemination. Most modern academies do not offer stipends to researchers (and may even require their members to contribute annual fees), while some earlier academies (Paris, Berlin, and St Petersburg) did provide their members with salaries and research funds (McClellan 1985).

Because scientific academies have assumed most of the functions now typical of other institutions, it is possible to find partial analogies between academies and these other components of the social system of science. For instance, it may be difficult in some cases to draw a sharp demarcation between scientific academies and other institutions such as discipline-based professional associations, national laboratories and research institutes, foundations (like Rockefeller in the US), national agencies for the development of science (CNRS in France, NSF or NIH in the US, CNR in Italy, etc.), or even university science departments.

Similar problems emerge when we try to distinguish scientific academies from other less scientific-sounding associations which, nevertheless, promote or promoted the production of knowledge about nature. In this category we find early modern philosophical salons (usually established and run by women (Lougee 1976)), religious orders that supported collective work in mathematics, astronomy, and natural history (like the Society of Jesus), provincial academies of natural philosophy, belles lettres, and history (common in Europe and America throughout the nineteenth century), nonprofessional associations for the popularization of science (which may be seen as the modern heirs to earlier provincial academies), or contemporary associations of amateur scientists. The same taxonomical difficulties emerge when one looks for some essential demarcation between academies and collection-based institutions like the Smithsonian Institution in Washington and other museums of science and natural history, and botanical gardens. In the premodern period, such institutions tended to be associated with academies and, as shown by the American Museum of Natural History in New York, may still perform some of the research functions of their historical ancestors. The same may be said about astronomical observatories. Many of them (Greenwich, Paris, Berlin, St Petersburg, etc.) were developed within scientific academies or soon became annexed to them, but later evolved into independent institutions or became linked to other state agencies (like the *Bureau de Longitude* in nineteenth-century France).

In sum, one either runs the risk of treating 'academy' as a synonym for 'scientific institution' (in the same way some apply the term 'laboratory' to anything from large-scale international organizations like CERN and private industrial entities like Bell Labs, to early modern alchemical workshops or to Uraniborg—Tycho Brahe's sixteenth-century aristocratic observatory-in-a-castle (Christianson 2000)) or, in a reverse move, of identifying academies solely with institutions bearing that name (but likely to display remarkably different structures and functions), while leaving out a slew of other associations whose activities may in fact overlap with those pursued, at one point or another, by 'proper' academies.

A possible solution to this definitional puzzle is to take a genealogical (rather than taxonomical) approach. In any given historical and national context there is a division of labor and functions between scientific academies and the surrounding institutions of science and of the state bureaucracy. It is this institutional ecology that we need to look at to understand which role academy fulfills in any given context.

If we take peer-based management to be the distinctive trait of academies, then a reasonable starting point of their genealogy is the development of legal statutes and bylaws; that is, of instruments for the establishment of their corporate form of life. This makes the Royal Society of London (chartered in 1662) the first scientific academy. This criterion excludes a number of well-known seventeenth-century academies (such as the Lincei (1603–1631), the Cimento (1657–1667), and even the early *Academie Royale des Sciences* (which began to gather around 1666 but obtained its first statute only in 1699).

Academies that did not have legal statutes or charters gathered at the will of a prince who sponsored them, and operated within the rules and system of exchange typical of the patronage system. They can be seen as the extension of the model of informal court gatherings and aristocratic literary salons to the domain of natural philosophy. They were prince-dependent not only in the sense that they were funded by princes, but their work, publications, membership, and sociability were structured by their direct, quasi-personal relationship to the patrons who, in several cases, participated in them. In these contexts, academicians were more princely subjects than collaborating scientific peers (Biagioli 1996).

The next step—the development of charters, statutes, and bylaws—marked the transition from the patronage framework to institutions which, while still connected to royal power, had a more formal and bureaucratic relationship to the state. This institutional development followed two different models, one exemplified by the Royal Society of London, the other by the *Academie Royale des Sciences*. These two models matched quite closely the structure and discourse of royal power in those two countries: absolutism in France and constitutional monarchy in England.

In fact, despite its name, the Royal Society was a private institution (some may say a large gentlemen's club) that, while chartered by the king, received negligible funding and virtually no supervision from the crown (Hunter 1989). Its members were nominated and approved by the Society itself. Similar protocols were followed for the selection of the president and other officials. There were no paid positions except that of the secretary and the curator of experiments, and the operating budget came mostly from annual membership fees which were typically hard to collect. The training of young practitioners was not one of the Society's stated goals.

The *Academie des Sciences*, instead, was much more of a state agency. The French crown funded it, provided stipends, and closely controlled its projects, membership, and publications. Its members were grouped according to disciplinary taxonomies, and organized hierarchically according to seniority (with students at the bottom) and, sometimes, social status. The king selected crown bureaucrats to run its operation (Hahn 1971).

These two models and their various permutations were adopted during the remarkable development (almost an explosion) of scientific academies in the eighteenth century. Driven by a mix of national pride, emulation, and the state's growing appetite for technical expertise, virtually all European states, from England to Russia, developed such academies (McClellan 1985). Academies proliferated not only across but within nations, moving from the capitals to the periphery (Roche 1978). Reflecting the logic of political absolutism, state academies tended to follow the French paradigm, while provincial and private academies, having little or no connections to central state power, looked to the Royal Society as their primary model. The center–periphery distinction maps quite well on the disciplinary scope of early scientific academies: provincial institutions often included literature and history sections, while centrally located academies tended to specialize in natural philosophy.

Until the French Revolution, academies constituted the primary site of scientific activity, epitomized the very notion of scientific institution, and provided science with a kind of social and professional legitimation it had struggled to achieve in previous periods. Some military schools (especially in France) shared the academies' concern with research. But with the exception of Bologna, Pavia, and Gottingen, early modern universities usually limited themselves to the teaching of (not the research in) natural philosophy.

If the eighteenth century was the golden age of scientific academies, the nineteenth century saw the beginning of their decline, or at least their slow but steady reframing from research institutions into prestige-bearing ones. New kinds of institutions emerged and older ones were reformed as the social system of science developed in scale and specialization. The remarkable complexity of this scenario is such that only a few general trends can be discussed here, and only in reference to their impact on the role of academies.

First, starting with Germany, the restructuring of the university led to an increased representation of the sciences in its curriculum and, more importantly, to a slow but steady trend toward research, not only teaching, in the natural sciences. In the second half of the nineteenth century, this trend was followed by other countries including the US, where new universities (first Johns Hopkins and then the so-called land-grant state universities) were developed with an eye on European research models—models that were slowly adopted by Ivy League universities as well. This trend eroded much of the academies' pedagogical and research role.

Second, with the slow but progressive rise of science-based industry, the private sector (often in collaboration with universities) provided more niches for research and for the employment for fast-growing cadres of scientists. Widespread industrial development eroded another aspect of the academies' traditional function: that of judge of technological innovation. The emergence of the patent system, first in England but, after 1800, in most other European countries and the US, placed the reward and protection of technological innovation in the domain of the law and of the market and disconnected it from its authoritative assessment by academies (as had been the case in early modern France and other countries).

Third, the establishment or growing role of state or military technical agencies and schools (like, say, the Corps of Engineers and Geological Survey in the US, the *Ecole Politechnique* and the *Ecole des Ponts et Chaussees* in France) greatly reduced the role of scientific academies as providers of technical and scientific expertise to the state (Shinn 1980).

Fourth, with the branching of science in increasingly numerous disciplines, a slew of professional associations emerged and, with them, increasingly specialized journals. Not only did these discipline-based associations erode the academies' quasi-monopoly on scientific publishing and translations, but they also took up much of their function as international nodes of communication, collaboration, and standardization of methodologies, terminology, and units of measurement. The 'internationalism' of science which largely had been connected not only to networks of communication among academies but also to the export and import of academicians across national boundaries (most conspicuously in the eighteenth century) was replaced by more specific disciplinary and professional networks and by the migration of students (and later post doctorates) between universities and, later, institutes and laboratories. Similarly, the academies' role in the diffusion of scientific knowledge was eroded by these trends, as well as by the development of a wider nonprofessional audience for science and of

the popular publications and magazines that catered to them.

All these trends continued and were further accelerated in the twentieth century, when the additional creation of national agencies for the promotion and funding of science and the growing role of private foundations in the patronage of science took on yet another role that had been traditionally played by academies. Even large-scale, state-sponsored technical and military projects (which, historically, had seen the direct or indirect participation of scientific academies) have become commonly structured around collaborations between the state, the university, and industry. International scientific collaborations are also primarily managed by universities and national science agencies and, in the case of science-based industry, through joint ventures, licensing, patent sharing, or mergers and acquisitions. (These trends, however, are typical of Western contexts. In the former Soviet Union, the Soviet Academy of Science played a dominant role in research, training, and rewards at a time when its western counterparts had largely shed those functions (Vucinich 1984).)

In sum, it is possible to identify at least three phases in the genealogy and role of academies within the broader ecology of the social system of science: (a) patronage-based princely academies without statutes and corporate protocols up to the end of the seventeenth century; (b) peer-based academies with statutes, publications, and, in many cases, formalized relations with the state since the late seventeenth century, and mostly during the eighteenth century; and (c) dramatic increase of the scale and complexity of the social system of science associated with the multiplication of more specialized scientific institutions taking up most of the traditional roles of scientific academies (since the early nineteenth century).

The net result of this historical trajectory is that academies have moved from being informal gatherings structured by the curiosity and philosophical interests of princes and gentlemen, to comprehensive and multifunctional corporate entities crucial to the production and legitimation of science and its social system, to prestigious institutions that are marginally involved in research but still maintain an important advising role to the state and other constituencies, and bestow professional recognition on leading scientists through membership and awards. In many ways, the changing role of prizes awarded by academies encapsulates this trajectory: In the early modern period, prizes were seen as means to promote new research (not unlike today's grants) but now they function as rewards of important work that scientists have done in the past.

The importance of the largely symbolic role of modern scientific academies, however, should not be underestimated. In an age when 'lobbying' has become the dominant mode of corporate participation in political decisions (especially in the US), academies remain the authoritative agents of corporate science, no matter how accurately they may be able to represent the interests and concerns of such a large and diversified community.

Scientific Academies in Asia

The criterion for selection of the institutions described in this article is that academic research is their main function. Hence, academies that focus mainly on teaching, and policy-oriented research institutes, are not included. Taiwan's Academia Sinica is examined in terms of organization and research accomplishment, as well as its role in society. Similar research academies in mainland China and in Japan are also briefly introduced.

1. The Academia Sinica, Taiwan

1.1 Organization

The Academia Sinica was founded in mainland China 1928 in with two major missions: to undertake research in science and the humanities and to instigate, coordinate and encourage academic research. In 1949, after the Chinese civil war, the Academia was moved to Taiwan and re-established at the present site in 1954. The Academia has been headed by seven presidents since its founding, and the current president, Dr. Lee Yuan-Tseh, a Nobel laureate in chemistry, took office in 1994.

The upper-level organization of the Academia Sinica comprises three parts: the convocation, the council, and the central advisory committee. The convocation is a biennial meeting attended by preeminent Chinese scholars from all over the world who are elected to be academicians of the Academia Sinica. The year 2000 saw the 26th convocation and most of the 193 academicians—an honorary lifetime title—gathered to elect new academicians and council members. They also proposed research policies for the Academia Sinica. The council consists of 18 *ex officio* members, including all directors of research institutes, and 35 elected members. Specific functions of the council include review of research projects, evaluation of proposals related to institutional changes, promotion of academic cooperation within and outside Taiwan and, perhaps most importantly, to present a shortlist of three candidates for the presidency of the Academia Sinica to the President of the Republic of China, who make the final decision. The central advisory committee, established in 1991, includes chairpersons of the advisory committees of individual institutes and three to nine specialists nominated by the president of the Academia Sinica. Their tasks are to recruit scholars of various disciplines as well as to suggest long-term and interdisciplinary research plans to the president. The committee is also responsible for evaluating large-scale cross-institutional research projects, applications for postdoctoral research posts, and the annual awards for junior researchers' publications.

But the core of the Academia Sinica is made up of the 25 institutes/preparatory offices classified into three divisions: Mathematics and Physical Sciences, Life Sciences, and Humanities and Social Sciences (see Table 1). In 2000, 815 research staff (including 13 distinguished research fellows, 324 research fellows, 197 associate research fellows, 138 assistant research fellows, and 143 research assistants) conducted active research either individually or in groups within, as well as across, institutions. In addition to the research staff, postdoctoral researchers, contracted research assistants, and administrative officers add up to approximately 3,000 people working in the Academia Sinica.

1.2 Research Focus and Achievements

There are six fundamental principles or basic goals guiding academic research in Academia Sinica (Lee 1999) Examples of research accomplishments, landmark research projects and significant publications are discussed below.

1.2.1 A balance between scientific and humanitarian research. Critics have condemned the dominance of

[a] Preparatory Office

scientific over humanitarian research in Taiwan. This imbalance came about because of the general need to modernize the country's economy in the postwar years. During this process, most resources were allocated to technology-oriented research. As a result, natural science and the life sciences enjoyed a major share of manpower as well as of budget. In later years, especially after the lifting of martial law on Taiwan in the 1980s, the environment for social sciences research improved greatly. The humanities and social sciences (at least in the Academia Sinica) have received relatively fair treatment if adequacy of regular budget is used as an indicator. This is perhaps a rare phenomenon worldwide.

The Academia Sinica claims to have achieved balanced development among its three divisions:

Mathematics and Physical Sciences, Life Sciences, and Humanities and Social Sciences. This has been achieved by setting different criteria for the various divisions with regard to both their research direction and evaluation, and by building up a lively academic community that allows researchers from various divisions to work on the same topic.

A recently completed study on Taiwanese aboriginals is one example of such a project. Under the coordination of a researcher from the Institute of Ethnology, staff from Biomedical Sciences, along with scholars from universities and hospitals, jointly investigated the migratory history, the hereditary traits from blood samples, and the ethnic differences of aboriginals in order to establish possible genetic polymorphic markers. This type of joint endeavor by different disciplines continues and is given priority in the funding process. An ongoing study of cardiovascular-related disease, the second leading cause of death in Taiwan, is another example. The study intends to collect multifaceted community data to help combat this disease. Funded by the Academia Sinica, researchers in epidemiology, social demography, economics and statistics have formed an interdisciplinary team to tackle the issue from various angles.

1.2.2 A balance between indigenous and international research. In the late 1990s the question of the relative priority of indigenization versus internationalization of academic research was much debated among social scientists in Taiwan. Supporters of indigenization emphasized the particularistic or the unique aspect of social science studies in Taiwan and the importance of avoiding the influence of dominant Western models. To others, however, internalization of social sciences is regarded as an inevitable global trend fitting into the theme of 'knowledge without national boundaries.'

Regarding debates on the nature of the research, the Academia Sinica takes a balanced stand. On the one hand, it encourages active participation in the valued conventional research areas. On the other hand, focusing on Taiwan's particular social issues and disseminating relevant research findings is considered to be important for the intellectual community and for mankind in general. Hence, the Academia Sinica has funded large-scale research projects that have both of the above purposes in goal.

A recent group project on the long-term development of capitalism in Taiwan has the potential to extend the Taiwanese experience to other Asian economies. This study encompasses the history of agricultural and industrial developments in Taiwan, trade and navigational expansion, macroeconomic performance, and the role the Taiwan Development Company played in the consolidation of capitalism in the territory. From the colonial era to the period of Japanese rule and the postwar era, Taiwan has gone through significant social transitions in its capitalist development. Although each stage may be characterized by different sets of institutions, one common factor emerges from the historical process: the expansion of exports (from tea, sugar, rice, processed foods, to light manufactured goods and producer goods). The exploration of the origin and the evolution of capitalist development in Taiwan will not only benefit the local academies, but will enhance the comparative study of economic development in other countries.

1.2.3 A balance between basic and applied research. Academic research is the main function of the Academia Sinica. However, increasing demands are being made on it to provide research results for applied use. The Academia Sinica recognizes the necessity to respond to important social phenomena and the need for technological development in its research endeavors. Heavy emphasis has been placed on the implementation of findings from basic research. An equal amount of effort has also been allocated to promoting applied research that may shed light on the consequent academic research. Two illustrations from Information Science and Life Science will highlight this recent focus.

A study on natural language understanding is directed towards the construction of a computer program with a knowledge system that is capable of understanding human perception of various recognition systems. The project has successfully developed a concept recognition mechanism called the 'Information Map.' This map arranges human knowledge in a hierarchical fashion with a cross-referencing capability. Using the information map, concept understanding can be reduced to intelligent semantic search in the knowledge system. This project has already produced a semantic 'Yellow Page' search for a telephone company and an automatic question and answer agent on the internet. A popular product of its Chinese phonetic input system is a typing software package widely used by the public. Another well-known research project with excellent applied values is the method for detecting differentially expressed genes. The research group has developed a DNA microarray with colorimetric detection system to simultaneously monitor the expression of thousands of genes in a microarray format on nylon membrane. Testing on filter membranes and quantifying the expression levels of the target genes in cells under different physiological or diseased states will reduce each screening process to a couple of days.

It is clear that the applied research is basically restricted to non-social sciences. In social science divisions, market-oriented or consumer-involved

studies remain quite rare. Researchers are mostly committed to basic research funded by the institute or by the National Science Council. Although policy study is ostensibly given a high priority, the fact that institutes to be established in the near future will still specialize in the basic disciplines reflects a general emphasis on this area. At present, few policy-oriented research projects are undertaken by individuals.

1.2.4 Coordination and promotion of academic research in Taiwan. Under the new organizational law, which allows more flexibility for research institutes to establish ad hoc research centers, the Academia Sinica will be given the responsibility of proposing a national academic research agenda, coordinating academic research in Taiwan, and training intellectual manpower. These tasks reflect the central role of the Academia Sinica in Taiwanese academies. In order to meet these requirements, the Academia has attempted to collaborate with various universities by exchanging teaching and research staffs. *Ad hoc* research committees and specific research programs including scholars from different institutes have also been established.

The committees on Sinological Research, on Social Problems, on Taiwan Studies, and on Mainland China Studies—all established since 1997—exemplify such an effort. These committees are interdisciplinary in nature, and comprise scholars from within as well as outside the Academia Sinica. The committee may focus on a few selected research issues and organize related seminars/conferences. The committee is also allowed to form various taskforces to plan future collaborative research topics. Besides the *ad hoc* research committees, the promotion of large-scale cross-institutional research projects has become important to the Academia Sinica. A so-called 'thematic project' will share a common research framework and will include several individual research topics proposed by researchers from different institutes and universities. The study of the organization-centered society represents one of these group efforts. In the investigation of modern social structure, nine subprojects were proposed, all funded exclusively by the Academia Sinica. Their findings on the importance of impersonal trust in Taiwan's economic development—instead of the traditional interpersonal trust—as key to organizational success, has given rise to the future research perspective that a modern society such as Taiwan is organization-centered. Similar thematic projects aiming to promote collaborative work among various academic institutes have been encouraged by the granting of funds.

However, it should be pointed out that playing a central role does not equate to having the central planning function. Taiwanese social scientists, in comparison with life scientists or Japanese colleagues, have a strong inclination to pursue individual researches. Various researchers joining together in a large communal laboratory or generations of scholars working in the same topic are not common at all. The thematic project in the Academia Sinica, or the joint project promoted by the National Science Council, is more of an initiative to encourage collaborative teamwork rather than a reaction to the present research demand. Whether individual projects maintain their importance or are replaced by group efforts will not change the expectations placed on the Academia Sinica—to respect individual research freedom and to facilitate research needs in Taiwan.

1.2.5 Encouragement of international collaboration. Active participation in international research has always been a priority in Taiwan. Researchers are encouraged to present their findings at international meetings and to build collaborative relationships with foreign research groups. Renowned scholars abroad are also frequently invited to visit and to work with research staff at the Academia Sinica. In line with this trend, a proposal has been made to establish an international graduate school at Academia Sinica (Chang 2000). The aim of this program is to attract highly qualified young people to do their Ph.D. degree under the guidance of top researchers in Taiwan. The competitive program is intended to provide the opportunity for independent inquiry as well as dynamic peer interaction; it is assumed that the supportive research environment will facilitate the training of future intellectual leaders and creative scholars. Although this program is yet to be finalized, the Academia Sinica has clearly revealed its interest in taking a concrete step towards globalization by investment in brilliant young minds.

1.2.6 Feedback into society. It is the firm belief among academicians that any type of feedback to society from members of the Academia Sinica must be based on solid academic research. Several feedback patterns have been adopted. With regard to emergent social issues, researchers with related knowledge and research findings are encouraged to air their suggestions by organizing conferences or public hearings. The problem of the over-plantation of betel nuts on hills and mountains and their harmful effect on the environmental protection is an example. Short-term research projects—such as the analysis of juvenile delinquency initiated by the committee on social problems—are another possible strategy.

Furthermore, the Academia Sinica opens its campus annually and individual research institutes sponsor introductory lectures to interested students and visitors. Numerous data sets from social science or biological researches, as well as valuable original historical files, are gradually released for public use.

1.3 The Role of the Academia Sinica

Whether the Academia Sinica should play a role beyond pure academic research and beyond research-based feedback to various social problems has always hotly debated. Some of the more articulate members have been quite vocal in insisting that it should have a stronger role in economic and social life. When it comes to how far the institute should involve itself in politics, however, the issue is more delicate. The subject is closely linked with the role of contemporary intellectuals in Taiwan (Chang 2000), where it is considered permissible for intellectuals to vocalize their moral conscience with regard to significant political issues. Nevertheless, it is precisely because most intellectuals are respected for their professional scholarship, not necessarily the correctness of their political views, that the appropriateness of actual political participation is seriously questioned.

For most ordinary members of the Academia Sinica, the pressure to produce excellent research is the foremost stimulus. Academic ambition is factored into the evaluation of promotion, the review criteria for assessing institutes' research accomplishment, the process of planning new research development, and in the regular report to the Legislative Yuan. Nevertheless, considering that research staff are government employees, the public perhaps has a right to voice concerns about the public utility of the Academia Sinica, whatever its academic credentials and quality of research.

When challenged about its value to the Taiwanese taxpayer, the Academica Sinica usually reminds the public of its past research accomplishments and its dynamic future role, concrete evidence of which can be found in several newly established research institutes.

When it comes to past achievements, the most senior institute in the Humanities and Social Science division—the Institute of History and Philology—is often cited. It was established in the same year as the Academia Sinica (1928). Early collective projects such as the An-Yang excavation, the study of Chinese dialects, and the reconstruction of ancient histories gained international fame for the institute. The institute is also engaged in the systematic compilation and organization of valuable Chinese historical documents, which contributes enormously to the field of Sinology and further enhances its academic status.

Far from resting on the academic achievements of the past, the Academia Sinica is constantly trying to stay on the cutting edge of research, as can be seen by the recently established institutes. In the division of Mathematics and Physical Sciences, the Institute of Astronomy and Astrophysics (1993) and the Institute of Applied Science and Engineering Research (1999) are the two latest research institutes. The separation between pure and applied science, especially in the life sciences, is obviously not applicable any more. Within the division of Humanities, the Institute of Taiwan History (1993) and the Institute of Linguistics (1997) were formed after drastic social changes had taken place in Taiwan. The Taiwan History institute is in the forefront of indigenous research in Taiwan and it has become the focal coordinating agency for Taiwan studies.

In short, Taiwan's Academia Sinica is a government-sponsored research institute. With funding available from the regular budget, academic research has been its main prescribed task. The highly trained research staff represents the research elite in Taiwan and has full liberty in deciding on individual projects. In recent years, the Academia Sinica has made a conscious effort to promote major interdisciplinary research programs both in fulfillment of its leadership role in the Taiwanese academies and as a response to changing societal expectations. A review of recent developments within the Academia Sinica reveals its intention to gain a greater global profile on the basis of its academic performance and generous research resources.

2. Research Academies in Mainland China

2.1 The Chinese Academy of Sciences

The Chinese Academy of Sciences was founded in 1949, the same year in which the Academia Sinica moved to Taiwan. With basic research as its main task, this academy has perhaps the largest organization of any institution of its type in the world. Besides the headquarters in Beijing, 22 branches made up of no fewer than 121 research institutes are scattered all over the country. Among five academic divisions (Mathematics and Physics, Chemistry, Biological Science, Earth Science, Technological Science), more than 40,000 scientists and technical professionals work for the Academy. Among them, nearly 10,000 are regarded as basic research staff, and 230 members of the Academy (out of the current 584 members who are elected as the most preeminent scientists in mainland China) also actively engage in research at the Academy. Members of the Academy enjoy the highest academic prestige. They play a planning and consulting role in China's scientific and technological development as well as providing reports and suggestions regarding important research issues.

A review of the general research orientation of the Chinese Academy of Sciences reveals at least two important characteristics which may differentiate it from the Academia Sinica in Taiwan. First, basic research with highly applied values was a major priority of the Academy from the beginning. High-tech research and development centers are growing rapidly and the support staff composed of well-trained professionals has become a major facilitating force. Second, collaboration with industrial sectors and with foreign institutes has contributed to the Academy's

research resources. The cooperative relationship has been substantial and extensive in that more than 3,000 enterprises have joined the industry–education–research development program. The international exchange program involves 7,000 personnel annually. This program has benefited both the research staff and the postgraduates of the Academy and fulfilled an important training function: more than 14,000 staff and graduate students have received advanced training abroad since 1978 and over 8,000 have completed their studies and returned to the Academy.

2.2 The Chinese Academy of Social Sciences

The Chinese Academy of Social Sciences was formally established in 1977 from the former Philosophy and Social Sciences division of the Chinese Academy of Sciences. The central headquarters in Beijing is made up of 14 research institutes employing 2,200 staff. Among these centralized institutes are Economics, Archeology, History, Law, and Ethnology. As is the case with the Academy of Sciences, there are many branch institutes throughout China so that the staff complement totals 4,200 in 31 research institutes.

According to much of the publicity material on the Academy of Social Sciences, the needs of the country appear to be of the utmost importance in the selection of research projects. The material and spiritual development and the democratization of the nation are constantly cited as basic motives to conduct relevant studies. This bias probably owes more to the fact that funding is from central government than to any policy implications. For example, the national philosophy and social sciences committee has organized several selected research topics every five years, such as the study of changes among rural families under the economic reform coordinated by Beijing University during the 7th national Five-year Plan. A substantial proportion of research undertaken by the Academy of Social Sciences consists of special commissions of this sort.

Because the availability of funding is the key to the commencement of any research, there is a substantial reliance on foreign funding. Funding from foreign foundations is usually generous enough to greatly enhance the possibility of conducting extensive studies across different regions of the nation. But collaboration with foreign institutes, especially in social science surveys, tends to be limited to data collection. Highly quality academic written manuscript from the collaborative project in Academy of Social Sciences is relatively inadequate and waits to be promoted in the future.

As in the Academy of Sciences, there is a long-standing international academic exchange program in the Academy of Social Sciences. More than 4,100 research staff and graduate students have participated in this program since 1978 and positive outcomes are revealed in new research projects as well as publications. The 82 academic journals published by the Academy cover various disciplines such as sociology, law, history, literature, world economics, etc.

3. Research Academies in Japan

There are basically two lines of research institutions in Japan: one under the Ministry of Education and the other under the Science and Technology agencies. University-affiliated research institutes, as well as independent national research institutes with graduate schools, come under the jurisdiction of Ministry of Education. As of 1997, among 587 Japanese universities, 62 had affiliated research institutes of which 20 were open to all researchers in Japan. There are also 14 independent research institutes in Japan, unaffiliated with any university, carrying out major academic research projects. These so-called inter-university research institutes are set up because of a specific demand to undertake academic research that requires resources and manpower beyond the university boundary. The National Laboratory for High Energy Physics was the first of this kind to be established (1971). The famous National Museum of Ethnology (1974) and the National Institute of Multimedia Education (1997), which aim at scientific research, data collection, and curricula development, have a substantial research complement of their own and are staffed by visiting scholars from abroad as well as local ones. The actual contribution of the inter-university research institutes lies in the nature of basic research. Large-scale facilities and data resources as well as human resources seconded from universities throughout Japan are considered important mechanisms in enhancing the progress of scientific research in Japan.

Other national research institutes, mostly concerned with natural sciences but also including social sciences (such as the noted National Institute of Population and Social Security Research and Economic Research Institute), fall into the domain of Science and Technology agencies. The population and social security research institute was founded in 1996 by combining two government research organizations: the Institute of Population Problems and the Social Development Research Institute. It is now affiliated with the Ministry of Health and Welfare. A research staff of 45 is located in seven research departments. Although policy-oriented research comprises a major proportion of the institute's work and is self-defined by the staff, academic research is still encouraged through both institutional and individual efforts. Surveys concerning population and social security are carried out to produce primary and secondary data for policy formulation. At the same time, these data also give rise to future academic studies on social and economic issues.

There is also a national advisory board on the scientific development of Japan. The Science Council

of Japan, attached to the Prime Minister's office, was established in 1949. Unlike the Japan Academy or academicians and academy members in Taiwan and mainland China, the 210 distinguished scientists from all fields who sit on the board are not given honorary lifetime titles but serve three-year terms of office. The council enjoys great academic prestige and represents Japanese scientists domestically as well as internationally. The council has the right to advise the government to initiate important scientific research programs, and the government may seek professional recommendations from the council as well. The council is also actively engaged in bilateral scientific exchanges and other forms of international participation. The council is also expected to coordinate academic research in Japan and facilitate the implementation of important decisions concerning academic development in Japan.

With a few exceptions, such as the Nihon University Population Research Institute, most academies in Japan are national. But the restrictions stemming from their organizational structure (they come under the jurisdiction of various government ministries) may translate into less research freedom or a higher demand for policy-oriented studies. In addition, those academies or research institutes affiliated with universities are usually also expected to carry out teaching functions at the individual researcher's level.

4. Conclusion

This article has briefly outlined the national character of research organizations in Taiwan, mainland China, and Japan. The importance of the government's role in academic development in this region can be clearly observed. The private sector, in contrast, plays only a minor role, if any, in academic research. However, several differences may be distinguished among the three territories. Taiwan's Academia Sinica is perhaps foremost in terms of both research autonomy and social services research. Benefiting from the cultural tradition and the expectations of the society in which it functions, researchers there also appear to enjoy more resources in funding and in social prestige. The motivation for research can be stated in purely academic terms and no policy orientation is required in order to receive adequate funding. In addition, Taiwanese scholars have shown a stronger preference for individual research projects. Mainland China, in comparison, launched its modern social science sector in the late 1970s, a time when a few basic disciplines such as sociology were still under suspicion. That contextual factor has certainly introduced an added element to the Chinese academy—the importance of correct political attitudes. As a consequence, research aims are required to be framed within the mainstream ideology and group efforts are more likely to be observed. Japan has a different tradition regarding academies. Although research autonomy is encouraged and political factors are not necessarily emphasized, research still tends to be applied in nature. This is largely because of structural factors, in that most academies are affiliated with various government ministries or with research institutes that are concerned with policy formulation and teaching as well as pure research. Also, Japanese social scientists are more inclined to participate in group projects headed by a leader in the field. Whether this is consistent with the national character remains to be explored.

With the relatively positive outlook for economic growth in the near future, the academies in Taiwan, mainland China, and Japan may experience substantial concomitant development and may thus reach new horizons in certain research fields. Nevertheless, academic collaboration within the region itself is still comparatively rare and may be a focus in the future agenda. Hopefully, a unique Asian perspective may be developed from persistent and extensive social science studies in these areas.

Scientific Concepts: Development in Children

This article examines the development of children's scientific understanding. It is organized into four

sections: initial understanding; development of physical concepts; development of biological concepts; and learning processes.

1. Initial Understanding of Scientific Concepts

A large amount of recently obtained evidence indicates that infants' conceptual understanding is considerably more sophisticated than previously assumed. Traditionally, researchers relied on children's verbal explanations and/or their actions as measures of their conceptual understanding. These methods often underestimated infants' and very young children's understanding, owing to their inarticulateness and poor motor coordination. However, a new method, the violation-of-expectation paradigm, has made it possible to assess infants' physical knowledge by examining how long they look at 'possible' and 'impossible' events. A typical experiment involves habituating the child to a series of physically possible events and then presenting either a different possible event or an impossible event. The assumption is that children who understand the impossibility of the one event will look longer at it, because they are surprised to see the violation of the principle.

Studies using this violation of expectation paradigm have revealed impressive initial understanding of physical concepts. Even infants possess certain core concepts and understand several principles that govern the mechanical movement of objects (Spelke and Newport 1998). For example, 4-month-olds have a notion that one solid object cannot move through the space occupied by another solid object. In the studies that demonstrated this phenomenon, infants were first habituated to a display in which a ball was dropped behind a screen, which was then removed to reveal the ball on the floor. They then saw two events. In the consistent condition, the ball was again dropped, and when the screen was removed, infants saw the ball resting on a platform above the stage floor. In the inconsistent event, the ball was resting on the stage floor under the platform. Infants looked longer at the inconsistent event than at the consistent one, as if they were surprised to see the violation of the object–solidity principle. Other studies with a similar approach have also revealed infants' understanding of gravity and other physical regularities. Infants appear to understand that an unsupported object should move downward and that objects do not ordinarily move without any external force being applied.

Infants' knowledge of physical regularities is gradually refined over the first year, as demonstrated by their understanding of collisions. Most 3-month-olds appear surprised to see a stationary object move when not hit by another object. Six-month-olds can appreciate how the features of objects affect a collision. They appeared to be surprised when an object moves further following a collision with a small moving object than it does after colliding with a larger moving object. Later during the first year, infants responded differently to events in which the object that was struck moved at an angle perpendicular to the motion of the object that struck it than when it moved in a more standard path.

Other researchers, however, raise concerns about the use of such paradigms to draw inferences about infants' conceptual knowledge (e.g., Haith and Benson 1998). They argue that differential looking only indicates that infants discriminate between two events and that perceptual rather than conceptual features might drive this discrimination. Thus, infants' visual preference or looking time might have been incorrectly interpreted as evidence of an appreciation of physical principles.

Early conceptual understanding is not limited to understanding of physics principles. By age 3 years, children can distinguish living from nonliving things. They recognize that self-produced movement is unique to animals. In one study that made this point, preschoolers were shown brief videotapes in which animals or inanimate artifacts moved across the screen. Then the children were asked to make judgments about internal causes (does something inside this object make it move) and external causes (did a person make this move). Children typically attributed the cause of the animate object's motion to internal features ('it moves itself;' 'something inside makes it move'). In contrast, they were more likely to attribute the motion of an artifact to an external agent (Gelman 1990).

Preschoolers are also sensitive to differences in the 'types of stuff' inside animate and inanimate objects. They draw inferences about identity and capacity to function based on internal parts, associating, for example, internal organs, bones, and blood with animals and 'hard stuff' or 'nothing' with inanimate objects. After hearing a story about a skunk that was surgically altered so that it looked like a raccoon, young children reported that the animal was still a skunk, despite its altered appearance. However, children did not reason in the same way when they heard similar stories about artifacts; a key that was melted down and stamped into pennies was no longer a key (Keil 1989).

2. Developing Understanding of Physical Concepts

Rudimentary understanding of basic concepts does not imply full-blown appreciation of physical principles. Even older children's concepts and theories often involve substantial misconceptions. Understanding of physical concepts undergoes substantial change with age and experience. One good example involves physical causality and mechanical movement. When Event A precedes Event B, many 3- and 4-year-olds fail to choose A consistently as the cause, whereas

5- and 6-year-olds are considerably more likely to choose A. Children also hold intuitive theories of motion that are inconsistent with fundamental mechanical principles. For example, when asked to predict how a ball would travel after rolling through a spiral tube, only one-fourth of 9-year-olds and less than half of 11-year-olds correctly predicted the ball's trajectory.

Misconceptions also occur with other concepts. For example, children's conceptions of matter, weight, volume, and density undergo substantial change with age. Most 3-year-olds have undifferentiated notions of the roles of density, weight, and volume in producing buoyancy of objects placed in liquids. Most 4- and 5-year-olds have some conception of density, although their judgments are also affected by other features of the objects (i.e., weight and volume). Eight- and 9-year-olds, in contrast, rely consistently on density in judging whether objects will sink or float.

On some physical tasks, children's increasing understanding can be characterized as a series of increasingly adequate rules. One such task is Siegler's (1976) balance scale task. On each side of the scale's fulcrum were four pegs on which metal weights could be placed. In each trial, children were shown a configuration of weights on pegs and were asked to predict whether the scale would balance or whether one side would go down after release of a lever that held the scale motionless. Most children based their predictions on one of four rules. The large majority of 5-year-olds relied solely on weight (Rule I). This involved predicting that the scale would balance if both sides had the same amount of weight and that the side with more weight would go down if the two sides had different amounts of weight. Nine-year-olds often used Rule II. This involved predicting that the side with more weight would go down when one side had more weight, but predicting that the side with its weight further from the fulcrum would go down when weights on the two sides were equal. Some 9-year-olds and most 13–17-year-olds used Rule III. They considered both weight and distance on all problems, and predicted correctly when weights, distances, or both were equal for the two sides. However, when one side had more weight and the other side's weights were further from the fulcrum, children muddled through, not relying consistently on any identifiable approach. Rule IV allowed children to solve all balance scale problems. It involved choosing the side with greater torque ($W_L D_L$ vs. $W_R D_R$) when one side had more weight (W) and the other had its weight further from the fulcrum (D). Few children or adults used Rule IV. Similar sequences of rules have been shown to characterize the development of a variety of tasks, including projection of shadow, probability, water displacement, conservation of liquid and solid quantity, and time, speed, and distance.

A related way of conceptualizing the development of scientific understanding is as a succession of increasingly adequate mental models. One good example of such a succession involves understanding of the Earth as an astronomical object (Vosniadou and Brewer 1992). Some children, particularly young ones, conceive of the Earth as a flat, solid, rectangular shape. A slightly more sophisticated mental model is to think of the Earth as a disk. Three yet more advanced incorrect approaches are the 'dual Earth model,' which includes a flat, disk-like Earth where people live and a spherical Earth up in the sky; the 'hollow sphere model,' in which people live on flat ground inside a hollow sphere; and the 'flat sphere model,' in which, people live on flat ground on top of a hollow sphere. All three of these models allow children to reconcile their perception that the Earth looks flat with their teachers' and textbooks' insistence that the Earth is round. The proportion of children who possess the correct 'spherical model' of the Earth increases from 15 percent to 40 percent to 60 percent from first to third to fifth grade.

3. *Developing Understanding of Biological Concepts*

Young children have a concept of living things, but it does not perfectly match the concept of older children and adults. Until about age 7 years, most children do not view plants as living things. In addition, 3-year-olds fairly often attribute life to powerful, complex, or moving inanimate objects, such as robots and the Sun. A similar mix of understandings and misunderstandings is evident in preschoolers' views regarding internal parts of living things. They know that animals have bones and hearts, but have little idea of their functions.

Children's understanding of other uniquely biological concepts, such as growth, inheritance, and illness, also undergoes substantial change with age and experience. Preschool children have some appreciation of biological growth. They expect animals to grow, appreciate that growth can only occur in living things, and understand that growth is directional (small to big). However, preschoolers also believe that living things may or may not grow, and have difficulty accepting that even small things, such as a worm or butterfly, grow. Not until age 5 or 6 years do children realize the inevitability of growth; one cannot keep a baby pet small and cute just because one wants to do so.

Children's understanding of inheritance, another uniquely biological process, also develops with age and experience. Preschoolers understand that like begets like: Dogs have baby dogs, rabbits have baby rabbits, and offspring generally share biological properties with parents (Wellman and Gelman 1998). They also believe that animals of the same family share physical features even when they are raised in different environments. For example, preschoolers believe that

a rabbit raised by monkeys would still prefer carrots to bananas. However, other studies suggest that not until 7 years of age do children understand birth as part of a process mediating the acquisition of physical traits and nurturance as mediating the acquisition of beliefs. Only older children clearly distinguish between properties likely to be affected by heredity and properties likely to be affected by environment. For example, not until school age do children expect a boy to resemble his biological father in appearance but to resemble his adoptive father in beliefs. Thus, younger children seem to have different intuitions about the mechanisms of inheritance than do older children and adults.

Even preschoolers show some understanding of illness, yet another biological process. For example, preschoolers have a notion that an entity can induce illness or be contaminated and that contamination may occur through the workings of invisible, physical particles. Four- and 5-year-olds have some understanding of contagion; they believe that a child is more likely to get sick from exposure to another person who caught the symptom by playing with a sick friend than from another person who developed the symptom through other means. Although preschoolers may have a general idea that germs can cause symptoms, they do not differentiate the effects of symptoms caused by germs from those caused by poison, for example. The mature concept of illness, which is characterized as uniting various components such as its acquisition, symptoms, treatment, and transmission, is not mastered until much later (Solomon and Cassimatis 1999).

As with physical concepts, children's understanding of biological concepts involves substantial developmental change. For some concepts, changes involve enrichment, as children learn more and more details and phenomena relevant to the concepts. For others, developmental changes involve radical conceptual reorganization. There are some interesting parallels between the redefining and restructuring involved in the history of scientific understanding and the changes that occur within an individual lifetime (Carey 1985).

4. *Learning Processes*

Acquisition of scientific understanding involves the discovery of new rules and concepts through direct experience, as well as through instruction. Children's misconceptions can be overcome through experience that contradicts them. Only recently, however, have researchers directly examined the learning processes involved in the acquisition of scientific concepts. One approach that has proved particularly useful for learning about changing understanding of scientific concepts is the microgenetic method. This approach involves observing changing performance on a trial-by-trial basis, usually as children gain experience that promotes rapid change. Thus, the approach yields the type of high-density data needed to understand change processes (Siegler and Crowley 1991).

One example of the usefulness of the approach is provided by Siegler and Chen's (1998) study of preschoolers' learning about balance scales. The children were presented problems in which the two sides of the scale had the same amount of weight, but one side's weight was further from the fulcrum. The goal was to see if children acquired Rule II, which correctly solves such problems, as well as problems on which weight on the two sides varies but distance does not. Children's rules were assessed in a pretest and posttest in which children were asked to predict which side of the scale would go down or whether it would remain balanced. In the feedback phase between the pretest and post-test, children were repeatedly asked to predict which side of the balance, if either, would go down if a lever that held the arm motionless was released; then the lever was released and the child observed the scale's movement; and then the child was asked to explain the outcome they had observed. The trial-by-trial analysis of changes in children's predictions and explanations allowed the examination of the learning processes involved in rule acquisition. Four learning processes were identified. The first component of learning involves *noticing* potential explanatory variables (e.g., the role of distance) which previously had been ignored. The second step involves *formulating* a rule that incorporated distance as well as weight. To be classified as formulating a rule, children needed to explain the scale's action in one trial by stating that a given side went down because its disks were further from the fulcrum, and then in the next trial to predict that the side with its disks further from the fulcrum would go down. The third component involves *generalizing* the rule to novel problems by using it in most trials after it was formulated. Finally, the last component involves *maintaining* the new rule under less facilitative circumstances, by using the new rule in the posttest, where no feedback was given.

The componential analysis proved useful for understanding learning in general and also developmental differences in learning. The key variable for learning of both older and younger children, and the largest source of developmental differences in learning, involved the first component, noticing the potential explanatory role of distance from the fulcrum. Most 5-year-olds noticed the potential role of distance during learning, whereas most 4-year-olds did not. Children of both ages who noticed the role of distance showed high degrees of learning; those of both ages who did not, did not. The same componential analysis of children's learning of scientific concepts has proved useful in examining children's learning about water displacement and seems applicable to many other concepts also.

Although children often discover new rules, modify their mental models, or acquire new concepts through

direct experience both in physical and biological domains, direct observation of the natural world is often inadequate for learning new concepts. Indeed, daily experience sometimes hinders children's understanding. For example, children's misconceptions about the shape and motion of the Earth might result from the fact that the world looks flat. Well planned instruction is essential for helping children to overcome these misconceptions and to gain more advanced understanding.

The effects of instruction on children's scientific understanding can be illustrated by a study of the acquisition of the variable control principle (Chen and Klahr 1999). The variable control principle involves manipulating only one variable at a time so that an unconfounded experiment can be conducted and valid inferences can be made about the results. Most early elementary school children do not discover the variable control concept on their own. This observation led Chen and Klahr (1999) to test whether second, third and fourth graders could learn the concept through carefully planned instruction. Children were asked to design experiments to test the possible effects of different variables (whether the diameter of a spring affects how far it stretches, whether the shape of an object affects the speed with which it sinks in water, etc.). An unconfounded design would contrast springs that differed only in diameter but not in length, for example. Providing direct instruction proved to be effective in acquiring the control of variables concept. Both older and younger children who received instruction in designing tests in a specific task were able to understand the rationale and to apply the principle to other tasks. However, the older children were more able to extend the principle to novel contexts. When receiving training in designing tests involving the diameter of a spring, for example, second graders were able to apply the concept only to testing other variables involving springs (e.g., wire size). Third graders used the principle in designing experiments involving other mechanical tasks, such the speed with which objects sank in water. Only fourth graders, however, were able to apply the principle to remote contexts, such as experiments on the causes of plant growth.

In summary, recent research has revealed that infants, toddlers, and preschoolers have considerably greater scientific knowledge than previously recognized. However, their knowledge is far from complete, though. Developmental changes in children's scientific understanding involve both enrichment and structural reorganization. Older children possess more accurate and coherent rules and mental models. These understandings arise, at least in part, from their richer experience, their more advanced abilities to encode and interpret that experience, and their superior ability to separate their theories from the data (Kuhn et al. 1995). Older children also generalize the lessons from instruction more effectively than do younger children.

Although there is general agreement that early understanding of scientific concepts is surprisingly strong, there are disagreements about exactly what knowledge or concepts to attribute to infants, toddlers, and preschoolers. Even less is known about how children progress from their initial understanding of scientific concepts to more advanced understanding. Addressing the issue of how change occurs remains a major challenge, as well as a fruitful direction for future research.

Scientific Controversies

Science in general can be an object of controversy such as in disputes between science and religion. Particular scientific findings can also generate controversies either within or outside science. The importance of scientific controversy has been recognized by scholarship within science and technology studies (S&TS) since the 1970s. Indeed the study of controversies has become an important methodological tool to gain insight into key processes that are not normally visible within the sciences.

What makes something a scientific controversy? It is important to distinguish longstanding disputes, such as that between science and religion, or the merits of sociobiological explanation as applied to humans, or whether the fundamental constituents of matter are particles or waves, from more localized disputes such as over the existence of a new particle or a new disease transmitting entity. The latter sorts of controversy are more like a 'hot spot' that erupts for a while on the surface of science than a deeply entrenched long-running battle. Also controversies are not be confused with the bigger sea changes which science sometimes undergoes during scientific revolutions. Although defining a scientific revolution is itself contested, the all-pervasive nature of the changes in physics brought about by quantum mechanics and relativity seems different from, for example, the controversy over the detection of large fluxes of gravitational radiation or over the warped zipper model of DNA. Similarly, long-running debates on the relative impacts of nature and nurture on human behavior have a different character from more episodic controversies, such as the possibility of interspecies transfer of prion disease. Of course, intractable disputes and revolutions share some of the features associated with controversies, but it is the bounded nature of controversies which has led to their becoming an object of study in their own right, especially within the tradition of S&TS associated with the sociology of scientific knowledge (SSK).

One metaphor for understanding why controversies have taken on such methodological importance is that of 'punching' a system. On occasions scientists gain insight into natural systems by punching, or destabilizing, them. For example, one may learn more about the laws of momentum by bouncing one billiard ball off another than by watching a stationary billiard ball. Similarly Rutherford famously used scattering experiments in which gold foil was bombarded with alpha particles to uncover the structure of the atom and in particular the presence of the nucleus. The methodological assumption underpinning the study of controversies is similar. By studying a scientific controversy, one learns something about the underlying dynamics of science and technology and their relations with wider society. For instance, during a controversy the normally hidden social dimensions of science may become more explicit. Sites of contestation are places to facilitate the investigation of the metaphors, assumptions, and political struggles embedded within science and technology.

We can note four different influential approaches towards the study of scientific controversies. The school of sociological research associated with Robert Merton (1957) first recognized the importance of controversies within science. Of particular interest to Merton was the existence of priority disputes. Many well-known controversies center on who is the first scientist to make a particular scientific discovery. A second approach toward the study of scientific controversy developed in the 1960s as concerned citizens increasingly protested what they took to be the negative effects of science and technology. Here the source of controversy is the perceived negative impact of science and technology on particular groups and it is the study of these political responses that forms the core of the analysis. The new SSK which emerged in the 1970s and which largely displaced the Mertonian School provides a third approach towards the study of controversies. Here the focus is on controversies at the research frontiers of science where typically some experimental or theoretical claim is disputed within an expert community. Modern S&TS owe a heavy debt to SSK but are less likely to make distinctions between the content of science and its impact. Within this fourth approach, controversies are seen as integral to many features of scientific and technological practice and dissemination. Their study forms a key area of the discipline today.

1. *Merton and Priority Disputes*

Merton's interest in priority disputes stemmed from his claim that science has a particular normative structure or 'institutional ethos' with an accompanying set of rewards and sanctions. Because so much of the reward structure of science is built upon the recognition of new discoveries, scientists are particularly concerned to establish the priority of their findings. Such priority disputes are legion, such as the famous fight between Newton and Leibnitz over who first discovered the calculus.

It was Thomas Kuhn (1962) who first raised a fundamental problem for the analysis of priority

disputes. A priority dispute is predicated upon a model of science, later known as the 'point model' of scientific discovery, which can establish unambiguously who discovered what and when. Asking the question of who discovered oxygen, Kuhn showed that the crucial issue is what counts as oxygen. If it is the dephlogisticated air first analyzed by Priestly then the discovery goes to him, but if it is oxygen as understood within the modern meaning of atomic weights then the discovery must be granted to Lavoisier's later identification. The 'point model' requires discovery to be instantaneous, and for discoveries to be recognized and dated. A rival 'attributional model' of discovery, first developed by Augustin Brannigan (1981), draws attention to the social processes by which scientific discoveries are recognized and 'attributed.' This approach seems to make better sense of the fact that what counts as a discovery can vary over time. In short, it questions the Eureka moment of the point model.

For example, Woolgar (1976), in his analysis of the pulsar's discovery, shows that the date of the discovery varies depending on what stage in the process is taken to be the defining point of the discovery. If the discovery is the first appearance of 'scruff' on Jocelyn Bell's chart recording of signals from the radio telescope, then it will be dated earlier than when it was realized that the unambiguous source of this 'scruff' was a star. This case was particularly controversial because it was alleged by the dissonant Cambridge radio astronomer Fred Hoyle that the Nobel Prize winners for this discovery should have included Jocelyn Bell, who was then a graduate student. Priority disputes can touch in this way on the social fabric of science, such as its gender relationships and hierarchical structure.

Despite the challenge posed by the attributional model, it is the point model of discovery that is embedded in the reward system of science. As a result, priority disputes still abound. In modern technoscience, discovery can mean not only recognition, but also considerable financial reward, as for example with patents, licensing arrangements, or stock in a biotech company. In such circumstances, priority disputes have added salience. One has only to think of the unseemly battle between Robert Gallo and the Pasteur Institute over priority in the discovery that HIV is the cause of AIDS. In this case, there was not only scientific priority at stake, but also the licensing of the lucrative blood test for identifying AIDS. The controversy could only be settled by intervention at the highest political level. The Presidents of the USA and France, Ronald Reagan and Jacques Chirac, agreed to share the proceeds from the discovery. Again what was at stake scientifically was not simply who was first past the post; the protagonists initially claimed to have isolated different retroviruses and disagreed over the effectiveness of the various blood tests. This case was marked by additional controversy because of allegations of scientific misconduct raised against Gallo that led to Congressional and National Institute of Health (NIH) investigations.

2. *Controversy over the Impact of Science and Technology*

That a priority dispute could require the intervention of national political leaders is an indication of just how important science and technology can become for the wider polity. In response to the AIDS crisis, activist groups have campaigned and pressured scientists and government officials to do more scientifically. They have also intervened in matters of research design, such as the best way to run clinically controlled trials. Such activist engagement dates back to the political protests that science and technology generated in the 1960s in the context of Vietnam-era issues such as war and environmentalism. There has been increasing recognition that science and technology are neither neutral nor necessarily beneficial and that many developments stemming from modern science and technology, such as nuclear power, petrochemical industries, and genetic engineering, raise profound and controversial issues for a concerned citizenry.

Dorothy Nelkin, a pioneer in analyzing these types of disputes identified four types of political, economic, and ethical controversies that engage the public in the US (Nelkin 1995). One set revolves around the social, moral, and religious impact of science. Issues such as the teaching of evolution in US schools, animal rights, and the use of fetal tissue fall into this first category. A second type of controversy concerns a clash between the commercial and economic values surrounding science and technology and that of the environmental movement. Ozone depletion, toxic waste dumps, and greenhouse gases are pertinent examples. A third set has been provoked by health hazards arising from the transformation of food and agricultural practices by the use of modern science and technology. Genetically modified foods, the carcinogenic risks posed by food additives, and the use of bovine growth hormones in the dairy industry all belong in this category. A fourth group centers on conflicts between individual rights and group rights: a conflict that has been heightened by new developments in science and technology. For example, the mass fluoridation of water to improve dental health denies individuals the right to choose for themselves whether they want fluoride in their water supply.

Research on these sorts of controversies has focused mainly on the interest politics of the groups involved. How and why do they get involved in political action over science and technology; what underlying political values do such groups exhibit; and how do they effectively intervene to protest some perceived deleterious development stemming from science, technology, or medicine? The positions taken by the

participants are consistent with their interests, although these interests may not enable the outcome or closure of a debate to be predicted. For instance, the demise of nuclear power had as much to do with economics as with political protest. Since scientists themselves often play an active part in these disputes, a full analysis will touch upon how scientists deploy their science for political aims. But, by and large, this research tradition has avoided using the entry of scientists into these disputes to examine the core processes by which scientific knowledge is developed and certified. In short, the attention was focused upon seeing how scientists became political rather than upon how politics might itself shape scientific knowledge. Political controversies were treated as analytically separable from epistemic controversies and as resolved by distinct processes of closure (Engelhardt and Caplan 1987). Typically, epistemic controversies were thought to be closed by application of epistemic and methodological standards, while political controversies were closed through the intervention of 'non-scientific factors,' such as economic and political interests.

3. *Scientific Controversy and the Sociology of Scientific Knowledge*

With the emergence of the SSK in the late 1970s, it was no longer possible to avoid examining how scientific knowledge was shaped and how this shaping contributed to the dynamics of controversies. A key tenet of this new sociology of science, as formulated by David Bloor (1991) in his 'Strong Programme,' was that of symmetry. This principle called upon sociologists to use the same explanatory resources to explain both successful and unsuccessful knowledge claims. It raised to methodological status the necessity of examining the processes by which science distinguishes the wheat of truth from the chaff of error. SSK soon turned its attention towards examining scientific controversies because it is during such controversies that this symmetry principle can be applied to good effect. With each side alleging that it has 'truth' on its side, and disparaging the theoretical and experimental efforts of the other, a symmetrical analysis can explain both sides of the controversy using the same sorts of sociological resources. This differs from the earlier interest approach to controversies in that it applies this symmetrical sociological analysis to the very scientific claims made by the participants.

Bloor and his colleagues of the Edinburgh school pursued their program mainly through theoretical analysis supported by historical case studies. H. M. Collins and the 'Bath School' by contrast, developed an empirical method for studying the SSK in contemporaneous cases: a method based primarily upon the study of scientific controversies. One early application of the method was to the study of parapsychology (Collins and Pinch 1982). Collins and Pinch suggested that controversies such as that provoked by parapsychology were resolved by boundary crossing between two different forums of scientific debate: the constitutive and the contingent. Generalizing from several case studies of controversies, Collins (1981) argued that during controversies scientific findings exhibited 'interpretative flexibility,' with the facts at stake being debated and interpreted in radically different ways by the parties in the controversy.

This interpretative flexibility did not last forever: by following a controversy over time, researchers could delineate the process of 'closure' by which controversy vanished and consensus emerged. Collins defined the group of scientists involved in a controversy as the 'core set.' Only a very limited set of scientists actively partook in controversies; the rest of the scientific community depended upon the core set for their expert judgment as to what to believe. This was particularly well illustrated by Martin Rudwick (1985) in his study of the great Devonian Controversy in the history of geology.

As researchers followed controversies from their inception to the point of closure, it became necessary to address matters of scientific method as they were faced in practice by the participants. Factors that had usually been seen as issues of method or epistemology thus became open to sociological investigation: for example, the replication of experiments, the role of crucial experiments, proofs, calibration, statistics, and theory. In addition, other factors such as reputation, rhetoric, and funding were shown to play a role in the dynamics of controversies.

An important finding of this research was what Collins (1992) called the 'experimenter's regress.' Controversies clearly were messy things and were very rarely resolved by experiments alone. Collins argued that in more routine science experiments were definitive because there was an agreed-upon outcome which scientists could use as a way of judging which scientists were the competent practitioners. If one could get one's experiment to work, one had the requisite skills and competence; if one failed, one lacked the skills and competence. The trouble was that when there was a dispute at the research frontiers there was no agreed upon outcome by which to judge the competent practitioners. Experiments had to be built to investigate a claimed new phenomenon, but failure to find the new phenomenon might mean either there was no new phenomenon to be found or that the experimenter failing to find it was incompetent. This regress was only broken as a practical matter by the operation of a combination of factors such as rhetoric, funding, and prior theoretical dispositions.

Often the losing side in a scientific controversy continues to fight for its position long after the majority consensus has turned against it. Those who continue will meet increasing disapprobation from

their colleagues and may be forced to leave science altogether. 'Life after death' goes on at the margins and often finally passes away only when the protagonists themselves die or retire (Simon 1999). The uncertain side of science is clearest during moments of controversy. Most scientists never experience controversies directly, and often it is only after exposure to a controversy that scientists become aware of the social side of science, start reading in science studies, and even employ ideas drawn from science studies to understand what has happened to them.

This work on scientific controversy has been exemplified by a number of case studies of modern science such as memory transfer, solar neutrinos, gravity waves, high-energy physics, and famously cold fusion. Historians have also taken up the approach used by sociologists and the sociological methods have been extended to a number of historical case studies. Such studies pose particular methodological challenges because often the losing viewpoint has vanished from history. Shapin and Schaffer's (1985) study of the dispute between Robert Boyle and Thomas Hobbes over Boyle's air pump experiments was a landmark in research on scientific controversy, because it showed in a compelling way how the wider political climate, in this case that of Restoration Britain, could shape the outcome of a controversy. It showed how that climate could help institutionalize a new way of fact-making experiments in the Royal Society at the same time. In addition, it drew attention to the literary and technological dimensions of building factual assent in science. By documenting the witnesses to particular experimental performances, a culture of 'virtual witnessing' was born.

The SSK approach to scientific controversy has also been influential in the study of technology. The social construction of technology (SCOT) framework uses concepts imported from the study of scientific controversy such as 'interpretative flexibility' and 'closure.' A variety of competing meanings are found in technological artifacts and scholars study how 'closure mechanisms' such as advertising produce a stable meaning of a technology (Pinch and Bijker 1987, Bijker 1995).

Another influential approach to the study of controversies in sciences and technology has been that developed by Bruno Latour and Michel Callon. Again, the initial impetus came from studies of scientists. Callon's (1986) article on a controversy over a new method of harvesting scallops is one of the first articulations of what later became known as Actor Network Theory (ANT). Callon argues that the outcome of a controversy cannot be explained by reference to the social realm alone, but the analyst must also take account of the actions of non-human actors, such as scallops, which play a part in shaping the outcome. Subsequently Latour's work on how 'trials of strength' are settled in science and technology has become especially influential within the new SSK. Such struggles, according to Latour (1987), involve aligning material and cognitive resources with social ones into so-called 'immutable mobiles' or black boxes, objects which remained fixed when transported along scientific networks and which contain embedded within them sets of social, cognitive, and material relationships.

Latour and Woolgar (1979) in their now classic study of a molecular biology laboratory showed that literary inscriptions play a special role in science. They indicated how controversies could be analyzed in terms of whether certain modalities are added to or subtracted from scientific statements making them more or less fact-like. The role of discourse in scientific controversies has been examined in great depth in a study of the oxidative phosphorylation controversy by Gilbert and Mulkay (1984). They showed how particular repertoires of discourse, such as the 'empiricist repertoire' and the 'contingent repertoire,' are used selectively by scientists in order to bolster their own claims or undermine those of their opponents. Subsequently there has been much work on how a variety of rhetorical and textual resources operate during controversies (e.g., Myers 1990). Sometimes the resolution of controversy is only possible by drawing boundaries around the relevant experts who can play a role in the controversy. Sometimes particular scientific objects cross such boundaries and form a nexus around which a controversy can be resolved. Such 'boundary work' (Gieryn 1983) and 'boundary objects' (Star and Griesemer 1989) form an important analytical resource for understanding how controversies end.

In addition to analyzing scientific controversies, SSK has itself become a site of controversy. Most notably, lively controversies have occurred over the viability of interest explanations, over the extent to which the sociology of science should itself be reflexive about its methods and practices, and over the role of non-human actors. The 'science war' involving debates between natural scientists and people in science studies over the methods and assumptions of science studies and cultural studies of science is another area of controversy that is ripe for sociological investigation.

4. *Scientific Controversy in Science and Technology Studies Today*

In contemporary S&TS, the sites of contestation chosen for analysis have become more heterogeneous. One strength of the new discipline of S&TS is the wide terrain of activities involving science and technology that it examines. For example, similar methods can be used to examine controversies involving science and technology in the courtroom, the media, quasi-governmental policy organizations, and citizens' action groups. Indeed, many of the most contentious political issues facing governments and citizens today involve

science and technology: issues such as genetically modified foods, gene therapy, and *in vitro* fertilization.

The study of controversies in modern techno-science—with its porous boundaries between science, technology, politics, the media, and the citizenry—also calls for the analyst to broaden the array of analytical tools employed. Although the fundamental insights produced by SSK remain influential, such insights are supplemented by an increased understanding of how macro-political structures such as the state and the legal system enable and constrain the outcome of scientific controversies. Examples of this sort of work include:

Jasanoff's (1990) investigations of how technical controversies are dealt with by US agencies such as the Environmental Protection Agency (EPA) and the Food and Drug Administration (FDA),

Lynch and Jasanoff's (1998) work on science in legal settings such as the use of DNA evidence in courtrooms, and

Epstein's (1996) work on the AIDS controversy.

In the latter case Epstein deals not only with the dispute about the science of AIDS causation, but also turns to social movements research to understand how AIDS activists outside of science got sufficient influence actually to affect the design of clinical trials by which new AIDS drugs are tested.

Particularly interesting methodological issues have been raised by the study of controversies that overtly impinge upon politics. When studying controversies within science SSK researchers were largely able to adopt the neutral stance embodied in the symmetry principle of the Strong Programme (see *Epigenetic Inheritance*). However, some scholars have argued that, when dealing with cases where analysis could have a direct impact upon society, it is much harder to maintain neutrality. Researchers studying these sorts of disputes, such as whether Vitamin C is an effective cancer cure, find they can become 'captured' by the people they are studying. This complicates the possibility of producing the sort of neutral analysis sought after in SSK. A number of solutions have been proposed to this dilemma (see Ashmore and Richards 1996).

Several authors have attempted to produce typologies of scientific controversies (Engelhardt and Caplan 1987, Dascal 1998). Unfortunately, such typologies are not as useful as they could be because they are confounded by their underlying epistemological assumptions. For example, within an SSK approach it makes little sense to work with a category of, say, 'sound argument,' for closing a controversy because in SSK 'sound argument' is seen as part of the controversy. What counts as a 'sound argument' can be contested by both sides. Martin and Richards in their (1995) review adopt a fourfold typology. This review is particularly useful because it distinguishes between the different types of epistemological assumptions underlying the different analytical frameworks employed: namely, positivist, group politics, SSK, and social structural.

Traditional history and the philosophy of science according to one account (Dascal 1998) are becoming more cognizant of the phenomenon of scientific controversy. But the call to examine scientific controversy by historians and philosophers makes strange reading to scholars immersed in S&TS. It is as if the historians and philosophers of controversy simply have ignored or failed to read the relevant literatures. Thus neither Nelkin's (1992) influential volume, *Controversies* nor a special edition of *Social Studies of Science* edited by H. M. Collins (1981), *Knowledge and Controversy*, which sets out the SSK approach towards scientific controversy, are referenced. That the best way to study scientific controversy is still controversial within the academy could scarcely be more obvious.

Scientific Culture

1. Modern Scientific Culture

All human societies develop knowledge about their natural and social worlds. Even hunter-gatherers possess remarkable local knowledge about plants, animals, and climate. The great world civilizations had a more complex division of labor that allowed priests, doctors, smiths, farmers, and other specialists to develop more elaborate and less local knowledge systems about astronomy, psychology, medicine, metallurgy, agriculture, and other fields. Researchers tend to reserve the term 'science' for the elaborated, written knowledge systems of the great world civilizations—such as ancient Greek or Chinese science—and they tend to describe other, more local knowledge systems as ethnomedicine, ethnoastronomy, ethnobotany, and so on.

Many attempts have been made to describe the distinctive features of the type of science that emerged in Western Europe around 1500–1700 (Cohen 1997). The term 'modern science' is somewhat clearer than 'Western science,' not only because Western science was built up in part from non-Western sources, but also because Western science rapidly became globalized. However, two clarifications are in order. First, the term 'scientist' did not emerge until the nineteenth century; in earlier centuries the term 'natural philosopher' was more common. Second, the term 'modern' is used here to refer to a society characterized by a family of institutions that includes modern science, constitutional democracy, capitalism, religious pluralism, social mobility, and a universalistic legal system. Although some of those institutions can be found in some of the world's societies prior to 1500, their development as a system occurred in the West and accelerated after 1500. As an institution, science soon found a niche in modern societies by providing research and/or ideological support for the emerging capitalist industries, the state, and the churches (e.g., ballistics, mining, navigation, taxation, public health, critiques of magic).

Modern societies provided more than financial resources that supported the growth of modern science as an institution; the culture of modernity provided intellectual resources that contributed to the emergence of modern scientific inquiry. Three of the central values of modern scientific culture are empiricism, formalism, and mechanism. Although each of the distinctive features of modern scientific culture can be found in other scientific cultures (and may not be found across all modern scientific disciplines), as a family of features they have some value in characterizing modern scientific culture, and in showing its points of confluence with the cultures of modernity more generally.

Empiricism refers to the value placed on observations as a means for resolving disputes about natural and social knowledge. In some sciences, empiricism was developed as experimentalism; in other words, observations could be brought into the laboratory and subjected to experiments that were, in principle, reproducible by competent members of the scientific community. However, other fields remained non-experimental, such as the fieldwork-based sciences. Because observations are always subject to interpretation, their use as a resource for dispute resolution was in turn rooted in broader societal cultures. Scientists had to trust each other not to lie (Shapin 1994), and they required societies and journals in which they could debate and share results. Those

requirements were met in the European societies that fostered the emergence of a 'relatively autonomous intellectual class' (Ben-David 1991, p. 304) and a public sphere of open debate (Habermas 1989).

The relationship between empiricism and the broader society went beyond institutional requirements; other sectors of society were also characterized by an empirical cultural style. For example, constitutional democracies and markets were based on the 'empiricism' of elections and consumer purchases. Likewise, some Protestant churches replaced church dogma with the empiricism of direct interpretation of Bibles, and they emphasized knowledge of God through study of his works (Hooykaas 1990, p. 191, Merton 1973, Chap. 11). In this sense, the empiricism of science emerged as part of a more general way of resolving conflicting opinions about the world through recourse to data gathering and evidence.

Formalism refers to the value placed on increasingly higher levels of generalization. As generalization progresses in science, concepts and laws tend to become increasingly abstract and/or explicit. In some fields, the generalizations took the form of mathematical laws that encompassed a wide range of more specific observations. In physics, for example, it became possible to apply the same set of formal laws to the mechanics of both terrestrial and celestial objects, and space and time were analyzed in terms of geometry (Koyré 1965). In other fields, the generalizations took the form of increasingly formal and abstract taxonomies and systems of classification, as in early modern biology (Foucault 1970).

Again, broader institutions and values contributed to the emergence of this specific form of inquiry. When researchers found support for societies that published journals where an archive of research could be located, they found the institutional resources that allowed them to conjugate their work with that of others. Likewise, as Western colonial powers expanded, they sent out scientific expeditions that incorporated local knowledges and new observations into existing research fields. As 'Western' science became increasingly cosmopolitan, it also became more abstract. Again, however, the relationship with the broader society went beyond institutional influences to shared values. For example, scientific formalism developed in parallel with modernizing, Western political systems and social contract theories that emphasized the abstraction of general laws from particular interests, or of a general good from individual wills.

A third common feature is the value of mechanism as a form of explanation. Over time, modern science tended to rule out occult astrological forces, vitalistic life forces, and so on. When the concept of force was retained, as in Newton's gravitational force, it was subjected to the restraints of a formal law. Again, general social and cultural resources supported this development. The attack on occult forces was consistent with reformation campaigns against popular magic (Jacob 1988), and the disenchantment of the world that mechanistic models depended on was both supported by Christianity and intensified by some forms of Protestantism. The development and spread of clocks and constitutions provided an early metaphor of mechanism, and as new technologies and social charters were developed, new metaphors of mechanism continued to emerge (Kammen 1987, pp. 17–8, Shapin 1996, pp. 30–7). Sciences that violate the cultural value of mechanism, such as parapsychology (the study of claimed paranormal phenomena), are rejected. Likewise, the incorporation of local sciences has tended to occur after filtering out occult or vital forces. For example, in response to demand from patients and cost efficiency concerns, acupuncture and Chinese medicine are being incorporated into cosmopolitan biomedicine. However, even as the practices are being incorporated, the vitalistic concept of 'chi' and Chinese humoral concepts are being translated into mechanistic concepts consistent with modern biology and physics.

Just as values such as empiricism, formalism, and mechanism have been used to describe the intellectual culture of modern science, so a related family of concepts has been used to describe its institutional culture. Most influential was sociologist Robert Merton's (1973, Chap. 13) list of four central norms. Although subsequent research suggested that norms were frequently violated and better conceptualized as an occupational ideology (Mulkay 1976), Merton's analysis did have the advantage of pointing to the fundamental preconditions for the existence of modern scientific culture. Perhaps the basic underlying institutional value is autonomy. In other words, there is a value placed on leaving alone a certified community of qualified peers to review and adjudicate the credibility of various claims of evidence and consistency, rather than have the function ceded to the fiat of kings, dictators, church leaders, business executives, and others who do not understand the research field. The value of autonomy creates an interesting tension between science and another modern institution, constitutional democracy. Although scientific communities have suffered greatly under nondemocratic conditions, their demand for some degree of autonomy based on expertise also entails a defense of a type of elitism within a modern, democratic social order that values egalitarianism. The tension is reduced by valuing egalitarianism within the field of science, that is, by reserving it for those persons who have obtained the credentials to practice as a scientist.

2. *Variations in Scientific Culture(s)*

Going beyond the focus on modern science as a whole, much research on scientific culture has been devoted to its variations over time and across disciplines. Historians occasionally use the concept of periods as a way

of ordering cultural history, for example in the divisions of music history from baroque to classical to romantic. Although periodization is very approximate and relatively subjective, it nonetheless helps to point to some of the commonalities across scientific disciplines within the same time period, and some of the disjunctures in the history of science over time (Foucault 1970). Changes in conceptual frameworks and research programs across disciplines within a time period usually are part of broader cultural changes. For example, in the nineteenth century political values were frequently framed by grand narratives of progress (shared with the 'white man's burden' of colonialism among other ideologies), and likewise new scientific fields such as cosmology, thermodynamics, and evolutionary biology evidenced a concern with temporal issues. In the globalized information society of the twenty-first century, concerns with complex systems have become more salient, and scientists in many disciplines are developing research programs based on ideas of information processing and systemic complexity.

Science is to some extent universal in the sense that, for example, physicists throughout the world agree upon the basic laws and empirical findings of physics. However, there are also significant cultural variations in science across geographic regions. The variations are more salient in the humanities and social sciences, where distinctive theoretical frameworks often have a regional flavor. For example, one may speak of French psychoanalysis or Latin American dependency theory. The variations are also obvious for the institutional organization of scientific communities, laboratories, and university systems (Hess 1995).

Furthermore, variations in the institutional organization are sometimes associated with differing research traditions in the content of a field. For example, the salary and power structure of German universities in the first third of the twentieth century favored a more theoretical approach to genetics and a concern with evolution and development. In contrast, the relatively collegial governance structures of the American universities, together with their location in agricultural schools, contributed to the development of American genetics in a more specialized, empirical, and applied direction (Harwood 1993). Sometimes variations in institutional structures and conditions are also associated with differences in laboratory technologies, which in turn restrict the selection of research problems. For example, in Japan, funding conditions for physics have in part shaped the emergence of detector designs that differ substantially from those in the USA (Traweek 1988).

In addition to the temporal and national cultures of science, a third area of variation in scientific cultures involves disciplinary cultures. For example, both high-energy physics and molecular biology are considered 'big science,' but their disciplinary cultures are substantially different (Knorr-Cetina 1999). Regarding their intellectual cultures, in high-energy physics data are widely recognized as heavily interpretable, whereas in molecular biology the contact with the empirical world is much more hands-on and direct. Regarding the institutional cultures of the two fields, laboratories in high-energy physics are very large-scale, with the individual's work subordinated to that of the cooperative team, even to the point of near anonymity in publication. In contrast, in molecular biology the laboratories are smaller, even for the genome project, and competition among individual researchers remains salient, with frequent disputes over priority in a publication byline.

3. *Multiculturalism and Science*

A third approach to the topic of scientific culture involves the ongoing modernization of scientific cultures. Although modern science is increasingly international and cosmopolitan, its biases rooted in particular social addresses have constantly been revealed. Science has been and remains largely restricted to white men of the middle and upper classes in the developed Western countries (Harding 1998, Rossiter 1995, Schiebinger 1989). As scientific knowledge and institutions have spread across the globe and into historically excluded groups, they have sometimes undergone changes in response to perspectives that new groups bring to science. For example, in the case of primatology, humans and monkeys have coexisted for centuries in India. Consequently, it is perhaps not surprising that Indian primatologists developed new research programs based on monkey–human interactions that challenged the romanticism of Western primatologists' focus on natural habitats (Haraway 1989). More generally, as scientific disciplines become globalized, different national cultural traditions intersect with the globalized disciplinary cultures to reveal unseen biases and new possibilities for research.

As women and under-represented ethnic groups have achieved a place in scientific fields, they have also tended to reveal hidden biases and develop new possibilities. Although the reform movements of multiculturalism in science can be restricted to the institutional culture of science (such as reducing racism and sexism in hiring practices), they sometimes also extend to the intellectual culture or content of science. Theories and methods—particularly in the biological and social sciences—that seem transparently cosmopolitan and truthful to white, male colleagues often appear less so to the new groups. Whether it is the man-the-hunter theory of human evolutionary origins (Haraway 1989), the 'master' molecule theory of nucleus to cytoplasm relations (Keller 1985), or biological measures of racial inferiority (Harding 1993), scientific disciplines find themselves continually challenged to prove their universalism and to modify

concepts and theories in response to anomalies and new research.

In some cases the members of excluded groups do more than replace old research methods and programs with new ones; they also create new research fields based on their identity concerns. A prime example is the work of the African American scientist George Washington Carver. Although best known in American popular culture for finding many new uses for the peanut, Carver's research was embedded in a larger research program that was focused on developing agricultural alternatives to King Cotton for poor, rural, African American farmers (Hess 1995).

4. Conclusions

It is important not to think of the embeddedness of scientific cultures in broader cultural practices as a problem of contamination. The broader cultures of modern science provide a source of metaphors and institutional practices that both inspire new research and limit its possibilities. For example, if evolutionary theory could not be thought before the progressivist culture of the nineteenth century, it cannot help but to be rethought today. Not only have new research findings challenged old models, but the broader cultural currents of complex systems and limits to growth have also inspired new models and empirical research (DePew and Weber 1995). In turn, today's concepts and theories will be rethought tomorrow. The broader societal cultures are not weeds to be picked from the flower bed of scientific culture(s) but the soil that both nurtures and limits its growth, even as the soil itself is transformed by the growth that it supports.

Scientific Disciplines, History of

The scientific discipline as the primary unit of internal differentiation of science is an invention of nineteenth century society. There exists a long semantic prehistory of *disciplina* as a term for the ordering of knowledge for the purposes of instruction in schools and universities. But only the nineteenth century established real disciplinary communication systems. Since then the discipline has functioned as a unit of structure formation in the social system of science, in systems of higher education, as a subject domain for teaching and learning in schools, and finally as the designation of occupational and professional roles. Although the processes of differentiation in science are going on all the time, the scientific discipline as a basic unit of structure formation is stabilized by these plural roles in different functional contexts in modern society.

1. Unit Divisions of Knowledge

Disciplina is derived from the Latin *discere* (learning), and it has often been used since late Antiquity and the early Middle Ages as one side of the distinction *disciplina* vs. *doctrina* (Marrou 1934). Both terms

meant ways of ordering knowledge for purposes of teaching and learning. Often they were used synonymously. In other usages *doctrina* is more intellectual and *disciplina* more pedagogical, more focused on methods of inculcating knowledge. A somewhat later development among the church fathers adds to *disciplina* implications such as admonition, correction, and even punishment for mistakes. This concurs with recent interpretations of discipline, especially in the wake of Michel Foucault, making use of the ambiguity of *discipline* as a term always pointing to knowledge and disciplinary power at the same time (cf. Hoskin in Messer-Davidow et al. 1993). Finally, there is the role differentiation of teaching and learning and the distinction *doctrina/disciplina* is obviously correlated with it (Swoboda 1979).

One can still find the same understandings of *doctrina* and *disciplina* in the literature of the eighteenth century. But what changed since the Renaissance is that these two terms no longer refer to very small particles of knowledge. They point instead to entire systems of knowledge (Ong 1958). This goes along with the ever more extensive use by early modern Europe of classifications of knowledge and encyclopedic compilations of knowledge in which disciplines function as unit divisions of knowledge. The background to this is the growth of knowledge related to developments such as the invention of printing, the intensified contacts with other world regions, economic growth and its correlates such as mining and building activities. But in these early modern developments there still dominates the *archival function of disciplines*. The discipline is a place where one deposits knowledge after having found it out, but it is not an active system for the production of knowledge.

2. *Disciplines as Communication Systems*

A first premise for the rise of disciplines as production and communication systems in science is the specialization of scientists and the role differentiation attendant on it (Stichweh 1984, 1992). Specialization is first of all an intellectual orientation. It depends on a decision to concentrate on a relatively small field of scientific activity, and, as is the case for any such decision, one needs a social context supporting it, that is, other persons taking the same decision. Such decisions are rare around 1750 when encyclopedic orientations dominated among professional and amateur scientists alike, but they gained in prominence in the last decades of the eighteenth century. Second, specialization as role differentiation points to the educational system, which is almost the only place in which such specialized roles can be institutionalized as occupational roles. From this results a close coupling of the emerging disciplinary structures in science and the role structures of institutions of higher education. This coupling is realized for the first time in the reformed German universities of the first half of the nineteenth century and afterwards quickly spreads from there to other countries. Third, role differentiation in institutions of higher education depends on conditions of organizational growth and organizational pluralization. There has to be a sufficient number of organizations which must be big enough for having differentiated roles and these organizations must be interrelated in an ongoing continuity of interactions.

The emergence of *communities of specialists* is a further relevant circumstance. In this respect the rise of disciplines is synonymous with the emergence of *scientific communities* theorized about since Thomas Kuhn (Kuhn 1970). Scientific communities rest on the intensification of interaction, shared expertise, a certain commonality of values, and the orientation of community members towards problem constellations constitutive of the respective discipline. Modern science is not based on the achievements of extraordinary individuals but on the epistemic force of disciplinary communities.

Scientific communities are *communication systems*. In this respect the emergence of the scientific discipline is equivalent to the invention of new communication forms specific of disciplinary communities. First of all one may think here of new forms of *scientific publications*. In the eighteenth century a wide spectrum of publication forms existed; they were not, however, specialized in any way. There were instructional handbooks at the university level, journals of a general scientific nature for a regional public interested in utility, and academy journals aiming at an international public, each covering a wide subject area but with rather limited communicative effects. It was only after 1780 that in France, in Germany, and finally, in England, nationwide journals with a specific orientation on such subjects as chemistry, physics, mineralogy, and philology appeared. In contrast to isolated precursors in previous decades, these journals were able to exist for longer periods exactly because they brought together a *community of authors*. These authors accepted the specialization chosen by the journal; but at the same time they continually modified this specialization by the cumulative effect of their published articles. Thus the status of the scientific publication changed. It now represented the only communicative form by which, at the macrolevel of the system of science—defined originally by national but later by supranational networks—communication complexes specialized along disciplinary lines could be bound together and persist in the long run (Stichweh 1984, Chap. 6, Bazerman 1988).

At the same time the scientific publication became a formal principle interfering in every scientific production process. Increasingly restrictive conditions were defined regarding what type of communication was acceptable for publication. These conditions

included the requirement of identifying the problem tackled in the article, the sequential presentation of the argument, a description of the methods used, presentation of empirical evidence, restrictions on the complexity of the argument accepted within an individual publication, linkage with earlier communications by other scientists—using citations and other techniques—and the admissibility of presenting speculative thoughts. In a kind of feedback loop, publications, as the ultimate form of scientific communication, exercised pressure on the scientific production process (i.e., on research) and were thereby able to integrate disciplines as social systems.

This reorganization of the *scientific production process* adheres to one new imperative: the *search for novelties*. The history of early modern Europe was already characterized by a slow shift in the accompanying semantics associated with scientific truth, from an imperative to preserve the truth to an interest in the novelty of an invention. The success achieved in organizing traditional knowledge, as well as tendencies towards empirical methods and increased use of scientific instruments, worked toward this end. In this dimension, a further discontinuity can be observed in the genesis of the term *research* in the years after 1790. In early modern times the transition from the preservation to the enlargement of knowledge could only be perceived as a continual process. In contrast, *research* from about 1800 refers to a fundamental, and at any time realizable, questioning of the entire body of knowledge until then considered as true. Competent scientific communication then had to be based on research in this sense. What was communicated might be a small particle of knowledge, as long as it was a new particle of knowledge. Scientific disciplines then became research disciplines based on the incessant production of novelties.

The link between scientific disciplines and organizations of higher education is mediated by two more organizational structures. The first of these are *disciplinary careers*. Specialized scientists as members of disciplinary communities do not need only specialized occupational roles. Additionally there may be a need for careers in terms of these specialized roles. This again is a condition which sharply distinguishes eighteenth from nineteenth century universities. Around 1750 you still find, even in German universities, hierarchical career patterns which implied that there was a hierarchical succession of chairs inside of faculties and a hierarchical sequence of faculties by which a university career was defined as a progression of steps through these hierarchized chairs. One could, for example, rise from a chair in the philosophical faculty to an (intellectually unrelated) chair in the medical faculty. The reorganization of universities since early nineteenth century completely discontinued this pattern. Instead of a succession of chairs in one and the same university, a scientific career meant a progression through positions inside a discipline, which normally demands a career migration between universities. This presupposes intensified interactions and competitive relations among universities which compete for qualified personnel and quickly take up new specializations introduced elsewhere. In Germany such regularized career paths through the national university system were especially to be observed from around 1850.

This pattern is again closely related to *disciplinary curricula*, meaning that one follows one's disciplinary agenda not only in one's research practice and personal career, but furthermore that there exist institutional structures favoring teaching along lines close to current disciplinary core developments. The unity of teaching and research is one famous formula for this, but this formula does not yet prescribe disciplinary curricular structures which would demand that there should be a complete organization of academic studies close to the current intellectual problem situation and systematics of a scientific discipline. Only if this is the case does there arise a *professionalization of a scientific discipline*, which means that a systematic organization of academic studies prepares for a non-academic occupational role which is close to the knowledge system of the discipline. Besides professionalization there is then the effect that the discipline educates its own future research practitioners in terms of the methods and theories constitutive of the discipline. A discipline doing this is not only closed on the level of the disciplinary communication processes, it is also closed on the level of socialization practices and the attendant recruitment of future practitioners (on the operational closure of modern science see Luhmann 1990, Stichweh 1990).

3. *The Modern System of Scientific Disciplines*

It is not sufficient to analyze disciplines as individual knowledge producing systems. One has to take into account that the invention of the scientific discipline brings about first a limited number, then many scientific disciplines which interact with one another. Therefore it makes sense to speak of a modern system of scientific disciplines (Parsons 1977, p. 300ff., Stichweh 1984) which is one of the truly innovative social structures of the modern world.

First of all, the modern system of scientific disciplines defines an *internal environment* (*milieu interne* in the sense of Claude Bernard) for any scientific activity whatsoever. Whatever goes on in fields such as physics, sociology, or neurophysiology, there exists an internal environment of other scientific disciplines which compete with that discipline, somehow comment on it, and offer ideas, methods, and concepts. There is *normal science* in a Kuhnian sense, always involved with problems to which solutions seem to be at hand in the disciplinary tradition itself; but normal science is

always commented upon by a parallel level of interdisciplinary science which arises from the conflicts, provocations and stimulations generated by other disciplines and their intellectual careers.

In this first approximation it is already to be seen that the modern system of scientific disciplines is a very dynamic system in which the dynamism results from the intensification of the interactions between ever more disciplines. Dynamism implies, among other things, ever changing disciplinary boundaries. It is exactly the close coupling of a *cognitively defined discipline* and a *disciplinary community* which motivates this community to try an expansionary strategy in which the discipline attacks and takes over parts of the domain of other disciplines (Westman 1980, pp. 105–6). This was wholly different in the disciplinary order of early modern Europe, in which a classificatory generation of disciplinary boundaries meant that the attribution of problem domains to disciplines was invariable. If one decided to do some work in another domain, one had to accept that a change over to another discipline would be necessary to do this.

Closely coupled to this internally generated and self-reinforcing dynamics of the modern system of scientific disciplines is the openness of this system to new disciplines. Here again arises a sharp difference to early modern circumstances. In early modern Europe there existed a closed and finite catalogue of scientific disciplines (Hoskin 1993, p. 274) which was related to a hierarchical order of these disciplines (for example philosophy was a higher form of knowledge than history, and philosophy was in its turn subordinated to faculty studies such as law and theology). In modern society no such limit to the number of disciplines can be valid. New disciplines incessantly arise, some old ones even disappear or become inactive as communication systems. There is no center and no hierarchy to this system of the sciences. Nothing allows us to say that philosophy is more important than natural history or physics more scientific than geology. Of course, there are asymmetries in influence processes between disciplines, but no permanent or stable hierarchy can be derived from this.

The modern system of scientific disciplines is a global system. This makes a relevant difference from the situation of the early nineteenth century, in which the rise of the scientific discipline seemed to go along with a strengthening of national communities of science (Crawford et al. 1993, Stichweh 1996). This nationalization effect, which may have had to do with a meaningful restriction of communicative space in newly constituted communities, has since proved to be only a temporary phenomenon, and the ongoing dynamics of (sub-) disciplinary differentiation in science seems to be the main reason why national communication contexts are no longer sufficient infrastructures for a rapidly growing number of disciplines and subdisciplines.

4. *The Future of the Scientific Discipline*

The preponderance of subdisciplinary differentiation in the late twentieth century is the reason most often cited for the presumed demise of scientific discipline postulated by a number of authors. But one may object to this hypothesis on the ground that a change from disciplinary to subdisciplinary differentiation processes does not at all affect the drivers of internal differentiation in modern science: the relevance of an internal environment as decisive stimulus for scientific variations, the openness of the system to disciplinary innovations, the nonhierarchical structure of the system. Even if one points to an increasing importance of interdisciplinary ventures (and to problem-driven interdisciplinary research) which one should expect as a consequence of the argument on the internal environment of science, this does not change the fact that disciplines and subdisciplines function as the form of consolidating interdisciplinary innovations. And, finally, there are the interrelations with the external environments of science (economic, political, etc.), which in twentieth and twenty-first century society are plural environments based on the principle of functional differentiation. Systems in the external environment of science are dependent on sufficiently stable addresses in science if they want to articulate their needs for inputs from science. This is true for the educational environment of science which has to organize school and higher education curricula in disciplinary or interdisciplinary terms, for role structures as occupational structures in the economic environment of science, and for many other demands for scientific expertise and research knowledge which always must be able to specify the subsystem in science from which the respective expertise may be legitimately expected. These interrelations based on structures of internal differentiation in science which have to be identifiable for outside observers are one of the core components of modern society which, since the second half of the twentieth century, is often described as *knowledge society*.

Scientific Discovery, Computational Models of

Scientific discovery is the process by which novel, empirically valid, general, and rational knowledge about phenomena is created. It is, arguably, the pinnacle of human creative endeavors. Many academic and popular accounts of great discoveries surround the process with mystery, ascribing them to a combination of serendipity and the special talents of geniuses. Work in Artificial Intelligence on computational models of scientific reasoning since the 1970s shows that such accounts of the process of science are largely mythical. Computational models of scientific discovery are computer programs that make discoveries in particular scientific domains. Many of these systems model discoveries from the history of science or simulate the behavior of participants solving scientific problems in the psychology laboratory. Other systems attempt to make genuinely novel discoveries in particular scientific domains. Some have produced new findings of sufficient worth that the discoveries have been published in mainstream scientific journals. The success of these models provides some insights into the nature of human cognitive processes in scientific discovery and addresses some interesting issues about the nature of scientific discovery itself (see *Scientific Reasoning and Discovery, Cognitive Psychology of*).

1. Computational Models of Scientific Discovery

Most computational models of discovery can be conceptualized as performing a recursive search of a space of possible states, or expressions, defined by the representation of the problem. Procedures are used to search the space of legal states by manipulating the expressions and using tests of when the goal or subgoals have been met. To manage the search, which is typically subject to potential combinatorial explosion, heuristics are used to guide the selection of appropriate operators. This is essentially an application of the theory of human problem solving as heuristic search within a symbol processing system (Newell and Simon 1972).

For example, consider BACON (Langley et al. 1987) an early discovery program which finds algebraic formulas as parsimonious descriptions of quantitative data. States in the problem search space of BACON include simple algebraic formulas; such as P/D or P^2/D, where, for instance, P is the period of revolution of planets around the sun and D is their distance from the sun. Tests in BACON attempt to find how closely potential expressions match the given quantitative data. Given quantitative data for the planets of the solar system, one step in BACON's discovery path finds that neither P^2/D nor P/D are constant and that the first expression is monotonically increasing with respect to the second. Given this relation between the expressions BACON applies its INCREASING operator to give the product of the terms, i.e., P^3/D^2. This time the test of whether the expression is constant, within a given margin of error, is true. $P^3/D^2 =$ constant is one of Kepler's planetary motion laws. For more complex cases with larger numbers of variables, BACON uses discovery heuristics based on notions of symmetry and the conservation of higher order terms to pare down the search space. The heuristics use the underlying regularities within the domain to obviate the need to explore parts of the search space that are structurally similar to previously explored states.

Following such an approach, computational models have been developed to perform tasks spanning a full

spectrum of theoretical activities including the formation of taxonomies, discovering qualitative and quantitative laws, creation of structural models and the development of process models (Langley et al 1987, Shrager and Langley 1990, Cheng 1992). The range of scientific domains covered is also impressive, ranging from physics and astronomy, to chemistry and metallurgy, to biology, medicine, and genetics. Some systems have produced findings that are sufficiently novel to be worthy of publication in major journals of the relevant discipline (Valdes-Perez 1995).

2. Scope of the Models

Computational models of scientific discovery have almost exclusively addressed theory formation tasks. However, the modeling of experiments has not been completely neglected as models have been built that design experiments, to a limited extent, by using procedures to specify what properties should be manipulated and measured in an experiment and the range of magnitudes over which the properties should be varied (Kulkarni and Simon 1988, Cheng 1992). For these systems, the actual experimental results are either provided by the user of the system or generated by a simulated experiment in the software. Discovery systems have also been directly connected to a robot which manipulates a simple experimental setup so that data collected from the instruments can be fed to the system directly, so eliminating any human intervention (Huang and Zytkow 1997). Nevertheless, few systems have simulated or supported substantial experimental activities, such as observing or creating new phenomena, designing experiments, inventing new experimental apparatus, developing new experimental paradigms, establishing the reliability of experiments, or turning raw data into evidence. This perhaps reflects a fundamental difference between the theoretical and experimental sides of science. While both clearly involve abstract conceptual entities, experimentation is also grounded in the construction and manipulation of physical apparatus, which involves a mixture of sophisticated perceptual abilities and motor skills. Developing models of discovery that include such capabilities would necessarily require other areas within AI beyond problem solving, such as image processing and robotics.

The majority of discovery systems model a single theory formation task. The predominance of such systems might be taken as the basis for a general criticism of computational scientific discovery. The models are typically poor imitations of the diversity of activities in which human scientists are engaged and, perhaps, it is from this variety that scientific creativity arises. Researchers in this area counter such arguments by claiming that the success of such single task systems is a manifestation of the underlying nature of the process of discovery, that it is composed of subprocesses or tasks that are relatively autonomous. More complex activity can be modeled by assembling systems that perform one task into a larger system, with the inputs to a particular component subsystem being the outputs of other systems. The handful of models that do perform multiple tasks demonstrate the plausibility of this claim (e.g., Kulkarni and Simon 1988, Cheng 1992). The organization of knowledge structures and procedures in those systems exploits the hierarchical decomposition of the overall process into tasks and subtasks.

This in turn raises the general question about the number and variety of different tasks that constitute scientific discovery and the nature of their interactions. What distinct search spaces are involved and how is information shared among them? Computational models of scientific discovery provide some insight into this issue. At a general level, many models can be characterized in terms of two spaces, one for potential hypotheses and the other a space of instances or sets of data (Simon and Lea 1974). Scientific discovery is then viewed as the search of each space mutually constrained by the search of the other. Inferring a hypothesis dictates the form of the data needed to test the hypothesis, while the data itself will determine whether the hypothesis is correct and suggest in what ways it should be amended (Kulkarni and Simon 1988). This is an image of scientific discovery that places equal importance on theory and experiment, portraying the overall process as a dynamic interaction between both components. This approach is applicable both to disciplines in which individual scientists do the theorizing and experimenting and to disciplines in which these activities are distributed among different individuals or research groups. The search of the theoretical and experimental spaces can be further decomposed into additional subspaces; for example, Cheng (1992) suggests three subspaces for hypotheses, models, and cases under the theory component, and spaces of experimental classes, setups, and tests under the experimental component.

3. Developing Computational Models of Discovery

One major advantage of building computational models over other approaches to the study of scientific discovery is the precision that is imposed by writing a running computer program. Ambiguities and inconsistencies in the concepts used to describe discovery processes become apparent when attempting to encode them in a programming language. Another advantage of modeling is the ability to investigate alternative methods or hypothetical situations. Different versions of a system may be constructed embodying, say, competing representations to investigate the difficulty

of making the discovery with the alternatives. The same system can be run with different sets of data, for example, to explore whether a discovery could have been made had there been less data, or had different data been available.

Many stages are involved in the development of the models, including: formulation of the problem, engineering appropriate problem representations, selecting and organizing data, design and redesign of the algorithm, actual invocation of the algorithm, and filtering and interpretation of the findings of the system (Langley 1998). Considering the nature and relative importance of these activities in the development of systems provides further insight into the nature of scientific discovery. In particular, the design of the representation appears to be especially critical to the success of the systems. This implies that generally in scientific discovery finding an effective representation may be fundamental to the making of discoveries. This issue has been directly addressed by computational models that contrast the efficacy of different representations for modeling the same historical episode (Cheng 1996). Consistent with work in cognitive science, diagrammatic representations may in some cases be preferable to informationally equivalent propositional representations. Although computational models argue against any special abilities of great scientists beyond the scope of conventional theories of problem solving, the models suggest that the ability of some scientists to modify or create new representations may be an explanation, at least in part, of why they were the ones to succeed.

4. Conclusions and Future Directions

Given the extent of the development work necessary on a discovery system, it seems appropriate to attribute discoveries as much to the developer as to the system itself, although without the system many of the novel discoveries would not have been possible. This does not imply that machine discovery is impossible, but that care must be taken in delimiting the capabilities of discovery systems. Further, the ability of the KEKEDA system (Kulkarni and Simon 1988) to change its goals to investigate any surprising phenomenon it discovers suggests that systems can be developed that would filter and interpret the output of existing systems, by constraining the search of the space defined by the outputs of those systems using metrics based on notions of novelty. Developing such a system, or other systems that find problems or that select appropriate representations, will require the system to possess a substantially more extensive knowledge of the target domain. Such knowledge based systems are costly and time consuming to build, so it appears that the future of discovery systems will be more as collaborative support systems for domain scientists rather than fully autonomous systems (Valdes-Perez 1995). Such systems will exploit the respective strengths of domain experts and the computational power of the models to compensate for each others' limitations.

Scientific Evidence: Legal Aspects

Expertise, scientific and otherwise, has been part of the legal landscape for centuries (Hand 1901). Over the last decades of the twentieth century the role of scientific evidence in the law has expanded rapidly, in both regulatory settings and in litigation. Statutes and

treaties routinely require agencies to provide scientific justifications for regulatory decisions within and among nations. National and international policy disputes are increasingly fought out within the risk assessment rhetoric of science (Craynor 1993).

Courts are another large consumer of science. In both criminal and civil cases, parties believe scientific testimony will make their case stronger. As science's role has grown, so has interest in the relationship between law and science. This essay reviews the present state of knowledge concerning the science–law relationship and mentions several areas ripe for investigation.

1. *What Law Wants from Science*

In both the administrative and the courtroom context, law is most frequently interested in acquiring scientific answers to practical questions of causation (e.g., does exposure to airborne asbestos cause lung cancer) and measurement (e.g., what is the alcohol level in a driver's blood). Both of these questions entail questions as to whether specific techniques (e.g., a breathalyzer) are capable of producing reliable measurements. Theoretical questions *per se* are frequently of secondary interest, useful insofar as they help courts and regulators to chose among conflicting measurements, extrapolations, or causal assertions.

Courts and agencies are both interested in questions of general and specific causation. Agencies are interested in the effects of nitrous oxide on the environment and the specific level of emissions from a particular plant. Courts may be interested in whether a given level of airborne asbestos causes lung cancer. And they may need to determine if a particular plaintiff's lung cancer was caused by asbestos exposure. It is often much more difficult to achieve a scientifically rigorous answer to this latter type of question.

An important difference between courts and agencies is the level of proof necessary to reach a conclusion. In administrative settings agencies may prevail if they can show that a substance poses a danger or a risk. In a courtroom however, in order to prevail, the plaintiff will be required to show both general and specific causation. Scientific evidence that is sufficient in the regulatory context may be considered insufficient in the court context. For example, animal studies showing a relationship between saccharin consumption and cancer may be sufficient to cause an agency to impose regulations on human exposure to the sweetener, but would not be sufficient to permit a groups of plaintiffs to prevail on a claim that they were actually injured by consuming saccharin in diet soft drinks, or even on the general causation claim that saccharin at human dose levels causes cancer in any humans.

2. *Legal Control of Scientific Evidence*

One of the more interesting aspects of the use of science in courts is the legal effort to control the terms of the law–science interaction. Judicial control of scientific experts is shaped by whether the court is operating in an inquisitorial or an adversarial system (van Kampen 1998). In inquisitorial systems, e.g., Belgium, Germany, France, Japan, the judge plays a large role in the production of evidence. Experts are almost always court appointed and are asked to submit written reports. Parties may be given the opportunity to object to a particular expert, question the expert about the opinion rendered, or hire their own expert to rebut the court-appointed expert; but it is very difficult to attack the admissibility of an expert's report successfully (Langbein 1985, Jones 1994). In adversarial systems the parties usually have far greater control over the production of evidence, including the selection and preparation of expert witnesses. Court-appointed experts are rare (Cecil and Willging 1994).

A similar pattern can be observed in the regulatory arena. Jasanoff (1991) compares the relatively closed, consensual, and non-litigious British regulatory approach to the open, adversarial and adjudicatory style found in the United States. Clearly, legal organization and legal culture shape the way in which legal systems incorporate science. In turn, legal organization is related to larger cross-cultural differences. For example, open, adversarial approaches are more pronounced in societies that are more individualistic and lower on measures of power distance (Hofstede 1980).

Judicial control of scientific expert testimony has become a high profile issue in the United States. Critics complain that the combination of adversarial processes and the use of juries in both criminal and civil trials encourages the parties to introduce bad science into the trial process. They argue, with some empirical support, that the use of experts chosen by the parties produces individuals who by their own account stray relatively further from Merton's four norms of science—universalism, communism, disinterestedness, and organized skepticism (Merton 1973). They submit that jurors are too easily swayed by anyone who is called a scientist regardless of the quality of the science supporting the expert's position. (See *Expert Witness and the Legal System*: *Psychological Aspects*.) Many now call upon judges to play a greater role in selecting and supervising experts, a role closer to that found in inquisitorial systems (Angell 1996).

The preference for an inquisitorial style makes several assumptions about the nature of science and the proper relationship between law and science. Similar assumptions underlie the admissibility rules employed by courts. The history of admissibility decisions in American courts provides a useful way to explore these assumptions.

Precisely because the knowledge possessed by the scientist is beyond the ken of the court, the judge (or

the jury) often is not in a good position to determine if what the expert is offering is helpful. In a 1923 decision a federal court offered one solution to this problem; acquiesce to the judgment of the community of elites who are the guardians of each specialized area of knowledge. Under the so-called *Frye* rule experts may testify only if the subject of their testimony had reached 'general acceptance' in the relevant scientific community. In 1993 in *Daubert* vs. *Merrell Dow Pharmaceuticals*, *Inc*., and subsequent opinions, the United States Supreme Court moved away from the *Frye* rule. In its place federal courts have developed a nonexclusive multifactor test designed to assess the validity of the science underlying the expert's testimony. Factors the courts have mentioned include: whether the theory or technique underlying the expert's testimony is falsifiable and had been tested; the error rate of any techniques employed; whether the expert's research was developed independent of litigation; whether the testifying expert exercised the same level of intellectual rigor that is routinely practiced by experts in the relevant field; whether the subject matter of the testimony had been subjected to peer review and publication in refereed journals; and, in a partial retention of the *Frye* test, whether the theory or technique had achieved general acceptance in the relevant scientific community.

The *Daubert*-inspired test offers an alternative to acquiescence, a do-it-yourself effort on the part of the courts. A number of the factors are consistent with an adversarial legal system that institutionalizes mistrust of all claims to superior authority. The adversary system itself is consistent with the values of a low-power distance culture that affords relatively less legitimacy to elite authoritative opinion and, therefore, is skeptical that scientists are entitled to a privileged language of discourse from which others are excluded. It is also consistent with a view of science strongly influenced by other forces in society. These are perspectives on the scientific enterprise that are associated with those who adopt a social constructionist view of science (Shapin 1996, Pickering 1992).

3. *Legal Understanding of the Scientific Enterprise*

Daubert, however, offers anything but a social constructionist test if by this we mean that scientific conclusions are solely the result of social processes within the scientific community. At its core, the opinion requires of judges that they become sufficiently knowledgeable about scientific methods so that they can fairly assess the validity of evidence offered at trial. This requirement that scientific testimony must pass methodological muster reflects a positivist approach that is slanted toward a Baconian view of science. The opinion cites with favor a Popperian view of how to distinguish the scientific enterprise from other forms of knowledge (Popper 1968). In this regard, the opinion is not unique.

In their use of scientific evidence, both courts and administrative agencies seem to distinguish the process of science from its products. They accept the constructionist insight that the process of doing science is a social enterprise and is subject to the buffeting, often distorting winds of social, political, economic, and legal influences. At the same time, courts, agencies, and legislatures cling to a realist belief that the products of science may state a truth about the world, or at least something so similar to truth as it is commonly understood at a given point in history that the particular discipline of law does not need to concern itself with the difference. The legal system's view of science adopts a strong version of what Cole (1992, p.x) calls a realist–constructivist position, i.e., science is socially constructed both in the laboratory and in the wider community, but the construction is constrained by input from the empirical world. It rejects what he calls a relativist–constructionist position that claims nature has little or no influence on the cognitive content of science.

The focus on methods is a search for some assurance that the expert has given the empirical world a reasonable opportunity to influence and constrain the expert's conclusions. Ultimately, the law's epistemology with respect to science holds that there are a set of (social) practices often given the shorthand name 'the scientific method' which increase the likelihood that someone will make positive contributions to knowledge; a set of practices that scientists themselves frequently point to as the sources of past scientific success (Goldman 1999).

There is a large dose of pragmatism in all of this, of course, and the *Daubert* rule itself has been cited as an example of 'the common law's genius for muddling through on the basis of experience rather than logic' (Jasanoff 1995, p. 63). Not surprisingly, some have criticized the courts for failing to adopt a philosophically coherent admissibility rule (Schwartz 1997). The court's admissibility rulings do seem to have proceeded in happy obliviousness to the 'science wars' that arguably began with Fleck (1979), flourished with Kuhn (1962) and raged for much of the last half of the twentieth century between the defenders of a more traditional, positivist view of science and those critics who emphasize its historical, political, social, and rhetorical aspects (Leplin 1997, Latour 1999). The same could be said of administrative use of science.

The rejection of relativist views of science does not mean that all legal actors hold identical views. It would be valuable to map the beliefs of legal actors on central disputes in the science wars, and how these beliefs impact their use of science. For example, if, as seems likely, plaintiff personal injury lawyers in the United States hold a more relativist view of science, how, if at all, does this affect their selection and

preparation of experts and, in turn, how are these experts received in courts?

4. *Law–Science Interdependence*

Law's approach to science should not be understood in terms of science alone but rather in terms of the law–science interaction. There are several dimensions to this relationship. First, although modern legal systems may recognize that scientists are influenced by the social world around them, permitting radical deconstruction that would undermine science's claim to special status is difficult to imagine (Fuchs and Ward 1994). The modern state is increasingly dependent upon science as a source of legitimacy. By turning to science for solutions to complex environmental and safety issues, legislatures are able to avoid making difficult political choices while giving the appearance of placing decision-making in the hands of apparently neutral experts who are held in very high esteem relative to other elites (Lawler 1996). The advantages of this approach are so great that agencies frequently engage in a 'science charade' in which they wrap their decision in the language of science even when there is very little research supporting a regulation (Wagner 1995).

Second, and related to the first observation, the law–science interaction is one of the important ways in which the state helps to produce and maintain science's dominant position in modern Western society. In both its administrative and judicial actions, the law defines what is and what is not scientific knowledge, and thereby assists science in important boundary maintenance work of excluding many from the community of 'scientists.' For example, in the case of *United States* vs. *Starzecpyzel*, the court permitted the state's handwriting experts to testify on the question of whether the defendants had forged documents, but only if they did not refer to themselves as 'scientists.' Moreover, legal decisions contain an implicit epistemology that reinstitutionalizes one view of the nature of scientific knowledge. When courts and other institutions of the state reject a relativist view of science that argues the empirical world has little, if any, influence on what is accepted as true by the scientific community, they help to marginalize anyone who adopts this position. There can be little doubt that the view is given little or no attention in law. A cursory search for the names of individuals most associated with these debates in American federal cases finds over 100 references to Popper alone, but no more than one or two passing references to the more prominent critics of traditional understandings of the scientific enterprise.

Third, the exact contours of the law–science interaction are shaped by a society's legal structure and its legal culture. For example, the American legal system's realist–constructivist understanding of science fits neatly with its own normative commitment to both 'truth' and 'justice' as legitimate dispute resolution goals. Ideally, cases should be correctly decided, should arrive at the truth. A realist view of science is consistent with the idea that a court may arrive at the correct outcome. But the truth is contested, and the courts should also give litigants the sense that they were listened to; that they received procedural justice (Tyler 1990). A constructivist understanding of the scientific enterprise legitimates the right of each party to find an expert who will present their view of the truth. We may hypothesize that all legal systems tend toward an epistemology of science and the scientific enterprise that fit comfortably within their dominant methods of law-making and dispute settlement. We might expect, therefore, that inquisitorial systems would be more skeptical of a constructivist view of the scientific enterprise than is the case in adversarial legal systems.

5. *Effects of Growing Interdependence*

As this essay attests, science's impact on legal processes grows apace. In many areas, an attorney unarmed with scientific expertise operates at a significant disadvantage. A growing number of treatises attempt to inform lawyers and judges of the state of scientific knowledge in various areas (Faigman et al. 1997). At the level of the individual case, there is some evidence that scientific norms are altering the way scientifically complex lawsuits are tried. Restrictive admissibility rules are one of several ways that courts in the United States may restrict traditional adversary processes when confronted with cases involving complex scientific questions.

What of law's effects on science? If the supply of science on some issue is affected by demand, legal controversy should draw scientists to research topics they might otherwise have eschewed. There is evidence that this does occur. The subject matter of scientific research is shaped by legal controversy in a wide number of areas, from medical devices (Sobol 1991) to herbicides (Schuck 1986). Some have argued that law's interest has an additional effect of causing the production of 'worse' science (Huber 1991), but it might also be argued that in areas such as DNA testing, law's interest has produced better science and better technology than might otherwise have existed. On the other hand, the threat of legal controversy may impede research into some areas, such as the development of new contraceptive devices.

Even if we believe all science is produced through a process of social construction, it is also the case that most scientists believe that their work is constrained by the empirical world (Segerstråle 1993). Moreover, they often attempt to surround themselves with a social structure that keeps society at a distance. Scientific groups are increasingly attempting to propa-

gate ethical standards for those who offer expert testimony in courts, reflecting the widespread belief that scientists who typically appear in legal arenas differ from their colleagues on these dimensions. Finally, legal use of science affects the closure of scientific debates (Sanders 1998). On the one hand, law may perpetuate controversy by supplying resources to both sides. On the other hand, it may help to bring a dispute to closure by authoritatively declaring one side to be correct.

Scientific Instrumentation, History and Sociology of

In the course of the last seventy years, historical and sociological analysis of instrumentation has changed considerably. World War II serves as an important watershed. Before the war, 'instrumentation' referred mainly to scientific instruments. They figured in experimentation, whose purpose was to demonstrate the truths of theory by making theoretical claims visible. After 1945 the ways in which instrumentation has been perceived and the functions attributed to it have multiplied and expanded, taking into account not only devices in the science laboratory, but also apparatus used in industry, government, health care, the military, and beyond. Instrumentation is now identified in many areas of science and technology

studies as central to research, engineering, industrial production, and to the processes of innovation. It is perceived as a mechanism that conditions the content of knowledge and affects the organization of work and even broader societal interactions.

In the writings of early twentieth-century students of science, instrumentation was seldom discussed and never highlighted. Historian-philosophers of science like Gaston Bachelard (1933, 1951) saw science chiefly in terms of the development of new theory. In this idealist historiographical tradition, experimentation received little attention, and instrumentation was only treated as a prop for experiments whose function was to document the discoveries embodied in scientific theories. Instruments did not invite study. Questions of instrument design, construction, and use, and their limitations, went unattended.

This is not to suggest, however, that there was no interest in scientific devices at the time. A few scholars were fascinated by them, and they strove to preserve apparatus and to unearth new devices. They were interested in the technical intricacies and novelty of instruments, for example those of Galileo Galilei. Devices were often viewed as antiquities, and due to this focus the distinction between the work of curators of science museums and instrument scholarship was sometimes a fine one. Here again, instrumentation was not treated as an active component in the knowledge production process, nor was it regarded as problematic in terms of its invention, use, or impact on the organization of research and science and technology communities.

Stimulating new perspectives in scientific instrumentation arose in the 1970s and 1980s in connection with historical and sociological investigations of post-1945 big science. For a long time most of the research that portrayed instrumentation as a central component of science and technology focused on devices in the physical sciences. The classic study by John Heilbron and Robert Seidel (1989) of the Berkeley cyclotron in the 1930s is emblematic of the new place of instrumentation in contemporary historiography. Issues of design, finance, engineering, and construction lay at the center of the cyclotron study. The cyclotron was portrayed as an instrument whose technical and social facets involved uncertainties. It was not a 'pure' instrument that reflected science's drive to probe the physical world. While the cyclotron in part served this objective, the instrument also reflected the economic and institutional environment of the San Francisco region, the hope for better healthcare, financial concessions wrung from the government, and involvement by wealthy research foundations and industry. This history demonstrates that scientific instrumentation may be guided by the scientific community, but that it is sometimes spawned by circumstances and forces outside the pale of science.

The idea that instruments are not neutral devices that serve science but elements that give structure to the scientific community first took root in studies of radio astronomy. This provocative concept was quickly extended to the sphere of high-energy physics at large (Krige 1996), oceanography (Mukerji 1992), and space science (Krige 2000). David Edge and Michael Mulkay (1976) first demonstrated that a scientific discipline, radio astronomy, which emerged in the 1950s and 1960s, was directly linked to or even defined by the design, construction, and diffusion of an altogether novel device: the radio telescope (itself an outgrowth of microwave technical research). The radio telescope discovered astronomical bodies and events. It contributed importantly to the birth of a new speciality, with its own university departments, journals, and national and international congresses. A new scientific instrument transformed knowledge, and it also affected the very institution of science.

In a more speculative, even iconoclastic representation of scientific instruments, they are depicted as the key to research career success, and yet more assertively, as decisive motors in determining what is true in science. In some areas of science, the equipment crucial to carrying out telling experiments is extremely scarce due to the expense of acquisition and operation. By virtue of possessing a monopoly in an area of instrumentation, a scientist or laboratory can exercise control over the production of the best experimental data. Studies in this vein have been done for the fields of biology (Latour and Woolgar 1979) and physics (Pickering 1984, Pinch 1986).

In this perspective Bruno Latour (1987) has suggested that scientific instruments yield not merely professional and institutional advantage, but more important, what is true and false, valid and invalid in science. A researcher's dealings with instruments empower him or her to be heard and to be 'right' during scientific controversies. By dint of possessing a strategic apparatus, a laboratory is well positioned to establish what is and is not a sound claim. Latour insists that arguments and findings based on 'weaker' instruments, on mathematics, and on rational evaluation are a poor match against a truly powerful scientific instrument. Analyses of this sort are diametrically opposite to those of pre-World War II idealist historiography.

A balanced, subtle, intellectual, and social contribution of instrumentation in the work of scientific research is found in the writings of Peter Galison. In *How Experiments End* (1987), this author argues that in twentieth-century microscopic experimental physics, instrument-generated signals are often crucial to settling rival claims, and he suggests that the work of separating noise from signals constitutes a key component in this process. In *Image and Logic*, Galison (1997) states that, contrary to what is often argued, scientific findings are not the outcome of interactions between theory and experimentation. He factors in a third element, namely instrumentation. Science thus derives from a triangular exchange between theory,

experimentation, and instrumentation. Galison speaks of a 'trading zone': a language and realm where these three currents merge, and where intelligibility is established. The brand of philosophical realism espoused by Ian Hacking (1983, 1989) likewise accords a central position to instrumentation. He insists that physical entities exist to the extent that instruments generate unarguably measurable effects. The classical example given by Hacking is the production of positrons whose presence induces palpable technical effects.

Today, other science and technology studies identify instrumentation as an element which influences and sometimes structures the organization of work. Instruments are depicted as rendering obsolete some activities (functions) and some groups, as stimulating fresh functions, and as helping create the backdrop for organizational transformations. In the case of early big science, high-energy physics, highly specialized physicists were replaced in the task of particle detection and tracking by armies of low skilled women observers because of the emergence of alternative large-scale photographic technologies and protocols. In parallel, new technical roles, framed by new work arrangements, arose for engineering and technician cadres who were assigned to design or maintain novel devices or to assure effective interfaces between instrument packages. In a different sphere, the introduction of the first electronic calculators and computers near the end of World War II transformed occupations and work organization as they spelled the end of the human calculators (mostly women) who during the early years of the war contributed to the military's high-technology programs. Due to the advent of the electronic computer in the late 1940s and 1950s, small horizontally organized work groups supplanted the former vastly bigger and vertically structured work system.

Outside science too, for example in the military and industry, instrumentation is also currently viewed as having a structuring impact on the organization of labor. Control engineering, connected as it is with chains of cybernetic-based instrument systems, is depicted as having profoundly modified the organization of certain activities in military combat operations, fire control, and guidance. Other studies highlight instrumentation as a force behind changes in the composition and organization of many industrial tasks and occupations, through automation and robotics (Noble 1984, Zuboff 1988). These alter the size of a work force and its requisite skills, and the internal and external chains of hierarchy and command.

Throughout the 1980s and 1990s, students of science and technology tracked and analyzed the development, diffusion, and implantation of devices in spheres increasingly distant from science and the laboratory. The concept 'instrumentation' took on a broader and different meaning from the initial historical and sociological concept of 'scientific instrumentation.'

Studies of medical instrumentation led the way in this important transformation. Stuart Blume's (1992) investigations of the emergence and diffusion of cat-scan devices, NMR imaging, and sonography illuminated the links between academic research, industrial research, the non-linear processes of industrial development of medical instrumentation, and the far-flung applications of such apparatus. Blume's and similar analyses had the effect of introducing significant complexities into the earlier fairly clear-cut notion of instrumentation. They blur the former understanding of a 'scientific instrument' by showing the multiple sites of its origins and development. They further show that an instrument may possess multiple applications, some in science and others in engineering, industry, metrology, and the military. One thing stands out with clarity; a scientific instrument is frequently coupled to industry in powerful ways: design, construction, diffusion, and maintenance. This link is historically situated in the late nineteenth and the twentieth centuries, and it appears to grow constantly in strength. This situation is pregnant with material and epistemological implications for science and beyond, as experiment design, laboratory work practices, reasoning processes, the organization of industry, and daily life are now all so interlocked with instrumentation.

With only a few exceptions, however, little historical and sociological work has thus far concentrated on firms specifically engaged in the design, construction, and diffusion of instrumentation. It was not until the late nineteenth and early twentieth centuries that the military general staffs and politicians of certain countries (Germany, France, Great Britain, and somewhat later the US, the USSR, and Japan) began to perceive that their nation's fate was tightly bound up with the quantity and quality of the instrumentation that endogenous industry could conceive and manufacture. In part because of this new consciousness, as well as the growth of scientific research, the number of companies involved in instrument innovation and production increased impressively. Mari Williams (1994) indicates that instrument companies must be thought of as key components in national systems of education, industry, government policy, and the organization of science. During much of the nineteenth century, France enjoyed the lead. England challenged the French instrument industry at the turn of the century, but by this time leadership clearly belonged to recently united Germany. Success in the scientific instrument industry appears to have been associated with tight organic bonds between specific firms and specific research laboratories, which was the case in England for companies close to the Cavendish. Germany's immense success was the product of an organic association between the military, government, industrial manufacturing, and instrument making firms (Joerges and Shinn 2001). In the twentieth century, such proximity (not only geographic but perhaps more

particularly in terms of working collaborations and markets) similarly proved effective in the United States.

Does there exist an instrument-making or instrument-maker culture? This question too has received little attention, and any answer would have to be historically limited. Nevertheless, one often-cited study does address this issue, albeit indirectly. For a sample of post-World War II US instrument specialists, the sociologist Daniel Shimshoni (1970) looked at instrument specialists' job mobility. He discovered that when compared to other similarly trained personnel, instrument specialists changed jobs more frequently than other categories of employees. However, the reasons behind this high mobility received scanty attention. One interpretation (not raised by Shimshoni) is that instrument specialists change employers in order to carry their instruments into fresh environments. Alternatively, once instrument specialists have performed their assigned tasks, perhaps employers encourage their departure from the firm, and instrument men are consequently driven to seek work elsewhere.

One theme that has gained considerable attention during the 1980s and 1990s is the relationship between innovation and instrumentation. In an influential study, the sociologist of industrial organization and innovation Eric Von Hippel (1988) has explored the sites in which instrument innovations arise, and has examined the connections between those sites and the processes of industrial innovation. He indicates that a sizable majority of industrially relevant instrument novelties comes from inside industry, and definitely not from academia or from firms specialized in instrumentation. The instruments are most frequently the immediate and direct consequence of locally experienced technical difficulties in the realms of product design, manufacture, or quality control. Instrumentation often percolates laterally through a company, and is thus usually home used as well as home grown. Many devices do not move beyond the firm in which they originate. Hence, while in some instances dealings with academia and research may be part of industry practice, instrumentation is normally only loosely tied to science. When the connection between instrumentation development and science is strong, it is, moreover, often the case that industry-spawned instrumentation percolates down to the science laboratory rather than academia-based devices penetrating industry.

Some sociologists of innovation suggest that instrumentation in industry is linked to research and development, and through it to in-house technology and to company performance. According to some studies, during the 1970s and 1980s instrumentation correlated positively with industrial performance and company survival for US plants in a range of industrial sectors (Hage et al. 1993). Firms that exhibited small concern for advanced technology tended to stumble or close when compared with companies that actively sought new technologies. According to the Von Hippel hypothesis, an important fraction of innovative technology would take the form of in-house instrument-related innovation.

The connection between academia, instrument innovation, and economic performance has been approached from a different perspective in a more narrowly researched and fascinatingly speculative study carried out by the economic historian Nathan Rosenberg (1994). Rosenberg suggests that many key instrument innovations having a great impact on industry spring from fundamental research conducted in universities. To illustrate this claim, he points to the university-based research on magnetic spin and resonance conducted by Felix Bloch at Stanford University in the late 1940s and 1950s. This basic physical research (theoretical and experimental) gave rise to nuclear magnetic resonance (NMR) and to NMR instrumentation; and in turn, NMR apparatus and related devices have spread outward in American industry, giving rise to new products and affecting industrial production operations. The best-known use of NMR instrumentation is in the area of medical imaging. Rosenberg suggests that the spillover effect of academic instrument research has been underestimated, and that the influence of academic research through instrumentation is characterized by a considerable multiplier effect.

In the final analytical orientation indicated here, instrumentation is represented as a transverse epistemological, intellectual, technical, and social force that promotes a convergence of practices and knowledge among scientific and technological specialities. Instrumentation acts as a force that partly transcends the distinctions and differentiations tied to specific divisions of labor associated with particular fields of practice and learning.

This transcending and transverse function is reserved to a particular category of instrumentation: 'research-technology' (Shinn 1993, 1997, 2000, Joerges and Shinn 2001). Research-technology is built around 'generic' devices that are open-ended general instruments. They result from basic instrumentation research and instrument theory. Examples include automatic control and registering devices, the ultracentrifuge, Fourier transform spectroscopy, the laser, and the microprocessor. Practitioners transfer their products into academia, industry, state technical services, metrology, and the military. By adapting their generic products to local uses, they participate in the development of narrow niche apparatus. The research-technologist operates in an 'interstitial' arena between established disciplines, professions, employers, and institutions. It is this in-between position that allows the research-technologist to design generalist non-specific generic devices, and then to circulate freely in and out of niches in order to diffuse them. Through this multi-audience diffusion, a form of

practice-based universality arises, as a generic instrument provides a lingua franca and guarantees stable outcomes to multiple groups involved in a sweep of technical projects.

Throughout the 1980s and 1990s studies devoted to instrumentation, or studies in which instrumentation plays a leading role, grew appreciably. The impressive number of instrument-related articles appearing in many of the major journals of the social studies of science and technology testify to the fact that the theme is now strong. Two general tendencies characterize today's enquiries into instrumentation: first, a great diversity in the number of analytic currents and research schools which perceive instrumentation as basic to past and contemporary cognitive and organizational activities; and second, considerable variety in the spheres of activity that are putatively affected by instrumentation and in the mechanisms that allegedly underpin instrument influence.

Scientific Knowledge, Sociology of

1. Origins

The central concern of the sociology of knowledge is the idea that what people take to be certain is an accident of the society in which they are born and brought up. It is obvious that religious or political truths are largely affected by their social settings. If the truths are moral then such relativism is more troubling. But if the truths are scientific, then the idea of social determination is widely regarded as subversive, or self-defeating—since the science which purports to show that science is socially situated is itself socially situated. The sociology of knowledge, as formulated by Mannheim (1936), avoided these dangerous and dizzying consequences by putting scientific and mathematical knowledge in a special category; other kinds of knowledge had roots in society but the knowledge of the natural sciences was governed by nature or logic. Scientific method, then, when properly applied, would insulate scientists from social influences and their knowledge should be more true and more

universal than other kinds of knowledge. From the early 1970s, however, groups of sociologists, philosophers, historians, and other social scientists began programs of analysis and research which treated scientific knowledge as comparable with other kinds of knowledge. Their work broke down the barrier between ordinary knowledge and scientific knowledge.

The post-1970s Sociology of Scientific Knowledge (SSK), which included major contributions from historians of science, shows us how to understand the impact of social influences on all knowledge. We can use the field's own approach to query its intellectual origins. A suitable model is a well-known paper by a historian, Paul Forman (1971), who argued that the rise of quantum theory owed much to the 'Weltanschauung' of Weimar Germany. In the same way it could be argued that the 1960s saw the growth of postwar prosperity in Europe which allowed the development of new markets with young people becoming powerful consumers of goods and producers of culture—much of it consisting of a rebellion against traditional forms of expression; it saw the development of the birth control pill, making possible a (temporary) breakdown of sexual mores; and it saw experiments with perception-affecting drugs, while protests against the Vietnam war threatened old lines of institutional authority. The new order had its counterpart in academe. Antipsychiatry questioned the barriers between the sane and the insane, while in Europe at least, romanticized versions of Marxism dominated debate. SSK's questioning of the traditional authority of science can plausibly be seen as a product of this social ferment.

The emblematic book of the period as far as science was concerned was Thomas Kuhn's (1962) *The Structure of Scientific Revolutions*. Kuhn's book was influential in helping to reinforce the intellectual atmosphere in which radical ideas about science could flourish. Kuhn's notion of the incommensurability of paradigms, and paradigm revolution, provided a way of thinking about scientific knowledge as a product as much of culture as of nature. The book was not widely discussed until late in the 1960s, when the new social movements were at their height, and this adds force to the argument.

Philosophy of science in the early 1970s was also affected by this turn. The so-called 'Popper–Kuhn' debate (Lakatos and Musgrave 1970) pitted Karl Popper's (e.g., 1959) notion that scientific theories could be falsified with near certainty, even if they could not be proved, against Thomas Kuhn's (1961, 1962) claim that what was taken to be true or false varied in response to sudden revolutions in scientific world view. The 'Duhem–Quine thesis' (Losee 1980) showed that scientific theories were supported by networks of observations of ideas such that no one observation could threaten any other part of the network directly. Imre Lakatos's ([1963]/1976) brilliant analysis of the history of Euler's theorem showed that falsification of a theory was only one choice when faced with apparently recalcitrant observations. Lakatos's work was particularly attractive to the social analyst of science because it dealt with the detailed history of a real case rather than arising from general principles. Lakatos was showing how mathematicians argued (or could have argued in principle). This was the world of philosophical activity into which the sociology of scientific knowledge was born.

Like any other group of knowers, sociologists of scientific knowledge prefer models of the genesis of their own ideas which reflect their self-image as 'rational creatures' or, in Mannheim's phrase, 'free floating intellectuals.' In these models Kuhn plays a much smaller role. There are two intellectual stories. One turns on Ludwik Fleck's ([1935]/1979) *Genesis and Development of a Scientific Fact*, which Kuhn cites in the preface of his 1962 book, and which already contained many of the key ideas found therein. Furthermore, Fleck's book anticipated the developments in sociology of scientific knowledge which came in the 1970s in that, unlike *The Structure of Scientific Revolutions*, it included a case study of a contemporaneous scientific episode, Fleck's own research on the Wasserman reaction for the diagnosis of syphilis. Indeed, Fleck's book remains unique in sociology of science in that his social analysis was of a pioneering piece of scientific research which he himself was pioneering. Thus it is the most perfect piece of participant observation yet done in the social study of scientific knowledge.

Fleck's book, however, was not widely known until many years after Kuhn's was published, and not until long after the sociology of scientific knowledge had established its own way of doing things. Fleck, then, was the first to set out some of the crucial ideas for SSK, but he had little influence on the new movement except through his influence on Kuhn, while Kuhn helped open up the social and intellectual space for what came after rather than providing intellectual foundations or methodological principles; in other words, Kuhn provided the intellectual space but not, to use his own term, the paradigm.

The origin of SSK's intellectual and methodological *paradigm* has to be understood by looking at more direct influences. In the 1970s a group of philosophers, concerned with defending science against what they perceived as its critics, put forward the argument that sociological analysis could be applied only to knowledge that was in error, whereas true knowledge remained insulated from social forces. The intellectual source for the sociologists who inspired these initial attacks and fought against them was yet another philosopher, Ludwig Wittgenstein, whose work was central to the anthropological debate about whether there were universal standards of rationality (Wilson 1970). Readings of Ludwig Wittgenstein's later philosophy (1953, 1956, Winch 1958) were the crucial theoretical resource for the work in sociology of

scientific knowledge that had its origins in the mid-1970s. The 'Edinburgh School' and its 'strong program' argued on philosophical grounds that 'symmetrical analysis'—analysis that treated true knowledge and false knowledge equally—was possible. Historical studies conducted in this framework showed how social influence affected scientific conclusions, in science in general, in early studies of the brain, in the development of statistics, and in high-energy physics (Bloor 1973, 1983, Barnes 1974, Shapin 1979, MacKenzie 1981, Pickering 1984). Independently, a group at the University of Bath applied Wittgensteinian ideas to contemporary episodes of science, particularly controversies in physics and the fringe sciences, and developed the methodology of interviewing at networks of competing scientific centers. Its program became known as the 'Empirical Programme of Relativism' (EPOR; Collins 1975, 1985, Pinch 1977, 1986, Travis 1980, 1981). These approaches were to become quite widely adopted in the early years of SSK.

As the 1970s turned into the 1980s other groups, more strongly influenced by anthropological practice, entered and influenced the field. The Edinburgh–Bath approach was influenced by anthropology in that much of the discussion of the meaning of Wittgensteinian philosophy for the social sciences turned on questions to do with the knowledge of isolated 'tribes' and its relationship to Western knowledge. The newer contributors, however, took their methodological approach as well as their philosophy from anthropology. Their work founded the tradition of 'laboratory studies.' In the Strong Program the source of material tended to be historical archives; in EPOR the method was interviews with members of the 'core-set' of scientific laboratories contributing to a scientific controversy; in laboratory studies the method was a long sojourn in, or deep study of, a single laboratory (Latour and Woolgar 1979, Knorr Cetina 1981). The setting for the laboratory studies tended to be the life sciences rather than the hard sciences or fringe sciences.

Another important input was the interpretive tradition in sociology associated with phenomenology and ethnomethodology. Indeed the term 'social construction' is a widely used description of the approach: 'social construction of scientific knowledge' was taken from the title of a well-known book by Peter Berger and Thomas Luckman (1967)—though Berger's *Invitation to Sociology* (1963) probably had more direct impact on the field. Ethnomethodology strongly influenced all those who practiced SSK and especially the detailed analyses of scientific practice such as those by Lynch (1985 [but written much earlier than its publication date]), Woolgar (1976), and especially the move of some authors into what became known as 'discourse analysis' (Knorr Cetina and Mulkay 1983).

As the 1980s turned into the 1990s the concentration on language that began with the move to discourse analysis helped SSK to come to seem a part of the much larger movement known as 'postmodernism.' The influence of French philosophers of literature and culture such as Derrida became marked. Since then 'cultural studies of science,' which share with SSK what could broadly be called a 'social constructivist' approach to science, have attracted large numbers of followers in the humanities as well as the social sciences. The respective methods and, more especially, the attitudes to methodology, make it possible to separate cultural studies from SSK. Crucially, SSK practitioners still take natural science as the touchstone where matters of method are concerned, though the model of science is very far from the narrow statistically-based notion of science that informed the 'scientific sociology' of the 1950s and early 1960s and continues to dominate much mainstream sociological practice in the USA. SSK stresses the more general values of careful empirical observation and repeatability. Cultural studies, on the other hand, takes philosophical literary criticism, or semiotics, as the model to be followed.

2. *Concepts*

Among sociology's traditional topics was the study of the social factors which affected scientists' choice of research topic. The sociology of scientific knowledge, however, took it that the *outcomes* of research projects were also affected by their social setting. SSK showed that theoretical and experimental procedures did not determine, or fully determine, the conclusions of scientific research. The philosophical ideas described above provided an important starting point, but sociology developed its own concepts set in the working world of the scientist rather than the abstract world of the philosopher. One strand of research showed how difficult it was to transfer the skills of physics experimentation between settings, that it was even harder to know that such skills had been transferred, and that it was harder still to know when an experiment had been satisfactorily completed. This meant we did not know whether a negative experiment should be taken to contradict a positive one. This argument became known as 'the experimenter's regress' (Collins 1975, 1985), and revealed the scope for 'interpretive flexibility' regarding the outcomes of passages of experimentation and theorization. It also means that even while SSK stresses the importance of empirical research and repeatability, it is aware that, by themselves, such procedures cannot turn disputed knowledge into certainty in either the natural or social sciences.

Even if experimental science produced widely accepted data, as Pinch (1981) showed, their 'evidential significance' could vary and the same finding could count as revolutionary or insignificant. Sociological studies also described the process between the dis-

ordered activities of the laboratory and the orderly 'findings' (Latour and Woolgar 1979, Knorr Cetina 1981) or 'discoveries' (Brannigan 1981) reported—or constructed—in the published literature. Latour and Woolgar demonstrated the way that 'modalities'—phrases that qualified a finding or referred to the particular time and place of its generation—were successively stripped from publications as the finding became established. What they called 'inversion' was the way the stripping of the modalities, and like processes, comprised the establishment of the finding—a reversal of the accepted direction of the causal arrow. It was also shown that, with some exceptions, 'distance lends enchantment,' that is, certainty about scientific outcomes tends to increase as the intepreter's distance from the laboratory increases (Collins 1985, MacKenzie 1998). This explained why commentators' accounts often seemed far more confident than the reports of the scientists themselves, and explained much about the way scientific knowledge was diffused beyond the specialists.

Mechanisms were described by which potentially open-ended disputes were brought to a close around a particular interpretation, with EPOR concentrating on fringe sciences, the 'French School' concentrating on the interplay of actors within networks (Latour 1987), and the 'Edinburgh School' concentrating on large-scale political influences on the content of ideas (Shapin 1979, MacKenzie 1981, Shapin and Schaffer 1987). More recently, work on closure has broadened to include studies in the social construction of technology, the public understanding of science and law and science.

3. *Significance*

As the recent so-called 'science wars' have revealed, outsiders consider that the importance of SSK and related analyses of science lies in the impact they have on the perception of the meaning of science in the wider world. SSK is widely seen as a radical relativist attack on science. But both the philosophical and political radicalism of the social analysis of science varies from program to program and study to study.

For example, 'epistemological relativism' implies that one social group's way of justifying its knowledge is as good as another's and that there is no external vantage point from which to judge between them; all that can be known can be known only from the point of view of one social group or another. Ontological relativism is the view that, in social groups such as those described above, reality itself is different. A combination of epistemological and/or ontological relativism can be referred to as 'philosophical relativism.' This attitude is nicely captured by McHugh in the following quotation: 'We must accept that there are no adequate grounds for establishing criteria of truth except the grounds that are employed to grant or concede it—truth is conceivable only as a socially organized upshot of contingent courses of linguistic, conceptual and social behaviour' (1971, p. 329). Philosophical relativism is, then, a philosophically radical viewpoint.

A still more philosophically radical position is the 'actor (or actant) network theory' (ANT) most closely associated with Michel Callon and Bruno Latour. The approach was first signaled by Latour and Woolgar when, in 1986, they changed the subtitle of *Laboratory Life* (Latour and Woolgar 1979) from *The Social Construction of Scientific Facts* to *The Construction of Scientific Facts* so as to signify that the 'social' in their view no longer deserved special mention in the shaping of scientific knowledge. Subsequently, as Callon and Latour developed their ideas, scientific facts came to be seen as emerging from the interplay of 'actants' in the 'text,' of life—suggesting that ANT should most properly be included under cultural studies of science rather than SSK. Within Callon and Latour's 'text,' terms such as 'social' and 'natural' are themselves outcomes of the interplay of actants rather than original causes. Therefore, to draw attention to the social as a special factor is to begin the discussion at too low a level of generality. Under this approach 'constructivism' has ceased to be *social* and among the actants nonhumans are given as much reality-forming agency as humans (Callon 1986). The philosophical radicalness of ANT is clear in its refusal to accept even the notion of human and nonhuman as primary.

Methodological relativism, by contrast, says nothing direct about reality or the justification of knowledge. Methodological relativism is an attitude of mind recommended by some of those who practice SSK; it says that the sociologist or historian of science should act as though the beliefs about reality of any competing groups being investigated are not caused by the reality itself. The intention is to limit analysis to the kind of causes of scientific beliefs that are located in the domain of the social. Methodological relativism is meant to push exploration of the social causes of belief to the limit without having it cut off by the argument that a belief was widely accepted because it was rational. Methodological relativism is, then, not at all radical as a philosophy, it is a (social) scientific method.

Relativism may be called time-bounded if it claims only that scientific procedures are often inconclusive in the short term whatever the deeper significance of the consensuses that are attained in the long term. This kind of relativism, which has no philosophical potency, is all that is needed to support much current social analysis of contemporary science, especially controversies that impact on the public domain (e.g., Collins and Pinch 1993, Richards 1991, Epstein 1996).

The relationship between philosophical radicalism and political radicalism is, however, perverse. Time-bounded relativism has consequences for contemporary scientific controversies such as engage

environmentalists and the like: it has this power because it shows that, contrary to the way these things are treated in textbooks and the like, the 'short-term' period when scientific disputes are being resolved is often many decades long. The empirical and analytic tools of SSK explain why this is likely to be so and it means that we should not expect speedy science-based resolutions to our current technological dilemmas. From this it can be argued that the decision-making power once monopolized by scientific experts should be more widely shared (Wynne 1987). Methodological relativism, which is philosophically quietist, tends to be disturbing to the scientific community as it blatantly ignores scientific consensus however well established. To go the other extreme, ANT, the most philosophically radical position of all, by removing humans from the central position they hold in *social* constructivism, recreates a relationship between scientists and their nonhuman objects of study which is similar to that which held before the revolutions of the 1960s and 1970s (Collins and Yearley 1992, Callon and Latour 1992, Fuller 2000). What about philosophical relativism? Scientists and philosophers seem to believe that philosophical relativism can be used to justify nonscientific beliefs such as astrology or creationism, though its proponents deny it fervently, and at least one critic (Fuller 2000) has argued that it is politically quietist. SSK, of course, argues that as knowledge moves from its seat of creation to a wider audience, it tends to be stripped down and simplified, so it is not surprising that the subtleties of the various relativist positions have escaped the more outspoken critics of the social analysis of scientific knowledge.

Scientific Reasoning and Discovery, Cognitive Psychology of

The cognitive psychology of scientific reasoning and discovery refers to the study of the cognitive processes that scientists use in all aspects of science. Researchers have used interviews and historical records, cognitive experiments on components of scientific thinking, computational models based on particular scientific discoveries, and investigations of scientists as they reason live, or '*in vivo*,' in an effort to uncover the thinking and reasoning strategies that are important in science. In this article, six different approaches to scientific reasoning are discussed. One important point to note is that scientific thinking builds upon many different cognitive components such as induction, deduction, analogy, problem solving, priming, and categorization, that are objects of study in their own rights. Research specifically concerned with scientific thinking tends to use content domains that are from an established domain of science (such as physics, biology, or chemistry), or looks at how different cognitive processes such as concepts and deduction are used together in areas like experiment design. Useful books on the nature of scientific thinking are Tweeney et al. (1982), Giere (1992), and Klahr et al. (2000).

1. *Interviews and the Historical Record*

Two frequently used and related approaches that have been used to investigate scientific thinking have been interviews with scientists and the analysis of historical records and documents such as notebooks. One of the earliest accounts of scientific thinking and reasoning was the interview of Albert Einstein conducted by the Gestalt Psychologist Max Wertheimer (1959). Wertheimer argued that a key strategy used by Einstein was to search for invariants. Wertheimer saw the velocity of light as a key invariant around which Einstein built his theory. Wertheimer incorporated his analysis into a Gestalt theory of thought. More recently, researchers have conducted interviews in the context of principles from cognitive science. For example, Paul Thagard (1999) has conducted many interviews with the scientists who proposed that ulcers are caused by bacteria. Thagard has pointed to the important roles of serendipity, observation, and analogy in this discovery. A related line of inquiry is the use of historical documents. Using the scientists' lab books, biographical, and autobiographical materials, researchers attempt to piece together the reasoning strategies that the scientists used in making a discovery. For example, Nersessian (1992) has conducted extensive analyses of the physicist Faraday's notebooks and has argued that the key to understanding his discoveries is in terms of his use of mental models. By mapping out the types of mental models that Faraday used and showing how these types of models shaped the discoveries that Faraday made, Nersessian offered a detailed account of the mental processes that led to a particular discovery. Another cognitive approach using the historical record is to take a real scientific discovery, such as Monod and Jacob's Nobel Prize-winning discovery of a mechanism of genetic control and give people the same problem, using a simulated scientific laboratory, and determine whether people use the same discovery strategies that the scientists used to make the discovery, such as focusing on unexpected findings (Dunbar 1993).

2. *Scientific Reasoning as Problem Solving and Concept Formation*

Two common approaches to scientific thinking have been to see it as a way of discovering new concepts or

as a form of problem solving. Beginning with Bruner et al.'s (1956) classic experiments in which college students were asked to induce the rule that determines whether an item is, or is not, a member of a category, these researchers attempted to discover the types of inductive reasoning strategies used to acquire new concepts. Bruner et al. argued that much of science consists of inducing new concepts from data and that the memory loads that different strategies require will make certain types of inductive reasoning strategies more common than others. More recently, Holland et al. (1986) provided an account of the different inductive learning procedures that could be used to acquire new concepts in science.

Herbert Simon (1977) argued that concept formation is a form of problem solving, thus the two approaches can be seen as complimentary (see Klahr et al. 2000). Simon argued that scientific thinking consists of a search in a problem space with the two main spaces being a hypothesis space and an experiment space. The hypothesis and experiment spaces refer to all possible hypotheses, experiments, and operators that can be used to get from one part of the space to the next part of the space, such as grouping common elements (the grouping operator) in sets of results to form a new hypothesis. Simon has taken specific scientific discoveries and mapped out the types of heuristics (or strategies), such as heuristics for designing experiments that a scientist used in searching the experiment space. Using the notion of searching in a problem space, other researchers have analyzed the types of search heuristics that are used in all aspects of scientific thinking and have conducted experiments on the problem-solving heuristics that people use in designing experiments, formulating hypotheses, and interpreting results (Dunbar 1993, Klahr et al. 2000). These approaches specify the types of knowledge that an individual must possess and the heuristics that are used to formulate hypotheses, design experiments, and interpret data.

3. *Errors in Scientific Thinking*

One of the most frequently investigated aspects of scientific thinking and reasoning has been the finding that both scientists and participants in psychology experiments attempt to confirm their hypothesis when they conduct an experiment, sometimes called 'confirmation bias' (see Tweeney et al. 1982). Following from the writings of the philosopher Karl Popper, many psychologists have assumed that attempting to confirm a hypothesis is a faulty reasoning strategy. Numerous studies have revealed that, when given an hypothesis to test, people will design experiments that will confirm their hypothesis and not conduct experiments that could falsify their own hypothesis. This is a pervasive phenomenon that is difficult to eradicate; even when given instructions to falsify hypotheses, people find it difficult to do. Thus, many researchers have concluded that both people in psychology experiments as well as scientists at large make this faulty reasoning error. However, Klayman and Ha (1987) argued that conducting experiments that confirm a hypothesis is not necessarily a scientific reasoning error. They argued that if the prior probability of confirming one's hypothesis is low, then even if the scientist is attempting to confirm the hypothesis, it can still be disconfirmed. One other interpretation of the phenomenon of confirmation bias is that early in developing a theory or a hypothesis people will attempt to confirm the hypothesis; however once the hypothesis is fleshed out and confirmed, people will attempt to conduct disconfirming experiments (see Tweeney et al. 1980).

4. *Science 'In vivo': How Scientists Think in Naturalistic Contexts*

One important issue in scientific reasoning and discovery is that most accounts have tended to use indirect evidence such as lab notebooks, biographies, and interviews with scientists to determine the thinking and reasoning strategies that scientists use. Another approach is to conduct experiments on isolated aspects of scientific thinking. See Dunbar (1995) for an analysis of these standard approaches that he has termed '*in vitro*.' Both approaches, while very informative, do not look at scientists directly. Thus, a complimentary approach has been to investigate real scientists' thinking and reasoning strategies while they are conducting real research. Using this '*in vivo*' approach, Dunbar (1999) has identified the specific ways that scientists use analogies, deal with unexpected findings, and use collaborative reasoning strategies in their research. He found that scientists use analogies to similar entities (or 'local analogies') when fixing experimental problems, analogies to entities from the same class of items (or 'regional analogies') when formulating new hypotheses, and analogies to very dissimilar domains ('long-distance analogies') when explaining scientific issues to others. Furthermore, Dunbar found that over half the findings that scientists obtain are unexpected, and that the scientists have specific strategies for dealing with these unexpected findings: First, scientists provide methodological explanations using local analogies that suggest ways of changing their experiments to obtain the desired result. If the changes to experiments do not provide the desired results, then the scientists switch from blaming the method to formulating hypotheses; this involves the use of 'regional analogies,' as well as collaborative reasoning in which groups of scientists build models and theories together. Dunbar has further brought back these '*in vivo*' findings into the cognitive laboratory to conduct controlled experi-

ments, which, taken together, have been used to build new accounts of the ways that analogy, collaborative reasoning, and causal reasoning are used in scientific thinking (Dunbar 1999).

5. The Development of Scientific Thinking Skills

Beginning with the work of Piaget, many researchers have noted that children are similar to scientists. This 'child-as-scientist' metaphor has two main strands. First, children's acquisition of new concepts and theories is said to be similar to the large conceptual changes that occur in scientific fields. Researchers investigating this view have pointed to parallels between changes in children's concepts, such as their concepts of heat and temperature, and changes in the concepts of heat and temperature in the history of physics (see Chi 1992, Carey 1992). The second strand of the child-as-scientist metaphor is that children reason in identical ways to scientists, ranging from deduction and induction to experimental design. Some researchers have argued that there is little difference between a scientist and a three-year-old; while scientists clearly have considerably more knowledge of specific domains than children, their underlying competencies are viewed as the same. Other researchers have taken this 'child-as-scientist' view even further and argued that infants are basically scientists. Yet other researchers have argued that there are fundamental differences between children and scientists and that scientific thinking skills follow a developmental progression (see Klahr et al. 2000 for an overview of this debate).

6. Cognitively Driven Computational Discovery: Twenty-first Century Scientific Discovery

One development that has occurred in many sciences is the placing of vast amounts of information in computer databases. In the year 2000 the entire human genome was mapped and now exists in databases. Similar developments have occurred in physics, where the entire universe has been mapped and put on a database. In the case of the human genome, data consists of long sequences of nucleotides, each of which is represented by a letter such as A for Adenine. Databases consist of strings of letters such as ATGTC with each letter representing a particular nucleotide. These strings or sequences can extend for hundreds of millions of nucleotides without interruption. Buried in these sequences are genes, and most of the genes are of unknown function. One goal of researchers is to search the database, find genes, and determine the function of the genes and how the genes interact with each other. This new wave of scientific investigation incorporates many of the principles of analogical reasoning, inductive reasoning and problem-solving strategies discussed here, as well as many of the algorithms (neural nets, Markov models, and production systems) discovered by cognitive psychologists in the 1980s and 1990s to discover the functions of genetic sequences and the properties of certain types of matter in the universe. One interesting aspect of this development has been that rather than computer programs being expected to make an entire discovery from beginning to end, they are a tool that can be used by scientists to help make a discovery. The cognitive psychology of scientific reasoning has moved from being a description of the scientific mind to an active participant in scientific practice.

Scientific Revolution: History and Sociology of

1. The Term 'Scientific Revolution'

The term 'Scientific Revolution' was introduced to denote what has been considered since the nineteenth century one of the most important discontinuities in the history of European science (H F Cohen 1994, I B Cohen 1985, Lindberg and Westman 1990). It covered roughly the period between Copernicus and Newton, and led from Aristotelian natural philosophy (see *Aristotle (384–322 BC)*) deriving its dogmatic authority from the Church to the establishment of the classical sciences and their institutions, i.e., the period between 1500 and 1700 (see *Scientific Disciplines, History of Scientific Academies, History of*).

This period can be characterized as one in which a new social group, the 'engineer-scientists' (consisting of engineers, scientists, inventors, artists, and explorers), emerged and became institutionalized. This group confronted traditional natural philosophy with the challenges of practice and experience, but also engaged in self-contained explanations of natural phenomena, expecting that science is a means to master nature, as Francis Bacon put it. Among the lasting achievements of the Scientific Revolution were the establishment of heliocentric astronomy, classical mechanics, as well as numerous contributions to optics, chemistry, physiology and other areas of modern science (for an overview see Butterfield 1965, Dijksterhuis 1986, Hall 1954). Many of these achievements became, in fact, the basis for technological breakthroughs. However, these breakthroughs occurred, as a rule, much later than anticipated by the protagonists of the Scientific Revolution. Further, the intellectual breakthroughs responsible for the revolution's lasting impact on the development of science were mainly attained towards its end and only a generation or more after their proclamation by the early pioneers (Damerow et al. 1992).

The Scientific Revolution has become a paradigmatic reference for all approaches to the history and philosophy of science (see *History of Science*). At least since the Enlightenment it has been conceived as the triumph of the scientific method over the irrationalism of religious beliefs (see *Science and Religion*). Opposition to this view, together with a growing professionalization of historical studies, has opened up the space for other accounts, including attempts—such as that by Pierre Duhem—to deny that the Scientific Revolution actually represented a radical break, claiming instead that it merely constituted an episode within a continuous accumulation of scientific knowledge since the Middle Ages (Duhem 1996). Furthermore, the traditional emphasis on the role of outstanding protagonists of the Scientific Revolution, such as Bacon, Galileo, and Descartes, and their individual 'discoveries' (see e.g., Koyré 1978) has, in recent scholarship, increasingly receded in favor of an analysis of contexts tracing scientific achievements back to cultural, social, and economic conditions (Osler 2000, Porter and Teich 1992, Shapin 1996). The Scientific Revolution, on the other hand, itself provided a model for historical explanations when Thomas Kuhn (see *Kuhn, Thomas S (1922–96)*) radically challenged traditional historiography with his notion of 'scientific revolution' conceived of as a general structure of knowledge development (Kuhn 1962).

2. Historical and Sociological Context

From a sociological perspective, the Scientific Revolution appears as part of a wider social process in which technical knowledge assumed a new role in the organization of European societies (see *Renaissance*; *Enlightenment*). This process took off in the late Middle Ages and was primarily rooted in the larger cities, which saw an ever more diversified and developed artisanal culture and a growing accumulation of merchandise capital. The cities of early modern Europe thus offered favorable conditions for the rapid growth of technical knowledge and the reflection of this growth in political, philosophical and religious thinking. Large-scale ventures involving technical expertise, such as projects of military architecture, water regulation, military adventures, or seafaring expeditions (see *History of Technology*), involved types of resources, social mobility, and an outlook on the world available only in urban centers such as Florence, Venice, Paris and London, which in fact became, long after they had attained an outstanding economic role, also the nuclei of the Scientific Revolution. Historians such as Edgar Zilsel (Zilsel 2000) have considered the early modern engineering projects as a decisive condition for the practical orientation and empirical knowledge base that distinguish the science of this period from its medieval antecedents.

Beginning in the fifteenth century, ambitious practical ventures (such as the building of the cupola of Florence Cathedral, the search for a sea route to India, or the development of a new military technology) increasingly relied on expert knowledge comprising both logistic and technological competencies exceeding those of traditional practitioners and artisans. Such competencies could only be gained on the basis of broader reflection on the relevant practical and theoretical knowledge resources available. This reflection became the specialty of the new group of engineer-scientists such as Filippo Brunelleschi, Christopher Columbus, Leonardo da Vinci, Niccolo Tartaglia, and Galileo Galilei. While the states of the time (if not actually at war) competed with each other in the pursuit of practical ventures, for example, building projects and seafaring expeditions, the knowledge acquired in such ventures was nevertheless constantly spread among the engineer-scientists employed by them. In the social fabric of the early modern period, engineer-scientists occupied a place similar to that earlier conquered by Renaissance humanists, administrators and artists (see *Art History*). These practically oriented intellectuals were, as a rule, highly mobile, offering their services to whatever patronage was available. At the same time, they constituted, as a social group, a collective memory, accumulating and transmitting the new knowledge long before appropriate institutions of learning emerged and in spite of the frequent political and military turnovers of the time.

The characteristic features of the engineer-scientists and their work become understandable against the background of their uncertain social status and their dependence on the patronage of courts and city governments (see e.g., Biagioli 1993) with rapidly changing power structures. Examples are their incessant engagement with projects for potential future patrons; their usually unrealistic promises regarding the practical benefits of their theories, inventions or projects; the secretiveness with which they treated their discoveries; their frequent involvement in priority struggles; as well as the striving to ennoble their practical knowledge by the claim of creating 'new sciences.'

The social and political ambitions of the engineer-scientists were reflected in their pursuit of a literary culture of technical knowledge, largely emulating the humanist culture of the courts, including their reference to ancient Greek and Roman canons. Their contribution to the literary culture was in turn welcomed by those interested in challenging the transcendent, religious legitimization of the feudal order as an argument for the possibility of an immanent explanation of both the natural and the social world. This affinity, together with the fact that an all-encompassing explanation of the world on the basis of Aristotelian philosophy had been adopted as the official doctrine of the Catholic Church, brought the engineer-scientists almost unavoidably into conflict with its power structures (Feldhay 1995).

Other developments contributed to turning the growth of technological and scientific knowledge into a force driving profound changes in the established structures of European society. The invention of printing offered a revolutionary new means of dissemination that challenged the exclusiveness of a literary culture based on manuscripts. The new dissemination technique contributed to overcoming the traditional separation between various branches of practical knowledge, confined by a transmission process relying exclusively on participation and oral communication as well as restricted by guild regulations. It also bridged the social gulf between such practical knowledge and the theoretical knowledge transmitted via scholarly texts at universities, monasteries, and courts. As a result, knowledge resources of different provenance were integrated and became widely available. Together with the accumulation of new knowledge in the context of the great practical ventures of the time, this process formed part of a veritable explosion of knowledge, both in the sense of its expansion and of its spreading across traditional social barriers.

In reaction to this knowledge explosion and its growing significance for the functioning of the advanced European societies, new institutions of learning such as the Accademia del Cimento (1657), the Royal Society (1660), and the Académie Royale des Sciences (1666) emerged in the middle of the seventeenth century (see *Knowledge Societies*; *Scientific Academies, History of*). Traditional institutions, such as those of the Church, on the other hand, had to accommodate to the new situation, as may be illustrated by the prominent involvement of Jesuits in the scientific culture of the time (Wallace 1991). Parallel to this process of institutionalization, science had, towards the end of the period here under consideration, gradually emancipated itself from the expectation of immediate practical benefits and could increasingly be pursued for its own sake. In summary, as a result of the Scientific Revolution, not only the production and transmission of technological knowledge but also its representation by scientific theories became an essential factor in the social, economic, and cultural development of European societies. This is the context in which scientists such as Huygens, Leibniz, Hook, Newton, and Wallis, traditionally identified with the completion of the Scientific Revolution by the creation of classical terrestrial and celestial mechanics, achieved their celebrated results.

3. *Structures and Achievements*

The cognitive, social, and material structures and achievements of the Scientific Revolution have been extensively studied and discussed amid much contro-

versy. Recent scholarship in the context of a cultural history of science has emphasized the possibility of an integrative treatment of these various dimensions. From the point of view of the traditional history of ideas, the Scientific Revolution appears primarily as the renewal of a knowledge development going back to antiquity, as a renaissance of Greek science. In fact, the ancient tradition of mathematical science, and in particular the 'Elements' of Euclid, provided the protagonists of the Scientific Revolution with the canonical model for a mathematical theory, a model which they systematically applied to new areas such as ballistics (Tartaglia) and even ethics (Spinoza). But the ancient tradition also had in stock designs for a theory of nature not based on Aristotelian views which they could hence exploit in their struggle against scholasticism, in particular Platonism and atomism. The ancient tradition finally offered a substantial corpus of knowledge in such domains as geometry, mathematical astronomy, and mechanics, serving as a point of departure for new scientific endeavors. The perception of their work as a renewal of antique science was typical of the self-image of the protagonists of the Scientific Revolution, who honored each other by such titles as that of a 'new Archimedes.' In short, the characterization of the Scientific Revolution as a renaissance of antique science by historians of ideas such as Koyré is in agreement with the claims of contemporary scientists to have accomplished a radical break with Aristotelian scholasticism (Koyré 1978).

This characterization, however, is in apparent conflict with the results of studies inaugurated by scholars in the tradition of Duhem, pointing to a conceptual continuity between early modern science and its medieval predecessors (and even with contemporary scholasticism), in spite of the anti-Aristotelian polemics (Duhem 1996). Such studies have provided evidence that the intellectual means available to the engineer-scientists engaged in creating new sciences were essentially still rooted in traditional conceptual frameworks. For instance, Galileo Galilei and his contemporaries allowed their investigations of motion and mechanics to be shaped by such Aristotelian notions as the distinction between natural and violent motion and the assumption that violent motion is caused by a moving force (Damerow et al. 1992). Studies of medieval natural philosophy have revealed, on the other hand, that the advanced explanations of phenomena such as projectile motion, by which early modern scientists distinguished themselves from Aristotelian natural philosophy, make use of concepts of causation such as that of 'impetus' (or 'impressed force') and techniques for conceptualizing change such as Oresme's doctrine of the 'latitude of forms' that had already been developed by late antique or medieval commentators on Aristotle (Clagett 1968).

Such contrasting accounts of early modern science appear less incompatible if other dimensions of the development of scientific knowledge are taken into account. For instance, epistemological considerations have suggested that one should differentiate between the claim of Renaissance engineer-scientists to have created a new science or a new scientific method, on the one hand, and the knowledge base they shared with their contemporaries, on the other hand. Using the terminology introduced by Elkana (1988) we can say that their ambitious claim resulted from their 'image of knowledge,' which was determined by their fragile social status. This image is to be distinguished from the shared 'body of knowledge' comprising the antique and medieval heritage which determined what challenges they were able to master. The role of this shared knowledge for the Scientific Revolution has been analyzed not only from the point of view of the history of ideas but also from the viewpoint of its actual function in the social and material contexts of this revolution. It has thus turned out that the material culture of the Scientific Revolution decisively shaped the way in which the knowledge of antique and medieval science was taken up or newly interpreted.

It has become evident, for instance, that the knowledge resources available to the engineer-scientists, largely structured by traditional conceptual frameworks, were challenged by their application to the new objects of a rapidly expanding range of experience, acquired in the context of the practical ventures in which the engineer-scientists were engaged. While investigations of 'challenging objects' such as the pendulum, the trajectories of artillery, purified metals, the dissected human body, the terrestrial globe, and the planetary system often remained less successful than their protagonists hoped and claimed, they nevertheless triggered elaborations and modifications of these traditional frameworks creating the foundations for the accomplishments of the age of classical science. Columbus searched for the sea route to India, but discovered America. Kepler tried in the Pythagorean tradition to unravel the harmonies of the world but from the harmonies he found only three laws of planetary motion that became the starting point of Newtonian cosmology. Galileo explained ballistics and pendulum motion on the basis of the impetus concept, but in fact he contributed to a new mechanics, which expelled this concept once and for all from science. Harvey defended Aristotle's claim of the primacy of the heart among the organs, but became the founder of an anti-Aristotelian theory, a mechanistic medicine. All these achievements resulted from coping with challenging new objects while relying on essentially traditional intellectual means.

Classical science, often considered an accomplishment of the Scientific Revolution, was actually established for the most part only in the course of the eighteenth century. Even classical mechanics, the pilot and model science of the Scientific Revolution, assumed the formulation familiar from today's physics textbooks only in the aftermath of Newton's pion-

eering work. The characteristics of classical science, relatively stable theoretical frameworks and generally accepted standards for the production of knowledge serving as the canonical reference for a scientific community, were, in any case, not yet shared by the scientific endeavors of the Scientific Revolution.

The conceptual framework of classical science comprising basic concepts such as inertia, a new methodical canon including the experimental method and mathematical techniques such as the differential calculus, new images of knowledge such as the mechanization of the world view, and the new institutions of classical science such as the academies were nevertheless consequences of the Scientific Revolution, as a belated result of reflection on its accumulated experience.

Scientometrics

1. Introduction

Scientometrics can be defined as the study of the quantitative aspects of scientific communication, R&D practices, and science and technology (S&T) policies. The objective is to develop indicators of the intellectual and social organization or the sciences using network relations between scientific authors and texts. The specialty has developed in relation to the increased capacities of computer storage and information retrieval of scientific communications (e.g., citation analysis). Archival records of scientific communications contain institutional address information, substantive messages (e.g., title words), and relational information from which one is able to reconstruct patterns and identify the latent characteristics of both authors and document sets. Using scientometric techniques, one is thus able to relate institutional characteristics at the level of research groups with developments at the level of scientific disciplines and specialties.

Citations, for example, can be used for retrieving documents on the basis of author names, or vice versa. The scientometric representation is formal: it remains in need of an interpretation. The focus on uncertainty contained in the distribution relates scientometrics additionally to the (neo-evolutionary) study of complex and adaptive systems. Simulation models are increasingly used for the study of the role of science-based technologies in innovation processes. However, the specialty remains data driven because of its mission to provide indicators to S&T policy processes and R&D management.

2. A Metric of Science?

In 1978, the journal *Scientometrics* was launched as a new medium to stimulate the quantitative study of scientific communication. Derek de Solla Price, one of the founding fathers of the specialty, proclaimed in his introduction the development of scientometrics as the

emergence of a 'relatively hard' social science. This claim has generated discussion from the very beginning of the specialty. In that same year (1978), leading sociologists of science published an edited volume entitled *Toward a Metric of Science: The Advent of Science Indicators*, dedicated to 'Paul F. Lazarsfeld (1901–76), Master of Quantitative and Qualitative Social Research' (Elkana et al. 1978).

The systematic comparison of science indicators across fields of science was made possible by the creation of the *Science Citation Index* by Eugene Garfield of the Institute of Scientific Information (Garfield 1979). A preliminary version of this index became available in 1962. The creation of the database has stimulated the development of new perspectives on studies in various traditions. For example, the growth of scientific disciplines and specialties can be discussed in quantitative terms using this database (e.g., Price 1963), 'invisible colleges' can be explained in terms of network structures (Crane 1969), and theories of citations can perhaps be developed and tested (cf. Braun 1998).

The development of the specialty went hand in hand with the need for a means of legitimating science policies (Wouters 1999). Narin (1976) elaborated an instrumentarium for the systematic development of the biennial series of *Science Indicators* which the National Science Foundation of the USA began providing in 1972. (In 1987, the name of this series was changed to *Science and Engineering Indicators*.) With the further development of S&T policies in other nation-states and with the gradual emergence of such policies at the European level, scientometrics became a booming business during the 1980s. By comparing radio-astronomy facilities at the international level, Martin and Irvine (1983) showed the feasibility of comparing research groups in terms of quantitative performance indicators.

In a special issue of *Social Studies of Science* about performance indicators, Collins (1985) raised the question of the unit of analysis: what is being assessed in terms of what? The authors, the papers, or the cognitions shaped in terms of sociocognitive interactions among authors and discourses? In relation to French traditions of linguistic analysis, Callon et al. (1983) proposed using words and their co-occurrences instead of citations and co-citations (Small 1973) as units of analysis. Citations can be considered as subtextual codifications, while words indicate the variation at the level of texts. Words may change both in meaning and in terms of their observable frequency distributions.

3. *Methodologies*

The availability of well-organized relational databases on an annual basis challenges the scientometrician to develop comparative statistics. How is the structure in each of these years to be depicted, and how may changes in structure be distinguished from and related to changes in the observable variation? Can the difference over time be identified as 'growth of science,' or is it mainly a difference between two measurement errors? How significant are differences when tested against simulation results?

In principle, the idea of a dynamic mapping of science requires an independent operationalization of structural (that is, latent) dimensions of the maps and observable variation which is to be pencilled into these maps. Science, however, develops not only in terms of the variation, but also by changing its structural dimensions. Because of the prevailing reflexivity within the science system, previous structures can be felt as constraints and at the same time be used as resources. The construction of structure may historically be stabilized, but reflexive actors are able to deconstruct and to assess the previous constructions with hindsight.

The methodological apparatus for the mapping of science in terms of multivariate statistics (multidimensional scaling, cluster analysis, etc.) has been a product of the 1980s (e.g., Van Raan 1988). The 1990s have provided the evolutionary turn: what does history mean in relation to (envisaged?) future options? How can the system itself be informed reflexively with respect to its self-organizing capacities (Leydesdorff 1995)? The relation to technometrics and the measurement of 'systems of innovation' has become central to a shifting research agenda. The development of the sciences has increasingly been contextualized in relation to science-based technologies and innovation systems (Gibbons et al. 1994).

3.1 *Comparative Statistics of Science*

Various methods for the mapping of science can be based on relational indicators such as citations, words, co-occurrences of each of these categories, etc. Clustering, however, requires the choice of a similarity criterion and a clustering algorithm. The distinction between positional (or factor analytical) and relational (or graph analytical) approaches is also relevant: the network is expected to contain an architecture in which actors have a position. A nearby position does not necessarily imply a relation. The methodological reflection may thus help to clarify the theoretical analysis (Burt 1982).

The mapping requires a specific perspective for the projection. Each perspective assumes a position or a window. If the multidimensional space is highly structured, the different positions may provide nearly incommensurable projections. In an article on the development of the relation between scientometrics and other subfields of S&T studies, Leydesdorff and Van den Besselaar (1997) showed that the mappings depicting science studies from the perspective of the journals *Scientometrics, Social Studies of Science*, and *Research Policy*, respectively, are increasingly different

Figure 1
The emergence of the modern citation in the February issues of *Journal of the American Chemical Society* (1890–1910) (after Leydesdorff and Wouters 1999, p. 175).

during the 1990s. Citation relations among these core journals tend to decrease. The authors characterize *Social Studies of Science* as the 'codifier' of the field (along the historical axis), *Scientometrics* as the 'formalizer,' and *Research Policy* as the 'utilizer.' Only a few scholars in 'Science, Technology, and Innovation Studies' have developed competences for communicating across these subdisciplinary boundaries.

3.2 Time-series Methodologies

During the 1980s a debate raged in the community concerning the scientometric indication of a 'decline of British science.' Eventually, a special issue of *Scientometrics* was devoted to the debate in 1991 (Martin 1991). Some agreement could be reached that the inclusion and exclusion of data types *and* the framework for the comparison can be crucial for the dynamic evaluation. Should one compare with reference to a previous stage (for example, in terms of an *ex ante* fixed journal set), or should one with hindsight reconstruct the relevant data? For example, not only has the number of biotechnology journals changed, but also our understanding of 'biotechnology' is changing continuously. The sociological understanding of scientific knowledge production and control seems to have eroded Price's dream of developing scientometrics as a relatively 'hard social science.'

Using time-series analysis, one is always able to increase the fit of the curve by allowing for higher-order polynomials. Here again, the theoretical appreciation has to guide the choices of the parameters. For example, if one wishes to measure growth, it may be useful to include a second- or third-order polynomial in addition to the linear fit. Figure 1, for example, depicts the emergence of the modern citation itself as a historical phenomenon, but using theoretically informed helplines. Scientific citation emerged around the turn of the twentieth century as a means to search in both the textual and the social dimensions of science. Thus, the citation can be considered as an indicator of the complexity of sociocognitive interaction in science after its institutionalization in the nineteenth century.

3.3 Neo-evolutionary Methodologies

The networks of texts and the networks of authors operate upon each other in a selective mode. The distributions are expected to contain information, and this information may be increasingly codified by recurrent selections. As the systems 'lock-in' (in terms of their mutual information), the closure of the communication into a paradigm is one among various possibilities. The uncertainties which prevail in these networks can interactively generate codifications, which can be expected to perform a 'life-cycle.' Both participants and observers are able to hypothesize these structures reflexively, and new information can be expected to induce an update. Thus, the codification drives the knowledge production process. Codification also provides instruments for local control of otherwise global developments.

The relational operation is recursive. For example, citations refer to other texts and/or to citations in other texts. The networks resulting from this operation are expected to have an architecture (which can be mapped at each moment in time). Operations are expected to be reproduced if they are able to further the production of new knowledge and the latter's retention into cognitive structures. What is functional, however, is decided at a next moment in time, that is, at the level of a reflexive hypernetwork that overlays the historically generated ones. The distributions indicate the patterns of the expected operations. Thus, the process of new knowledge claims is propelled and made more precise and selective in tradeoffs of references in social and cognitive dimensions.

Scientometric studies can be helpful in revealing the patterns of intellectual and social organization which may have remained (partially) latent to the knowledgable actors involved. Simulation studies using scientometric mappings as input enable us to indicate the difference that the moves of the players can make. The complexity of the scientists' worlds is reflected in the scientometric reconstructions. The recognition of these objectified reconstructions recursively assumes and potentially refines the cognition within the discourses at both levels.

Over time, the cognitive reconstruction becomes thoroughly selective: citations may be 'obliterated by incorporation' into the body of knowledge, and social factors may play a role in further selections, e.g., in

terms of reputations. In this co-evolution between communications and authors, distributions of citations function, among other things, as contested boundaries between specialties. Since the indicators are distributed, the boundaries remain to be validated. Functions are expected to change when the research front moves further. By using references, authors position their knowledge claims within one specialty area or another. Some selections are chosen for stabilization, for example, when codification into citation classics occurs. Some stabilizations are selected for globalization at a next-order level, for example, when the knowledge component is integrated into a technology.

4. Conclusion

The focus on evolutionary dynamics relates scientometrics increasingly with the further development of evolutionary economics (Leydesdorff and Van den Besselaar 1994). How can systems of innovation be delineated? How can the complex dynamics of such systems be understood? How is the (potentially random) variation guided by previously codified expectations? How can explorative variation be increased in otherwise 'locked-in' trajectories of technological regimes or paradigms?

From this perspective, the indication of newness may become more important than the indication of codification. The Internet, of course, offers a research tool for what has also now been called 'sitations' (Rousseau 1997). 'Webometrics' may develop as a further extension of scientometrics relating this field with other subspecialities of science and technology studies, such as the public understanding of science or the appropriation of technology and innovation using patent statistics.

Screening and Selection

1. Introduction

In order to assist in selecting individuals possessing either desirable traits such as an aptitude for higher education or skills needed for a job or undesirable ones such as having an infection, illness or a propensity to lie, screening tests are used as a first step. A more rigorous selection device, e.g., diagnostic test or detailed interview is then used for the final classification.

For some purposes, such as screening blood donations for a rare infection, the units classified as positive are not donated but further tests on donors may not be given as most will not be infected. Similarly, for estimating the prevalence of a trait in a population, the screening data may suffice provided an appropriate estimator that incorporates the error rates of the test is used (Hilden 1979, Gastwirth 1987, Rahme and Joseph 1998). This article describes the measures of accuracy used to evaluate and compare screening tests and issues arising in the interpretation of the results. The importance of the prevalence of the trait on the population screened and the relative costs of the two types of misclassification are discussed. Methods for estimating the accuracy rates of screening tests are briefly described and the need to incorporate them in estimates of prevalence is illustrated.

2. *Basic Concepts*

The purpose of a screening test is to determine whether a person or object is a member of a particular class, C or its complement, $C-$. The test result indicating that the person is in C will be denoted by S and a result indicating non-membership by $S-$. The *accuracy* of a test is described by two probabilities:

$$\eta = \mathrm{P}[S \mid C]$$

being the probability that someone in C is correctly classified, or the sensitivity of the test; and

$$\theta = \mathrm{P}[S- \mid C-]$$

being the probability that someone not in C is correctly classified, or the specificity of the test. Given the prevalence, $\pi = \mathrm{P}(C)$, of the trait in the population screened, from Bayes' theorem it follows that the predictive value of a positive test (PVP) is

$$\mathrm{P}[C \mid S] = \pi\eta/[\pi\eta + (1-\pi)(1-\theta)].$$

Similarly, the predictive value of a negative test is

$$\mathrm{P}[C- \mid S-] = (1-\pi)\theta/[(1-\pi)\theta + \pi(1-\eta)].$$

In the first two sections, we will assume that the accuracy rates and the prevalence are known. When they are estimated from data, appropriate sampling errors for them and the PVP are given in Gastwirth (1987).

For illustration, consider an early test for HIV, having a sensitivity of 0.98 and a specificity of 0.93, applied in two populations. The first has a very low prevalence, 1.0×10^{-3}, of the infection while the second has a prevalence of 0.25. From Eqn. (1), the PVP in the first population equals 0.0138, i.e., only about one-and-one-half percent of individuals classified as infected would actually be so. Nearly 99 percent would be false positives. Notice that if the fraction of positives, expected to be 0.0797, in the screened data were used to estimate prevalence, a severe overestimate would result. Adjusting for the error rates yields an accurate estimate. In the higher prevalence group, the PVP is 0.8235, indicating that the test could be useful in identifying individuals. Currently-used tests have accuracy rates greater than 0.99, but even these still have a PVP less than 0.5 when applied to a low prevalence population. A comprehensive discussion is given in Brookmeyer and Gail (1994).

The role of the prevalence, also called the base rate, of the trait in the screened population and how well people understand its effect has been the subject of substantial research, recently reviewed by Koehler (1996). An interesting consequence is that when steps are taken to reduce the prevalence of the trait prior to screening, the PVP declines and the fraction of false-positives increases. Thus, when high-risk donors are encouraged to defer or when background checks eliminate a sizeable fraction of unsuitable applicants prior to their being subjected to polygraph testing the fraction of classified positives who are truly positive is small.

In many applications screening tests yield data that are ordinal or essentially continuous, e.g., scores on psychological tests or the concentration of HIV antibodies. Any value, t, can be used as a cut-off point to delineate between individuals with the trait and 'normal.' Each t generates a corresponding sensitivity and specificity for the test and the user must then incorporate the relative costs of the two different errors and the likely prevalence of the trait in the population being screened to select the cut off. The receiver operating characteristic (ROC) curve displays the trade-off between the sensitivity and specificity defined by various choices of t and also yields a method for comparing two or more screening tests.

To define the ROC curve, assume that the distribution of the measured variable (test score or physical quantity) is $F(x)$ for the 'normal' members of the population but is $G(x)$ for those with the trait. The corresponding density functions are $f(x)$ and $g(x)$ respectively and $g(x)$ will be shifted (to the right (left) if large (small) scores indicate the trait) of $f(x)$ for a good screening test. Often one fixes the probability ($\alpha = 1 - y\theta$ or one minus the specificity) of classifying a person without the characteristic as having it at a small value. Then t is determined from the equation $F(t) = 1 - \theta$. The sensitivity, η, of the test is $1 - G(t)$. The ROC curve plots η against $1 - \theta$. A perfect test would have $\eta = 1$ so the closer the ROC is to the upper left corner in Fig. 1, the better the screening test. In Fig. 1 we assume f is a normal density with mean 0 and variance 1 while g_1 is normal with mean 1 and the same variance. For comparison we also graphed the ROC for a second test, which has a density g_2 with mean 2 and variance 1. Notice that the ROC curve for the

Figure 1
The ROC curves for screening tests 1 and 2. The solid line is the curve when the diseased group has mean 1 and the dashed curve is for the second group with mean 2

second test is closer to the left corner (0,1) than that of the first test.

A summary measure (Campbell 1994), which is useful in comparing two screening tests is the area, A, under the ROC. The closer A is to its maximum value of 1.0, the better the test is. In Fig. 1, the areas under the ROC curves for the two tests are 0.761 and 0.922, respectively. Thus, the areas reflect the fact that the ROC curve for the second test is closer to what a 'perfect' test would be. This area equals the probability a randomly chosen individual will have a higher score on the screening test than a normal one. This probability is the expected value of the Mann–Whitney form of the Wilcoxon test for comparing two distributions and methods for estimating it are in standard non-parametric statistics texts.

Non-parametric methods for estimating the entire ROC curve are given by Wieand et al. (1989) and Hilgers (1991) obtained distribution-free confidence bounds for it. Campbell (1994) uses the confidence bounds on F and G to construct a joint confidence interval for the sensitivity and one minus the specificity in addition to proposing alternative confidence bounds for the ROC itself. Hseih and Turnbull (1996) determine the value of t that maximizes the sum of sensitivity and specificity. Their approach can be extended to maximizing weighted average of the two accuracy rates, suggested by Gail and Green (1976). Wieand et al. (1989) also developed related statistics focusing on the portion of the ROC lying above a region, α_1 and α_2 so the analysis can be confined to values of specificity that are practically useful. Greenhouse and Mantel (1950) determine the sample sizes needed to test whether both the specificity and sensitivity of a test exceed pre-specified values.

The area A under the ROC can also be estimated using parametric distributions for the densities f and g. References to this literature and an alternative approach using smoothed histograms to estimate the densities is developed in Zou et al. (1997). They also consider estimating the partial area over the important region determined by two appropriate small values of α.

The tests used to select employees need to be reliable and valid. Reliability means that replicate values are consistent while validity means that the test measures what it should, e.g., successful academic performance. Validity is often assessed by the correlation between the test score (X) and subsequent performance (Y). Often X and Y can be regarded as jointly normal random variables, especially as monotone transformations of the raw scores can be used in place of them. If a passing score on the screening or pre-employment test is defined as $X \geqslant t$ and successful performance is defined as $Y \geqslant d$, then the sensitivity of the test is $\mathrm{P}[X > t \mid Y > d]$, the specificity is $\mathrm{P}[X < t \mid Y < d]$ and the prevalence of the trait is $\mathrm{P}[Y > d]$ in the population of potential applicants. Hence, the aptitude and related tests can be viewed from the general screening test paradigm.

When the test and performance scores are scaled to have a standard bivariate normal distribution, both the sensitivity and specificity increase with the correlation, ρ. For example, suppose one desired to obtain employees in the upper half of the performance distribution and used a cut-off score, t, of one-standard deviation above the mean on the test (X). When $\rho = 0.3$, the sensitivity is 0.217 while the specificity is 0.899. If $\rho = 0.5$, the sensitivity is 0.255 and the specificity is 0.937. The use of a high cut-off score eliminates the less able applicants but also disqualifies a majority of applicants who are in the upper half of the performance distribution. Reducing the cut-off score to one-half a standard deviation above the average raises the sensitivities to 0.394 and 0.454 for the two values of ρ but lowers the corresponding specificities to 0.777 and 0.837. This trade-off is a general phenomenon as seen in the ROC curves.

3. *The Importance of the Context in Interpreting the Results of Screening Tests*

In medical and psychological applications, an individual who tests positive for a disease or condition on a screening test will be given a more accurate confirmatory test or intensive interview. The cost of a 'false positive' screening result on a medical exam is

often considered very small relative to a 'false negative,' which could lead to the failure of suitable treatment to be given in a timely fashion. A false positive result presumably would be identified in a subsequent more detailed exam. Similarly, when government agencies give employees in safety or security sensitive jobs a polygraph test, the loss of potentially productive employee due to a false positive was deemed much less than the risk of hiring an employee who would might be a risk to the public or a security risk.

One can formalize the issue by including the costs of various errors and the prevalence, π, of the trait in the population being screened in determining the cut-off value of the screening test. Then the expected cost, which weights the probability of each type of error by its cost is given by

$$w\alpha(1-\pi)+(1-w)\pi G(t).$$

Here the relative costs of a false positive (negative) are w and $1-w$, respectively and as before $t = F^{-1}(1-\alpha)$. The choice of cut-off value, t_o, minimizing the expected cost satisfies:

$$\frac{g(t)}{f(t)} = \frac{w(1-\pi)}{(1-w)\pi} \tag{1}$$

Whenever the ratio, $g{:}f$, of the density functions is a monotone function the previous equation yields an optimum cut-off point, t_o, which depends on the costs and prevalence of the trait. Note that for any value of π, the greater the cost of a false positive, the larger will be the optimum value, t_o. This reflects the fact that the specificity needs to be high in order to keep the false positive rate low.

Although the relative costs of the two types of error are not always easy to obtain and the prevalence may only be approximately known, Eqn. (1) may aid in choosing the critical value. In practice, one should also assess the effect slight changes in the costs and assumed prevalence have on the choice of the cut-off value.

The choice of t that satisfies condition (1) may not be optimal if one desires to estimate the prevalence of the trait in a population rather than classifying individuals. Yanagawa and Tokudome (1990) determine t when the objective is to minimize the relative absolute error of the estimator of prevalence on the basis of the screening test results.

The HIV/AIDS epidemic raised questions about the standard assumptions about the relative costs of the two types of error. A 'false positive' classification would not only mean that a well individual would worry until the results of the confirmatory test were completed, they also might have social and economic consequences if friends or their employer learned of the result.

Similar problems arise in screening blood donors and in studies concerning the association of genetic markers and serious diseases. Recall that the vast majority of donors or volunteers for genetic studies are doing a public service and are being screened to protect others or advance knowledge. If a donation tests positive, clearly it should not be used for transfusion. Should a screened-positive donor be informed of their status? Because the prevalence of infected donors is very small, the PVP is quite low so that most of the donors screened positive are 'false.' Thus, blood banks typically do not inform them and rely on approaches to encourage donors from high-risk groups to exclude themselves from the donor pool (Nusbacher et al. 1986). Similarly, in a study (Hartge et al. 1998) of the prevalence of mutations in two genes that have been linked to cancer the study participants were not notified of their results.

The screening test paradigm is useful in evaluating tests used to select employees. The utility of a test depends on the costs associated with administering the test and the costs associated with the two types of error. Traditionally, employers focused on the costs of a false positive, hiring an employee who does not perform well, such as termination costs, and the possible loss of customers. The costs of a false negative are more difficult to estimate.

The civil-rights law, which was designed to open job opportunities to minorities, emphasized the importance of using appropriate tests, i.e., tests that selected better workers. Employers need to check whether the tests or job requirements (e.g., possession of a high school diploma) have a disparate impact upon a legally protected group. When they exclude a significantly greater fraction of minority members than majority ones, the employer needs to validate it, i.e., show it is predictive of on the job performance. Arvey (1979) and Paetzold and Willborn (1994) discuss these issues.

4. *Estimating the Accuracy of the Screening Tests*

So far, we have assumed that we can estimate the accuracy of the screening tests on samples from two populations where the true status of the individuals is known with certainty. In practice, this is often not the case and can lead to biased estimates of the sensitivity and specificity of a screening test, as some of the individuals believed to be normal have the trait, and vice versa.

If one has samples from only one population to which to apply both the screening and confirmatory test, then one cannot estimate the accuracy rates. The data would be organized into a 2×2 table, with four cells, only three of which are independent. There are five parameters, however, the two accuracy rates of the two tests plus the prevalence of the trait in the

population. In some situations, the prevalence of the trait may vary amongst sub-populations. If one can find two such sub-populations and if the accuracy rates of both tests are the same in both of those sub-populations, then one has two 2×2 tables with six independent cells, with which to estimate six parameters. Then estimation can then be carried out (Hui and Walter 1980).

This approach assumes that the two tests are conditionally independent given the true status of the individual. When this assumption is not satisfied, Vacek (1985) showed that the estimates of sensitivity and specificity of the tests are biased. This topic is an active area of research, recently reviewed by Hui and Zhou (1998). A variety of latent-class models have been developed that relax the assumption of conditional independence (see Faraone and Tsuang 1994 and Yang and Becker 1997 and the literature they cite).

5. *Applications and Future Concerns*

Historically screening tests were used to identify individuals with a disease or trait, e.g., as a first stage in diagnosing medical or psychological conditions or select students or employees. They are being increasingly used, often in conjunction with a second, confirmatory test, in prevalence surveys for public health planning. The techniques developed are often applicable, with suitable modifications, to social science surveys.

Some examples of prevalence surveys illustrate their utility. Katz et al. (1995) compared two instruments for determining the presence of psychiatric disorders in part to assess the needs for psychiatric care in the community and the available services. They found that increasing the original cut-off score yielded higher specificity without a substantial loss of sensitivity. Similar studies were carried out in Holland by Hodiamont et al. (1987) who found a lower prevalence (7.5 percent) than the 16 percent estimate in York. The two studies, however, used different classification systems illustrating that one needs to carefully examine the methodology underlying various surveys before making international comparisons. Gupta et al. (1997) used several criteria based on the results of an EKG and an individual's medical history to estimate the prevalence of heart disease in India.

Often one has prior knowledge of the prevalence of a trait in a population, especially if one is screening similar populations on a regular basis, as would be employers, medical plans, or blood centers. Bayesian methods incorporate this background information and can yield more accurate estimates (see Geisser 1993, and Johnson, Gastwirth and Pearson 2001). A cost-effective approach is to use an inexpensive screen at a first stage and retest the positives with a more definitive test. Bayesian methodology for such studies was developed by Erkanli et al. (1997).

The problem of misclassification arises often in questionnaire surveys. Laurikka et al. (1995) estimated the sensitivity and specificity of self-reporting of varicose veins. While both measures were greater than 0.90, the specificity was lower (0.83) for individuals with a family history than those with negative histories. Sorenson (1998) observed that often self-reports are accepted as true and found that the potential misclassification could lead to noticeable (10 percent) errors in estimated mortality rates. The distortion misclassification errors can have on estimates of low prevalence traits because of the high fraction of false positive classifications, was illustrated in the earlier discussion of screening tests for HIV/AIDS. Hemenway (1997) applies these concepts to demonstrate that surveys typically overestimate rare events; in particular the self-defense uses of guns. Thus it is essential to incorporate the accuracy rates into the prevalence estimate (Hilden 1979, Gastwirth 1987, Rahme and Joseph 1998).

Sinclair and Gastwirth (1994) utilized the Hui-Walter paradigm to assess the accuracy of both the original and re-interview (by supervisors) classifications in labor force surveys. In its evaluation, the Census Bureau assumes that the re-interview data are correct; however, those authors found that both interviews had similar accuracy rates. In situations where one can obtain three or more classifications, all the parameters are identifiable (Walter and Irwig 1988) Gastwirth and Sinclair (1998) utilized this feature of the screening test approach to suggest an alternative design for judge–jury agreement studies that had another expert, e.g., law professor or retired judge, assess the evidence.

6. *Conclusion*

Many selection or classification problems can be viewed from the screening test paradigm. The context of the application determines the relative costs of a misclassification or erroneous identification. In criminal trials, society has decided that the cost of an erroneous conviction far outweighs the cost of an erroneous acquittal. While, in testing job applicants, the cost of not hiring a competent worker is not as serious. The two types of error vary with the threshold or cut-off value and the accuracy rates corresponding to these choices is summarized by the ROC curve.

There is a burgeoning literature in this area as researchers are incorporating relevant covariates, e.g., prior health status or educational background into the classification procedures. Recent issues of *Biometrics and Multivariate Behavioral Research, Psychometrika* and *Applied Psychological Measurement* as well as the medical journals cited in the article contain a variety of

articles presenting new techniques and applications of them to the problems discussed.

Search, Economics of

The economics of search study the implications of market frictions for economic behavior and market performance. 'Frictions' in this context include anything that interferes with the smooth and instantaneous exchange of goods and services. The most commonly-studied problems arise from imperfect information about the location of buyers and sellers, their prices, and the quality of the goods and services that they trade. The key implication of these frictions is that individuals are prepared to spend time and other resources on exchange; they *search* before buying or selling. The labor market has attracted most

theoretical and empirical interest in this area of research, because of the heterogeneities that characterize it and the existence of good data on flows of workers and jobs between activity and inactivity, which can be used to test its propositions.

1. Historical Background

The first formal model of individual behavior, due to Stigler (1961), was in the context of a goods market: choosing the optimal number of sellers to search before buying at the lowest price. Stigler's rule, known as a fixed-sample rule, was abandoned in favor of sequential stopping rules: choosing the optimal reservation price and buying at the first store encountered which sells at or below the reservation price (see McCall 1970 for an early influential paper).

The first big momentum to research in the economics of search came with the publication of Phelps et al. (1970), which showed that search theory could be used to analyze the natural rate of unemployment and the inflation-unemployment trade off, the central research questions of macroeconomics at that time. Although interest in the inflation-unemployment trade-off has since waned, interest in search theory as a tool to analyze transitions in the labor market and equilibrium unemployment has increased. The momentum in this direction came in the 1980s, when contributions by Diamond (1982), Mortensen (1982) and Pissarides (1985) showed that search theory could be used to construct equilibrium models of the labor market with more accurate predictions than the traditional neoclassical model (see Pissarides 2000, Mortensen and Pissarides 1999a, 1999b for reviews). The appearance of comprehensive data on job and worker flows, which can be studied with the tools of search theory, also contributed to interest in this direction (see Leonard 1987, Dunne et al. 1989, Davis et al. 1996, Blanchard and Diamond 1990). This article reviews major developments since the mid 1980s, with explicit reference to labor markets.

2. Job Search

An individual has one unit of labor to sell to firms, which create jobs. The valuation of labor takes place under the assumptions that agents have infinite horizons and discount future income flows at the constant rate r, they know the future path of prices and wages and the stochastic processes that govern the arrival of trading partners, and they maximize the present discounted value of expected incomes. Let U_t be the expected present discounted value of a unit of labor before trade at time t (the 'value' of an unemployed worker) and W_t the expected value of an employed worker. During a short time interval δt the unemployed worker receives income $b\delta t$, and a job offer arrives with probability $a\delta t$. The frictions studied in the economics of search are summarized in the arrival process. In the absence of frictions, $a \to \infty$. With frictions and search, $a > 0$; with no search, $a = 0$. A large part of the literature is devoted to specifying the arrival process, an issue addressed in Sect. 3.1. The choice of search intensity has also been studied, by making a an increasing function of search effort, but this issue is not addressed here (see Pissarides 2000, Chap. 5).

If a job offer arrives, the individual has the option of taking it, for an expected return $W_{t+\delta t}$; or not taking it and keeping instead return $U_{t+\delta t}$. If no offer arrives, the individual's return is $U_{t+\delta t}$. Therefore, with discount rate r, U_t satisfies the Bellman equation

$$U_t = b\delta t + a\delta t \frac{\max(W_{t+\delta t}, U_{t+\delta t})}{1+r\delta t} + (1-a\delta t)\frac{U_{t+\delta t}}{1+r\delta t} \quad (1)$$

Rearrangement of terms yields

$$rU_t = b + a(\max(W_{t+\delta t}, U_{t+\delta t}) - U_{t+\delta t}) + \frac{U_{t+\delta t} - U_t}{\delta t} \quad (2)$$

Taking the limit of (2) as $\delta t \to \infty$, and omitting subscripts for convenience, yields

$$rU = b + a(\max(W, U) - U) + \dot{U} \quad (3)$$

where $\dot{U}$ denotes the rate of change of U.

Equation (3) is a fundamental equation in the economics of search. It can be given the interpretation of an arbitrage equation for the valuation of an asset in a perfect capital market with risk-free interest rate r. This asset yields coupon payment b and at some rate a, it gives its holder the option of a discrete change in its valuation, from U to W. Optimality requires that the option is taken (and the existing valuation given up) if $W \geqslant U$. The last term, $\dot{U}$, shows capital gains or losses due to changes in the market valuation of the asset. In most of the economics of labor-market search, however, research concentrates on 'steady states,' namely, on situations where the discount rate, transition rates, and income flows are all constant. With infinite horizons there are then stationary solutions to the valuation equations, obtained from (3) with $\dot{U} = 0$.

One simple way of solving (3) is to assume that employment is an 'absorbing state,' so when a job that offers wage w is accepted, it is kept for life. Then, $W = w/r$, and if the individual is sampling from a known wage offer distribution $F(w)$, the stationary version of (3) satisfies

$$rU = b + a(\int \max(w/r, U)\, \mathrm{d}F(w) - U) \quad (4)$$

The option to accept a job offer is taken if $w/r \geqslant U$, giving the *reservation wage* eqn.

$$\xi = rU \tag{5}$$

The reservation wage is defined as the minimum acceptable wage, and it is obtained as the solution to (4) and (5).

Partial models of search and empirical research in the duration of unemployment have explored generalized forms of Eqn. (4) to derive the properties of transitions of individuals from unemployment to employment (see Devine and Kiefer 1991). For a known $F(w)$ with upper support A, Eqn. (4) specializes to

$$\xi = b + \frac{a}{r}\int_{\xi}^{A}(w-\xi)\,\mathrm{d}F(w) \tag{6}$$

Various forms of (6) have been estimated by the empirical literature or used in the construction of partial models of the labor market. The transition from unemployment to employment (the unemployment 'hazard rate') is $a(1-F(\xi))$ and it depends both on the arrival of offers and on the individual's reservation wage. a, r, and the parameters of the wage offer distribution can be made to depend on the individual's characteristics. The empirical literature has generally found that unemployment compensation acts as a disincentive on individual transitions through the influence of b on the reservation wage, but the effect is not strong. The offer arrival rate increases the hazard rate, despite the fact that the reservation wage increases in a. A number of personal characteristics influence reservation wages and transitions, including age, education, and race.

3. Two-sided Matching for Given Wages

Recent work in the economics of search has focused mainly on the equilibrium implications of frictions and search decisions. An equilibrium model needs to specify the decisions of firms and solve for the offer arrival rate a. In addition, a mechanism is needed to ensure that search is an ongoing process. The latter is achieved by introducing a probability $\lambda\delta t$ that a negative shock will hit a job during a short time interval δt. When the negative shock arrives the job is closed down ('destroyed'), and the worker has to search again to find another job. For the moment, λ is assumed to be a positive constant (see Sect. 5).

3.1. The Aggregate Matching Function

To derive the equilibrium offer arrival rate, suppose that at time t there are u unemployed workers and v vacant jobs. In a short time interval δt each unemployed worker moves to employment with probability $a\delta t$, so in a large market the total flow of workers from unemployment to employment, and the total flow of jobs from vacant state to production, are both $au\delta t$. A key assumption in the equilibrium literature is that the total flows satisfy an *aggregate matching function*. The aggregate matching function is a black box that gives the outcome of the search process in terms of the inputs into search. If the u unemployed workers are the only job seekers and they search with fixed intensity of one unit each, and firms also search with fixed intensity of one unit for each job vacancy, the matching function gives

$$m = m(u, v) \tag{7}$$

with m standing for the flow of matches, au. The function is usually assumed to be continuous and differentiable, with positive first partial derivatives and negative second derivatives, and to satisfy constant returns to scale (see Petrongolo and Pissarides 2000 for a review). A commonly-used matching function in the theoretical literature, derived from the assumption of uncoordinated random search, is the exponential

$$m = v(1-\mathrm{e}^{-ku/v}), \quad k > 0 \tag{8}$$

The empirical literature, however, estimates a log-linear (constant elasticity) form, which parallels the Cobb–Douglas production function specification, with the elasticity on unemployment estimated in the range 0.5–0.7.

The fact that job matching is pairwise implies that the transition rates of jobs and workers are related Poisson processes. Given $au = m$, the rate at which workers find jobs is $a = m/u$. If q is the rate of arrival of workers to vacant jobs, then total job flows $vq = au$, and so $q = m/v$. The equilibrium literature generally ignores individual differences and treats the average rates m/u and m/v as the rates at which jobs and workers, respectively, arrive to each searching worker and vacant job. By the properties of the matching function,

$$q = m\left(\frac{u}{v}, 1\right) \tag{9}$$

$$\equiv m(\theta^{-1}, 1) \equiv q(\theta) \tag{10}$$

with $q'(\theta) < 0$ and elasticity $-\eta(\theta) \in (-1, 0)$. Here, θ is a measure of the *tightness* of the market, of the ratio of the inputs of firms into search to the inputs of workers. Similarly, the transition rate of workers is

$$a = m\left(1, \frac{v}{u}\right) \equiv \theta q(\theta) \tag{11}$$

By the elasticity properties of $q(\theta)$, $\partial a/\partial\theta > 0$. In the steady state, the inverse of the transition rates, $1/q(\theta)$ and $1/\theta q(\theta)$, are the expected durations of a vacancy and unemployment respectively.

The influence of tightness on the transition rates is independent of the level of wage rates. If there are more vacant jobs for each unemployed worker, the arrival rate of workers to the typical vacancy is lower and the arrival rate of job offers to the typical unemployed worker is higher, irrespective of the level of wages. When a worker and a firm meet and are considering whether or not to stay together, they are not likely to take into account the implications of their action for market tightness and the transition rates of other unmatched agents. For this reason, the influence of tightness on the transition rates is known as a *search externality*. Several papers in the economics of search have explored the efficiency properties of equilibrium given the existence of the externality (see Sect. 4.3.2 and Diamond 1982, Mortensen 1982, Pissarides 1984, Hosios 1990).

3.2 Job Creation

A job is an asset owned by the firm and is valued in a perfect capital market characterized by the same risk-free interest rate r. Suppose that in order to recruit a worker, a firm has to bear set-up cost K to open a job vacancy and in addition has to pay a given flow cost c for the duration of the vacancy. The flow cost can be interpreted as an advertising and recruitment cost, or as the cost of having an unfilled position in what might be a complex business environment (which is not modeled).

Let V be the value of a vacant position and J the value of a filled one. Reasoning as in the case of the value of a job seeker, U, the Bellman equation satisfied by V is

$$rV = -c + q(\theta)(J - V) \tag{12}$$

The vacant job costs c and the firm is offered the option to take a worker at rate $q(\theta)$.

Since the firm has to pay set-up cost K to create a job, it will have an incentive to open a job if (and only if) $V \geqslant K$. The key assumption made about job creation is that the gains from job creation are always exhausted, so jobs are created up to the point where

$$V = K \tag{13}$$

Substitution of V from (12) into (13) yields

$$J = K + \frac{rK + c}{q(\theta)} \tag{14}$$

Competition requires that the expected present discounted value of profit when the worker arrives, the value of a filled job J, should be just sufficient to cover the initial cost K and the accumulated costs for the duration of the vacancy, interest on the initial outlay rK and ongoing costs c for the expected duration of the vacancy, $1/q(\theta)$.

Let productivity be a constant p in all jobs and the wage rate a constant w. With break-up rate λ, the value of a job satisfies the Bellman equation

$$rJ = p - w - \lambda J \tag{15}$$

The flow of profit to the firm is $p - w$ until a negative shock arrives that reduces its value to 0. Replacing J in (14) by its expression in (15) yields the *job creation condition*

$$\frac{p - w}{r + \lambda} - K - \frac{rK + c}{q(\theta)} = 0 \tag{16}$$

Equation (16) determines θ for each w and parallels the conventional labor demand curve. A higher wage rate makes it more expensive for firms to open jobs, leading to lower market tightness. Frictions slow down the arrival of suitable workers to vacant jobs and so the firm incurs some additional recruitment costs. If the arrival rate is infinitely fast, as in Walrasian economics, $q(\theta)$ is infinite and the last term in (16) disappears. The assumptions underlying (13) ensure that at the margin, the recruitment cost is just covered.

4. Wage Setting

With search frictions, there is no supply of labor that can be equated with demand to give wages. The conventional supply of labor is constant here: there is a fixed number of workers in the market, which is usually normalized to unity, and each supplies a single unit of labor.

In search equilibrium there are local monopoly rents. Firms and workers who are together can start producing immediately. If they break up, they can start producing only after they find another partner through an expensive process of search. The value of the search costs that they save by staying together correspond to a pure economic rent; they could be taken away from them and they would still stay together. Wages need to share those rents.

Two approaches dominate in the literature. The first and more commonly-used approach employs the solution to a Nash bargaining problem (see Diamond 1982, Pissarides 2000). The Nash solution allocates the rents according to each side's 'threat points.' The threat points in this case are the returns from search, and the Nash solution gives to each side the same surplus over and above their expected returns from search. Generalizing this solution concept, wages are determined such that the net gain accruing to the

worker from the match, $W-U$, is a fixed proportion β of the total surplus, the sum of the worker's and the firm's surplus, $J-V$. This sharing rule can be obtained as the maximization of the product

$$(W-U)^{\beta}(J-V)^{1-\beta}, \quad \beta \in (0, 1) \tag{17}$$

The coefficient β can be given the interpretation of bargaining strength, although strictly speaking, bargaining strength in the conventional Nash solution is given by the threat points U and V (see Binmore et al. 1986 for an interpretation of β in terms of rates of time preference).

The second approach to wage determination postulates that the firm 'posts' a wage rate for the job, which the worker either takes or leaves. The posted wage may be above the worker's reservation wage because of some 'efficiency wage' type arguments, for example, in order to reduce labor turnover, encourage more effort or attract more job applicants.

4.1 Bargaining

The value of an employed worker, W, satisfies the Bellman eqn.

$$rW = w - \lambda(W-U) \tag{18}$$

The worker earns wage w and gives up the employment gain $W-U$ when the negative shock arrives. No worker has an incentive to quit into unemployment or search for another job whilst employed, for as long as $w \geqslant b$, which is assumed.

With (15) and (17) in place, the Nash bargaining solution to (18) gives the sharing rule

$$W-U = \beta(W-U+J-V). \tag{19}$$

Making use of the value equations and sharing rule yields

$$w = rU + \beta(p-(r+\lambda)K - rU) \tag{20}$$

$$= (1-\beta)b + \beta[p-(r+\lambda)K + (rK+c)\theta] \tag{21}$$

There is a premium on the reservation wage which depends on the worker's bargaining strength and the net surplus produced. Wages depend positively on unemployment income and the productivity of the job, the first because of the effect that unemployment income has on the cost of unemployment and the second because of the monopoly rents and bargaining. Wages also depend on market tightness. In more tight markets they are higher, because the expected duration of unemployment in the event of disagreement is less. Empirical evidence supporting this wage equation has been found by a number of authors (e.g., Blanchflower and Oswald 1994), although it should be noted that similar wage equations can also be derived from other theoretical frameworks.

4.2 Equilibrium

Equation (21) replaces the conventional labor supply curve and closes the system. When combined with the job creation condition (16) it gives unique solutions for wages and market tightness. A variety of intuitive properties are satisfied by this equilibrium. For example, higher labor productivity implies higher wages and tightness; higher unemployment income implies higher wages but lower tightness. It remains to obtain the employment rate in equilibrium.

The labor force size is fixed, so by appropriate normalizations, if at some time t unemployment is u_t, employment is $1-u_t$. In a short time interval δt, $a_t u_t \delta t$ workers are matched and $\lambda(1-u_t)\delta t$ workers lose their jobs. Given that $a_t = \theta_t q(\theta_t)$, the evolution of unemployment is given by

$$u_{t+\delta t} = u_t + \lambda(1-u_t)\delta t - \theta_t q(\theta_t) u_t \delta t \tag{22}$$

Dividing through by δt and taking the limit as $\delta t \to 0$ yields

$$\dot{u} = \lambda(1-u) - \theta q(\theta) u \tag{23}$$

Because the solution for θ is independent of u, this is a stable differential equation for unemployment with a unique equilibrium

$$u = \frac{\lambda}{\lambda + \theta q(\theta)} \tag{24}$$

Equation (24) is often referred to as the Beveridge curve, after William Beveridge who first described such a 'frictional' equilibrium. Plotted in space with vacancies on the vertical axis and unemployment on the horizontal is a convex-to-the origin curve. In the early literature the impact of frictions on the labor market was measured by the distance of this curve from the origin (see also Pissarides 2000, Blanchard and Diamond 1989).

4.3 Wage Posting

Wage posting is an alternative to wage bargaining, with different implications for search equilibrium. The firm posts a wage for the job and the worker who searches it either takes it or leaves it. Three different models of wage posting are examined.

4.3.1 Single offers, no prior information. Workers search sequentially one firm at a time, they discover the firm's offer after they have made contact and they have to accept it or reject it (with no recall) before they can sample another firm. The worker who contacts a firm that posts wage w_i has two options. Accept the wage offer of the firm and enjoy expected return W_i, obtained from (18) for $w = w_i$, or reject it and continue search for return U. The firm that maximizes profit chooses w_i subject to $W_i \geqslant U$. Since the firm will have no incentive to offer the worker anything over and above the minimum required to make workers accept its offer, in this model wages are driven to the worker's reservation wage, $w_i = b$ (Diamond 1971).

In terms of the bargaining solution, the 'Diamond' (see (20), (21)) equilibrium requires $\beta = 0$. The model can then be solved as before, by replacing β by 0 in the job creation condition and wage equation. Tightness, and consequently unemployment, absorb all shocks other than those operating through unemployment income, which also change wages. (There is a paradox in this model, in that if wages are equal to unemployment income no worker will have an incentive to search.)

4.3.2 Competitive search. The next model increases the amount of information that workers have before they contact the firm (Moen 1997). Workers can see the wage posted by each firm but because of frictions they cannot be certain that they will get the job if they apply. If the probability of a job offer across firms is the same, all workers will apply for the highest-wage job. Queues will build up and this will reduce the probability of an offer. In equilibrium, the wage offer and queue characterizing each job have to balance each other out, so that all firms get applicants.

The length of the queue is derived from the matching process. The firm that posts wage w_i makes an offer on average after $1/q(\theta_i)$ periods and a job applicant gets an offer on average after $1/\theta_i q(\theta_i)$ periods. Implicit in this formulation is the assumption that more than one firm offers the same wage, and firms compete for the applicants at this wage. Workers apply to only one job at a time.

Suppose now there is a firm, or group of firms, such that when workers join their queue they derive expected income stream $\bar{U}$, the highest in the market. The constraint facing a firm when choosing its wage offer is that the worker who applies to it derives at least as much expected utility as $\bar{U}$. The expected profit of the firm that posts wage w_i solves

$$rV_i = -c + q(\theta_i)\,(J_i - V_i) \tag{25}$$

$$rJ_i = p - w_i - \lambda J_i \tag{26}$$

The worker's expected returns from applying to the firm posting this wage satisfy the system of equations

$$rU_i = b + \theta_i q(\theta_i)(W_i - U_i) \tag{27}$$

$$rW_i = w_i - \lambda(W_i - \bar{U}) \tag{28}$$

The firm chooses w_i to maximize V_i subject to $U_i \geqslant \bar{U}$. The first-order maximization conditions imply that all firms offer the same wage, which satisfies

$$W - U = \frac{\eta}{1-\eta}(J - V) \tag{29}$$

Comparison of (29) with (19) shows that the solution is indeed similar to the Nash solution but with the share of labor given by the (negative of the) elasticity of $q(\theta)$, (which is equal to the unemployment elasticity of the underlying matching function). The rest of the model can be solved as in the Nash case.

There is a special significance to the share of labor obtained in this formulation. In the case where wages are determined according to the Nash rules, the firm and worker choose the wage after they meet, so it is unlikely that they will internalize the search externalities; they do not take into account the effect of their choices on the transition rates of unmatched agents. It can be shown that with constant returns to scale there is a unique internalizing rule which requires $\beta = \eta$, the solution of the wage posting model considered here (Hosios 1990, Pissarides 1984, 2000). For this reason, this particular wage posting model is often called the *competitive search* equilibrium. The key assumption that gives efficiency is the relaxation of the informational restrictions on workers, which lets them know both the firm's wage offer and the length of the queue associated with it.

4.3.3 Wage differentials. The third version of the wage posting model relaxes the assumption that workers have the choice of at most one wage offer at a time but does not allow workers knowledge of the wage offer before they apply (Burdett and Judd 1983, Burdett and Mortensen 1998, Montgomery 1991). The easiest way to introduce this is to allow workers the possibility of search on the job, i.e., to let them continue looking for a better job after they accepted one. Suppose for simplicity that job offers arrive to searching workers at the same rate a, irrespective of whether they are employed or unemployed. Suppose also that job search is costless (except for the time cost) and job changing is costless. Then, if a worker is earning w now and another offer paying w' comes along, the worker accepts the new offer if (and only if) $w' > w$. The worker's reservation wage is the current wage.

Unemployment pays b, so no firm can pay below b and attract workers. Consider a firm that pays just above b. Anyone applying for a job from the state of unemployment will accept its offer, but no one else will. Employed job seekers will have no incentive to quit their jobs to work at a wage close to b. In addition, this firm's workers will be quitting to join other firms, which may be paying above b. So a firm paying a low wage will have high turnover and will be waiting long before it can fill its vacancies.

A firm paying a high wage will be attracting workers both from unemployment and from other firms paying less than itself. Moreover, it will not be losing workers to other firms. So high-wage firms will have fewer vacant positions.

Now suppose the two firms have access to the same technology. The low-wage firm enjoys a lot of profit from each position, but has a lot of vacant positions. The high-wage firm enjoys less profit from each position, but has them filled. It is possible to show under general conditions that high wage and low wage firms will co-exist in equilibrium.

Burdett and Mortensen (1998) show this by assuming that there is a distribution of wage offers for homogeneous labor, $F(w)$, and demonstrating that (a) no two firms will offer the same wage, (b) firms can choose any wage between the minimum b and a maximum $\bar{w}$, and enjoy the same profit in the steady state. The maximum is given by

$$\bar{w} = p - \left(\frac{\lambda}{a+\lambda}\right)^2 (p-b) \tag{30}$$

where as before p is the productivity of each worker and λ the job destruction rate.

The interesting result about wage posting in this model is that once the assumption that the worker can only consider one offer at a time is relaxed, a distribution of wage offers for homogeneous labor arises. The distribution satisfies some appealing properties. As $a \to 0$, the upper support tends to $\bar{w} = b$, the Diamond solution. At the other extreme, as $a \to \infty$, it can be shown that all wage offers converge to p, the competitive solution. Intuitively, $a = 0$ maximizes the frictions suffered by workers and $a = \infty$ eliminates them.

5. Job Destruction

A body of empirical literature shows that there is a lot of 'job churning,' with many jobs closing down and new ones opening to take their place. It is also found that both the job creation and job destruction rates, especially the latter, vary a lot over the cycle (see Leonard 1987, Dunne et al. 1989, Davis et al. 1996). This is an issue addressed by search theorists. Returning to the model with a Nash wage rule, the job creation flow is the matching rate $m(u, v)$. The job creation *rate* is defined as the job creation flow divided by employment, $m(u, v)/(1-u)$, which is

$$\frac{m(u, v)}{1-u} = \theta q(\theta)\frac{u}{1-u} \tag{31}$$

Since both θ and u are endogenous variables of the model that respond to shocks, the model predicts a variable job creation rate that can be tested against the data (see Mortensen and Pissarides 1994, Cole and Rogerson 1996).

But the job destruction flow is $\lambda(1-u)$, so the job destruction rate is a constant λ, contrary to observation. Two alternative ways of making it variable are considered.

5.1 Idiosyncratic Shocks

In the discussion so far, the productivity of a job is p until a negative shock arrives that reduces it to zero. Generalizing this idea, suppose that although initially the productivity is p, when a shock arrives it changes it to some other value px. The component p is common to all jobs but x is specific to each job. It has distribution $G(x)$ in the range [0, 1]. New jobs start with specific productivity $x = 1$; over time shocks arrive at rate λ that transform this productivity to a value between 0 and 1, according to the distribution G. The firm has the choice of either continuing to produce at the new productivity, or closing the job down. The idea is that initially firms have a choice over their product type and technique and choose the combination that yields maximum productivity. Over time techniques are not reversible, so if the payoffs from a given choice change, the firm has the choice of either continuing in the new environment or destroying the job.

As in the case where workers are faced with take-it-or-leave-it choices from a given wage distribution, Mortensen and Pissarides (1994) show that when the firm has the choice of either taking a productivity or leaving it, its decision is governed by a reservation productivity, denoted R. The reservation productivity depends on all the parameters of the model. Profit maximization under the Nash solution to the wage bargain implies that both workers and firms agree about the optimal choice of R, i.e., which jobs should be closed and which should continue in operation. With knowledge of R, the flow of job closures generalizes to $\lambda G(R)(1-u)$, the fraction of jobs that get shocks below the reservation productivity. The job destruction rate then becomes $\lambda G(R)$, which responds to the parameters of the economy through the responses of R to shocks.

An interesting feature of the job creation and job destruction rates, which conforms to observation, is

that because the job creation rate depends on unemployment, which is a slow-moving variable, whereas the job destruction rate does not depend on it, the job destruction rate is more volatile than the job creation rate. For example, a rise in general productivity p, associated with a positive cyclical shock, reduces job destruction immediately by reducing the reservation productivity, but increases job creation at first and then reduces it, as tightness rises at first but unemployment falls in response.

5.2 Technological Progress and Obsolescence

Another way of modeling job destruction borrows ideas from Schumpeter's theory of growth through creative destruction (see Aghion and Howitt 1994, Caballero and Hammour 1994). Jobs are again created at the best technology but once created, their technology cannot be updated. During technological progress, the owners of the jobs have the option of continuing in production with the initial technology or closing the job down and opening another, more advanced one. As new jobs are technologically more advanced, the wage offers that workers can get from outside improve over time. There comes a time when the worker's outside options have risen sufficiently to render the job obsolete.

Formally, the model can be set up as before, with the technology of the job fixed at the frontier technology at creation time and wages growing over time because of growth in the returns from search. The value of a job created at time 0 and becoming obsolete at T is

$$J_0 = \int_0^T \mathrm{e}^{-(r+\lambda)t}\,[p(0)-w(t)]\,\mathrm{d}t \tag{32}$$

As before, r is the discount rate and λ is the arrival rate of negative shocks that may lead to earlier job destruction. $p(0)$ is the initial best technology and $w(t)$ the growing wage rate. The job is destroyed when $w(t)$ reaches $p(0)$; i.e., the job life that maximizes J_0 is defined by $w(T^*) = p(0)$.

A useful restriction to have when there is growth is to assume that both unemployment income and the cost of recruitment grow at the exogenous rate of growth of the economy. As an example, consider the wage eqn. (21) with the restriction $K = 0$ and $b(t) = b\mathrm{e}^{gt}$, $c(t) = c\mathrm{e}^{gt}$, where g is the rate of growth of the economy. T^* then satisfies

$$\mathrm{e}^{gT^*} = \frac{(1-\beta)p}{(1-\beta)b+\beta c\theta} \tag{33}$$

Jobs are destroyed more frequently when growth is faster, when unemployment income is higher and when the tightness of the market is higher.

Job destruction in this model has two components, the jobs destroyed because of the arrival of shocks, $\lambda(1-u)$, and those destroyed because of obsolescence. The latter group was created T^* periods earlier and survived to age T^*, $\theta q(\theta)u\mathrm{e}^{-\lambda T^*}$ (note that in the steady state the job creation flow is a constant $\theta q(\theta)u$). Therefore, the job destruction rate now is $\lambda + \theta q(\theta)u\mathrm{e}^{-\lambda T^*}/(1-u)$, which varies in response to changes in T^* but also in response to changes in the job creation rate $\theta q(\theta_u)/(1-u)$.

Second Language Acquisition

Humans are all born with the capacity to learn and to use a language; but they are not born with a language. It is not part of human genetical endowment that 'horse' means 'equine quadruped,' that the past tense is marked by '-ed,' or that the negation follows the finite verb; this knowledge must be derived from the input with which the learner is confronted. The ways which lead this innate language faculty to the knowledge of a particular linguistic system vary considerably, depending on factors such as age, nature of input and whether this task is undertaken for the first time ('first language acquisition,' FLA) or not ('second language acquisition,' SLA). SLA is not a homogeneous phenomenon, for at least two reasons. First, it need not wait until the learner has completed FLA; hence, there is a continuous transition from bilingual FLA, in which a child is exposed more or less simultaneously to two systems from birth, to the adult's struggles with a new kind of linguistic input. Second, there is a wide range of ways in which the human language faculty gains access to a second linguistic system, ranging from metalinguistic description, as in traditional Latin classes, to language learning by everyday communication, as in the case of a foreign worker. In the history of mankind, explicit teaching of a language is a relatively late phenomenon, and untutored learning was, and probably still is, the most common case; but due to its practical importance, SLA in the classroom still dominates research.

Linguists and laymen alike tend to consider children's way to their mother tongue to be the most important type of language acquisition. This view seems most natural; but it leads easily to a distorted picture of how the human language faculty functions, and what its typical manifestations are. FLA is a very complex mixture of cognitive, social and linguistic developments, and it is not easy to isolate its purely linguistic components. The acquisition of the English tense and aspect system, for example, not only requires the learning of a particular mapping of forms and meanings, but also the development of the concept of time itself. Moreover, most people learn more than one language, albeit to different degrees of perfection. Therefore, the *normal* manifestation of the human language faculty is a 'learner variety,' i.e., a linguistic system which comes more or less close to the linguistic habits of a particular social group. In a child's case, the final learner variety is usually a 'perfect replication' of these habits; children who grow up in multilingual communities often achieve two or even three such perfect replications. Adults who set out to learn another language hardly ever reach a stage where they speak like those from whom they learn; their 'learner varieties' normally fossilize at an earlier stage. This does not mean that their final learner variety is less of a language, or less efficient; there is no reason to assume that a linguistic system which says 'He swam yesterday' is a superior manifestation of the human language faculty than a system which says 'He swimmed yesterday' or even 'He swim yesterday.' It is just the way the English do it, and deviations from their norms are stigmatized. If the study of language acquisition, and of SLA in particular, should inform us about the nature of the human language faculty, then it must not focus on issues of perfect replication and why it fails sometimes, but try to clarify how the human language faculty deals under varying conditions with particular forms of linguistic input to which it has access. The first step to this end is to isolate the crucial factors which play a role in this process, and to look at ways they can vary. The second step is to investigate what happens under varying constellations. The final step is to draw generalizations from these findings and to turn them into a theory not just of language acquisition, but the nature of human language itself (Klein 1986).

The picture which research on SLA offers at the time of writing is much less systematic. As with so many other disciplines, it has its origin in practical concerns; researchers were looking for scientific ways to improve foreign language teaching, and this seems impossible without a deeper understanding of the principles of SLA. Therefore, most empirical work in this field is still in the classroom. A second source of inspiration was research on FLA, which started much earlier and therefore set the theoretical and methodological stage. More recently, work in theoretical linguistics has increasingly influenced research on SLA. These and other influences, for example from cognitive and social psychology, resulted in a very scattered picture of theories, methods and findings. Rather than reviewing this research, the following discussion will concentrate on three key issues (useful surveys are found in Ellis 1994, Ritchie and Bhatia 1996, Mitchell and Myles 1998, Braidi 1999).

1. SLA and Foreign Language Instruction

The pedagogical background of SLA research has led naturally to a particular view on SLA, for which two assumptions are constitutive:

(a) There is a well-defined target of the acquisition process—the language to be learned. This *target language* is a clearly fixed entity, a structurally and functionally balanced system, mastered by those who have learned it in childhood, and more or less correctly described in grammars and dictionaries.

(b) SLA learners miss this target at varying degrees and in varying respects—they make errors in production as well as in comprehension, because they lack the appropriate knowledge or skills.

This is the *target deviation perspective*. It is the teacher's task to erase, or at least to minimize, the deviations; it is the researcher's task to investigate which 'errors' occur when and for which reasons. As a consequence, learners' performance in production or comprehension is not studied very much in its own right, as a manifestation of learning capacity, but in relation to a set norm; not in terms of what learners do, but in terms of what they fail to do. The learners' utterances at some time during the process of acquisition are considered to be more or less successful attempts to reproduce the structural properties of target language utterances. Learners try to do what the mature speaker does, but do it less well. Three reasons make the target deviation perspective so natural and attractive, in fact, almost self-evident. First, it is the natural perspective of the language teacher: language teaching is a normative process, and the teacher is responsible for moving students as closely to some norm as possible. Second, it is also the natural perspective of all of those who had to learn a second language in the classroom—and that means, also, of practically every language researcher. Third, the target deviation perspective provides the researcher with a simple and clear design for empirical work. There is a yardstick against which the learners' production and comprehension can be measured: the target language, or actually what grammar books and dictionaries say about it. What is measured is the differences between what learners do and what the set norm demands. Therefore, the dominant method in SLA research was, and is, error analysis: Learners' errors are marked and then either counted and statistically analyzed, or they are interpreted individually (Corder 1981, Ellis 1994, pp. 561–664).

There are two problems with this perspective. First, it does not tell us what learners *do* but what they are *not able* to do. Second, its results reflect not just the principles according to which the human language faculty functions, but the efficiency of a particular teaching method. Therefore, this approach may be of eminent importance to the language teacher, but it is of limited value if we want to understand the nature of human language.

2. FLA and SLA

Experience shows that FLA normally leads to 'perfect command' of the target language, whereas SLA hardly ever does. Why this difference? Is perfect attainment of a second language possible at all? Does the learning process only stop at an earlier point, or does it follow different principles?

The last question has found two opposite answers. The *identity hypothesis*, advocated by many researchers in the early 1970s, claims that the underlying processes are essentially the same across all types of acquisition. Under this view, the fact that the learner already knows a language plays no role: there is no transfer from the 'source language' (Odlin 1989). Evidence came mainly from the order in which certain grammatical phenomena, such as inflectional morphemes or the position of negation, are acquired. It turned out, however, that these similarities are quite isolated; there are hardly any supporters of the identity hypothesis anymore. Under the opposite view, it is mainly structural differences between source and target language that cause problems for learners. This *contrastive hypothesis* has given rise to a number of contrastive grammars for pedagogical purposes. But while there are many clear cases in which learners' first language interferes in the learning process, structural contrasts can at best account for some properties of the acquisitional process. In acquisition outside the classroom, for example, all learners regularly develop a particular type of 'learner variety' which is essentially independent of source and target language (see Klein and Perdue 1997). The net result of thirty years of research is simply that there are similarities as well as dissimilarities.

The varying success in final attainment could be due to (a) age differences, or (b) to the fact that there is already a language which blocks the acquisition of a

second language. The second possibility is ruled out by the fact that school age children normally have no problem in learning a second language to perfection; hence, the varying success must be an age effect. Apparently, the capacity to learn a language does not disappear, but it deteriorates with age. Since this capacity is stored in the brain, it seems plausible to assume that changes in the brain are responsible for the age effect. The clearest statement of this view is Lenneberg's theory of a biologically fixed 'critical period,' during which the brain is receptive for language; it ranges approximately from birth to puberty. After this period, linguistic knowledge can only be learned in a different form, roughly like the knowledge of historical or geographical facts (Lenneberg 1967). This theory has the seductive charm of simple solutions, and hence has been welcomed with great enthusiasm. But as far as is known, all potentially relevant changes in the brain occur in the first four years of life, rather than around puberty. Moreover, all available evidence shows that the capacity to learn a new language deteriorates only gradually; there is no clear boundary at puberty or at any other time. Finally, it could be shown that 'perfect attainment' is perhaps rare but definitely possible after puberty (see Birdsong 1999). It appears, therefore, that there is no clear biological threshold to language acquisition; the age effect is due to a much wider array of factors (Singleton 1989).

3. *SLA and Theoretical Linguistics*

The apparent ease and speed with which children, despite deviant and insufficient input, become perfect speakers of their mother tongue has led Noam Chomsky and other generative grammarians to assume that a great deal of the necessary linguistic knowledge is innate. Since every newborn can learn any language, this innate knowledge must be universal, and it is this 'universal grammar' (UG) which is the proper object of linguistic theory. Since languages also differ in some respects (otherwise, SLA would be superfluous), the competence of mature speakers is supposed to include a 'peripheral part,' which includes all idiosyncratic properties and must be learned by input analysis, and a 'core.' The core consists of a number of universal principles—the UG. Initially, these principles include a number of 'open parameters,' i.e., variable parts which must be fixed by input analysis. Chomsky made this point only for FLA, and only in the mid 1980s was the question raised whether UG is still 'accessible' in SLA.

A number of empirical studies tested the potential 'resetting' of various parameters. Spanish, for example, allows the omission of a subject pronoun, a property which is structurally linked to other features such as a relatively rich inflectional word order and relatively free word order; these and other properties form the 'pro-drop parameter.' English children have set this parameter the opposite way when acquiring their language. Are adult English learners of Spanish able to 'reset' it, or do they have to learn all of these properties by input analysis? Results are highly controversial (see e.g., Eubank 1991, Epstein et al. 1997). Although inspired by theoretical linguistics, most empirical research in this framework keeps the traditional 'target deviation perspective'; with only a few exceptions, it deals with acquisition in the classroom, hence reflecting the effects of teaching methods. Moreover, there is no agreement on the definition of the parameters itself; in fact, more recent versions of generative grammar have essentially abandoned this notion. Finally, it is an open issue as to which parts of linguistic knowledge form the core and which parts belong to the periphery, and hence must be learned from the input. These language-specific parts clearly include the entire lexicon, the inventory of phonemes, inflectional morphology, all syntactic properties in which languages can differ—in short, almost everything. It seems more promising, therefore, to look at how learners construct their learner varieties by input analysis.

4. *Learner Varieties*

The alternative to the target deviation perspective is to understand the learners' performance at any given time as an immediate manifestation of their capacity to speak and to understand: form and function of these utterances are governed by principles, and these principles are those characteristic of the human language faculty. Early attempts in this direction are reflected in notions such as 'interlanguage,' 'approximate systems' and so on. Since the 1980s, most empirical work on SLA outside the classroom has taken this 'learner variety perspective' (von Stutterheim 1986, Perdue 1993, Dietrich et al. 1995). In its most elaborate form, it can be characterized by three key assumptions (Klein and Perdue 1997).

(a) During the acquisitional process, learners pass through a series of learner varieties. Both the internal organization of each variety at a given time, as well as the transition from one variety to the next, are essentially systematic in nature.

(b) There is a small set of principles which are present in *all* learner varieties. The actual structure of an utterance in a learner variety is determined by a particular interaction of these principles. The kind of interaction may vary, depending on various factors, as the learner's source language. With ongoing input analysis, the interaction changes. Picking up some component of noun morphology from the input, for example, may cause the learner to modify the weight of other factors to mark the grammatical status of a noun phrase. Therefore, learning a new feature is not adding a new piece of puzzle which the learner has to

put together. Rather, it entails a sometimes minimal, sometimes substantial reorganization of the whole variety, where the balance of the various factors approaches the balance characteristic of the target language successively.

(c) Learner varieties are not imperfect imitations of a 'real language' (the target language), but systems in their own right. They are characterized by a particular lexical repertoire and by a particular interaction of structural principles. Fully developed languages, such as Spanish, Chinese or Russian, are only special cases of learner varieties. They represent a relatively stable state of language acquisition—that state where learners stop learning because there is no difference between their variety and the variety of their social environment, from which they get input.

Thus, the process of language acquisition is not to be characterized in terms of errors and deviations, but in terms of the twofold systematicity which it exhibits: the inherent systematicity of a learner variety at a given time, and the way in which such a learner variety evolves into another one. If we want to understand the acquisitional process, we must try to uncover this two fold systematicity, rather than look at how and why a learner misses the target.

Second World War, The

1. The Second World War: A Narrative

World War II was an event of massive significance. For at least fifty years after its end in 1945 it continued to condition societies and ideas throughout the world. Much of the politics of the second half of the twentieth century can be read as occurring in an 'after-war' context. The war exacted a death toll of at least 60 million, and probably tens of millions more than that (figures for China and the rest of Asia are mere guesses and the USSR's sacrifice has risen from seven to 20 to 29 or more million as time has passed, circumstances varied, and the requirements of history altered). A majority of the casualties were civilians, a drastic change from World War I when some 90 percent of deaths were still occasioned at the fronts. Moreover, the invention of the atom bomb during the war and its deployment by the USA at Hiroshima and Nagasaki (August 6 and 9, 1945) suggested that, in any future nuclear conflict, civilians would compose 90 percent or more of the victims. When this apparent knowledge was added to the revelations of Nazi German barbarism on the eastern front and the Nazis' massacre of European Jewry, either in pit killings or when deliberately transported to such death camps as Auschwitz-Birkenau, Treblinka, Sobibor, Chelmno, Belzec, and Majdanek, another casualty of the war seemed to be optimism itself. Certainly at 'Auschwitz' and perhaps at Hiroshima, 'civilization,' the modernity of the Enlightenment, the belief in the perfectibility of humankind, had led not to hope and life but instead to degradation and death.

This more or less open fearfulness, with its automatic resultant linking of a pessimism of the intellect to any optimism of the will among postwar social reformers, may be the grandest generalization that can be made about the meaning of World War II. Big history, however, should not lose sight of microhistory. Actually World War II was fought on many fronts, at different times, for different reasons, and with different effects. In this sense, there was a multiplicity of World War II's.

In September 1939, a war broke out between Nazi Germany and authoritarian Poland. The liberal democratic leadership of Britain and France intervened

saying that they would defend Poland, although in practice they made do with 'phoney war' until the Nazi forces took the military initiative, first in Denmark and Norway, and then in the Low Countries and France in April–May 1940. In June 1940, Fascist Italy entered the war as had been envisaged in the 'Pact of Steel' signed with its Nazi ally in May 1939. War now spread to the Italian empire in North and East Africa and, from October 1940, to the Balkans. Italian forces botched what they had hoped would be a successful Blitzkrieg against Greece and the effect over the next year was to bring most of the other Balkan states into the conflict. Often these fragile states dissolved into multiple civil wars, the most complicated and the one of most lasting significance began in Yugoslavia from March–April 1941.

On June 22, 1941, the Nazi Germans invaded the Soviet Union, commencing what was, in some eyes, the 'real' World War II, and certainly the one that was inspired by the most direct ideological impulse and which unleashed the most horrendous brutality. In the course of the campaign in the east it is estimated that the Germans sacked 1,710 towns and 70,000 villages. During the epic siege of Leningrad from 1941 to 1944, a million or so of the city's inhabitants starved to death. In their invasion, the Germans were joined by an assortment of anticommunist allies and friends, including military forces from authoritarian Romania and Fascist Italy. Many Lithuanians, Latvians, and Estonians, and quite a few anti-Soviet elements within the USSR (Ukrainian nationalists, people from the Caucasus, and others) acted an auxiliaries of Nazi power. The Nazis were even embarrassed by a 'Russian' army under General A. A. Vlasov, willing to fight on their side against Stalin and his system. Volunteers also came from pro-fascist circles in France, and from Spain and Portugal, states ruled by clerical and reactionary dictators who hated communists but were not fully reconciled to the radical thrust of much Nazi-fascist rhetoric and some Nazi-fascist policy.

On December 7, 1941, the war widened again when the Japanese airforce attacked the American Pacific fleet at anchor at Pearl Harbor in Hawaii. In the following weeks, the Japanese army and navy thrust south and east, dislodging the British from Singapore by January 15, 1942. They went on to seize the Philippines and Dutch East Indies (later Indonesia) and were in striking distance of Australia before being checked at the Battle of the Coral Sea in June 1942. They simultaneously continued the terrible campaign that they had been waging in China since 1937 (or rather since 1931, when they had attacked Manchukuo or Manchuria). In their special wars, the militarist Japanese leadership tried to throw off what they called the imperialist yoke of US capitalism and the older 'white' metropolitan empires. The purity of their anti-imperial motives was damaged, however, by their own commitment to empire and by their merciless killing of Asians. Moreover, as in Europe, their invasions often touched off varieties of civil war provoked by the highly complex stratification of society in the region. At the forefront of such campaigns were often local nationalists who imagined communities subservient neither to European powers nor the Japanese.

On December 11, 1941, Germany and Italy, loyal to the terms of the anti-Comintern pact, had also declared war on the USA, somewhat ironically so, given that Japan, checked by military defeats in an unofficial war against the USSR at Khalkin Gol and Nomonhan in 1938–9, had now engaged with other enemies. The Italians would find out the implications in North Africa, the Germans after the Allied invasion of France on 'D-Day' (June 6, 1944), as well as in Italy from September 8, 1943 (the Fascist dictator, Benito Mussolini, overthrown on July 25, was thereafter restored as a sort of German puppet in northern Italy; allied forces moved slowly up the peninsula from the south, liberating Rome on June 4, 1944 but only reaching Milan at the end of the war in late April 1945). Of the participants in the war, the USA, once fully mobilized, possessed the biggest and most productive economy, and was therefore of crucial importance in the eventual defeat of the anti-Comintern powers. The campaign the Americans fought with the most passion, and with an evident racism of their own, was the war against Japan. In another sense, the USA had a relatively soft war, not disputed on its own territory and not requiring the sort of physical or spiritual sacrifice obligatory from most other combatants. The USA's special World War II was not really a visceral one.

If the war was fought in many different ways, it is equally true that the variety of conflicts did not all end at the same time and in the same way. The Nazi armies surrendered on May 8, 1945, the Japanese on August 15. But matters were more complicated than that. France's special World War II would commemorate 'victory' from the date of the liberation of Paris on August 25, 1944 (and General Charles De Gaulle would firmly proclaim that Paris and France had liberated themselves). In most of Nazi-fascist occupied Europe and in parts of Asia, partisan movements had never altogether accepted defeat. Communists were invariably prominent in such resistance, even if quite a few still envisaged themselves as fighting as much for the Soviet revolution as for the liberty of their own nation state. Every successive 'liberation,' in Europe most frequently coming after the military victory of the Red Army, and in the Pacific that of the USA, had its own special character. Yugoslavia and China were two especially complicated places where the resistance was very strong but where it was contested, not only by the Nazi-fascists and the Japanese but also by local anti-communist and nationalist or particularist forces. The effects and memory of their wars were by definition to be very different from such societies as the USA, Australia, and the UK which did not endure foreign

occupation, though the last, with its severe experience of bombing, was itself different from the other two.

In sum, World War II was not just an enormously influential event but also an extraordinarily complicated one. Its complexity has in turn stimulated many passionate and long-lasting debates about its historical meaning.

2. *The Causes of War*

For many years it was customary to argue that World War II as compared to World War I had a simple cause. This was 'Hitler's war.' Mainstream analysis continues to ascribe to the Nazi dictator great responsibility for the invasion of Poland and for the spreading of the war thereafter, and especially for the launching of Operation Barbarossa against the USSR. Nonetheless, from the 1960s, the course of historiography, especially as exemplified in the rise of social history, did not favor a 'Great Man' view of the past and tended to urge that even dictators had limits to their free will. As early as 1964, English radical historian A. J. P. Taylor (1964) argued in a book entitled *The Origins of the Second World War* that the several crises which led up to September 1939 and what he sardonically called the 'War for Danzig' needed to be understood in a variety of contexts, including the peace settlements at the end of World War I, the course of German political and social history, the institutionalization of the Russian revolution, with its victorious but feared and paranoid communist and then Stalinist regime, and the lights and shadows of democratic liberalism in Western Europe.

Taylor wrote with a flaunted stylistic brilliance and practiced a brittle historical cleverness. He was destined to be misunderstood and often gloried in the misunderstanding. His book thus produced an enormous controversy, the first of many to be sparked by attempts to define the meaning of World War II. At the same time, Taylor's idiosyncrasies ensured that his work could easily enough be dismissed by those mainstream historians who liked to feel the weight of their commitment to Rankean principles and to make their liking evident.

Nonetheless the issues raised by Taylor did not go away. In West Germany, the so-called 'Fischer controversy,' sparked by the Hamburg liberal historian Fritz Fischer's *Griff nach der Weltmacht*, a massively documented study of German aims during World War I and also published in 1961, raged through the decade. Although Fischer, then and thereafter, wrote almost exclusively about World War I and about imperial Germany, he was read as commenting on World War II and, indeed, on Germany's divided fate in its aftermath. Two issues were prominent. Was imperial Germany an aggressive power in a way that bore comparison with the Nazi regime during the 1930s? Was the motive of the German leadership as much domestic as foreign—did they seek foreign adventure and even world war in order to divert the pressure building for social democracy? Was the appalling conflict from 1939 to 1945 caused by the 'German problem,' which may have begun as early as 1848 and may have continued after 1945?

Fischer's work was more directly influential than Taylor's and the issue of the relationship between *Innenpolitik* and *Aussenpolitik* fitted neatly into the preoccupations of new social historians who, by the 1970s, were scornfully dismissing the work of 'old fashioned diplomatic historians.' For all that, specialist works on the causation of World War II continued to privilege the power of Hitler and acknowledge the ideological thrust of Nazism. English independent Marxist, Tim Mason, may have tried to pursue a Fischerian line in asking how much the diplomatic crises of 1938–9 were prompted by the contradictions of Nazi economic and social policy, but his essays remained at the periphery of most analysis. Rather such firmly Rankean historians as Gerhard Weinberg and Donald Watt assembled evidence which, in their eyes, only confirmed that the war was caused by Hitler. The newest and most authoritative English-language biographer of the Führer, Ian Kershaw, despite his background in social history, does not disagree. Hitler may have been erratic as an executive. Nazi totalitarian state and society, contrary to its propaganda about militant efficiency and a people cheerfully bound into a *Volksgemeinschaft*, may in practice have often been ramshackle. But the dictator, Kershaw argued, did possess power. Indeed, so all-embracing was his will that Germans strove to 'work towards' their Führer, to accept his ideas and implement his policies before he had fully formulated them. For a generation in the wake of the Fischer controversy, scholarship on Nazism had separated into 'intentionalists' (advocates of Great Man history) and 'functionalists' (those who preferred to emphasize the role of structures and contexts and who were especially alert to the 'institutional darwinism' of the Nazi regime). Now Kershaw, often a historian of the golden mean, seemed to have found a way to resolve and end that conflict.

The only major variants on this reaffirmation that Hitler had provoked the war came from certain conservative viewpoints. Some anticommunist historians focused on the Ribbentrop–Molotov pact (August 23, 1939), placing responsibility for the war on 'Stalin' and the Russian revolution in what seemed to others a highly tendentious effort to blame the victim. More common was the view expressed most succinctly by Zionist historian Lucy Dawidowicz that the whole conflict was in essence a 'war against the Jews.' In this interpretation, German nationalism, German anticommunism, German racism towards Slavs, Nazi repression of the socialist and communist left, none in any sense equated with Hitlerian anti-

Semitism. Hitler (or, in the variant recently made notorious by Daniel Goldhagen, the Germans) wanted to kill Jews; that was the purpose of the Nazi regime; that was the aim of its wars.

In other ex-combatant societies, further examples of local focus are evident. In England, fans of appeasement still existed, the most prominent being John Charmley. For him, the problem with the war lay simply in Britain's engagement in it. As far as the British empire was concerned, Nazism did not need to be fought and the USSR should never have been an ally. Worst of all was the fact that the USA had dominated the post war world. Charmley has never quite said so, but implication of his work is that the 'real' World War II for Britain, and the one it most dramatically lost, was implicitly fought against its American 'cousins.'

The Asian-Pacific conflict has similarly been subject to historical revision. In the 1960s Gabriel Kolko and other American 'new leftists' applied a Marxian model to their nation's foreign policy, being very critical of the gap between its idealistic and liberal theory and its realist and capitalist practice. They were in their turn duly subjected to withering fire from more patriotic and traditional historians. Nonetheless a consensus grew that, at least in regard to the onset of the American–Japanese war, US policy makers carried some responsibility. By the 1980s, liberal historian John Dower was even urging that the two rivals had been 'enemies of a kind,' neither of them guiltless of racism and brutality.

In Japan, by contrast, an officially sponsored silence long hung over everything to do with the war. The Ministry of Education was particularly anxious that schoolchildren not be exposed to worrying facts about such terrible events as the massacre in Nanking in 1937, the practice of germ warfare, the exploitation of 'comfort women,' and the many other examples of Japanese murder, rape, and pillage in Asia and the Pacific. Nonetheless, a stubborn undercurrent of opinion exemplified in the work of historian Ienaga Saburo continued to contest the Ministry line and, by the 1990s, the Japanese leadership had gone further than ever before in admitting some of the misdeeds of its militarist predecessors. Fully critical history may still not be especially appreciated in Tokyo. But, by the end of the 1990s, Japan was not the only society to behave that way in that world in which the ideology of economic rationalism had achieved unparalleled hegemony backed by what American democratic historian Peter Novick has called 'bumper sticker' lessons from the past.

3. *The Course of the War*

In the preceding paragraphs it has not always been possible to keep fully separate discussions about the coming of World War II from what happened after hostilities commenced. In any case, military history in the pure sense, just like diplomatic history, after 1945 soon lost ground professionally. To most eyes, the military history of the war can swiftly enough be told. Of the anti-Comintern states, Germany and Japan but not Italy, won rapid initial victories, exulting in their respective Blitzkriegs. But their triumphs were always brittle. Germany and its allies may have been good at getting into wars, but their ideologies made it difficult for them thereafter to contemplate any policy except the complete liquidation of the enemy. Hitler and the Japanese imperial and military leadership thus made no attempts to offer compromise from a position of strength, and Mussolini's occasional flirtation with the idea always involved Nazi sacrifice in their wars, especially that in the east, rather than Italian loss.

Nor did the anti-Comintern states make the most of the huge territories, which they had conquered, and the immense material resources that they therefore controlled. Nazi Germany is something of a case study in this regard. In the West, where the war was always gentler, the Nazis found plenty of direct and indirect collaborators. They were thus, for example, able to harness a very considerable proportion of the French economy to their cause. They also started to construct a new economic order that was not utterly unlike some of the developments, which would occur in Western Europe after Nazi-fascism had been defeated. With extraordinary contradiction for a state built on an utter commitment to racial purity, Nazi Germany, already before 1939, needed immigrants to staff its economy. Once the war began, this requirement became still more pressing. One partial solution was to import workers by agreement with its ally Italy and by arrangement with the friendly Vichy regime in France. Not all such French 'guest-workers' came unwillingly and not all had especially bad wars. In Germany they joined other, more reluctant, immigrants from the east, who were often little more than slave laborers. Poles and Soviet prisoners of war constituted the majority of these; at first they were frequently worked to death. However, as the Nazi armies turned back and the war settled into one of attrition and retreat, as symbolized by the great defeat at Stalingrad (November 1942–January 1943), the Germans began to treat even laborers from the east in a way that allowed some minimum chance of their survival and which also permitted some tolerable productivity from their labor.

The exception was, of course, the Jews, who, from September–October 1941, became the objects of the 'Final Solution,' a devotion to murder confirmed by officials who attended the Wannsee conference in January 1942. In terms of fighting a war, the adoption of the policy of extermination was, of course, counterproductive in many senses, among which was the economic. In staffing and fueling the trains, which transported the Jews to the death camps, in the low

productivity of these and the other camps, the Nazis wasted resources needed at the front. Saul Friedlander will write elsewhere in this volume about the debates about the meaning of the Holocaust. It is worth noting in this segment, however, that each combatant society has argued about its particular experience of being visited by the Nazi war machine and therefore of being exposed to collaboration with it. Two important examples occurred in France and the USSR.

The spring of 1940 brought disaster to the Third French Republic. Now was the time of what Marc Bloch, one of the founders of the great structuralist historical school of the *Annales*, a patriotic Frenchman and a Jew, called the 'strange defeat.' Military historians have demonstrated that France was not especially inferior in armament to the invading Germans. Rather, France lost for reasons to do with morale and the domestic divisions of French society. As a result, by June 1940 the French state and empire had collapsed. During the next four years, the inheritance of the Third Republic was disputed between the Vichy regime headed by Marshal Pétain within the rump of French metropolitan territories, the 'Free French' under General Charles De Gaulle, resident in London, and there, however reluctantly and churlishly, dependent on Allied goodwill and finance, and a partisan movement which gradually became more active in the occupied zones. This last was typically divided between communists and other forces, some of which disliked communists as much as they hated the invaders. The years of Axis occupation were thus also the time of the 'Franco-French civil war,' with killings and purge trials extending well beyond liberation.

The meaning of war, occupation, and liberation in France has been much disputed after 1945. It took a film maker, Marcel Ophuls in *Le Chagrin et la pitié* (1971), and an American historian, Robert Paxton, to break a generation of silence about the troubling implications of this period of national history, although Socialist President François Mitterrand (1981–95), with his own equivocal experience of Vichy, was scarcely an unalloyed advocate of openness during his term in office. Historian Henry Rousso has brilliantly examined the 'Vichy syndrome' and done much to expose some of the obfuscations favored by many different leadership groups in post-1945 French politics. Perhaps his work does not go far enough, however. With its fall, and then with decolonization after 1945, France had lost its political empire, promising to become just another European state. However, this loss was curiously compensated by the rise and affirmation of French culture. In almost every area of the humanities, such French intellectuals as De Beauvoir, Braudel, Barthes, Foucault, Lévi-Strauss, Lyotard, Baudrillard, and Nora, charted the way to postmodernity. They did so sometimes invoking the pro-Nazi philosopher Martin Heidegger and almost always without much reckoning of the collapse of the French nation state in 1940. The intellectuals of France were much given to forgetting their nation's fall, the better to affirm their own rights to cultural imperium.

If France provides a case study of the transmutation of defeat into victory, the USSR offers the reverse example of a victor whose people would eventually learn that 'actually' they had lost. The nature of the Soviet war effort is still in need of research. Sheila Fitzpatrick, a historian of Soviet social history, has depicted a population by 1939 brutalized and depressed by the tyranny, incompetence, and contradictions of Stalinism. Her work does not really explain, however, how that same populace fought so stubbornly 'for the motherland, for Stalin.' No doubt the absurd murderousness of Nazi policies gave them little alternative. No doubt the aid which eventually flowed through from the USA was of great significance. But something does remain unexplained about how 'Stalin's Russia' won its 'Great Patriotic War.'

4. *The Consequences of the War*

By now very clear, however, are the consequences of the war for the USSR. In the short term the war made the Soviet state the second superpower, the global rival to the USA, and gave Stalin, until his death in 1953, an almost deified status. However, as the postwar decades passed, it became clear that the USSR and its expanded sphere of influence in Eastern Europe were not recovering from the war with the speed being dramatically exemplified in Western Europe and Japan. Indeed, the history of the USSR, at least until Gorbachev's accession to the party secretaryship in 1985 and, arguably, until the fall of the Berlin Wall and the collapse of communism (1989–91), should best be read as that of a generation who had fought and won its wars (including the terrible domestic campaigns for collectivization as well as the purges of the 1930s). Leaders and people were unwilling or unable to move beyond that visceral experience. After 1945, the USSR became the archetypal place 'where old soldiers did not die nor even fade away.' Brezhnev, Chernenko, and their many imitators further down the power structure were frozen into a past that had an ever-diminishing connection with a world facing a new technological and economic revolution.

Other ex-combatant societies were more open to change than the USSR but a certain sort of remembering and a certain sort of forgetting can readily enough be located in them, too. Memory proved most threatening in Yugoslavia. There the victorious partisans under Josip Broz Tito seemed for a time to have won a worthwhile victory. The special history of their campaigns against the Nazi-fascist occupiers of their country allowed them claims to independence from the USSR, which they duly exercised after 1948. At the same time the barbarity, during the war, of the collaborationist Croat fascist regime under Ante

Pavelić, whose savagery embarrassed even the Germans, seemed to suggest that the region was indeed best administered by a unitary state. The fall of communism, however, also brought down a communist Yugoslavia in which such Serb leaders as Slobodan Milosevic, unable to believe in official ideals, increasingly recalled the nationalism of wartime Cetniks rather than the internationalist Marxism once espoused by the partisans. This memory of war and murder justified new wars and new murders, even if with the somewhat ironical result that, by the end of the 1990s, the (Serb) winners of the last war had become losers and the (Slovene, Croat, Bosnian Moslem, and Kosovar) losers had become winners.

In Italy, the country with the largest communist party in the West and a polity which had a 'border idiosyncrasy,' bearing some comparison with Yugoslavia's role in the Eastern Bloc, the inheritance of war and fascism similarly possessed peculiar features. Postwar Italy began by renouncing fascism, empire, and war, in 1946 abandoning the monarchy that had tolerated the imposition of Mussolini's dictatorship and, in 1947, adopting a constitution which made considerable claim that the new Republic would be based on labor. In practice, however, Italy took its place in the Cold War West. Its purging of ex-Fascists was soon abandoned and both the power elites and the legislative base of the new regime exhibited much continuity with their Fascist predecessors. Nonetheless, from the 1960s, an ideology of antifascism was accorded more prominence in a liberalizing society. From 1978 to 1985, Sandro Pertini, an independent socialist who had spent many years in a Fascist jail and been personally involved in the decision to execute Mussolini, became Italy's president. Widely popular, he seemed an embodiment of the national rejection of the Fascist past.

Once again, however, the process of memory was taking a turn and a different useable past was beginning to emerge. Left terrorists in the 1970s had called themselves the new Resistance and declared that they were fighting a Fascist-style state—the governing Christian Democrats were thought to be merely a mask behind which lurked the Fascist beast. The murder of Aldo Moro in 1978 drove Italians decisively away from this sort of rhetoric and, in the 1980s and 1990s, Italians sought instead a 'pacification' with the past in which ex-Fascists had as much right to be heard as ex-partisans. Among historians, 'anti-anti-Fascists,' led by Renzo De Felice, the biographer of Mussolini, provided evidence and moral justification for this cause. Media magnate and conservative politician Silvio Berlusconi joined those who agreed that Italy's World War II had lost its ethical charge.

Among the Western European ex-combatants states perhaps the UK was the place where the official myth of the war survived with least challenge. A vast range of British society and behavior was influenced by Britain's war. The Welfare State, as codified by the postwar Labor government under Clement Attlee, was explained and justified as a reward for the effort of the British people in the 'people's war.' Wartime conservative Prime Minister, Winston Churchill, despite his many evident limitations, remained a national icon. British comedies from the Goons in the 1950s to *Dad's Army* in the 1970s and 1980s to *Goodnight Sweetheart* in the 1990s were obsessively set in the war. From the alleged acuteness of their secret service activities to the alleged idealism of their rejection of Nazism, the British have constantly sought to preserve the lion's share of the positives of World War II for themselves. The suspicion of a common European currency and the many other examples of continuing British insularity in turn reflect the British cherishing of the fact that they fought alone against the Nazi-fascists from 1940 to 1941, and express their associated annoyed perplexity that somehow their wartime sacrifice entailed a slower route to postwar prosperity compared with that of their continental neighbors.

Memory after memory, history after history, World War IIs, in their appalling plenitude, still eddy around. As the millennium ended, another historian wrote a major book about the meaning of an aspect of the war, and about the construction of that meaning. Peter Novick's *The Holocaust in American Life* (1999) daringly wondered whether the privileging of the Nazi killing of the Jews in contemporary Jewish and even gentile American discourse is altogether a positive. Being a historical victim at one time in the past, he argued cogently, can obscure as well as explain. His caution is timely. It is probably good that World War IIs are with us still; it will be better if the interpretation of so many drastic events can still occasion democratic debate, courteous, passionate, and humble debate, and if we can therefore avoid possessing a final solution to its many problems.

Secondary Analysis: Methodology

Secondary analysis refers to a set of research practices that involve utilizing data collected by someone else or data that has been collected for another purpose (e.g., administrative records). It is used, to varying degrees, across a wide range of disciplines and throughout the world. Given this breadth, it is not surprising that it has taken on numerous forms. It is also conducted for several distinct reasons. Although not a research methodology, *per se*, several features distinguish it from other research activities. In turn, these features create opportunities and limitations for the secondary analyst. Central issues concern: (a) data availability, access, and documentation; (b) maintaining confidentiality and privacy pledges made by primary researchers; and (c) proprietary rights and data ownership.

1. Secondary Analysis as a 'Methodology'

The use of secondary data in behavioral and social sciences is ubiquitous, appearing in a number of traditional (i.e., quantitative) and untraditional (i.e., qualitative) forms. Despite its rather extended roots in the social and behavioral sciences, it is not widely celebrated as a method. As partial evidence of its relative obscurity, consider the fact that between 1978 and the present, a search of *PsychInfo* uncovered only 36 articles and books using the keyword 'secondary analysis.' Furthermore, the phrase 'secondary analysis' appeared in fewer than half of the article or book titles. Books on the topic are also relatively scarce; fewer than a dozen were uncovered through the same search (e.g., Boruch et al. 1981, Elder et al. 1993, Hyman 1972, Stewart 1984).

Ironically, the apparent obscurity of secondary analysis as a methodology is due to its pervasiveness. That is, the use of secondary data sources is so commonplace in many fields (e.g., economics, education, and sociology) that there is little need in calling attention to it as a separable methodology. This makes sense because unlike ethnography, survey research, or quasi-experimentation which each have distinctive methodological procedures and practices, secondary analysis does not involve a new or different set of tactics. Even from a statistical point of view, there is little to distinguish it from primary analysis, and most of the measurement, design, and statistical issues facing the secondary analyst are largely the same as those faced by a primary analyst. The obvious exception is that the secondary analyst is constrained by scope and nature of the design (e.g., the sample, sample sizes, attrition, missing data, measures, and research design) inasmuch as these have been specified by someone else (McCall and Appelbaum 1991). As such, secondary analysis boils down to a data resource, not a methodology, *per se*. However, the use of secondary data—especially when micro data records are used—does involve a unique set of logistical, ethical and practical considerations.

2. Varieties of Secondary Analysis

Because primary data can assume a number of forms (e.g., data based on cross-sectional surveys, administrative records, panel surveys, observations), secondary analysis has taken on a variety of forms. Two

main categories can be identified: (a) some data are developed for the explicit purpose of serving as a national resource; and (b) other forms of data are byproducts of the actions of individuals and organizations. The latter are included in the definition of secondary analysis because they play a large role in contemporary research. Given the increased use of the Internet, more administrative records, facts, and statistics (public and private) also will be readily available for use in research.

2.1 Traditional Forms of Secondary Analysis

The most common forms of secondary data include population censuses, continuous or regular surveys, national cohort studies, multisource data sets, administrative records, and one-time surveys or research studies. In the US, interest in secondary analysis was prompted by the appearance of public opinion polls and surveys in the 1940s and 1950s, and continued in the 1960s, when the federal government began, in earnest, gathering data through large-scale surveys based on representative sampling (Hyman 1972).

Of particular interest to social science researchers are the large scale, nationally representative, longitudinal (panel) surveys. In the USA, even cursory literature searches reveal hundreds of publications in economics and sociology that use data drawn from, for example, the Panel Study of Income Dynamics (PSID), the National Longitudinal Survey of Youth (NLSY), and the General Social Survey (GSS). In the United Kingdom, the General Household Survey (GHS) has been conducted annually since the beginning of the 1970s. The reuse of large-scale survey data is also evident across many nations simultaneously, as when Ravillion and Chen (1997) examined the correspondence between the rate of growth in gross domestic product and changes in poverty rates. The willingness of domestic and foreign governments to invest in data collection prompted Cherlin (1991) to speculate that the term secondary analysis will become obsolete. Many large-scale surveys are being sponsored by governments with no primary data analyses in mind.

Whereas large-scale surveys like the PSID are deliberately fielded to answer a multitude of research questions about populations and subgroups, substantial data gathering also is undertaken by governments as byproducts of their operation, to monitor their own processes and outcomes, or to assess environmental conditions or events (e.g., weather, rainfall). These are generally referred to as administrative or governmental records. The use of governmental records in research has a long tradition; over 100 years ago, Emile Durkheim used government statistics to examine some of the causes of suicide (Cherlin 1991).

Individual research studies also are fodder for secondary analysis. These reanalyzes are undertaken to check the accuracy of statistical conclusions in primary studies; for testing new statistical procedures or substantive hypotheses; resolving conflicts among researchers; for testing supplemental hypotheses suggested in primary analyses. The latter are usually conducted by the primary analyst, and this category represents the prevalent use of the term 'secondary analysis.' In recent years, secondary analysts reanalyzed multiple studies that use the same instrumentation, a tactic more akin to the spirit of meta-analysis.

A particularly important role for secondary analysis of individual studies is testing or demonstrating the superiority of new statistical methods. A thoughtful example is provided by Muthen and Curran (1997). They showed that latent growth curve models produced larger intervention effects than had been previously reported by exerting greater control over extraneous sources of error. More generally, in the past 25 years, efforts to address causal questions with extant data have produced substantial advances in statistical modeling (Duncan 1991). And, reanalysis of data from program evaluation studies has been undertaken to assure policy-makers that the results of primary studies are technically sound (Boruch et al. 1981).

2.2 Less Traditional Forms of Secondary Analysis

Although not a traditional form of secondary analysis, Webb et al. (1965) demonstrated that a substantial amount of 'data' are produced by individuals and organizations (public and private) as byproducts of their daily transactions. In their now classic text *Unobtrusive Measures: Nonreactive Research in the Social Sciences*, they identified a host of unconventional ways in which researchers can reuse existing data. In making their case, they showed how physical traces (erosion and accretion); the content of running records (e.g., mass media, judicial records), private records (sales records, credit card purchases), and contrived observations (e.g., hidden cameras) can be used as sources of data in research. The literature is filled with studies based on creative uses of these artifacts. Examples include assessing: the type, amount, and 'quality' of household garbage to assess the dietary and recycling habits of Arizona residents; the amount of trash left in the streets by revelers at Marti Gras to estimate the size of the daily crowd; and the differential wear and tear seen in separate sections to ascertain the popularity of sections of the *International Encyclopedia of the Social Sciences*. Finally, whereas secondary analysis has been historically viewed as a quantitative endeavor, reanalysis of qualitative data is now regarded as a legitimate part of the enterprise.

It would appear that Webb et al. (1965) had a substantial influence on subsequent generations of primary researchers. The most underacknowledged uses of secondary data are within primary evaluation

studies, where a mix of new and existing data are increasingly being used to evaluate the effectiveness of social interventions. The use of mixed method evaluation designs represents a core feature of contemporary evaluation theory and practice (Lipsey and Cordray 2000).

2.3 Advantages and Disadvantages of Secondary Analysis

Secondary analysis offers several advantages over primary data collection in behavioral and social sciences, but it also has its shortcomings. On the positive side of the ledger, re-use of data is efficient. These efficiencies include: (a) replication (or not) of findings across investigators; and (b) the discovery of biases in conventional statistical methods. Both of these benefit science by winnowing false hypotheses more quickly and offering new evidence (estimates) in their place. Testing new hypotheses, beyond those envisioned by the data developers, add to the efficiency of knowledge acquisition. These benefits have served as partial justification for the cost of conducting large scale, nationally representative surveys (using cross-sectional and panel designs) that query individuals on a wide array of topics. Some topics involving special populations (e.g., twins) or long time frames cannot be investigated without reliance upon archives and data sharing among investigators.

Alternatively, secondary data impose limits on what can be studied, where, and over what period of time. McCall and Appelbaum (1991) suggest using a Feasibility Matrix of Sample × Measure × Assessment Age as a tool for prescreening the potential utility of secondary data sets. In addition, technical problems (e.g., selection biases, sample attrition, and missing data) can be so severe as to limit the value of the primary data set. As such, assessing data quality probably needs to be included in the McCall–Appelbaum matrix. The existence of data can short-circuit one facet of the scientific process, tempting the analyst to 'mine' the data rather than initiate analyzes based on a theory or hypothesis. Although interesting results may emerge, such practices can lead to unreliable findings or findings limited to a single operationalization. The extent to which these problems in secondary analysis have influenced knowledge development is unknown. But, a mismatch between theory and data can be avoided with proper consideration of the relevance and quality of each data source.

3. What is Unique About Secondary Analysis?

Using data generated by someone else does raise several issues that make secondary analysis somewhat unique. Obviously, secondary analysis is possible only when it is available, easy to access, and in a form that is usable. Availability and access can be facilitated or impeded by a number of factors. In particular, because data do not 'speak for themselves,' they must be well documented. Data from government-sponsored, large surveys, panels and so on are often routinely archived and well documented. This is not uniform across all types of secondary data. Data sharing among individual investigators can become contentious, especially in light of questions about proprietary rights and data ownership. Researchers are obliged to honor original pledges of confidentiality and privacy. Balancing the desire to share data with these ethical requirements may require configuring the data in a way that may limit how it is disclosed and the methodological options available to the secondary analyst.

3.1 Availability, Access and Documentation

Establishment of data archives, advances in computer technology, and the emergence of the World Wide Web (WWW) have greatly facilitated access to data and solved some of the early problems that plagued the first generation of secondary analysts (e.g., poor documentation, noncommon data formats and language). Since the 1960s, the Interuniversity Consortium for Political and Social Research (ICPSR) has functioned as a major repository and dissemination service in the US. The National Archives have served a similar function for some governmental data. Increasingly, these roles have been devolved to individual governmental agencies that have developed skills in storing and disseminating their own data. In addition, the Internet has the potential for revolutionizing the use and transfer of data.

Secondary analysis also has been institutionalized within journal and professional codes of conduct. To facilitate access to data appearing in scientific journals, many journals have adopted policies whereby contributing authors are expected to make the data from their studies available for a designated period (usually three to five years) of time. Similarly, professional associations (e.g., the American Psychological Association) have incorporated data sharing into their codes of ethical behavior. Whereas archives and agencies require that data be properly documented, journals and professional associations are generally silent on this aspect of the data sharing process. Because data documentation is a process that records analytic decisions as they unfold over the course of the study, primary study authors need to be aware of these nontrivial editorial and ethical demands (see Boruch et al. 1981).

3.2 Ethical Considerations and Disclosure

The need to protect the confidentiality and privacy of research participants is sometimes at odds with the desire to make data available to others. Resolving these competing values requires careful consideration

at the time that primary research is conducted, documented, stored, and disseminated. Concealing the identity of participants can often be accomplished by removing personal identifiers from the data file. To the extent that identification is still possible through deductive disclosure (combining information to produce a unique profile of an individual), alternative procedures are needed. If identifiers are needed to link records (as in longitudinal research), additional layers of protection are needed. Fortunately, Boruch and Cecil (1979) provide a comprehensive treatment of the available statistical procedures (e.g., inoculating raw data with known amounts of error, randomized response techniques, collapsing categories) and institutional procedures (e.g., third parties who would serve as 'data brokers') that can be used to relax these problems. Data sharing among individual researchers requires explicit attention to ethical, statistical, organizational, and logistical (e.g., video editing and image modification) issues throughout the research process.

3.3 Proprietary Rights and Data Ownership

Changing policies, practices, and technology will facilitate data sharing and, as a consequence, increase use of data collected by someone else. Alternatively, secondary analysis of data for the purposes of addressing disputes among analysts can be quite difficult to negotiate. When conflict arises, it often revolves around who 'owns' the data and if, when, how and how much of it should be disclosed to others. Establishing proprietary rights to research and evaluation data is not a simple matter. Data ownership depends on how the research was financed, policies of the sponsoring and host organizations, conditions specified in laws (e.g., Freedom of Information Act, Privacy Act), data sharing polices of the journal in which the research is published, and ethical guidelines of professional associations to which authors belong. As researchers embark on primary or secondary analyses, it is necessary to understand these avenues and constraints.

4. A Summary Note

Access to quantitative and qualitative data from governments, businesses, and individual researchers has greatly facilitated the practice of secondary analysis. Changes in information technology—notably greater use of the World Wide Web—will undoubtedly enhance these practices even further at primary and secondary levels of research and evaluation.

D. S. Cordray

Secrecy, Anthropology of

A simple definition of secrecy as the deliberate concealment of information has served cross-cultural comparison (e.g., Tefft 1980, Bok 1982). Under this definition, people in cultures everywhere have secrets. Since a secret may turn out to be 'empty'—no hidden information in fact exists—some anthropologists have suggested that definition be refocused on the practice or the 'doing' of secrets rather than on a secret's

informational content. Anthropologists have been primarily interested in what could be called public, or institutionalized, secrecy: those persistent practices of hiding information within kinship, religious, political, or economic groups. Areas of research have included concealments of ritual knowledge and the social functions of secret societies. Uses of more personal, or private, secrets have also attracted attention insofar as these relate to cultural constructions of personhood and to the dynamics of interpersonal relationships. The study of secrets has posed obvious methodological and ethical problems for ethnographers.

1. *The Paradox of Secrecy*

The revelation of secrets is as important as the keeping of them. Ethnographers have called this the 'paradox' of secrecy (Bellman 1984). For a secret to persist within a social order, it must eventually be told to someone who may in turn keep the secret until it passes along again. Furthermore, the social consequence of secrets rests on the fact that people know of their existence even though content remains hidden.

Public awareness of the existence of secrets can afford prestige and power to those who know what others do not. Many accounts of secrecy revisit Georg Simmel's ground-breaking analysis of secrecy and secret societies (1950 [1908]), including his observation that secrets are a form of 'inner property.' Simmel suggested that secrets are a type of 'adornment'—a jewel or bauble that seduces public attention. Secrets with social consequence thus must be at least partly transparent and also periodically transacted and revealed.

2. *Public Secrecy*

Simmel's commodification opened the door to a political economy of secrecy. If secrets are property, then they are produced, exchanged, and consumed. Secrets are public because they have exchange value within a knowledge marketplace, and because such exchange has political consequence. Systems of political hierarchy may be grounded in an unequal distribution of secrets. Those in the know may dominate those who do not know so long as the ignorant grant that hidden knowledge has value.

2.1 *Secret Societies*

Anthropologists have pursued Simmel's original concern with secret societies, documenting a variety of secret groups, associations, lodges, and clubs in cultures around the world the members of which are pledged to maintain secrets, ritual and otherwise. The early comparative category 'secret society' was catholic enough to encompass Melanesian men's houses and grade societies, Australian totemic cults, Native American medicine lodges, West African male and female associations, and more (Webster 1908). Secrecy itself—the one attribute that these diverse organizations had in common—thus enticed anthropological attention (as Simmel predicted).

Liberal theories of democratic process and of the capitalist marketplace are suspicious of secrecy as they are of cabals and monopolies. Democracy requires an informed citizenry, and the market is supposed to depend on the free flow of information. From this perspective, secrecy generally goes against the public good. Structural-functionalist analysis, however, argued that secret societies commonly serve important social functions, including the education of children, preservation of political authority, punishment of lawbreakers, stimulation of the economy, and the like (Little 1949). Such 'social' secret societies address important community needs, unlike 'anti-social' secret societies whose goals are criminal or revolutionary (Wedgewood 1930).

2.2 *Secrecy and Power*

In the latter years of the twentieth century, anthropological attention returned to issues of power and inequality. Neutral definitions of culture as more-or-less shared knowledge gave way to new concerns with the contradictions, gaps, variation, and disparity in that knowledge. Secret knowledge and secret societies might have social functions, but they also maintain ruling political and economic regimes. The distribution of public secrets typically parallels that of other rights and powers. Adults hide information from children, often until the latter have been ritually initiated into adulthood. Men refuse to share ritual knowledge with women. Family and lineage groups own various sorts of genealogical, medical, or historical knowledge, sharing these only with kin.

Anthropologists have used a political economy of secrets to account for various forms of inequality. For example, the power of Kpelle elders over youth in Liberia was grounded in their management of the secrets of the Poro society (Murphy 1980). Beyond West Africa, anthropologists have argued that older, male keepers of secrets thereby acquired authority over women and the other uninitiated in various societies of Melanesia (Barth 1975), Native America (particularly Southwestern Pueblo cultures), and Australia (Keen 1994). Male appropriation of religious ritual, of access to the supernatural, of technology, of medicine, of sacred texts, of history, or of other valued information cemented men's authority over the ignorant.

Furthermore, women, children, and others in subordinate political position may be forced to reveal what they know, or otherwise denied rights to secrecy. Rights to have secrets are as consequential as the right to reveal information. Conversely, secrets can be a device to resist power. The dominated conceal what they know from authority. Women share knowledge kept from men. Slaves commune in secret languages. Children construct hidden worlds that evade adult awareness. In this reading, secrecy is a weapon of the weak that functions to resist and deflect supervision from above. Secrecy can also preserve a person's idiosyncratic beliefs and practices from public deprecation as in the case, for example, of middle-class English witches (Luhrmann 1989).

Alongside preservation of regimes of power, secrecy also contributes to perceptions of individual identity. Self-understanding may transform after a person has acquired secret information. Boys, for example, come to redefine themselves as men after progressing through an initiation ritual during which they learn adult secrets (Herdt 1990).

2.3 Rights to Reveal Secrets

Many analysts of secrecy systems have concluded that many secrets are not actually secret. Women know men's tricks: those spirit voices overheard during ritual are really bamboo flutes or bullroarers. Children pretend not to know that their parents are not really Santa Claus. Kin from one lineage are familiar with the supposedly secret names and genealogies of their neighbors. In oral societies, the leakiness of secret knowledge, in fact, helps maintain its viability within a community. If a secret holder dies, others are around to reveal lost knowledge if need be.

Systems of secrecy often rely upon inequalities in rights to reveal knowledge rather than on an effective concealment of information—rights that the Kpelle summarize in the term 'you cannot talk it' (Bellman 1984). Folk copyrights of this sort regulate who may speak about what (Lindstrom 1990). Even though someone may know the content of concealed information, that person may not repeat this knowledge in public without the copyright to do so. Family groups in Vanuatu, for example, own songs, myths, genealogies, and medical recipes that others may not publicly reveal without that family's permission. In private contexts, however, public secrets are surreptitiously discussed.

Knowledge is regulated not just by restricted transmission—by secrecy—but also by copyrights that limit who speaks publicly. Folk systems of copyright transform secrets into 'open' secrets. Those supposed not to know must pretend not to know. And those supposed to know pretend to think that only they, in fact, do know. Anthropological analyzes of the social and psychological dynamics of open secrecy prefigured work on other similar institutions, including the homosexual 'closet' (Sedgwick 1990, see also Taussig 1999 on public secrecy).

3. Personal Secrecy

Secrecy becomes possible given particular assumptions about personhood. The person must comprise some sort of inner self where secrets are stored along with an intention and capacity to conceal information. One can imagine a culture where notions of the person lacking such an inner self might deny the possibility of secrecy. No such culture exists although Western conceptions of childhood have often presumed that psychologically immature children lack competence with secrecy—that aptitudes to intentionally conceal information emerge as part of the child developmental process (Bok 1982).

Western historians, too, have suggested that there have been different regimes of secrecy in the past, related to shifts in constructions of personhood. Simmel (1950) connected the evolution of secrecy to that of individualization and urbane modernity (his argument recalls similar evolutionary accounts of personal privacy.) In pre-urban societies, lack of individualism and everyday intimacies of contact made secrecy difficult. Simmel supposed that secrets increased with developing opportunities for personal reserve and discretion.

More recent historians, stimulated by the work of Michel Foucault (1978) have argued instead that modernity shrinks opportunities for personal secrecy—that bureaucratic power structures increasingly have come to rely upon the monitoring of individuals, either by themselves or by institutional devices that extract information. According to Foucault, the origins of such extraction trace back to the Christian practice of confession. People are obliged to reveal their secrets to ecclesiastical, juridical, and other authorities. Revelation to authority confirms ones subjugation within a social order. The modern individual possesses inner capacities to conceal information but also contradictory urges and duties to reveal those secrets.

Stimulated by the work of Erving Goffman (1959) and others, students of interpersonal relationships have remarked the significance of secrets, masks, and 'face' in an everyday micropolitics of self-presentation. Such studies have noted more egalitarian uses of revelation. People strengthen their relationships, creating communities of trust, by revealing secret information. This may be a secret about themselves, or a secret about another that they pass along, often in return for the promise 'not to tell.' Such secrets are a kind of gossip (Bok 1982), the exchange of which remarks and maintains sentiments of friendship. Personal secrets are a social currency that people invest in

their relationships. Whereas public secrets maintain political value insofar as their transmission is restricted, the value of personal secrets flows from their easy everyday revelation.

4. The Study of Secrecy

Anthropology's interest in cross-cultural description as a whole can be taken to be the desire to learn and reveal other people's secrets (Taussig 1999). Methodologically, ethnographers face obvious problems of access to concealed information, but the study of secrecy raises even larger ethical puzzles. Anthropological codes of ethics generally require ethnographers to ensure that research does not harm the safety, dignity, or privacy of the people they study. Some researchers have described the structure and function of secrecy systems while avoiding details of secret knowledge content. Others have promised not to make their publications available to those members of a community (women, often) who should not have access to secret information. A few have refrained from publishing at all and restrict access to their fieldnotes. Ethical issues are thorniest where the secrets that anthropologists probe help maintain unjust social orders.

Secular Religions

The term 'secular religions' can be used to describe certain apparently secular enterprises that appear to share common features with enterprises usually thought of as 'religious.' 'Secular religion' is one of several terms—including 'civil religion,' 'invisible religion,' para-religion, and 'quasi-religion'—which draw attention to religious and religious-like beliefs and activities which do not fit easily into the Western folk conception of religion as a distinct institutional structure focused on a transcendent being or beings.

1. Examples of 'Secular Religions'

At first blush, the very notion of 'secular religion' would appear to be an oxymoron. In both popular and sociological usage, the term 'religion' is typically associated with the realm of the 'sacred' and contrasted with that of the 'secular.' However, a number of scholars have pointed out striking similarities between ostensibly religious and ostensibly secular undertakings. Secular ideologies it is argued may, like religions, unite followers into a community of shared beliefs. They may provide adherents with a sense of meaning and ultimate purpose. They may inspire in believers a sense of transcendence usually associated with religion. Attempts to find parallels between the sacred and the secular have been especially common in studies of the political realm and in studies of therapeutic organizations and activities.

1.1 Political 'Religions'

Numerous scholars have highlighted the religious aspects of political movements and ideologies. Communism, for example, has often been regarded as a secular religion. Zuo (1991) has recently described the veneration of Chairman Mao during the Chinese Cultural Revolution as a political religion replete with

sacred beings (Mao himself), sacred texts (the Little Red Book), and ritual (political denunciations). The term 'political religion' has also been employed to describe attempts made in developing societies to rally support for the concept of the nation. Crippin (1988) has gone so far as to argue the nationalism is the religion *par excellence* in modern society and that it is displacing more traditional forms of religion.

O'Toole (1977) has used the term 'sect' to describe certain political groups operating in Canada, including the Socialist Labor Party, followers of De Leon who wait for a Communist millennium which they regard as imminent. Such social movements as environmentalism, the animal rights movement, and the health food movement have been described as quasi-religions insofar as they provide adherents with a coherent worldview and sense of purpose at the same time that they command a great deal of loyalty.

1.2 Therapeutic 'Religions'

Many scholars have drawn attention to ritual aspects of western medical practice. Others have pointed out that psychiatrists have much in common with shamans and other religious healers. A number of researchers have pointed out the similarities that exist between self-help groups and religious organizations (Galanter 1989, Rudy and Greil 1988). One family within the self-help movement that is perhaps more obviously 'religious' in character than most of the others includes Alcoholics Anonymous (AA) and other 12-step or co-dependency groups. A few among many of the religious characteristics of AA are a conception of the sacred, ceremonies and rituals, creedal statements, experiences of transcendence, and the presence of an AA philosophy of life.

1.3 Other Examples

Other examples of attempts to point out analogies between apparently secular enterprises and religious ones abound in the social scientific literature. Within the realm of sport, attention has been paid to ritual elements and experiences of transcendence to be found in cricket, baseball, football, and the Olympic games. In the sphere of business, some writers have drawn attention to the sectarian characteristics of certain types of business, such as home-party sales organizations and direct sales organizations. It has now become commonplace among students of corporate culture to regard such ordinary activities as meetings, presentations and retirement dinners as rituals. Among the voluntary organizations that have been interpreted as quasi-religions are the Boy Scouts, groups of hobbyists and collectors, and 'fan clubs.' Jindra (1994) has described the phenomenon of Star Trek 'fandom' as religious in that it provides participants with a common worldview and inspires high levels of commitment. Several writers have attempted to characterize atheism itself as a religious enterprise, characterizing Ethical Culture and other humanist groups as analogous to religions. Still others have viewed faith in science as the dominant religious perspective of the contemporary era.

2. 'Secular Religions' and the Problem of Defining Religion

It may be argued that an interest in secular religion is a natural outgrowth of the functionalist perspective in classical sociology, which tended to view religion as serving a necessary function for the maintenance of society by uniting members of a society into a common moral universe. If, as many early sociologists thought, supernaturalistic conceptions of the universe were destined to recede in the face of industrialization and the increasing influence of science, the question arose as to what phenomena might serve as the 'social cement' of future societies. Comte's call for a 'religion of humanity' qualifies as an early sociological mention of the notion of a 'secular religion.' Durkheim's expectation that a 'cult of the individual' might play a similar role in the maintenance of society as that traditionally played by religions represents another early effort to provide intellectual justification for the idea that apparently secular ideologies may have religious characteristics.

As appealing and intuitive as the idea that secular enterprises may share important features with religions might be, the notion of a 'secular religion' must confront theoretical problems concerning the appropriate sociological definition of 'religion' and of 'the sacred.' Functional definitions of religion emphasize that the essential element in religion is the provision of an encompassing system of meaning or the ability to connect people to the ultimate conditions of their existence. Substantive definitions of religion argue that what distinguishes religion from other types of human activity is its reference to the sacred, the supernatural, or the superempirical.

The advantage of functional definitions is a breadth and inclusiveness that allows one to look at beliefs and practices not commonly referred to as religious but which may nonetheless resemble religious phenomena in important ways. One major disadvantage is that they may have the effect of so broadening the concept of religion that it becomes meaningless. While substantive definitions avoid this problem, they may result in allowing traditional Western conceptions of the nature of religion to determine what is to be included in the 'religious' category. Viewed from the perspective of the debate over the definition of religion, the theoretical problem with the concept of 'secular

religion' is that it seems to rely simultaneously on both a broad functional approach to religion and on a narrower substantive approach. The idea that environmentalism or nationalism could be properly called a religion relies on a functional definition, while the idea that such religions are 'secular' rather than 'sacred' necessarily depends on a substantive definition.

One might argue that both functional and substantive definitions of religion share the weakness that they privilege social scientists' conceptions of religion over folk conceptions of religion, that is to say the ways that people use the term 'religion' in everyday life. Some social scientists would therefore argue that the search for a scientifically valid definition of religion is futile and that the best that can be done is to define religion ethnographically, treating it as a 'category of discourse' with meanings that are changeable over time. The position that scholars take with regard to these definitional issues will necessarily influence the way in which they approach the study of 'secular religions.' This is perhaps one reason why there is at present no consensus within the social sciences with regard to the most appropriate method for studying phenomena residing on the border between the sacred and the secular.

3. *Approaches to the Study of 'Secular Religions'*

Within contemporary sociology and anthropology, there exist several different research traditions that focus on the boundary between the religious and the non-religious.

3.1 *The Notion of Civil Religion*

While Rousseau coined the term 'civil religion,' its development as a social scientific concept is attributed to Robert Bellah (1967). Working within the functionalist tradition, which sees religion as integrative for society, Bellah argued for the existence of a US civil religion, an 'institutionalized collection of sacred beliefs about the American nation,' which binds US citizens together in spite of denominational pluralism. A key tenet of US civil religion is the conception of the USA as a nation with a divinely ordained mission. Although the civil religion concept was developed in the US context, it has been applied to the analysis of many states including Canada, Israel, and Malaysia (see *Christianity: Evangelical, Revivalist, and Pentecostal*).

3.2 *The Implicit Religion Tradition*

Although the term 'implicit religion' was coined and popularized by Edward Bailey (1983), the concept owes much to the work of Thomas Luckmann (1967). Working with a broad functional definition of religion as the transcending of biological nature and the formation of a self, Luckmann argues that religion is a human universal. Luckmann maintains that traditional religions have become irrelevant in the modern world but that religion, rather than disappearing, has become personalized, privatized, and 'invisible' (see *Religiosity: Modern*). Following Luckmann's lead, Bailey's implicit religion approach looks for the experience of the sacred within events of everyday life ordinarily dismissed as profane. Thus, in a study of interaction in an English public house, Bailey interprets the ethos of 'being a man,' mastering alcohol and respecting the selves of others as implicitly religious.

3.3 *The Study of 'Religious' Forms*

There also exist a relatively large number of studies of general social 'forms' which are deemed to be relevant in both sacred and secular contexts. General discussions of 'secular ritual,' for example, fall into this category. Goffman's (1967) work on the functional significance of such rituals of everyday life as 'saving face' and showing 'deference' is particularly well known. Collins (1981) treats 'interaction ritual chains' as a key element in his attempt to lay a micro-sociological foundation for macro-sociology. Once conversations, social greetings, and athletic contests are allowed to count as ritual, ritual becomes virtually coterminous with social life. For this reason, some scholars reject 'ritual' as a meaningless category, while others argue that the ubiquity of ritual simply means that ritualizing is a fundamental human activity.

Many sociological studies of the commitment process either explicitly or implicitly present the commitment process as operating in much the same way in both sacred and secular contexts (Kanter 1972). A number of writers have developed models of the identity change process which highlight the similarity between religious conversion and other forms of identity change (Galanter 1989, Greil and Rudy 1983). Studies that employ the term 'sect' in the analysis of apparently secular organizations have already been discussed.

3.4 *The 'Quasi-religion' Approach*

The quasi-religion approach popularized by Greil (1993) and his colleagues relies on an ethnographic approach to the term 'religion,' regarding it, not as an objective category susceptible to social scientific definition, but as a claim negotiated in the course of social interaction. Greil distinguishes between para-religions and quasi-religions. Para-religions, which are ostensibly nonreligious entities that nonetheless deal with matters of ultimate concern, resemble the enterprises referred to in this article as 'secular religions.'

The term 'quasi-religion,' on the other hand, refers to groups, like AA or certain occult groups, which deal with matters of transcendence or ultimate concern, but which do not see themselves or present themselves unambiguously as religious. The concern here is not to determine whether a particular group is or is not a quasi-religion but to examine the process by which particular groups attempt to claim or repudiate the religious label and by which other groups and individuals respond to these claims.

4. The Theoretical Significance of Secular Religions

Pursuing the analogy between ostensibly secular enterprises and 'religion' as it is usually conceived raises important questions concerning the proper definition of religion, the process of secularization and the nature of religion in contemporary societies. The study of secular religions puts into bold relief the problematic nature of social scientific attempts to define religion. How one defines religion has important consequences for how one thinks about secular religions and for whether or not one regards the concept as useful. Attention to religious border phenomena presses one to consider the value of an ethnographic approach to definition that conceptualizes religion as a category of discourse whose precise meaning and implications are continually being negotiated in the course of social interaction. The study of secular religions also directs attention to difficulties in specifying and evaluating the secularization thesis, which claims that the influence of religion is declining in contemporary societies (see *Secularization*). It should be clear that one's approach to the question of secularization (including whether one even conceives of secularization as a theoretical possibility) depends on one's definition of religion and on one's treatment of religious border phenomena.

Several of the approaches to secular religion discussed here imply that traditional Western conceptions of religion as an institutionalized set of beliefs and practices focusing on a transcendent deity is beginning to lose its hold over many people. Likewise, many people seem to be tending to give expression to their experiences of transcendence in institutional contexts that have not typically been thought of as religious. If this is, in fact, the case, the line between religion and nonreligion may be expected to become even more blurred and the study of religious border phenomena even more central to the social scientific enterprise.

Secularization

In its precise historical sense, 'secularization' refers to the transfer of persons, things, meanings, etc., from ecclesiastical or religious to civil or lay use. In its broadest sense, often postulated as a universal developmental process, secularization refers to the progressive decline of religious beliefs, practices, and institutions.

1. The Term 'Secularization'

Etymologically, the term secularization derives from the medieval Latin word *saeculum*, with its dual temporal-spatial connotation of secular *age* and secular *world*. Such a semantic connotation points to the fact that social reality in medieval Christendom was structured through a system of classification which

divided 'this world' into two heterogeneous realms or spheres, 'the religious' and 'the secular.' This was a particular, and historically rather unique, variant of the kind of universal dualist system of classification of social reality into sacred and profane realms, postulated by Émile Durkheim.

In fact, Western European Christendom was structured through a double dualist system of classification. There was, on the one hand, the dualism between 'this world' (the City of Man) and 'the other world' (the City of God). There was, on the other hand, the dualism within 'this world' between a 'religious' and a 'secular' sphere. Both dualisms were mediated, moreover, by the sacramental nature of the church, situated in the middle, simultaneously belonging to both worlds and, therefore, able to mediate sacramentally between the two.

The differentiation between the cloistered *regular* clergy and the *secular* clergy living in the world was one of the many manifestations of this dualism. The term secularization was first used in canon law to refer to the process whereby a religious monk left the cloister to return to the world and thus become a secular priest. In reference to an actual historical process, however, the term secularization was first used to signify the lay expropriation of monasteries, landholdings, and the mortmain wealth of the church after the Protestant Reformation. Thereafter, secularization has come to designate any transfer from religious or ecclesiastical to civil or lay use.

1.1 Secularization as a Historical Process

Secularization refers to the historical process whereby the dualist system within 'this world' and the sacramental structures of mediation between this world and the other world progressively break down until the medieval system of classification disappears. Max Weber's expressive image of the breaking of the monastery walls remains perhaps the best graphic expression of this radical spatial restructuration initiated by the Protestant Reformation. This process, which Weber conceptualized as a general reorientation of religion from an other-worldly to an inner-worldly direction, is literally a process of secularization. Religious 'callings' are redirected to the *saeculum*. Salvation and religious perfection are no longer to be found in withdrawal from the world but in the midst of worldly secular activities. In fact, the symbolic wall separating the religious and the secular realms breaks down. The separation between 'this world' and 'the other world,' for the time being at least, remains. But, from now on, there will be only one single 'this world,' the secular one, within which religion will have to find its own place. To study what new systems of classification and differentiation emerge within this one secular world and what new place religion will have within it is precisely the analytical task of the theory of secularization.

Obviously, such a concept of secularization refers to a particular historical process of transformation of Western European Christian societies and might not be directly applicable to other non-Christian societies with very different modes of structuration of the sacred and profane realms. It could hardly be applicable, for instance, to such 'religions' as Confucianism or Taoism, insofar as they are not characterized by high tension with 'the world' and have no ecclesiastical organization. In a sense those religions which have always been 'worldly' and 'lay' do not need to undergo a process of secularization.

In itself such a spatial-structural concept of secularization describes only changes in the location of Christian religion from medieval to modern societies. It tells very little, however, about the extent and character of the religious beliefs, practices, and experiences of individuals and groups living in such societies. Yet the theory of secularization adopted by the modern social sciences incorporated the beliefs in progress and the critiques of religion of the Enlightenment and of Positivism and assumed that the historical process of secularization entailed the progressive decline of religion in the modern world. Thus, the theory of secularization became embedded in a philosophy of history that saw history as the progressive evolution of humanity from superstition to reason, from belief to unbelief, from religion to science.

2. The Secularization Paradigm

Secularization might have been the only theory within the social sciences that was able to attain the status of a paradigm. In one form or another, with the possible exception of Alexis de Tocqueville, Vilfredo Pareto, and William James, the thesis of secularization was shared by all the founders. Paradoxically, the consensus was such that for over a century the theory of secularization remained not only uncontested but also untested. Even Durkheim's and Weber's work, while serving as the foundation for later theories of secularization, offer scant empirical analysis of modern processes of secularization, particularly of the way in which those processes affect the place, nature and role of religion in the modern world. Even after freeing themselves from some of the rationalist and positivist prejudices about religion, they still share the major intellectual assumptions of the age about the future of religion.

For Durkheim, the old gods were growing old or already dead and the dysfunctional historical religions would not be able to compete with the new functional gods and secular moralities which modern societies were bound to generate. For Weber, the process of

intellectual rationalization, carried to its culmination by modern science, had ended in the complete disenchantment of the world, while the functional differentiation of the secular spheres had displaced the old integrative monotheism, replacing it with the modern polytheism of values and their unceasing and irreconcilable struggle. The old churches remain only as a refuge for those 'who cannot bear the fate of the times like a man' and are willing to make the inevitable 'intellectual sacrifice.'

Only in the 1960s one finds the first attempts to develop more systematic and empirically grounded formulations of the theory of secularization in the works of Acquaviva (1961), Berger (1967), Luckmann (1963), and Wilson (1966). It was then, at the very moment when theologians were celebrating the death of God and the secular city, that the first flaws in the theory became noticeable and the first systematic critiques were raised by Martin (1969) and Greeley (1972) in what constituted the first secularization debate. For the first time it became possible to separate the theory of secularization from its ideological origins in the Enlightenment critique of religion and to distinguish the theory of secularization, as a theory of the modern autonomous differentiation of the secular and the religious spheres, from the thesis that the end result of the process of modern differentiation would be the progressive erosion, decline and eventual disappearance of religion. Greeley (1972) already pointed out that the secularization of society, which he conceded, by no means implied the end of church religiosity, the emergence of 'secular man,' or the social irrelevance of religion in modern secular societies. Yet after three decades the secularization debate remains unabated. Defenders of the theory tend to point to the secularization of society and to the decline of church religiosity in Europe as substantiating evidence, while critics tend to emphasize the persistent religiosity in the United States and widespread signs of religious revival as damaging counterevidence that justify discarding the whole theory as a 'myth.'

3. *The Three Subtheses of the Theory of Secularization*

Although it is often viewed as a single unified theory, the paradigm of secularization is actually made up of three different and disparate propositions: secularization as differentiation of the secular spheres from religious institutions and norms, secularization as general decline of religious beliefs and practices, and secularization as privatization or marginalization of religion to a privatized sphere. Strictly speaking, the core and central thesis of the theory of secularization is the conceptualization of the historical process of societal modernization as a process of functional differentiation and emancipation of the secular spheres—primarily the state, the economy, and science—from religion and the concomitant specialized and functional differentiation of religion within its own newly found religious sphere. The other subtheses, the decline and privatization of religion, were added as allegedly necessary structural consequences of the process of secularization. Maintaining this analytical distinction should allow the examination and testing of the validity of each of the three propositions independently of each other and thus refocus the often fruitless secularization debate into comparative historical analysis that could account for obviously different patterns of secularization.

3.1 *The Differentiation and Secularization of Society*

The medieval dichotomous classification of reality into religious and secular realms was to a large extent dictated by the church. In this sense, the official perspective from which medieval societies saw themselves was a religious one. Everything within the *saeculum* remained an undifferentiated whole as long as it was viewed from the outside, from the perspective of the religious. The fall of the religious walls put an end to this dichotomous way of thinking and opened up an entire new space for processes of internal differentiation of the various secular spheres. Now, for the first time, the various secular spheres—politics, economics, law, science, art, etc.—could come fully into their own, become differentiated from each other, and follow what Weber called their 'internal and lawful autonomy.' The religious sphere, in turn, became a less central and spatially diminished sphere within the new secular system, but also a more internally differentiated one, specializing in 'its own religious' function and losing many other 'non-religious' (clerical, educational, social welfare) functions (Luhmann 1977). The loss in functions entailed as well a significant loss in hegemony and power.

It is unnecessary to enter into the controversial search for first causes setting the modern process of differentiation into motion. It suffices to stress the role which four related and parallel developments played in undermining the medieval religious system of classification: the Protestant Reformation; the formation of modern states; the growth of modern capitalism; and the early modern scientific revolution. Each of the four developments contributed its own dynamic to modern processes of secularization. The four of them together were certainly more than sufficient to carry the process through.

The Protestant Reformation by undermining the universalist claims of the Roman Catholic church helped to destroy the old organic system of Western Christendom and to liberate the secular spheres from religious control. Protestantism also served to legit-

imate the rise of bourgeois man and of the new entrepreneurial classes, the rise of the modern sovereign state against the universal Christian monarchy, and the triumph of the new science against Catholic scholasticism. Moreover, Protestantism may also be viewed as a form of internal secularization, as the vehicle through which Christian religious contents were to assume institutionalized secular forms in modern societies, thereby erasing the religious/secular divide.

If the universalist claims of the church as a salvation organization were undermined by the religious pluralism introduced by the Reformation, its monopolist compulsory character was undermined by the rise of a modern secular state which progressively was able to concentrate and monopolize the means of violence and coercion within its territory. In the early absolutist phase the alliance of throne and altar became even more accentuated. The churches attempted to reproduce the model of Christendom at the national level, but all the territorial national churches, Anglican, Lutheran, Catholic, and Orthodox, fell under the caesaro–papist control of the absolutist state. As the political costs of enforcing conformity became too high, the principle *cuius regio eius religio* turned into the principle of religious tolerance and state neutrality towards privatized religion, the liberal state's preferred form of religion. Eventually, new secular *raison d'état* principles led to the constitutional separation of church and state, even though some countries such as England and the Scandinavian Lutheran countries may have maintained formal establishment.

Capitalism, that revolutionizing force in history which according to Marx 'melts all that is solid into air and profanes all that is holy,' had already sprouted within the womb of the old Christian society in the medieval towns. No other sphere of the *saeculum* would prove more secular and more unsusceptible to religious and moral regulation than the capitalist market. Nowhere is the transvaluation of values which takes place from Medieval to Puritan Christianity as radical and as evident as in the change of attitude towards 'charity'—that most Christian of virtues—and towards poverty. Following Weber (1958), one could distinguish three phases and meanings of capitalist secularization: in the Puritan phase, 'asceticism was carried out of monastic cells into everyday life' and secular economic activities acquired the meaning and compulsion of a religious calling; in the utilitarian phase, as the religious roots dried out, the irrational compulsion turned into 'sober economic virtue' and 'utilitarian worldlines'; finally, once capitalism 'rests on mechanical foundations,' it no longer needs religious or moral support and begins to penetrate and colonize the religious sphere itself, subjecting it to the logic of commodification (Berger 1967).

The conflict between the church and the new science, symbolized by the trial of Galileo, was not as much about the substantive truth or falsity of the new Copernican theory as it was about the validity of the claims of the new science to have discovered a new autonomous method of obtaining and verifying truth. The conflict was above all about science's claims to differentiated autonomy from religion. The Newtonian Enlightenment established a new synthesis between faith and reason, which in Anglo-Saxon countries was to last until the Darwinian crisis of the second half of the nineteenth-century. Across the Channel, however, the Enlightenment became patently radicalized and militantly anti-religious. Science was transformed into a scientific and scientistic worldview which claimed to have replaced religion the way a new scientific paradigm replaces an outmoded one.

As each of these carriers—Protestantism, the modern state, modern capitalism, and modern science—developed different dynamics in different places and at different times, the patterns and the outcomes of the historical process of secularization varied accordingly. Yet it is striking how few comparative historical studies of secularization there are which would take these four, or other, variables into account. David Martin's *A General Theory of Secularization* is perhaps the single prominent exception. Only when it comes to capitalism has it been nearly universally recognized that economic development affects the 'rates of secularization,' that is, the extent and relative distribution of religious beliefs and practices. This positive insight, however, turns into a blinder, when it is made into the sole variable accounting for different rates of secularization. As a result, those cases in which no positive correlation is found, as expected, between rates of secularization and rates of industrialization, urbanization, proletarianization, education, in short, with indicators of socio-economic development, are classified as 'exceptions' to the 'rule.'

3.2 *The Decline of Religion Thesis*

The assumption, often stated but mostly unstated, that religion in the modern world was declining and would likely continue to decline has been until recently a dominant postulate of the theory of secularization. It was based primarily on evidence from European societies showing that the closer people were involved in industrial production, the less religious they became, or at least, the less they took part in institutional church religiosity. The theory assumed that the European trends were universal and that non-European societies would evince similar rates of religious decline with increasing industrialization. It is this part of the theory which has proven patently wrong.

One should keep in mind the inherent difficulties in comparative studies of religion. Globally, the evidence is insufficient and very uneven. There is often no consensus as to what counts as religion and even when there is agreement on the object of study, there is likely to be disagreement on which of the dimensions of religiosity (membership affiliation, official vs. popular

religion, beliefs, ritual and nonritual practices, experiences, doctrinal knowledge, and their behavioral and ethical effects) one should measure and how various dimensions should be ranked and compared.

Nevertheless, one can prudently state that since World War II, despite rapid increases in industrialization, urbanization, and education, most religious traditions in most parts of the world have either experienced some growth or maintained their vitality (Whaling 1987). The main exceptions were: the rapid decline of primal religions mostly in exchange for more 'advanced' ones (mainly Islam and Christianity), the sudden and dramatic decline of religion in communist countries, a process which is now being reversed after the fall of communism, and the continuous decline of religion throughout much of Western Europe (and, one could add, some of its colonial outposts such as Argentina, Uruguay, New Zealand, and Quebec).

What remains, therefore, as significant and overwhelming evidence is the progressive and apparently still continuing decline of religion in Western Europe. It is this evidence which has always served as the empirical basis for most theories of secularization. Were it not for the fact that religion shows no uniform sign of decline in Japan or the United States, two equally modern societies, one could still perhaps maintain the 'modernizing' developmentalist assumption that it is only a matter of time before the more 'backward' societies catch-up with the more 'modern' ones. But such an assumption is no longer tenable. Leaving aside the evidence from Japan, a case which should be crucial, however, for any attempt to develop a *general* theory of secularization, there is still the need to explain the obviously contrasting religious trends in Western Europe and the United States.

Until very recently, most of the comparative observations as well as attempts at explanation came from the European side. European visitors have always been struck by the vitality of American religion. The United States appeared simultaneously as the land of 'perfect disestablishment' and as 'the land of religiosity *par excellence*.' Yet, Europeans rarely felt compelled to put into question the thesis of the general decline of religion in view of the American counterevidence. Religious decline was so much taken for granted that what required an explanation was the American 'deviation' from the European 'norm.' The standard explanations have been either the expedient appeal to 'American exceptionalism' or the casuistic strategy to rule out the American evidence as irrelevant, because American religion was supposed to have become so 'secular' that it should no longer count as religion (Luckmann 1963).

From a global–historical perspective, however, it is the dramatic decline of religion in Europe that truly demands an explanation. A plausible answer would require a search for independent variables, for those independent carriers of secularization present in Europe but absent in the United States. Looking at the four historical carriers mentioned above, neither Protestantism nor capitalism would appear as plausible candidates. The state and scientific culture, however, could serve as plausible independent variables, since church–state relations and the scientific worldviews carried by the Enlightenment were significantly different in Europe and America.

What the United States never had was an absolutist state and its ecclesiastical counterpart, a caesaro–papist state church. It was the caesaro–papist embrace of throne and altar under absolutism that perhaps more than anything else determined the decline of church religion in Europe. Consistently throughout Europe, nonestablished churches and sects in most countries have been able to withstand the secularizing trends better than the established church. It was the very attempt to preserve and prolong Christendom in every state and thus to resist modern functional differentiation that nearly destroyed the churches in Europe.

The Enlightenment and its critique of religion became themselves independent carriers of processes of secularization wherever the established churches became obstacles to the modern process of functional differentiation or resisted the emancipation of the cognitive–scientific, political–practical, or aesthetic–expressive secular spheres from religious and ecclesiastical tutelage. In such cases, the Enlightenment critique of religion was usually adopted by social movements and political parties, becoming in the process a self-fulfilling prophecy. By contrast, wherever religion itself accepted, perhaps even furthered, the functional differentiation of the secular spheres from the religious sphere, the radical Enlightenment and its critique of religion became superfluous. Simply put, the more religions resist the process of modern differentiation, that is, secularization in the first sense, the more they will tend in the long run to suffer religious decline, that is, secularization in the second sense.

3.3 The Privatization of Religion Thesis

As a corollary of the thesis of differentiation, religious disestablishment entails the privatization of religion. Religion becomes indeed 'a private affair.' Insofar as freedom of conscience, 'the first freedom' as well as the precondition of all modern freedoms, is related intrinsically to 'the right to privacy'—to the modern institutionalization of a private sphere free from governmental intrusion as well as free from ecclesiastical control—and inasmuch as the right to privacy serves as the very foundation of modern liberalism and of modern individualism, then indeed the privatization of religion is essential to modern societies.

There is, however, another more radical version of the thesis of privatization which often appears as a corollary of the decline of religion thesis. In modern secular societies, whatever residual religion remains

becomes so subjective and privatized that it turns 'invisible,' that is, marginal and irrelevant from a societal point of view. Not only are traditional religious institutions becoming increasingly irrelevant but, Luckmann (1963) adds, modern religion itself is no longer to be found inside the churches. The modern quest for salvation and personal meaning has withdrawn to the private sphere of the self. Significant for the structure of modern secular societies is the fact that this quest for subjective meaning is a strictly personal affair. The primary 'public' institutions (state, economy) no longer need or are interested in maintaining a sacred cosmos or a public religious worldview.

The functionalist thesis of privatization turns problematic when instead of being a falsifiable empirical theory of dominant historical trends, it becomes a prescriptive normative theory of how religious institutions ought to behave in the modern world. Unlike secular differentiation, which remains a structural trend that serves to define the very structure of modernity, the privatization of religion is a historical option, a 'preferred option' to be sure, but an option nonetheless. Privatization is preferred internally as evinced by general pietistic trends, by processes of religious individuation, and by the reflexive nature of modern religion. Privatization is constrained externally by structural trends of differentiation which force religion into a circumscribed and differentiated religious sphere. Above all, privatization is mandated ideologically by liberal categories of thought which permeate modern political and constitutional theories.

The theory of secularization should be free from such a liberal ideological bias and admit that there may be legitimate forms of 'public' religion in the modern world, which are not necessarily anti-modern fundamentalist reactions and which do not need to endanger either modern individual freedoms or modern differentiated structures. Many of the recent critiques and revisions of the paradigm of secularization derive from the fact that in the 1980s religions throughout the world thrust themselves unexpectedly into the public arena of moral and political contestation, demonstrating that religions in the modern secular world continue and will likely continue to have a public dimension.

Segregation Indices

Measuring the residential segregation of racial and ethnic populations became very important to social scientists during the civil rights movement in the United States (Duncan and Duncan 1955; Taueber and Taueber 1965). Until the mid-1970s, when important critiques of the dissimilarity index stimulated efforts to develop alternatives, research almost exclusively relied upon this measure, and focused on the residential segregation of blacks from whites in the United States. Despite the many alternatives proposed, only the isolation index has really joined the dissimilarity index as a measure frequently used in empirical research on residential segregation. However, applications have extended substantially, to other racial and ethnic populations, and also to groups within and across races, defined by income, poverty, nativity, or other characteristics. Virtually all segregation indices are constructed by aggregating the observed distributions of the 'minority' and referent populations across a metropolitan area or city divided into small geographic areas—usually census tracts or census blocks in the United States. These geographic units are sufficiently small to be taken as rough approximations of neighborhoods whose residents would acknowledge and share some sense of common spatial identity, and hence some sense of community.

Massey and Denton's (1988) review and analysis of

20 indices that either had been or could be proposed for measuring distinct aspects of residential segregation represents the major watershed in the field. Massey and Denton suggested that the 20 indices measured five distinct dimensions of residential segregation:

(a) Evenness: indices that measure how the observed areal distributions of the minority and majority group populations in a metropolitan area deviate from distributions representing various definitions and criteria for equality or randomness.

(b) Exposure: indices based on the probability that the next person a minority group member encounters in their neighborhood or geographic area will also be a member of that group, or will instead be a member of the referent group.

(c) Concentration: indices that measure the degree to which a minority population is concentrated in a relatively small number of compact tracts.

(d) Centralization: indices that measure the degree to which a minority population resides close to the center or 'downtown' areas of a city.

(e) Clustering: indices that measure the degree to which the minority population disproportionately resides in neighborhoods or geographic units that adjoin one another, and hence form clusters or enclaves.

1. *Measures of Evenness*

The index of dissimilarity remains by far the most frequently used in empirical research on residual segregation. It is built on the premise that a metropolitan area or city would be integrated completely if all of its census tracts (or other areal units) had exactly the proportion of minority group and majority group residents as the metropolitan area or city as a whole. The index is calculated as the average deviation of the tracts or areal units from this proportionate representation, where the deviation is tract i is $|p_i - P|$. Thus,

$$D = \left(\sum_{1}^{n} [t_i |p_i - P|]\right) \Big/ [2TP(1-P)]$$

The resulting dissimilarity score can be interpreted as representing the percentage of the metropolitan area's minority residents who would have to move from tracts or areal units where the minority group is over-represented to areal units where they are under-represented to achieve proportionate representation or complete integration.

The primary criticism of the dissimilarity index is that it is insensitive to moves (or 'transfers') of minority group members among tracts where they are over-represented or under-represented. Several indices developed in literatures measuring income inequalities overcome this violation of the 'transfers principle.' The Gini coefficient averages the differences in the proportions of the minority group in every pair of tracts or areal units in the metropolitan area, where $|p_i - p_j|$ represents the difference in these proportions for tracts i and j

$$G = \left(\sum_{i=1}^{n} \sum_{j=1}^{n} [t_i t_j |p_i - p_j|]\right) \Big/ [2T^2 P(1-P)]$$

The Atkinson measures allow researchers to develop indices that weight tracts where the minority group is under-represented ($p_i < P$) and over-represented ($p_i > P$) equally ($b = 0.5$), or to weight under-representation ($0 < b < 0.5$) or over-representation ($0.5 > b > 1.0$) more heavily

$$A = [P/(1-P)] \left| (1/PT) \left(\sum_{1}^{n} (1-p_i)^{(1-b)} p_i^b t_i \right) \right|^{1/(1-b)}$$

The theoretical or conceptual value of the Atkinson indices lies in applications where one might be more interested in reducing under-representation (e.g., integrating 'lily-white' suburbs) or in reducing over-representation (e.g., desegregating all black or Hispanic ghettos or barrios).

Entropy or information indices are based on the concept that entropy is maximized and information minimized when distributions are in equilibrium. In segregation applications, this would occur when the proportions of the minority and majority group populations were equal (50 percent for two groups) in a metropolitan area. The entropy index measures the percentage of the metropolitan area's entropy that is represented by the average deviation of entropy in each tract or areal unit from that in the metropolitan area as a whole. Thus, where entropy in each tract i and in the metropolitan area or city are represented respectively, by

$$E_i = p_i \log(1/p_i) + (1-p_i) \log(1/(1-p_i))$$

and

$$E = P \log(1/P) + (1-P) \log(1/(1-P))$$

then

$$H = \left(\sum_{1}^{n} [t_i (E - E_i)]\right) \Big/ ET$$

2. *Measures of Exposure*

Scores on the entropy index depend on P, the proportion that the minority group represents of the metropolitan area or city population. This violates a

criterion that proposes the segregation indices should have 'compositional invariance,' that is, independent of the proportions of minority and majority group members in different cities or metropolitan areas. However, in many critical applications such as school desegregation, the very low percentages of minority or majority group students in a district constitute major barriers to increasing racial integration or balance. The conceptual appropriateness and theoretical value of indices that are influenced by the relative proportions of minority and majority group members is thus undeniable, and they are among the few measures besides the dissimilarity index that are used extensively in empirical research.

The interaction and isolation measures are designed specifically to measure segregation defined by the degree to which the relative sizes of the minority and majority populations, as well as their distributions across neighborhoods or areal units, affect the chances of their availability to interact with one another in those neighborhoods. The interaction index is the average, weighted by the proportion of the metropolitan area's minority group living in tract i, of the majority group's proportion in each tract or areal unit i. It can be interpreted as representing the probability that the next person that a minority resident of a neighborhood or tract encounters will belong to the majority population.

$$ {}_xP_y^* = \sum_1^n [(x_i/X)(y_i/t_i)] $$

Conversely, the isolation index measures the likelihood that minority residents in a tract encounter only each other, and is calculated as the minority-weighted average of the minority group's proportion in each other or areal unit i

$$ {}_xP_x^* = \sum_1^n [(x_i/X)(x_i/t_i)] $$

Because the interaction and isolation indices depend on the composition of the population, ${}_xP_y^*$ and ${}_xP_x^*$ will be equal only if the majority and minority groups represent equal proportions of the population. The correlation ratio, Eta^2, adjusts for the effects of proportion minority of the population, and indeed can be classified as an evenness measure.

$$ V = Eta^2 = ({}_xP_x^* - P)/(1-P) $$

3. *Measures of Concentration*

Concentration indices seek to measure the extent to which the minority population occupies less of the metropolitan area's or city's geographic area than the majority or total population, and hence also lives at higher densities. If the minority population was uniformly distributed throughout the city or metropolitan area, the proportion of the total minority population in tract or areal unit i would be equal to that tract's proportion of the total area in the metropolitan area (a_i/A). Delta measures concentration by aggregating the deviations from this expectation

$$ \Delta = 0.5\left(\sum_1^n |(x_i/X) - (a_i/A)|\right) $$

Like the index of dissimilarity, the score on delta can be interpreted as representing the percentage of the minority group population that would have to move from areas of higher to lower than average density for the group to live at uniform densities across the metropolitan area.

Massey and Denton (1988) proposed new measures of concentration. The absolute concentration index compares the observed distribution of the minority group in the metropolitan area against the theoretical minimum and maximum areas they could occupy. If tracts are ordered and the total population is cumulated from smallest to largest in area, the minimum area that could accommodate the minority group population is reached at tract n_1 where the cumulated population reaches or exceeds the total minority population (X) of the metropolitan area. Analogously, the maximum area that the minority population could occupy is obtained by cumulating the total population from the tracts largest in area to smallest, and finding the point n_2 where the cumulated population equals or exceeds the minority total.

$$ ACO = 1 - \left\{\left[\sum_1^n (x_i a_i/X) - \sum_1^n (t_i a_i/T_1)\right] \Big/ \left[\sum_{n_2}^n (t_i a_i/T_2) - \sum_1^{n_1} (t_i a_i/T_2)\right]\right\} $$

The relative concentration index compares the relative concentration observed for the minority and majority populations with the maximum ratio possible, which occurs if the minority population were concentrated in the smallest possible area, and the majority population spread across the largest.

$$ RCO = \left\{\left[\sum_1^n (x_i a_i/X)\right] \Big/ \left[\sum_1^n (y_i a_i/Y)\right] - 1\right\} \Big/ \left\{\left[\sum_1^n (t_i a_i/T_1)\right] \Big/ \left[\sum_{n_2}^n (t_i a_i/T_2)\right] - 1\right\} $$

The segregation indices usual range from 0.0 to 1.0. In contrast, the relative concentration index ranges from -1.0 to 1.0, with the negative values indicating that the minority population is less concentrated than the majority.

4. Measures of Centralization

Because older and cheaper housing is usually closer to the center of the city, and because housing discrimination prevented blacks and other minorities in the United States from suburbanizing for decades after whites did, minority populations are often concentrated in neighborhoods closer to the center of the city. Both centralization measures order the metropolitan area's tracts or areal units by increasing distance from the central business district. The absolute centralization index aggregates the deviations of the cumulative proportion of the minority (X_i) reached at each tract i from the proportion of the land area reached by that tract

$$ACE = \sum_{1}^{n} (X_{i-1}A_i) - \sum_{1}^{n} (X_i A_{i-1})$$

The relative centralization index, aggregates the deviations of the cumulative proportions of the minority (X_i) and majority (Y_i) populations reached at each tract i from what would be expected were they comparably distributed

$$RCE = \sum_{1}^{n} (X_{i-1}Y_i) - \sum_{1}^{n} (X_i A_{i-1})$$

The ACE ranges from 0.0 to 1.0, but the RCE from -1.0 to 1.0, with negative values indicating that the minority population is less centralized than the majority.

5. Measures of Clustering

The final dimension of residential segregation measures the degree to which tracts with disproportionately large minority populations adjoin one another, creating, for example, large ghettos or barrios, or are scattered throughout the metropolitan area. This is a form of the geographer's contiguity and checkerboard problems, and drawing on this literature, Massey and Denton (1988) proposed as a measure of absolute clustering.

$$ACL = \left\{ \sum_{1}^{n} \left[(x_i/X) \sum_{1}^{n} (c_{ij}x_j) \right] - \left[(X/n^2) \sum_{i=1}^{n} \sum_{j=1}^{n} (c_{ij}x_j) \right] \right\} \Big/ \left\{ \sum_{1}^{n} \left[(x_i/X) \sum_{1}^{n} (c_{ij}t_j) \right] - \left[(X/n^2) \sum_{i=1}^{n} \sum_{j=1}^{n} (c_{ij}) \right] \right\}$$

where $c_{ij} = \exp(-d_{ij})$, that is, the negative exponential of the distance d_{ij} between the centroids of tracts i and j (and where $d_{ij} = (0.6a_i)^{0.5}$). The negative exponential is used to estimate the otherwise massive contiguity matrix whose elements equal 1.0 when tracts i and j are contiguous, and 0.0 when they are not. The formula takes the average number of minority residents in nearby tracts as a proportion of the total population in those tracts. The absolute clustering index has a minimum of 0.0 and can approach, but never reach, 1.0.

The spatial proximity index compares the average proximity of minority group residents to one another (P_{xx}), and the majority group residents with one another (P_{yy}) to the average proximity among the residents in the total population (P_{tt}), weighted by the fraction that each group represents in the population. Thus

$$SP = (XP_{xx} + YP_{yy})/TP_{tt}$$

where

$$P_{xx} = \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}x_j x_j / X^2$$

and P_{yy} and P_{tt} are calculated by analogues of P_{xx}. Comparing the relative intragroup proximities of the minority and majority populations produces a measure of relative clustering.

$$RCL = (P_{xx}/P_{yy}) - 1$$

Clustering can also be measured by extending the concepts underlying the interaction and isolation measures to estimate how these probabilities should decay with distance. The distance–decay interaction and isolation indices can be constructed by aggregating, over each tract i, the probability that the next person one meets anywhere in the city is respectively a majority or minority resident from tract j, and that this probability exponentially decays with increasing distance between i and j. Thus

$$DP_{xy} = \sum_{1}^{n} \left[(x_i/X) \sum_{1}^{n} (k_{ij}y_j/t_{ij}) \right]$$

and

$$DP_{xx} \sum_{1}^{n} \left[(x_i/X) \sum_{1}^{n} (k_{ij}x_j/t_j) \right]$$

where

$$k_{ij} = [t_{ij} \exp(-d_{ij})] \Big/ \left[\sum_{1}^{n} (t_j \exp(-d_{ij}) \right]$$

6. Conclusion

Few empirical researchers have used more than one or two of these 20 indices in studying residential segregation, and the full spectrum remains of interest primarily to those devoted to constructing measures of the phenomenon in its varied dimensions. Massey and Denton (1988) used factor analysis to extract one index from each dimension and to define a concept of

hypersegregation for blacks in the United States based on their high segregation scores on each of the five dimensions. This has extended the use of measures beyond the dissimilarity and interaction/isolation indices. However, the literature is still far from developing an over-arching framework that might suggest how several measures might be used systematically to identify how urban areas vary in the five-dimensional space suggested or with what consequences. One might imagine, for example, identifying and comparing urban areas where high unevenness results from low integration in the suburbs rather than large ghettos; those with concentrated and perhaps centralized ghettos or barrios vs. others with comparably high unevenness or isolation but less clustered distributions of the minority population. The full set of indices has much potential value that remains to be developed.

Selection Bias, Statistics of

In almost all areas of scientific inquiry researchers often want to infer, on the basis of sample data, the characteristics of a relationship that holds in the relevant population. Frequently this is the relationship between a dependent variable and one or more explanatory variables. In some cases, however, although one may have complete information on the explanatory variables, information on the dependent variable is lacking for some observations or 'units.' Furthermore, whether or not this information is present may not be conditionally independent (given the model) of the value taken by the dependent variable itself. This is a case of selection bias.

1. Selection Bias

The following illustrates the basic problem. Suppose one hypothesizes the following relationship, in the population, between a dependent variable, Y^*, and a set of $j = 1,\ldots, J$ explanatory variables, X

$$y_i^* = x_i'\beta + \varepsilon_i \tag{1}$$

Here the unit-specific values of Y^* are denoted y_i^* (where i denotes the ith observation) and each unit's values of the X variables are contained in the vector x_i. ε is a random error and the parameter vector, β, is to be estimated. Specific assumptions about the distribution of ε will determine the choice of estimation technique.

If Y^* is considered as a latent variable, a variety of different statistical models can be generated from Eqn. (1) depending on the manner in which Y^* is actually observed (though still, at this point, assuming that Y^* is observed, in some fashion, for all units). To do this, write a second equation that defines the relationship between the observed variable Y, and the latent variable, Y^*. For example, where Y^* is completely observed

$$y_i = y_i^* \tag{2a}$$

but one might also have

$$\begin{aligned} y_i &= 1 \quad \text{if } y_i^* > 0 \\ y_i &= 0 \quad \text{otherwise} \end{aligned} \tag{2b}$$

In the case of Eqn. (2(b)) Y is the binary observed realization of the underlying latent variable, Y^*. More complex relationships between Y^* and Y are also possible.

To capture the idea of selection bias, suppose that there is another latent variable Z^* such that whether or not we observe a value for Y depends on the value of Z^* which is given by

$$z_i^* = w_i' \alpha + v_i \tag{3}$$

Here w is a vector of explanatory variables with coefficients α, and v is a random error term. The observed variable Z is defined as

$$\begin{aligned} z_i &= 1 \quad \text{if } z_i^* i > 0 \\ z_i &= 0 \quad \text{otherwise} \end{aligned} \tag{4}$$

Finally, define the observation equation for Y as depending on Z^* as follows

$$\begin{aligned} y_i &= y_i \quad \text{if } z_i = 1 \\ y_i &\text{ unobserved if } z_i = 0 \end{aligned} \tag{5}$$

Equations (1), (2), and (5), together with Eqns. (3) and (4), link the latent variable Y^* to its observed counterpart, Y, when observation of the latter depends on the value of another variable, Z^*. Selection bias occurs when there is a nonzero covariance between the error terms ε and v. More complex selection bias models can be generated by having, for instance, more than one Z^* variable. The censored regression (or Tobit) model is a simpler case in which whether Y is observed or not depends on whether it exceeds (or, in other cases, falls below) a given threshold value.

2. The Problem

Selection bias is a problem because if one tries to estimate β using normal statistical methods the resulting estimates will be poor and potentially misleading. For example, if Eqn. (2(a)) specifies the relationship between Y and Y^*, discarding cases where Y is unobserved and running an OLS regression on the remainder will give estimates that are biased and inconsistent.

Where might this kind of selection bias arise? Suppose one draws a random sample from a population and carries out a survey. Some respondents may refuse to answer some, though not all, questions. If the response to such a question played the role of dependent variable in a regression analysis there would be a selection bias problem if the probability of having responded to the item was not independent of the response value, given the specification of the regression model. This may not always be so: in the simplest case nonresponse might be random. Alternatively, response might be independent of the response value controlling for a set of measured covariates. In this case there is selection on observables (Heckman and Robb 1985). But often neither of these cases holds and a nonzero residual correlation between the selection Eqn. (3) and the outcome Eqn. (1) means that there is selection on unobservables.

In studies of the criminal justice system in which the population is all those charged with a crime, sentence severity is observed only for those found guilty. In studies of the effectiveness of university education the outcome (say, examination results) is only observed for those who had completed that period of education. In studies of women's earnings in paid work the earnings of women who are not in the labor force cannot be observed. To these examples could be added very many more. Selection bias is a pervasive problem. As a consequence a variety of methods has been proposed to deal with it.

The problem of selection bias arises because of the nonzero correlation of the errors in Eqns. (1) and (3), and this arises commonly in the following context. Suppose there is a nonexperimental comparison of two groups, one exposed to some policy treatment, the other not. In this case the outcome of interest, Y, could be observed for members of both groups. Let Z now be the indicator of group membership (so that, for instance, $Z = 0$ means membership of the comparison group and $Z = 1$ means membership of the treatment group). In the case where Eqn. (2(a)) holds write the equation for Y as

$$y_i = x_i' \beta + \gamma z_i + \varepsilon_i \tag{6}$$

and interest would focus on the estimate of γ as the gross effect on the outcome measure of being in the treatment, rather than the comparison, group. The problem of selection bias still arises to the extent that ε and v have a nonzero correlation. The difference between this and the type of selection bias discussed initially (namely that now Y is observed for both groups) is more apparent than real as an alternative formulation shows. For each unit Y is observed as the response to membership of either the treatment or comparison group, but not both. Let Y_1 be the outcome given treatment and Y_0 given no treatment. Then the ith individual unit's gain from treatment is simply $\Delta_i = Y_{1i} - Y_{0i}$. But Δ cannot be measured since one cannot simultaneously observe a unit's values of Y_1 and Y_0. Instead

$$Y_i = ZY_{1i} + (1 - Z)Y_{0i} \tag{7}$$

is observed. Eqn. (7) thus specifies the incomplete observation of two latent variables, Y_0 and Y_1. This set-up can easily be extended to cases with more than two groups. As might be expected, this approach is commonly encountered in the evaluation literature but one of its earliest formulations was by Roy (1951) as the problem of self-selection.

3. The Solutions

Broadly speaking there are two ways to address problems of selection bias: *ex ante* by research design, and *ex post* by statistical adjustment. The modern literature on correcting for selection bias is itself biased towards the latter, beginning with the work of Heckman in the 1970s (Heckman 1976, 1979) whose so-called 'two step' method is widely used and hard-wired into many econometrics programs. The argument that underlies this technique is the following. Assume the set-up as defined by Eqns. (1), (2(a)), (3), (4), and (5) and a nonzero covariance between ε and v. Then we can write the 'outcome equation' (i.e., the regression equation for Y, given its observability) as

$$E(y_i | z_i = 1, x_i) = x_i' \beta + E(\varepsilon_i | z_i = 1) \tag{8}$$

Because there are only observations of Y when $z = 1$ there is an extra term for the conditional expectation

of ε. Because of the nonzero covariance between ε and v and if, as is usually assumed, $E(\varepsilon) = 0$, then this conditional expectation cannot be zero. One can write

$$E(y_i|z_i = 1, x_i) = x'_i\,\beta + E(\varepsilon_i|v_i > w_i'\alpha) \qquad (9)$$

Using a standard result for the value of a truncated bivariate normal distribution, the second term on the right-hand side of this equation is given by

$$E(\varepsilon_i|v_i > w'_i\,\alpha) = \rho\sigma_\varepsilon\,\sigma_v\frac{\phi(w_i'\,\alpha)}{\Phi(w'_i\,\alpha)} \qquad (10)$$

Here the σs are the standard deviations of the respective error terms from Eqns. (1) and (3); ρ is the correlation between them; ϕ and Φ are, respectively, the density and distribution functions of the standard normal and their ratio, as it appears in Eqn. (10), is termed the 'inverse Mill's ratio.' Heckman's two-step method requires first running a probit regression with Z as the dependent variable, estimated using all the observations in the data. Then, for those observations for which Y is observed, the probit coefficient estimates are used to compute the value of the inverse Mill's ratio. This is then inserted as an extra variable in the OLS regression in which Y is the dependent variable to give

$$E(y_i|z_i = 1, x_i) = x_i'\,\beta + \theta\hat{\lambda}_i \qquad (11)$$

where λ is the inverse Mill's ratio and the 'hat' indicates that it is estimated. Its coefficient, θ, is then itself an estimate of $\rho\sigma_\varepsilon\sigma_v$. This is the covariance between ε and v (σ_v is set to unity in the probit). This approach is extended readily to the case in which an outcome is observed for both groups ($Z = 0$ and $Z = 1$).

What are the assumptions of this approach and what are the properties of the resulting estimator when we apply this method to data from a sample of the population? First, it is assumed that all the other requirements for an OLS regression are met. Second, in the set-up outlined above, the joint distribution of ε and v should be bivariate normal (though, in general, weaker assumptions suffice, namely that v be normally distributed; and the expectation of ε, conditional on v, should be linear in v: (see Olsen 1980)).

Given that the assumptions hold, the two-step estimator yields consistent estimates of the population β in Eqn. (1). The standard errors are incorrect (due to heteroscedasticity and the use of an estimated value of λ) but these are corrected readily. An alternative to the two-step approach is to estimate both the selection and outcome equations simultaneously using maximum likelihood (ML). The resulting estimates are asymptotically unbiased and more efficient than those from the two-step method (see Nelson 1984, who compares OLS, the two-step method and ML).

This two-step method is, in any case, applicable only when the relationship between Y^* and Y is as given by Eqn. (2(a)). When this relationship is given by, for example, Eqn. (2(b)), the two-stage method is inconsistent. In these cases ML is the most feasible option. If the outcome variable is itself binary, the joint log-likelihood of the selection and outcome equations has the same general as for a bivariate probit but one in which there are three, rather than four, possible outcomes. They are $z = 1$ and $y = 1$; $z = 1$ and $y = 0$; and $z = 0$ (in which case y is not observed).

Although the two-step method is probably the most widely used approach to correcting for selection bias it has been subjected to much criticism. Among the main objections are the following:

(a) *sensitivity to distributional assumptions*. Practical implementation of the method renders it particularly sensitive in this respect. If the assumptions are not met the estimator has no desirable properties (i.e., it is not even consistent).

(b) *identification and robustness*. It is common to find that the estimate of the inverse Mill's ratio is highly correlated either with the explanatory variables or with the intercept in Eqn. (11). The extent to which such problems will arise depends mainly on three things. They are:

(i) the specification of the selection equation;

(ii) the sample correlation between the two sets of explanatory variables, X and W (call this q);

(iii) the degree of sample selection in the sample (p, the proportion of cases for which $z = 1$).

For example, if X and W are identical, the two-equation system is identified only because of the nonlinearity of the probit equation. But for some ranges of p the probit function is almost linear, with the result that the estimated λ will be close to a linear function of the explanatory variables in the probit; and thus it will be highly correlated with the X variables in the outcome equation. In general, the correlation between the inverse Mill's ratio estimate and the other explanatory variables in this equation will be greater the greater is q and the closer is p to zero or one (this issue is discussed in detail in Breen 1996). If the selection equation does not discriminate well between the selected and unselected observations the estimated inverse Mill's ratio will be approximately a constant, and there will therefore be a high correlation between it and the intercept of the outcome equation.

Both these objections reflect genuine difficulties in applying the model. In principle the solution to the identification and robustness problems is simple: ensure that the probit equation discriminates well and do not rely on the nonlinearity of the probit for identification. In practice it may be rather difficult to achieve these things. On the other hand, the issue of distributional assumptions may be even less tractable, obliging recourse to semiparameteric or other approaches (Lee 1994; Cosslett 1991).

An alternative is to try to assess the likely degree of bias that sample selection might induce in a given case. Rubin (1977) presents a Bayesian approach in which the investigator computes the likely degree of bias, conditional on a prior belief about the relationship between the parameters of the distribution of Y in the selected and nonselected samples. The mean and the variance of the latter sample might, for example, be expressed as a function of their values in the selected sample, conditioning on the values of observed covariates. It is then straightforward to express the extent of selection bias for plausible values of the parameters of this function and to place a corresponding Bayesian probability interval around any estimates. Rosenbaum (1995, 1996) suggests and illustrates other sensitivity analyses for selection bias in nonexperimental evaluations.

4. *Program Evaluation and Selection Bias*

For several years now the literature on selection bias has been dominated by discussion of how to evaluate programs (such as job training programs) when randomized assignment to treatment and control group is not possible. In a very widely cited paper, Lalonde (1986) compared the measured effectiveness of labor market programs using a randomized assignment design with their effectiveness computed using the Heckman method and showed that they led to quite different results (but see also Heckman and Hotz 1989). While some have seen this as a fatal criticism of the method, one consequence has been the development of greater awareness of the need to ensure the suitability of different selection bias correction approaches for specific cases. Another has been a greater concern to identify other possible sources of bias in nonrandomized program evaluations.

In the statistical literature, matching methods commonly are advocated in program evaluations in the absence of randomization. They involve the direct comparison of treated and untreated units that share common, or very similar, values on a set of relevant covariates, X. The rationale for this is the assumption that, conditional on X, and assuming only selection on observables (all of which are in X), the observed outcome for nonparticipants has the same distribution as the unobserved outcome that participants would have had had they not participated (see Heckman et al. 1997). This then allows one to estimate Δ. In passing, note that matching is also used commonly to impute missing values in item nonresponse in surveys (Little and Rubin 1987). A central issue is how to carry out such matching. If there are K covariates, then the problem is one of matching pairs, or sets, of participants and nonparticipants in this K-dimensional space. But by a result due to Rosenbaum and Rubin (1983) (see also Rosenbaum 1995), matching using a scalar quantity called the propensity score is equally effective. The propensity score is simply the probability of being in the treatment, rather than the comparison group, given the observed covariates. Matching on the propensity score controls bias due to all observed covariates and, even if there is selection on unobservables, the method nevertheless produces treatment and comparison groups with the same distribution of X variables. This is so under the assumption that the true propensity score is known, but Rosenbaum and Rubin (1984) show that an estimated propensity score (typically using a logit model) appears to perform at least as well.

The use of matching draws attention to the problem of the possibly different distributions of covariates (or, equally, of propensity scores) in the treatment and comparison groups. There are two important aspects: first, the support of the propensity score may be different, so some ranges of propensity score values may be present in one group and not the other. More simply, some participants may have no comparable non-participants. Second, the distributions of the set of common values of propensity scores (i.e., which appear in both groups) may be different (Heckman et al. 1997, 1998). Hitherto, in practice, both of these sources of bias in evaluating the program's effects commonly would have been confounded with selection bias proper. The use of propensity scores can remove the former but, if there is also selection on unobservables (i.e., selection bias proper), matching cannot be expected to solve the problem. Indeed, it is possible that these different forms of bias may have opposite signs, so that correcting for some but not others may make the overall bias greater. Nevertheless, the ability to draw such finer distinctions among biases is a valuable development, not least because it allows one to focus on methods for controlling selection bias, free from the contaminating effects of other biases.

5. *Conclusion*

This article has only skimmed the surface of selection bias statistics. In particular, it has looked only at models for cross-sectional data: other approaches are possible given other sorts of data. For example, given longitudinal data, with observations of Y for each unit at two (or more) points in time, one prior to the program to be evaluated, the other after it, then it may be possible to specify and test a model which assumes that unobserved causes of selection bias are unit-specific and time-invariant and can therefore be removed by differencing (Heckman and Robb 1985, Heckman et al. 1997, 1998). Considerations of this sort draw attention to the *ex ante* approach to dealing with selection bias that was referred to earlier. Here the emphasis falls on designing research so as to remove, or at least reduce, selection bias. Random assignment is one possibility, though not always feasible in practice. Nevertheless, quasi-experimental approaches, interrupted time-series, and longitudinal

designs with repeated measures on the outcome variable are among a range of possibilities that could be considered in designing ones research to minimize selection bias problems (see Rosenbaum 1999 and associated comments). Even so, there will still be many instances in which analysts use data over whose collection they have had no control and where the use of *ex post* adjustments will be unavoidable.

To conclude: much work on the selection bias problem has been undertaken since the 1980s yet there is no widespread agreement on which statistical methods are most suitable for use in correcting for the problem. Some broad guidelines for practitioners can, however, be discerned:

(a) the need to ensure that methods to correct for selection bias are appropriate and that their requirements (such as distributional properties) are met;

(b) the need to be aware of other, possibly confounding, sources of bias;

(c) the usefulness of analyses of the sensitivity of conclusions to various possible magnitudes of selection bias; and of the sensitivity of the selection-bias corrected results to the assumptions of whatever method is employed; and

(d) the desirability of designing research so that selection bias problems are, as far as possible, eliminated without the need for complex and sometimes fragile *ex post* adjustment.

Self-concepts: Educational Aspects

The capacity to reflect one's own capabilities and actions is uniquely human. Early in life, young children begin to form beliefs about themselves which may serve as reference mechanisms for perceiving the world and oneself, and for regulating emotion, motivation, and action. Research on self-related beliefs can be traced back to the seminal writings of William James (1893) who distinguished the self as 'I' ('existential self') and as 'me' ('categorical self'), the latter implying cognitions about the self as an object of thinking (as represented in a sentence like 'I think about me'). Research was continued throughout the decades after that and gained a central status in personality and social psychology as well as educational research after the cognitive paradigm shift in

the 1950s and 1960s. At that time, behavioristic approaches were gradually replaced by cognitive perspectives, thus making it possible to acknowledge the importance of cognitive processes in human agency. Since then, the number of studies on self-concepts has increased drastically. This also applies to studies on the educational relevance of self-concepts (Hansford and Hattie 1982, Helmke 1992).

1. Definition of the Term 'Self-concept'

The term 'self-concept' is used in two interrelated ways. Talking about *the* self-concept of a person has to be differentiated from referring to a number of *different* self-concepts of this person. Usage of the term in self-concept research implies that 'the' self-concept may be defined as the total set of a person's cognitive representations of him- or herself which are stored in memory. In the plural sense, different self-concepts of a person are subsets of such representations relating to different self-attributes (like abilities, physical appearance, social status, etc.). In both variants, the term implies that self-concepts are self-representations which are more or less enduring over time, in contrast to situational self-perceptions. The definition is open as to whether these representations refer to factual reality of personal attributes, or to fictitious (e.g., possible or ideal) attributes.

There are two definitional problems which remain conceptually unresolved and impede scientific progress. First, it is unclear whether self-related emotions should be included or not. One may argue that emotions are different from cognition and should be regarded as separate constructs. From such a perspective, (cognitive) self-concepts and (emotional) self-related feelings might be subsumed under umbrella constructs like *self-esteem*, comprising both cognitive and affective facets, but should not be mixed up conceptually. On the other hand, prominent measures of the construct take more integrative perspectives by combining cognitive and affective self-evaluative items. One example are H. Marsh's widely used Self-Description Questionnaires (SDQ: Marsh 1988) measuring academic self-concepts both by cognitive items (e.g., 'I am good at mathematics') and by affective items (e.g., 'I enjoy doing work in mathematics).'

Second, there is no common agreement on the conceptual status of self-related cognitions linking the self to own actions and the environment. An example are self-efficacy beliefs pertaining to own capabilities to be successful in solving specific types of tasks, thus cognitively linking the self (own capabilities) to own actions (task performance) and to environmental demands (a domain of tasks; cf. Pajares 1996; see *Self-efficacy: Educational Aspects*). It may be argued that such self-representations should be regarded as part of a person's self-concept as well. However, terms like self-concept, on the one hand, and self-efficacy beliefs, control beliefs etc., on the other, have been used as if they were relating to conceptually distinct phenomena, and have been addressed by different traditions of research. These research traditions tend to mutually ignore each other in spite of overlapping constructs and parallel findings, implying that more 'cross-talk' among researchers should take place in order to reduce conceptual confusion and the proliferation of redundant constructs which still prevails at the beginning of the twenty-first century (Pajares 1996).

2. Facets and Structures of Self-concepts

Self-related cognitions can refer to different attributes of the self, and can imply descriptive or evaluative perspectives pertaining to the factual or nonfactual (e.g., ideal) reality of these attributes. Research has begun to analyze the structures of these different representational facets.

2.1 Representations of Attributes: Hierarchies of Self-concepts

Self-concepts pertaining to different attributes may vary along two dimensions: the domain of attributes which is addressed, and their generality. It may be theorized that self-concepts are hierarchically organized along these two dimensions in similar ways as semantic memory networks can be assumed to be, implying that more general self-concepts are located at top levels of the self-concept hierarchy, and more specific self-concepts at lower levels. In educational research, the hierarchical model put forward by Shavelson et al. (1976) stimulated studies on facets of self-concepts differing in generality. This model implied that a 'general self-concept' is located at the top of the hierarchy; an 'academic self-concept' pertaining to one's academic capabilities as well as social, emotional, and physical nonacademic self-concepts at the second level; self-concepts relating to different school subjects and to social, emotional, and physical subdomains at the third level; and more specific self-concepts implying evaluations of situation-specific behavior at lower levels.

Studies showed that correlations between academic self-concepts pertaining to different subjects tend to be near zero, in contrast to performance which typically is correlated positively across academic domains. An explanation has been provided by Marsh's internal–external frame of reference model (I/E model) positing that the formation of academic self-concepts may be based on internal standards of comparison implying within-subject comparison of abilities across domains, as well as external standards implying between-

subjects social comparison with other students (Marsh 1986). Applying internal standards may lead to negative correlations between self-concepts pertaining to different domains (e.g., perceiving high ability in math may lead to lowered estimates of verbal abilities, and vice versa). External standards would imply positive correlations since achievement in domains like mathematics and languages is positively correlated across students. The model assumes that students use both types of standards, implying that opposing effects may cancel out. Accordingly, the Shavelson et al. (1976) model has been reformulated by assuming that students hold math-related and verbal-related academic self-concepts, but no general academic self-concept (Marsh and Shavelson 1985).

2.2 *Different Perspectives on Attributes*

Self-representations can imply descriptive as well as evaluative accounts of attributes (e.g., 'I am tall' vs. 'I am an attractive woman'). In academic self-concepts, this distinction may often be blurred because descriptions of academic competence may use comparison information implying some evaluation as well (e.g., 'I am better at math than most of my classmates'). Any subjective evaluation of academic competence may use a number of different standards of evaluation, e.g. (a) social comparison standards and (b) intraindividual comparison across domains as addressed by Marsh's I/E model (see above), as well as (c) intraindividual comparison of current and past competence (implying an evaluation of one's academic development), (d) mastery-oriented comparison relating one's competence to content-based criteria of minimal or optimal performance in an academic domain, and (e) cooperative standards linking individual performance to group performance.

Beyond existing attributes ('real self'), self-representations can pertain to attributes of the self which do not factually exist, but might exist ('possible selves'), are wanted by oneself ('ideal self'), wanted by others ('ought self'), etc. Concepts of nonreal selves may be as important for affect and motivated self-development as concepts of the real self. For example, perceived discrepancies between ideal and real self may be assumed to trigger depressive emotion, whereas discrepancies between ought and real self may give rise to anxiety (Higgins 1987).

3. *Self-concepts and Academic Achievement*

The relation between self-concept and academic achievement is one of the most often analyzed problems in both self-concept and educational research. In the first stage of research on this problem, connections between the two constructs were analyzed by correlational methods based on cross-sectional field studies. Results implied that self-concepts and achievement may be positively linked. However, the magnitude of the correlation proved to depend on the self-concept and achievement constructs used. For example, in the meta-analysis provided by Hansford and Hattie (1982), the average correlation between self-concept and achievement/performance measures was $r = 0.22$ for general self-esteem, and $r = 0.42$ for self-concept of ability. When both self-concepts and achievement are measured in more domain-specific ways, correlations tend to be even higher (e.g., correlations for self-concepts and academic achievement in specific school subjects). This pattern of relations implies that the link gets closer when self-concept and criterion measure are matched, and when both are conceptualized in domain-specific ways.

In the second stage, researchers began to analyze the causal mechanisms producing these relations. From a theoretical perspective, the 'skill development' model maintained that academic self-concepts are the result of prior academic achievement, whereas the 'self-enhancement' approach implied that self-concepts influence students' achievement (cf. Helmke and van Aken 1995). In a number of longitudinal studies, both hypotheses were tested competitively by using cross-lagged panel analysis and structural equations modeling. Results showed that both hypotheses may be valid, thus implying that self-concepts and achievement may be linked by reciprocal causation: Prior academic achievement exerted effects over time on subsequent academic self-concepts, and self-concepts influenced later achievement, although effect sizes for the latter causal path were less strong and consistent (cf. Helmke and van Aken 1995, Marsh and Yeung 1997). This evidence suggests that academic self-concepts are partly based on information about own academic achievement, and may contribute to later academic learning and achievement.

Not much is known about the exact nature of these mechanisms. Investigators have just begun to explore possible mediators and moderators of self-concept/achievement relations. Judging from theory and available evidence, the following may be assumed.

3.1 *Effects of Achievement on Self-concepts*

Academic feedback of achievement (e.g., by grades) may underly the formation of self-representations of academic capabilities. The match between feedback and self-representations may depend on the cumulativeness and consistency of feedback, its salience, the reference norms used, and the degreee of congruency with competing information from parents, peers, or one's past. This implies that the impact of achievement on self-concepts may differ between schools, teachers, and classrooms using different standards and practices

of feedback (cf. Helmke 1992). Finally, beyond exerting effects of academic self-concepts, achievement feedback can be assumed to influence students' general sense of self-worth (Pekrun 1990), thus affecting students' overall psychological health and personality development as well.

3.2 Effects of Self-concepts on Achievement

Self-concepts may influence the formation of self-efficacy and success expectations when being confronted with academic tasks. These expectations may underly academic emotions and motivation, which may in turn influence effort, strategies of learning, and on-task behavior directly affecting learning and performance (Pekrun 1993). Research has shown that self-concepts implying moderate overestimation of own capabilities may be optimal for motivation and learning gains, whereas an underestimation may be rather detrimental. However, self-evaluations precisely reflecting reality may also be suboptimal for learning and achievement, indicating that there may be a conflict between educational goals of teaching students to be self-realistic vs. highly motivated (Helmke 1992).

4. Development of Self-concepts

4.1 Basic Needs Underlying Self-concept Development

Two classes of basic human needs seem to govern the development of self-representations (cf. Epstein 1973). One are general needs for maximizing pleasure and minimizing pain, from which needs for self-enhancement follow, implying motivation to establish and maintain a positive view of the self. The second category comprises needs to perceive reality and foresee the future in such ways that adaptation and survival are possible, thus implying needs for self-perceptions which are consistent with reality, and consistent with each other (needs for consistency). Self-enhancement and consistency may converge when feedback about the self is positive. However, they may be in conflict when feedback is negative: The need for self-enhancement would suggest not accepting negative feedback, whereas needs for reality-oriented consistency would imply endorsing it.

4.2 Developmental Courses across the Life Span

The development of self-concepts is characterized by the interplay of mechanisms driven by these conflicting basic needs. In general, in the absence of strong information about reality, humans tend to overestimate their capabilities in self-enhancing ways. At the same time, they search for self-related information, and tend to endorse this information even if it is negative on condition that such negative information is salient, consistent, and cumulative. For example, it has repeatedly been found that many children entering school drastically overestimate their competences to master academic demands, but adjust their self-evaluations downward when diverging cumulative feedback is given (Helmke 1992). The process of realistically interpreting self-related feedback may be impeded in young children by their lack of sufficiently sophisticated metacognitive competences. Nevertheless, the interplay of beginners' optimism and experts (relative) realism may characterize not only the early elementary years, but later phases of entering new institutions as well (university, marriage, a new job etc.), thus implying a dynamic interplay of self-related optimism and realism across much of the life span.

4.3 Impact of Educational Environments

The influence of social environments was addressed early in the twentieth century by symbolic interactionism postulating that interactions with significant others may shape the development of self-concepts (cf. the concept of the 'looking glass self,' Cooley 1902). Generally, a number of environmental variables may be influential. Self-concepts can develop according to direct attributions of traits and personal worth by other persons on condition that such attributions are consistent with other sources of information and interpreted accordingly. A second source of self-related information are indirect, implicit attributions which are conveyed by others' emotional and instrumental behavior towards the developing person. Of specific importance are acceptance and support by others implying attributions of personal worth, thereby influencing the development of a person's general self-esteem (Pekrun 1990).

Beyond attributions, social environments may define situational conditions for the development of knowledge, skills, motivation, and behavior, which may in turn contribute to self-perceptions of own competences. For example, instruction may build up knowledge and skills influencing knowledge-specific academic self-concepts; support of autonomy may foster the acquisition of self-regulatory abilities and, thereby, the development of related self-concepts of abilities; and consistent behavioral rules may enhance the cognitive predictability of students' environments which may also positively affect their overall sense of competence.

As outlined above, concerning academic self-concepts, feedback of achievement implying information about abilities and effort may be of specific importance, and the effects of such feedback may depend on

the reference norms used. Feedback given according to competitive, interindividually referenced norms implies that the self-concepts of high achievers may benefit, whereas low achievers may have difficulties protecting their self-esteem. In contrast, intraindividual, mastery-oriented and cooperative norms may be better suited to foster low achievers' self-concepts as well. Finally, classroom conditions may also be influential. Specifically, grouping of students may influence students' relative, within-classroom achievement positions, thus affecting their academic self-concepts when competitive standards of grading are used. For example, being in a low-ability class would help an average student to maintain positive academic self-concepts, whereas being in a class of highly gifted students would enforce downward adjustment of self-evaluation ('big-fish-little-pond effect,' Marsh 1987).

5. *Summary of Implications for Educational Practice*

Fostering students' self-concepts may be beneficial for their achievement and personality development. Furthermore, since positive self-esteem may be regarded as a key element of psychological health and well-being, nurturing self-esteem may be regarded as an educational goal which is valuable in itself. From the available research summarized above, it follows that education may contribute substantially to self-concept development. Concerning parents as well as academic institutions like the school, acceptance and support may be of primary importance for the development of general self-esteem. In addition, giving students specific feedback on achievement, traits, and abilities may help in shaping optimistic self-concepts and expectancies which nevertheless are grounded in reality. In designing feedback, it may be helpful to use mastery-oriented, individual, and cooperative reference norms instead of relying on social comparison standards and competitive grading. Furthermore, educational environments may help students' self-concept development by providing high-quality instruction, consistent normative and behavioral structures implying predictability, as well as sufficient autonomy support fostering students' sense of controllability and competence.

Self-conscious Emotions, Psychology of

Shame, guilt, embarrassment, and pride are members of a family of 'self-conscious emotions' that are evoked by self-reflection and self-evaluation. This self-evaluation may be implicit or explicit, consciously ex-

perienced or transpiring beyond our awareness. But either way, the self is the object of self-conscious emotions.

In contrast to 'basic' emotions (e.g., anger, fear, joy) which are present very early in life, self-conscious emotions have been described as 'secondary,' 'derived,' or 'complex' emotions because they emerge later and hinge on several cognitive achievements—recognition of the self separate from others and a set of standards against which the self is evaluated. For example, Lewis et al. (1989) showed that the capacity to experience embarrassment coincides with the emergence of self-recognition. Very young children first show behavioral signs of embarrassment during the same developmental phase (15–24 months) in which they show a rudimentary sense of self. Moreover, within this range, children who display self-recognition (in a 'rouge' test) are the same children who display signs of embarrassment in an unrelated task.

1. Shame and Guilt

The terms 'shame' and 'guilt' are often used interchangeably. When people do distinguish the two, they typically suggest that shame arises from public exposure and disapproval of a failure or transgression, whereas guilt is more 'private,' arising from one's own conscience. Recent empirical research has failed to support this public/private distinction. For example, Tangney et al. (1996) found that people's real-life shame and guilt experiences are each most likely to occur in the presence of others. More important, neither the presence of others nor others' awareness of the respondents' behavior distinguished between shame and guilt. Overall, there are surprisingly few differences in the types of events that elicit shame and guilt. Shame is somewhat more likely in response to violations of social norms, but most types of events (e.g., lying, cheating, stealing, failing to help another) result in guilt for some people and shame for others.

So what is the difference between shame and guilt? Empirical research supports Helen Block Lewis's (1971) notion that shame involves a negative evaluation of the global self, whereas guilt involves a negative evaluation of a specific behavior. This differential emphasis on self ('*I* did that horrible thing') vs. behavior ('I *did* that horrible *thing*') leads to different affective experiences.

Shame is an acutely painful emotion typically accompanied by a sense of shrinking, 'being small,' and by a sense of worthlessness and powerlessness. Shamed people also feel exposed. Although shame doesn't necessarily involve an actual observing audience, there is often the imagery of how one's defective self would appear to others. Not surprisingly, shame often leads to a desire to escape or hide—to sink into the floor and disappear.

In contrast, guilt is typically less painful and devastating because the primary concern is with a specific behavior, not the entire self. Guilt doesn't affect one's core identity. Instead, there is tension, remorse, and regret over the 'bad thing done' and a nagging preoccupation with the transgression. Rather than motivating avoidance, guilt typically motivates reparative action.

1.1 Implications of Shame and Guilt for Interpersonal Adjustment

Research has consistently shown that, on balance, guilt is the more adaptive emotion, benefiting relationships in a variety of ways (Baumeister et al. 1994, Tangney 1995). Three sets of findings illustrate the adaptive, 'relationship-enhancing functions' of guilt, in contrast to the hidden costs of shame.

First, shame typically leads to attempts to deny, hide, or escape; guilt typically leads to reparative action—confessing, apologizing, undoing. Thus, guilt orients people in a more constructive, proactive, future-oriented direction, whereas shame orients people toward separation, distance, and defense.

Second, a special link between guilt and empathy has been observed at the levels of both emotion states and dispositions. Studies of children, college students, and adults (Tangney 1995) show that guilt-prone individuals are generally empathic individuals. In contrast, shame-proneness is associated with an impaired capacity for other-oriented empathy and a propensity for 'self-oriented' personal distress responses. Similar findings are evident when considering feelings of shame and guilt 'in the moment.' Individual differences aside, when people describe personal guilt experiences, they convey greater empathy for others, compared to descriptions of shame experiences. It appears that by focusing on a bad behavior (as opposed to a bad self), people experiencing guilt are relatively free of the egocentric, self-involved focus of shame. Instead, their focus on a specific behavior is likely to highlight the consequences for distressed others.

Third, there is a special link between shame and anger, again observed at both the dispositional and state levels. At all ages, shame-prone individuals are also prone to feelings of anger and hostility (Tangney 1995). Moreover, once angered, they tend to manage their anger in an aggressive, unconstructive fashion. In contrast, guilt is generally associated with constructive means of handling anger. Similar findings have been observed at the situational level, too. In a study of couples' real-life episodes of anger, shamed partners were significantly more angry, more aggressive, and less likely to elicit conciliatory behavior from the offending partner (Tangney 1995). What accounts for this link between shame and anger? When feeling

shame, people initially direct hostility inward ('*I'm* such a bad person'). But this hostility may be redirected outward in a defensive attempt to protect the self by shifting the blame elsewhere ('Oh what a horrible person I am, and damn it, how could you make me feel that way!').

In sum, studies employing diverse samples, measures and methods converge. All things equal, it's better if your friend, partner, child, or boss feels guilt than shame. Shame motivates behaviors that interfere with interpersonal relationships. Guilt helps keep people constructively engaged in the relationship at hand.

1.2 Implications of Shame and Guilt for Psychological Adjustment

Although guilt appears to be the more 'moral' or adaptive emotion when considering social adjustment, is there a trade-off vis-à-vis individual psychological adjustment? Does the tendency to experience guilt or shame leave one vulnerable to psychological problems?

Researchers consistently report a relationship between proneness to shame and a whole host of psychological symptoms, including depression, anxiety, eating disorder symptoms, subclinical sociopathy, and low self-esteem (Harder et al. 1992, Tangney et al. 1995). This relationship is robust across measurement methods and diverse populations.

There is more controversy regarding the relationship of guilt to psychopathology. The traditional view is that guilt plays a significant role in psychological symptoms. Clinical theory and case studies make frequent reference to a maladaptive guilt characterized by chronic self-blame and obsessive rumination over one's transgressions. On the other hand, recent theory and research has emphasized the adaptive functions of guilt, particularly for interpersonal behavior. Tangney et al. (1995) argued that once one makes the critical distinction between shame and guilt, there's no compelling reason to expect guilt over specific behaviors to be associated with poor psychological adjustment.

The empirical research is similarly mixed. Studies employing adjective checklist-type (and other globally worded) measures find both shame-proneness and guilt-proneness correlated with psychological symptoms. On the other hand, measures sensitive to the self vs. behavior distinction show no relationship between proneness to 'shame-free' guilt and psychopathology.

1.3 Development of Guilt Distinct from Shame

The experience of self-conscious emotions requires the development of standards and a recognized self. In addition, a third ability is required to experience guilt (about specific behaviors) independent of shame (about the self)—the ability to make a clear distinction between self and behavior. Developmental research indicates that children do not begin making meaningful distinctions between attributions to ability (enduring characteristics) vs. attributions to effort (more unstable, volitional factors) until about age eight—the same age at which researchers find interpretable differences in children's descriptions of shame and guilt experiences (Ferguson et al. 1991).

2. Embarrassment

Miller (1996) defines embarrassment as 'an aversive state of mortification, abashment, and chagrin that follows public social predicaments' (p. 322). Indeed, embarrassment appears to be the most 'social' of the self-conscious emotions, occurring almost without exception in the company of others.

2.1 Causes of Embarrassment

In Miller's (1996) catalog of embarrassing events described by several hundred adolescents and adults, 'normative public deficiencies' (tripping in front of a large class, forgetting someone's name, unintended bodily induced noises) were at the top of the list. But there were many other types of embarrassment situations—awkward social interactions, conspicuousness in the absence of any deficiency, 'team transgressions' (embarrassed by a member of one's group), and 'empathic' embarrassment.

The diversity of situations that lead to embarrassment has posed a challenge to efforts at constructing a comprehensive 'account' of embarrassment. Some theorists believe that the crux of embarrassment is negative evaluation by others (Edelmann 1981, Miller 1996). This social evaluation account runs into difficulty with embarrassment events that involve no apparent deficiency (e.g., being the center of attention during a 'Happy Birthday' chorus). Other theorists subscribe to the 'dramaturgic' account, positing that embarrassment occurs when implicit social roles and scripts are disrupted. A flubbed performance, an unanticipated belch, and being the focus of 'Happy Birthday' each represent a deviation from accustomed social scripts.

Lewis (1992) distinguished between two types of embarrassment—embarrassment due to exposure and embarrassment due to negative self-evaluation. According to Lewis (1992), embarrassment due to exposure emerges early in life, once children develop a rudimentary sense of self. When children develop standards, rules and goals (SRGs), a second type of embarrassment emerges—'embarrassment as mild shame' associated with failure in relation to SRGs.

2.2 Functions of Embarrassment

Although there is debate about the fundamental causes of embarrassment, there is general agreement about its

adaptive significance. Gilbert (1997) suggests that embarrassment serves an important social function by signaling appeasement to others. When untoward behavior threatens a person's standing in an important social group, visible signs of embarrassment function as a nonverbal acknowledgment of shared social standards, thus diffusing negative evaluations and the likelihood of retaliation. Evidence from studies of both humans and nonhuman primates supports this remedial function of embarrassment (Keltner and Buswell 1997).

2.3 Embarrassment and Shame

Is there a difference between shame and embarrassment? Some theorists essentially equate the two emotions. A more dominant view is that shame and embarrassment differ in intensity of affect and/or severity of transgression. Still others propose that shame is tied to perceived deficiencies of one's core self, whereas embarrassment results from deficiencies in one's presented self.

Recent research suggests that shame and embarrassment are indeed quite different emotions—more distinct, even, than shame and guilt. For example, comparing adults' personal shame, guilt, and embarrassment experiences, Tangney et al. (1996) found that shame was a more intense, painful emotion that involved a greater sense of moral transgression. But controlling for intensity and morality, shame and embarrassment still differed markedly along many affective, cognitive, and motivational dimensions. When shamed, people felt greater responsibility, regret, and self-directed anger. Embarrassment was marked by more humor, blushing, and a greater sense of exposure.

2.4 Individual Differences in Embarrassability

As with shame and guilt, people vary in their propensity to experience embarrassment. These individual differences are evident within the first years of life, and are relatively stable across time. Research has shown that embarrassability is associated with neuroticism, high levels of negative affect, self-consciousness, and a fear of negative evaluation from others. Miller (1996) has shown that this fear of negative evaluation is not due to poor social skills, but rather a heightened concern for social rules and standards.

3. Pride

Of the self-conscious emotions, pride has received the least attention. Most research comes from developmental psychology, particularly in the achievement domain.

3.1 Developmental Issues

There appear to be substantial developmental shifts in the types of situations that induce pride, the nature of the pride experience itself, and the ways in which pride is expressed. For example, Stipek et al. (1992) observed developmental changes in the criteria children use for evaluating success and failure—and in the types of situation that lead to pride. Children under 33 months respond positively to task-intrinsic criteria (e.g., completing a tower of blocks), but they do not seem to grasp the concept of competition (e.g., winning or losing a race to complete a tower of blocks). It is only after 33 months that children show enhanced pride in response to a competitive win.

There are also developmental shifts in the importance of praise from others. Stipek et al. (1992) reported that all children 13–39 months smiled and exhibited pleasure with their successes. But there were age differences in social referencing. As children neared two years of age, they began to seek eye contact with parents upon completing a task, often actively soliciting parental recognition, which in turn enhanced children's pleasure with achievements. Stipek et al. (1992) suggests that the importance of external praise may be curvilinear across the lifespan. Very young children take pleasure in simply having immediate effect on their environment; as they develop self-consciousness (at about two), others' reactions shape their emotional response to success and failure. Still later, as standards become increasingly internalized, pride becomes again more autonomous, less contingent on others' praise and approval.

3.2 Two Types of Pride?

Both Tangney (1990) and Lewis (1992) have suggested that there are two types of pride. Paralleling the self vs. behavior distinction of guilt and shame, Tangney (1990) distinguished between pride in self ('alpha' pride) and pride in behavior ('beta' pride). Similarly, Lewis (1992) distinguished between pride (arising from attributing one's success to a specific action) and hubris (pridefulness arising from attributions of success to the global self). Lewis (1992) views hubris as largely maladaptive, noting that hubristic individuals are inclined to distort and invent situations to enhance the self, which can lead to interpersonal problems.

4. Future Research

Future research will no doubt focus on biological and social factors that shape individual differences in self-conscious emotions. In addition, we need to know more about the conditions under which guilt, shame, pride, and embarrassment are most likely to be adaptive vs. maladaptive. Finally, more cross-cultural research is needed. Kitayama et al. (1995) make the

compelling argument that, owing to cultural differences in the construction of the self, self-conscious emotions may be especially culturally sensitive.

Self-development in Childhood

In addition to domain-specific self-concepts, the ability to evaluate one's overall worth as a person emerges in middle childhood. The level of such global self-esteem varies tremendously across children and is determined by how adequate they feel in domains of importance as well as the extent to which significant others (e.g., parents and peers) approve of them as a person. Efforts to promote positive self-esteem are critical, given that low self-esteem is associated with many psychological liabilities including depressed affect, lack of energy, and hopelessness about the future.

1. Introduction

Beginning in the second year of life toddlers begin to talk about themselves. With development, they come to understand that they possess various characteristics, some of which may be positive ('I'm smart') and some of which may be negative ('I'm unpopular'). Of particular interest is how the very nature of such self-evaluations changes with development as well as among individual children and adolescents across two basic evaluative categories, (a) domain-specific self-concepts, i.e., how one judges one's attributes in particular arenas, e.g., scholastic competence, social (for a complete treatment of self-development in childhood and adolescence, see Harter 1999).

Developmental shifts in the nature of self-evaluations are driven by changes in the child's cognitive capabilities (see *Self-knowledge*: *Philosophical Aspects* and *Self-evaluative Process*, *Psychology of*). Cognitive-developmental theory and findings (see Piaget 1960, 1963, Fischer 1980) alert us to the fact that the young child is limited to very specific, concrete representations of self and others, for example, 'I know my ABCs' (see Harter 1999). In middle to later childhood, the ability to form higher-order concepts about one's attributes and abilities (e.g., 'I'm smart') emerges. There are further cognitive advances at adolescence, allowing the teenager to form abstract concepts about

the self that transcend concrete behavioral manifestations and higher-order generalizations (e.g., 'I'm intelligent').

2. Developmental Differences in Domain-specific Self-concepts

Domain-specific evaluative judgments are observed at every developmental level. However, the precise nature of these judgments varies with age (see Table 1). In Table 1, five common domains in which children and adolescents make evaluate judgments about the self are identified: Scholastic competence, Physical competence, Social competence, Behavioral conduct, and Physical appearance. The types of statements vary, however, across three age periods, early childhood, later childhood, and adolescence, in keeping with the cognitive abilities of each age period.

2.1 Early Childhood

Young children provide very concrete accounts of their capabilities, evaluating specific behaviors. Thus, they communicate how they know their ABCs, how they can run very fast, how they are nice to a particular friend, how they don't hit their sister, and how they possess a specific physical feature such as pretty blond hair. Of particular interest in such accounts is the fact that the young child typically provides a litany of virtues, touting his or her positive skills and attributes. One cognitive limitation of this age period is that the young child cannot distinguish the wish to be competent from reality. As a result, they typically overestimate their abilities because they do not yet have the skills to evaluate themselves realistically. Another cognitive characteristic that contributes to potential distortions is the pervasiveness of all-or-none thinking. That is, evaluations are either all positive or all negative. With regard to self-evaluations, they are typically all positive. (Exceptions to this positivity bias can be observed in children who are chronically abused, since severe maltreatment is often accompanied by parental messages that make the child feel inadequate, incompetent, and unlovable. Such children will also engage in all-or-none thinking but conclude that they are all bad.)

2.2 Middle to Later Childhood

As the child grows older, the ability to make higher-order generalizations in evaluating his or her abilities and attributes emerges. Thus, rather than cite prowess at a particular activity, the child may observe that he or she is good at sports, in general. This inference can further be justified in that the child can describe his or her talent at several sports (e.g., good at soccer, basketball, baseball). Thus, the higher-order generalization represents a cognitive construction in which an over-arching judgment (good at sports) is defined in terms of specific examples which warrant this conclusion. Similar processes allow the older child to conclude that he or she is smart (e.g., does well in math, science, and history). The structure of a higher-order generalization about being well behaved could include such components as obeying parents, not getting in trouble, and trying to do what is right. A generalization concerning the ability to make friends may subsume accounts of having friends at school, making friends easily at camp, and developing friendships readily upon moving to a new neighborhood. The perception that one is good-looking may be based on one's positive evaluation of one's face, hair, and body.

During middle childhood, all-or-none thinking diminishes and the aura of positivity fades. Thus, children do not typically think that they are all virtuous in every domain. The more common pattern is for them to feel more adequate in some domains than others. For example, one child may feel that he or she is good at schoolwork and is well behaved, whereas he or she is not that good at sports, does not think that he or she is good-looking, and reports that it is hard to make friends. Another child may report the opposite pattern.

There are numerous combinations of positive and negative evaluations across these domains that chil-

Table 1
Developmental changes in the nature of self-evaluative statements across different domains

Domains	Early childhood specific behaviors	Later childhood generalizations[a]	Adolescence abstractions[a]
Scholastic competence	I know my A,B,C's	I'm smart in school	I'm intelligent
Athletic competence	I can run very fast	I'm good at sports	I'm athletically talented
Social competence	I'm nice to my friend, Jason	It's easy for me to make friends	I'm popular
Behavioral conduct	I don't hit my sister	I'm well behaved	I think of myself as a moral person
Physical appearance	I have pretty blond hair	I'm good looking	I'm physically attractive

[a]Examples in the table represent positive self-evaluations. However, during later childhood and adolescence, negative judgments are also observed

dren can and do report. Moreover, they may report both positive and negative judgments within a given domain, for example, they are smart in some school subjects (math and science) but 'dumb' in others (english and social studies). Such evaluations may also be accompanied by self-affects that also emerge in later childhood, for example, feeling proud of one's accomplishments but ashamed of one's perceived failures (see also *Self-conscious Emotions*, *Psychology of*). This ability to consider both positive and negative characteristics is a major cognitive–developmental acquisition. Thus, beginning in middle to later childhood, these distinctions result in a profile of self-evaluations across domains.

Contributing to this advance is the ability to engage in social comparison. Beginning in middle childhood one can use comparisons with others as a barometer of the skills and attributes of the self. In contrast, the young child cannot simultaneously compare his or her attributes to the characteristics of another in order to detect similarities or differences that have implications for the self. Although the ability to utilize social comparison information for the purpose of self-evaluation represents a cognitive-developmental advance, it also ushers in new, potential liabilities. With the emergence of the ability to rank-order the performance of other children, all but the most capable children will necessarily fall short of excellence. Thus, the very ability and penchant to compare the self with others makes one's self-concept vulnerable, particularly if one does not measure up in domains that are highly valued. The more general effects of social comparison can be observed in findings revealing that domain-specific self-concepts become more negative during middle and later childhood, compared to early childhood.

2.3 *Adolescence*

For the adolescent, there are further cognitive-developmental advances that alter the nature of domain-specific self-evaluations. As noted earlier, adolescence brings with it the ability to create more abstract judgments about one's attributes and abilities. Thus, one no longer merely considers oneself to be good at sports but to be athletically talented. One is no longer merely smart but views the self more generally as intelligent, where successful academic performance, general problem-solving ability, and creativity might all be subsumed under the abstraction of intelligence. Abstractions may be similarly constructed in the other domains. For example, in the domain of behavioral conduct, there will be a shift from the perception that one is well behaved to a sense that one is a moral or principled person. In the domains of social competence and appearance, abstractions may take the form of perceptions that one is popular and physically attractive.

These illustrative examples all represent positive self-evaluations. However, during adolescence (as well as in later childhood), judgments about one's attributes will also involve negative self-evaluations. Thus, certain individuals may judge the self to be unattractive, unpopular, unprincipled, etc. Of particular interest is the fact that when abstractions emerge, the adolescent typically does not have total control over these new acquisitions, just as when one is acquiring a new athletic skill (e.g., swinging a bat, maneuvering skis), one lacks a certain level of control. In the cognitive realm, such lack of control often leads to overgeneralizations that can shift dramatically across situations or time. For example, the adolescent may conclude at one point in time that he or she is exceedingly popular but then, in the face of a minor social rebuff, may conclude that he or she is extremely unpopular. Gradually, adolescents gain control over these self-relevant abstractions such that they become capable of more balanced and accurate self-representations (see Harter 1999).

3. *Global Self-esteem*

The ability to evaluate one's worth as a person also undergoes developmental change. The young child simply is incapable, cognitively, of developing the verbal concept of his/her value as a person. This ability emerges at the approximate age of eight. However, young children exude a sense of value or worth in their behavior. The primary behavioral manifestations involve displays of confidence, independence, mastery attempts, and exploration (see Harter 1999). Thus, behaviors that communicate to others that children are sure of themselves are manifestations of high self-esteem in early childhood.

At about the third grade, children begin to develop the concept that they like, or don't like, the kind of person they are (Harter 1999, Rosenberg 1979). Thus, they can respond to general items asking them to rate the extent to which they are pleased with themselves, like who they are, and think they are fine, as a person. Here, the shift reflects the emergence of an ability to construct a higher-order generalization about the self. This type of concept can be built upon perceptions that one has a number of specific qualities; for example, that one is competent, well behaved, attractive, etc. (namely, the type of domain-specific self-evaluations identified in Table 1). It can also be built upon the observation that significant others, for example, parents, peers, teachers, think highly of the self. This process is greatly influenced by advances in the child's ability to take the perspective of significant others (Selman 1980). During adolescence, one's evaluation of one's global worth as a person may be further elaborated, drawing upon more domains and sources of approval, and will also become more abstract. Thus, adolescents can directly acknowledge

that they have high or low self-esteem, as a general abstraction about the self (see also *Self-esteem in Adulthood*).

4. Individual Differences in Domain-specific Self-concepts as well as Global Self-esteem

Although there are predictable cognitively based developmental changes in the nature of how most children and adolescents describe and evaluate themselves, there are striking individual differences in how positively or negatively the self is evaluated. Moreover, one observes different profiles of children's perceptions of their competence or adequacy across the various self-concept domains, in that children evaluate themselves differently across domains. Consider the profiles of four different children. One child, Child A, may feel very good about her scholastic performance, although this is in sharp contrast to her opinion of her athletic ability, where she evaluates herself quite poorly. Socially she feels reasonably well accepted by her peers. In addition, she considers herself to be well behaved. Her feelings about her appearance, however, are relatively negative. Child A also reports very high self-esteem. Another child, Child B, has a very different configuration of scores. This is a boy who feels very incompetent when it comes to schoolwork. However, he considers himself to be very competent, athletically, and feels well received by peers. He judges his behavioral conduct to be less commendable. In contrast, he thinks he is relatively good-looking. Like Child A, he also reports high self-esteem.

Other profiles are exemplified by Child C and Child D, neither of whom feel good about themselves scholastically or athletically. They evaluate themselves much more positively in the domains of social acceptance, conduct, and physical appearance. In fact, their profiles are quite similar to each other across the five specific domains. However, judgments of their self-esteem are extremely different. Child C has very high self-esteem whereas Child D has very low self-esteem. This raises a puzzling question: how can two children look so similar with regard to their domain-specific self-concepts but evaluate their global self-esteem so differently? We turn to this issue next, in examining the causes of global self-esteem.

5. The Causes of Children's Level of Self-esteem

Our understanding of the antecedents of global self-esteem have been greatly aided by the formulations of two historical scholars of the self, William James (1892) and Charles Horton Cooley (1902). Each suggested rather different pathways to self-esteem, defined as an overall evaluation of one's worth as a person (see reviews by Harter 1999, Rosenberg 1979). James focused on how the individual assessed his or her competence in domains where one had aspirations to succeed. Cooley focused on the salience of the opinions that others held about the self, opinions which one incorporated into one's global sense of self (see *Self: History of the Concept*).

5.1 Competence–Adequacy in Domains of Importance

For James, global self-esteem derived from the evaluations of one's sense of competence or adequacy in the various domains of one's life relative to how important it was to be successful in these domains. Thus, if one feels one is successful in domains deemed important, high self-esteem will result. Conversely, if one falls short of one's goal in domains where one has aspirations to be successful, one will experience low self-esteem. One does not, therefore, have to be a superstar in every domain to have high self-esteem. Rather, one only needs to feel adequate or competent in those areas judged to be important. Thus, a child may evaluate himself or herself as unathletic; however, if athletic prowess is not an aspiration, then self-esteem will not be negatively affected. That is, the high self-esteem individual can discount the importance of areas in which one does not feel successful.

This analysis can be applied to the profiles of Child C and Child D. In fact, we have directly examined this explanation in research studies by asking children to rate how important it is for them to be successful (Harter 1999). The findings reveal that high self-esteem individuals feel competent in domains they rate as important. Low self-esteem individuals report that areas in which they are unsuccessful are still very important to them. Thus, Child C represents an example of an individual who feels that social acceptance, conduct, and appearance, domains in which she evaluates herself positively, are very important but that the two domains where she is less successful, scholastic competence and athletic competence are not that important. In contrast, Child D rates all domains as important, including the two domains where he is not successful; scholastic competence and athletic competence. Thus, the discrepancy between high importance coupled with perceptions of inadequacy contribute to low self-esteem.

5.2 Incorporation of the Opinions of Significant Others

Another important factor influencing self-esteem can be derived from the writings of Cooley (1902) who metaphorically made reference to the 'looking-glass self' (see Oosterwegel and Oppenheimer 1993). According to this formulation, significant others (e.g., parents and peers) were social mirrors into which one gazed in order to determine what they thought of the

Figure 1
Findings on how competence in domains of importance and social support combine to predict global self-esteem

self. Thus, in evaluating the self, one would adopt what one felt were the judgments of these others whose opinions were considered important. Thus, the approval, support, or positive regard from significant others became a critical source of one's own sense of worth as a person. For example, children who receive approval from parents and peers will report much higher self-esteem than children who experience disapproval from parents and peers.

Findings reveal that both of these factors, competence in domains of importance and the perceived support of significant others, *combine* to influence a child's or adolescent's self-esteem. Thus, as can be observed in Fig. 1, those who feel competent in domains of importance and who also report high support, rate themselves as having the highest self-esteem. Those who feel inadequate in domains deemed important and who also report low levels of support, rate themselves as having the lowest self-esteem. Other combinations fall in between (data from Harter 1993).

6. Conclusions

Two types of self-representations that can be observed in children and adolescents were distinguished, evaluative judgments of competence or adequacy in specific domains and the global evaluation of one's worth as a person, namely overall self-esteem. Each of these undergoes developmental change based on age-related cognitive advances. In addition, older children and adolescents vary tremendously with regard to whether self-evaluations are positive or negative. Within a given individual, there will be a profile of self-evaluations, some of which are more positive and some more negative. More positive self-concepts in domains considered important, as well as approval from significant others, will lead to high self-esteem. Conversely, negative self-concepts in domains considered important, coupled with lack of approval from significant others, will result in low self-esteem. Self-esteem is particularly important since it is associated with very important outcomes or consequences. Perhaps the most well-documented consequence of low self-esteem is depression. Children and adolescents (as well as adults) with the constellation of causes leading to low self-esteem will invariably report that they feel depressed, emotionally, and are hopeless about their futures; the most seriously depressed consider suicide. Thus, it is critical that we intervene for those experiencing low self-esteem. Our model of the causes of self-esteem suggests strategies that may be fruitful, for example, improving skills, helping individuals discount the importance of domains in which it is unlikely that they can improve, and providing support in the form of approval for who they are as people. Future research, however, is necessary to determine the different pathways to low and high self-esteem. For example, for one child, the sense of inadequacy in particular domains may be the pathway to low self-esteem. For another child, lack of support from parents or peers may represent the primary cause. Future efforts should be directed to the identification of these different pathways since they have critical implications for intervention efforts to enhance feelings of worth for those children with low self-esteem (see also *Self-concepts*: *Educational Aspects*). Positive self-esteem is clearly a psychological commodity, a resource that is important for us to foster in our children and adolescents if we want them to lead productive and happy lives.

Self-efficacy

Self-efficacy refers to the individual's capacity to produce important effects. People who are aware of being able to make a difference feel good and therefore take initiatives; people who perceive themselves as helpless are unhappy and are not motivated for actions. This article treats the main concepts related to self-efficacy, their theoretical and historical contexts, their functions and practical uses, as well as developmental and educational/therapeutic aspects.

1. Concepts

Everything that happens is caused to happen (Aristotle). Making changes means being a cause or providing a cause that produces a change. As the true causes are difficult to identify, the terms *conditions* and *contingencies* are often used instead. An effect is contingent upon a condition or a set of conditions if it always occurs if the condition or the set of conditions is met. Such conditions are sufficient but not necessary for producing the effect.

Here we are interested in human actions as necessary conditions of change (see *Motivation and Actions, Psychology of*). Actions, too, depend on conditions. Considering person-related conditions of effective actions, we can differentiate aspects like knowledge, initiative, perseverance, intelligence, experience, physical force, help from others, and more. Thus, instead of saying that an actor is able to produce a certain effect, we can say more elaborately that an actor is endowed with certain means or conditions that enable him or her to attain certain goals (Fig. 1).

We say that individuals (or groups) are in *control* of a specific goal if they are able to produce the corresponding changes (horizontal line of Fig. 1). More elaborately, they are in control of a specific goal if they are aware of the necessary *contingencies* and if they are *competent* enough to make these contingencies work (both diagonal lines in Fig. 1). Control is complete if these contingencies are necessary and sufficient; control is partial if the contingencies are necessary but not sufficient. Instead of control, Bandura (1977) introduced the word *efficacy*, more specifically *self-efficacy*. We use control and self-efficacy interchangeably.

Figure 1
Means–ends relations and agency as components of control (adapted from Skinner et al. 1988 and Flammer 1990)

Controlling means putting control into action. This is not equivalent to having control or being in control: People are in control of certain states of affairs, if they can put control into action, even if they do not. For example, somebody has control over buying a new bicycle, even if he or she does not buy it.

People can have control over certain events without knowing it; they will then probably miss possible chances to activate such control. On the other hand, people may believe that they have some control, but in fact do not. That may make them feel good as long as there is no need to put this control into work. Obviously, it is important that people do not only have control, but that they also know that they have control. Not being in control of an important situation is equivalent to being helpless in this respect (Seligman 1975). It has been proved that the psychological effects of helplessness (HL) are different depending on whether the helpless person believes themself to be helpless for ever (chronic HL), whether being helpless is unique (personal vs. universal HL), and whether helplessness is related to a specific domain or to most domains of life (specific vs. global HL). In the worst case, helpless people are (a) deeply sad about not having control, (b) demotivated to take initiatives or to invest effort and perseverance, (c) cognitively blind for any alternative or better view of the state of the world, and (d) devaluate themselves.

Obviously, at least in subjectively important domains, we prefer self-efficacy to helplessness: self-efficacy beliefs provide us with security and pride. When we lack self-efficacy in important domains we either strive for self-efficacy (by fighting, learning, or training) or search for compensation. A common type of compensation consists of seeking help or delegating personal control (= *indirect control* or *proxy control*), e.g., to pay a gardener caring for one's garden or to put a doctor in charge with one's health or to pray to God for a favor in a seemingly hopeless situation. Another way of compensating lacking (primary) control is to use *secondary control* (Rothbaum et al. 1982). While control (i.e., primary control) consists of making the

world fit with one's goals and aspirations, secondary control accommodates personal aspirations or personal interpretations of the actual state in order to make them fit with the world (see *Coping across the Lifespan*).

2. *History of the Concept of Self-efficacy*

In the 1950s, Rotter (1954) suggested the concept *locus of control*, meaning the place where control of desired reinforcement for behavior is exerted. Internal control means control within the person, external control means control outside the person, possibly in powerful others, in objective external conditions, or in chance or luck. Rotter and his associates have developed valid measuring instruments that have been used in thousands (!) of studies demonstrating that internal locus of control is positively correlated with almost all desirable attributes of humans.

Fritz Heider (1944) who studied the subjective attributions for observed actions had already suggested the concepts of internality and externality. The true origin, i.e., the 'cause' of an observed action, is either attributed to the person (internal, personal liability) or to person-independent conditions (external, no personal liability). Heider's work has triggered a large research tradition on causal attributions. Results of this research were of use for successful differentiations of subjective interpretations concerning experiences of helplessness (see above; see also *Attributional Processes: Psychological*). Consequently, attribution theory remains an important element of self-efficacy theory.

Modern self-efficacy theory goes beyond Rotter's theory insofar as it is more differentiated (e.g., contingency vs. competence, primary vs. secondary), distinctively referred to specific domains of actions (e.g., health, school), and elaborated to also include aspects other than personality (e.g., motivation, development).

3. *Self-efficacy as an Important Element of a Happy and Successful Person*

Individuals with high self-efficacy beliefs also report strong feelings of well-being and high self-esteem in general (Bandura 1997, Flammer 1990). They are willing to take initiative in related domains, to apply effort if needed, and persevere in efforts as long as they believe in their efficacy. Potentially stressful situations produce less subjective stress in highly self-efficient individuals. However, while self-efficacy acts as a buffer against stress, it can also—indirectly—produce stress insofar as it can induce overly ambitious individuals to assume more responsibilities than they are able to cope with in sheer quantity.

Moreover, self-efficacy has been reported to exert a positive influence on recovery from surgery or illness and on healthy lifestyles. It is not surprising that high self-efficacy beliefs enhance school success; likewise, school failure inhibits relative self-efficacy beliefs, again partly depending on the individual's attributional patterns. Interestingly, it has been demonstrated repeatedly and in several cultures that in most domains healthy and happy individuals tend to slightly overestimate themselves. Realistic estimation of self-efficacy is rather typical for persons vulnerable to depressed mood, and clear underestimation increases the chance for a clinical (reactive) depression. On the other hand, major overestimation might result in painful and harmful clashes with reality.

4. *The Development of Self-efficacy Beliefs*

Evidently, the newborn baby does not have self-efficacy beliefs in our sense. The basic structure of the self-efficacy beliefs develops within the first three or four years. According to Flammer's (1995) analysis, the infant's development towards the basic understanding of self-efficacy proceeds through a developmental sequence consisting of the acquisition of (a) the basic event schema (i.e., that classes of events happen), (b) the elementary causal schema (conditions, i.e., actions, events), (c) the understanding of personally producing effects, (d) the understanding of success and failure in aiming at nontrivial goals (visible as pride and as shame, respectively), and (e) the discovery of being not only the origin of one certain change but also capable of producing such changes.

Obviously, this development proceeds in domains that are accessible by the infant so far. Later on, this development will have to be extended to further domains. As to the domain of school success, within the second half of the first decade of life, the child learns more and more differentiations of means towards the same ends. Thus, he or she gradually abandons a *global concept* of simply being or not being able and singles out—probably in this sequence—the factor *effort* (more effort is needed to solve tasks—a typical lesson to be learned early in school), the factors individual ability and task difficulty (higher difficulty requiring more ability), and finally the understanding of the compensatory relation between effort and ability (it is possible to reach the same goals by being less capable but more hard-working).

In adolescence and early adulthood more lessons have to be learned. More and more domains become accessible to personal control due to increased cognitive, physical, or economic strength and social power. This is exciting, indeed. However, individuals have permanently to select from the choices which are offered to them (Flammer 1996). Trying to control everything results in overburdening. One thing is to deselect control domains because they compete with higher priority control domains; another thing is to be forced to renounce control because no accessible

contingencies seem to exist. As long as there are enough attractive alternatives available, it is not painful, but it can severely hurt handicapped individuals and old people when they lose control of important domains. Old people are well advised both not to resign too early and to search for compensations. Such compensations consists of artifacts of all kinds (from memory aids to hearing aids), but they also include the above mentioned compensations like indirect control (social resources) and secondary control. Indeed, it seems that the extent and the importance of secondary control increases with the lifetime (Heckhausen and Schulz 1995). Under certain conditions, Baltes and Silverberg (1994) have even suggested that people in old people's homes adjust better if in certain domains they give up personal control at all. Alluding to the concept of learned helplessness, they called such behavior *learned dependency*. Learned dependency helps to avoid certain social conflicts; the only remaining personal control may be the control of giving in.

5. *Educational and Therapeutic Aspects*

According to the development of the basic structure of self-efficacy, contingent behavior by the caregivers is crucial already within the first weeks of life. Caregivers' behavior should be predictable, i.e., contingent at least upon the baby's actual behavior, and as far as ever possible upon the baby's perceptions, feelings, and intentions. This requires an enormous potential of sensitivity towards the child. Fortunately, researchers have demonstrated that parental empathy is partly a natural gift with the majority of attentive parents. Studies have shown that contingent behavior fosters children's happiness, but also their willingness to learn and their curiosity. If caregivers are judged as not reacting contingently enough, we also have to consider that some babies show quite unorganized behavior and make the caregiver's task very difficult ('difficult babies'). In such cases it is difficult to decide whether the noncontingency has originated from the caregiver or from the baby.

The subsequent steps in the development of self-efficacy require that caregivers provide freedom for experimentation, let the child try by himself or herself, and comment on the successes and failures in a way that the child can establish and maintain confidence in his or her efficacy (Schneewind 1995). Nevertheless, caregivers should try to prevent the child from dangerous and frequent hopeless experiences. Psychotherapy with individuals who have severely undermined self-efficacy beliefs is difficult. Teaching and trying to convince them that they are really capable even when they believe not to be does not help much. Helping them to recall from memory prior success experiences instead of being impressed by failures only is more efficient. Even more efficient are new and successful experiences. Helpless individuals not only interpret failures to their disadvantage, they also play down their contribution to eventual success. Parallel to these findings, memory research has demonstrated that depressed people's memories of own actions are biased towards recalling more of their failures than their own success.

This leaves us with an important contrast: while children and healthy adults tend to overestimate their self-efficacy, individuals who have lost confidence in themselves immunize such devastating beliefs by not trying anymore, by self-damaging attributions, and by recalling their biography in a way that is consistent with their beliefs. Given the pervasive influence of positive beliefs in self-efficacy, it is important to help individuals with establishing and maintaining self-efficacy beliefs at a high level, and to guide failure-expecting persons to positive experiences.

6. *Conclusion*

Within the last decades, theory and research have established self-efficacy beliefs as important elements in the understanding of human action and human well-being in a very large sense. However, little is known so far about differences in self-efficacy beliefs in different life domains and among different cultures. Further research should include more systematic comparisons between cultures, between life domains, and—if possible—between historical times. In addition, it is suggested that in the future investigators consider more seriously the fact that all changes are due to a multitude of necessary conditions. More specifically, there is a need for researchers to consider the efficacy and efficacy-beliefs of interacting people, that is, to examine concepts such as shared control or 'common efficacy.'

Self-efficacy and Health

The quality of human health is heavily influenced by lifestyle habits. By exercising control over several health habits people can live longer healthier and slow the process of aging (see *Control Beliefs: Health Perspectives*). Exercise, reduce dietary fat, refrain from smoking, keep blood pressure down, and develop effective ways of coping with stressors. If the huge health benefits of these few lifestyle habits were put into a pill it would be declared a spectacular breakthrough in the field of medicine. The recent years have witnessed a major change in the conception of human health and illness from a disease model to a health model. It is just as meaningful to speak of levels of vitality as of degrees of impairment. The health model, therefore, focuses on health promotion as well as disease prevention. Perceived self-efficacy plays a key role in the self-management of habits that enhance health and those that impair it.

1. *Perceived Self-efficacy*

Perceived self-efficacy is concerned with people's beliefs in their capabilities to exercise control over their own functioning and over environmental events. Such beliefs influence what courses of action people choose to pursue, the goals they set for themselves and their commitment to them, how much effort they put forth in given endeavors, how long they persevere in the face of obstacles and failure experiences, their resilience to adversity, whether their thought patterns are self-hindering or self-aiding, how much stress and depression they experience in coping with taxing environmental demands, and the level of accomplishments they realize (Bandura 1997, Schwarzer 1992).

In social cognitive theory, perceived self-efficacy operates in concert with other determinants in regulating lifestyle habits. They include the positive and negative outcomes people expect their actions to produce. These outcome expectations may take the form of aversive and pleasurable physical effects, approving and disapproving social reactions, or self-evaluative consequences expressed as self-satisfaction and self-censure. Personal goals, rooted in a value system, provide further self-incentives and guides for health habits. The perceived sociostructural facilitators and impediments operate as another set of determinants of health habits.

Self-efficacy is a key determinant in the causal structure because it affects health behavior both directly, and by its influence on these other determinants. The stronger the perceived efficacy, the higher the goal challenges people set for themselves, the more they expect their efforts to produce desired outcomes, and the more they view obstacles and impediments to personal change as surmountable.

There are two major ways which a sense of personal efficacy affects human health. At the more basic level, such beliefs activate biological systems that mediate health and disease. The second level is concerned with the exercise of direct control over habits that affect health and the rate of biological aging.

2. *Impact of Efficacy Beliefs on Biological Systems*

Stress is an important contributor to many physical dysfunctions (O'Leary 1990). Perceived controllability appears to be the key organizing principle in explaining the biological effects of stress. Exposure to stressors with the ability to exercise some control over them has no adverse physical effects. But exposure to the same stressors without the ability to control them impairs immune function (Herbert and Cohen 1993b, Maier et al. 1985). Epidemiological and correlational studies indicate that lack of behavioral or perceived control over stressors increases susceptibility to bacterial and viral infections, contributes to the development of physical disorders and accelerates the rate of progression of disease (Schneiderman et al. 1992).

In social cognitive theory, stress reactions arise from perceived inefficacy to exercise control over aversive threats and taxing environmental demands (Bandura 1986). If people believe they can deal effectively with potential stressors, they are not perturbed by them. But, if they believe they cannot control aversive events, they distress themselves and impair their level of functioning. Perceived inefficacy to manage stressors activates autonomic, catecholamine and opioid systems that modulate the immune system in ways that

can increase susceptibility to illness (Bandura 1997, O'Leary 1990).

The immunosuppressive effects of stressors is not the whole story, however. People are repeatedly bombarded with taxing demands and stressors in their daily lives. If stressors only impaired immune function people would be highly vulnerable to infective agents that would leave them chronically bedridden with illnesses or quickly do them in. Most human stress is activated while competencies are being developed and expanded. Stress aroused while gaining a sense of mastery over aversive events strengthens components of the immune system (Wiedenfeld et al. 1990). The more rapid the growth of perceived coping efficacy, the greater the boost of the immune system. Immunoenhancement during development of coping capabilities vital to effective adaptation has evolutionary survival value.

The field of health functioning has been heavily preoccupied with the physiologically debilitating effects of stressors. Self-efficacy theory also acknowledges the physiologically strengthening effects of mastery over stressors. As Dienstbier (1989) has shown, a growing number of studies is providing empirical support for physiological toughening by successful coping.

Depression is another affective pathway through which perceived coping efficacy can affect health functioning. It has been shown to reduce immune function, and to heighten susceptibility to disease (Herbert and Cohen 1993a). The more severe the depression, the greater the reduction in immunity. Perceived self-efficacy to exercise control over things one values highly produces bouts of depression (Bandura 1997).

Social support reduces vulnerability to stress, depression, and physical illness. But social support is not a self-forming entity waiting around to buffer harried people against stressors. People have to go out and find, create, and maintain supportive relationships for themselves. This requires a robust sense of social efficacy. Perceived social inefficacy contributes to depression both directly, and by curtailing development of social supports (Holahan and Holahan 1987). Social support, in turn, enhances perceived self-efficacy. Mediational analyses show that social support alleviates depression and fosters health-promoting behavior only to the extent that it boosts personal efficacy.

3. *Self-efficacy in Promoting Healthful Lifestyles*

Lifestyle habits can enhance or impair health (see *Health Behaviors*). This enables people to exert some behavioral control over their vitality and quality of health. Efficacy beliefs affect every phase of personal change: whether people even consider changing their health habits; whether they enlist the motivation and perseverance needed to succeed should they choose to do so; and how well they maintain the habit changes they have achieved (Bandura 1997).

3.1 *Initiation of Change*

People's beliefs that they can motivate themselves and regulate their own behavior play a crucial role in whether they even consider changing detrimental health habits. They see little point in even trying if they believe they do not have what it takes to succeed. If they make an attempt, they give up easily in the absence of quick results or setbacks. Among those who change detrimental health habits on their own, the successful ones have stronger perceived self-efficacy at the outset than nonchangers and subsequent relapsers.

Efforts to get people to adopt healthful practices rely heavily on persuasive communications in health education campaigns. Health communications foster adoption of healthful practices mainly by raising beliefs in personal efficacy, rather than by transmitting information on how habits affect health, by arousing fear of disease, or by increasing perception of one's personal vulnerability or risk (Meyerowitz and Chaiken 1987). To help people reduce health-impairing habits requires a change in emphasis, from trying to scare people into health, to enable them with the skills and self-beliefs needed to exercise control over their health habits. In community-wide health campaigns, people's pre-existing beliefs that they can exercise control over their health habits, and the efficacy beliefs enhanced by the campaign, both contribute to health-promoting habits (Maibach et al. 1991).

3.2 *Adoption of Change*

Effective self-regulation of health behavior is not achieved through an act of will. It requires development of self-regulatory skills. To build people's sense of efficacy, they must develop skills on how to influence their own motivation and behavior. In such programs, they learn how to monitor their health behavior and the social and cognitive conditions under which they engage in it; set attainable subgoals to motivate and guide their efforts; draw from an array of coping strategies rather than rely on a single technique; enlist self-motivating incentives and social supports to sustain the effort needed to succeed; and apply multiple self-influence consistently and persistently (Bandura 1997, Perri 1985). Once equipped with skills and belief in their self-regulatory capabilities, people are better able to adopt behaviors that promote health, and to eliminate those that impair it. A large body of evidence

reveals that the self-efficacy belief system operates as a common mechanism through which psychosocial treatments affect different types of health outcomes (Bandura 1997, Holden 1991).

3.3 Maintenance of Change

It is one thing to get people to adopt beneficial health habits. It is another thing to get them to adhere to them. Maintenance of habit change relies heavily on self-regulatory capabilities and the functional value of the behavior. Development of self-regulatory capabilities requires instilling a resilient sense of efficacy as well as imparting skills. Experiences in exercising control over troublesome situations serve as efficacy builders. Efficacy affirmation trials are an important aspect of self-management because, if people are not fully convinced of their personal efficacy, they rapidly abandon the skills they have been taught when they fail to get quick results or suffer reverses. Like any other activity, self-management of health habits includes improvement, setbacks, plateaus, and recoveries. Studies of refractory detrimental habits show that a low sense of efficacy increases vulnerability to relapse (Bandura 1997, Marlatt et al. 1995). To strengthen resilience, people need to develop coping strategies not only to manage common precipitants of breakdown, but to reinstate control after setbacks. This involves training in how to manage failure (see *Health: Self-regulation*).

4. Self-management Health Systems

Healthcare expenditures are soaring at a rapid rate. With people living longer and the need for healthcare services rising with age, societies are confronted with major challenges on how to keep people healthy throughout their lifespan, otherwise they will be swamped with burgeoning health costs. Health systems generally focus heavily on the supply side with the aim of reducing, rationing, and curtailing access to health to contain health costs. The social cognitive approach works on the demand side by helping people to stay healthy through good self-management of health habits. This requires intensifying health promotion efforts and restructuring health delivery systems to make them more productive.

Efficacy-based models have been devised combining knowledge of self-regulation of health habits with computer-assisted implementation that provides effective health-promoting services in ways that are individualized, intensive and highly convenient (DeBusk et al. 1994). In this type of self-management system, people monitor their health habits. They set short-term goals for themselves and receive periodic feedback of progress towards their goals along with guides on how to manage troublesome situations. Efficacy ratings identify areas in which self-regulatory skills must be developed and strengthened if beneficial changes are to be achieved and maintained. The productivity of the system is vastly expanded by combining self-regulatory principles with the power of computer-assisted implementation. A single implementer, assisted with a computerized coordinating and mailing system, provides intensive individualized training in self-management for large numbers of people simultaneously. The self-management system reduces health risk factors, improves health status, and enhances the quality of life in cost-effective ways (Bandura 1997).

The self-management system is well received by participants because it is individually tailored to their needs, provides continuing personalized guidance and informative feedback that enables them to exercise considerable control over their own change; is a home-based program that does not require any special facilities, equipment, or attendance at group meetings that usually have high dropout rates; serves large numbers of people simultaneously under the guidance of a single implementer; is not constrained by time and place; and provides valuable health-promotion services at low cost. By combining the high individualization of the clinical approach with the large-scale applicability of the public health approach, the self-management system includes the features that ensure high social utility. Linking the interactive aspects of the self-management model to the Internet can vastly expand its availability for preventive and promotive guidance.

Chronic disease has become the dominant form of illness and the major cause of disability. The treatment of chronic disease must focus on self-management of physical conditions over time rather than on cure. This requires, among other things, pain amelioration, enhancement and maintenance of functioning with growing physical disability and development of self-regulative compensatory skills. Holman and Lorig (1992) have devised a prototypical model for the self-management of different types of chronic diseases. Patients are taught cognitive and behavioral pain control techniques; proximal goal setting combined with self incentives as motivators to increase levels of activity; problem solving and self-diagnostic skills; and the ability to locate community resources and to manage medication programs. How healthcare systems deal with clients can alter their efficacy in ways that support or undermine their restorative efforts. Clients are, therefore, taught how to take greater initiative for their healthcare in dealings with health personnel. These skills are developed through modeling of self-management skills, guided mastery practice, and enabling feedback.

The self-management program retards the biological progression of the disease, raises perceived self-regulatory efficacy, reduces pain and distress, fosters better cognitive symptom management, lessens the

impairment of role functions, improves the quality of life, and decreases the use of medical services. Both the perceived self-efficacy at the outset, and the efficacy beliefs instilled by the self-management program predict later health status and functioning (Holman and Lorig 1992).

5. *Childhood Health Promotion Models*

Many of the lifelong habits that jeopardize health are formed during childhood and adolescence (see *Childhood Health*). For example, unless youngsters take up the smoking habit as teenagers they rarely become smokers in adulthood. It is easier to prevent detrimental health habits than to try to change them after they have become deeply entrenched as part of a lifestyle. The biopsychosocial model provides a valuable public health tool for societal efforts to promote the health of its youth.

Health habits are rooted in familial practices. But, schools have a vital role to play in promoting the health of a nation. This is the only place where all children can be easily reached so it provides a natural setting for promoting healthful habits and building self-management skills.

Effective health promotion models include several major components. The first component is informational. It informs people of the health risks and benefits of different lifestyle habits. The second component develops the social and self-regulative skills for translating informed concerns into effective preventive action. As noted earlier, this includes self-monitoring of health practices, goal setting, and enlistment of self-incentives for personal change. The third component builds a resilient sense of self-regulatory efficacy to support the exercise of control in the face of difficulties that inevitably arise. Personal change occurs within a network of social influences. Depending on their nature, social influences can aid, retard, or undermine efforts at personal change. The final component, therefore, enlists and creates social supports for desired changes in health habits (see *Social Support and Health*).

Educational efforts to promote the health of youth usually produce weak results. They are heavy on didactics but meager on personal enablement. They provide factual information about health, but do little to equip children with the skills and self-beliefs that enable them to manage the emotional, and social pressures to adopt detrimental health habits. Managing health habits involves managing emotional states and diverse social pressures for unhealthy behavior not just targeting a specific health behavior for change.

Health promotion programs that encompass the essential elements of the self-regulatory model prevent or reduce injurious health habits. Health knowledge can be conveyed readily, but changes in values, attitudes, and health habits require greater effort. The more behavioral mastery experiences provided in the form of role enactments, the greater the beneficial changes (Bruvold 1993). The more intensive the program and the better the implementation, the stronger the impact (Connell et al. 1985). Comprehensive approaches that integrate guided mastery health programs with family and community efforts are more successful in promoting health and preventing adoption of detrimental health habits, than are programs in which the schools try to do it alone (Perry et al. 1992).

6. *Efficacy Beliefs in Prognostic Judgment and Health Outcomes*

Much of the work in the health field is concerned with diagnosing maladies, forecasting the likely course of different physical disorders and prescribing appropriate remedies. Medical prognostic judgments involve probabilistic inferences from knowledge of varying quality and inclusiveness about the multiple factors governing the course of a given disorder. One important issue regarding medical prognosis concerns the scope of determinants included in a prognostic model. Because psychosocial factors account for some of the variability in the course of health functioning, inclusion of self-efficacy determinants in prognostic models enhances their predictive power (Bandura 2000).

Recovery from medical conditions is partly governed by social factors. Recovery from a heart attack provides one example. About half the patients who experience heart attacks have uncomplicated ones. Their heart heals rapidly, and they are physically capable of resuming an active life. But the psychological and physical recovery is slow for those patients who believe they have an impaired heart. The recovery task is to convince patients that they have a sufficiently robust heart to resume productive lives. Spouses' judgments of patients' physical and cardiac capabilities can aid or retard the recovery process (see *Social Support and Recovery from Disease and Medical Procedures*). Programs that raise and strengthen spouses' and patients' beliefs in their cardiac capabilities enhance recovery of cardiovascular capacity (Taylor et al. 1985). The couple's joint belief in the patients' cardiac efficacy is the best predictor of improvement in cardiac functioning. Those who believe that their partners have a robust heart are more likely to encourage them to resume an active life than those who believe their partner's heart is impaired and vulnerable to further damage. Pursuit of an active life strengthens the cardiovascular system.

Prognostic judgments are not simply inert forecasts of a natural course of a disease. Prognostic expectations can affect patients' beliefs in their physical efficacy. Therefore, diagnosticians not only foretell,

but may partly influence the course of recovery from disease. Prognostic expectations are conveyed to patients by attitude, word, and the type and level of care provided them. People are more likely to be treated in enabling ways under positive than under negative expectations. Differential care that promotes in patients different levels of personal efficacy and skill in managing health-related behavior can exert stronger impact on the trajectories of health functioning than simply conveying prognostic information. Prognostic judgments have a self-confirming potential. Expectations can alter patients' sense of efficacy and behavior in ways that confirm the original expectations. The self-efficacy mechanism operates as one important mediator of self-confirming effects.

7. *Socially Oriented Approaches to Health*

The quality of health of a nation is a social matter not just a personal one. It requires changing the practices of social systems that impair health rather than just changing the habits of individuals. Vast sums of money are spent annually in advertising and marketing products and promoting lifestyles detrimental to health. With regard to injurious environmental conditions, some industrial and agricultural practices inject carcinogens and harmful pollutants into the air we breathe, the food we eat, and the water we drink, all of which take a heavy toll on health. Vigorous economic and political battles are fought over environmental health and where to set the limits of acceptable risk.

We do not lack sound policy prescriptions in the field of health. What is lacking is the collective efficacy to realize them. People's beliefs in their collective efficacy to accomplish social change by perseverant group action play a key role in the policy and public health approach to health promotion and disease prevention (Bandura 1997, Wallack et al. 1993). Such social efforts take a variety of forms. They raise public awareness of health hazards, educate and influence policymakers, devise effective strategies for improving health conditions, and mobilize public support to enact policy initiatives.

While concerted efforts are made to change socio-structural practices, people need to improve their current life circumstances over which they command some control. Psychosocial models that work best in improving health and preventing disease promote community self-help through collective enablement (McAlister et al. 1991). Given that health is heavily influenced by behavioral, environmental, and economic factors, health promotion requires greater emphasis on the development and enlistment of collective efficacy for socially oriented initiatives.

Self-efficacy: Educational Aspects

Current theoretical accounts of learning and instruction postulate that students are active seekers and processors of information (Pintrich et al. 1986). Research indicates that students' cognitions influence the instigation, direction, strength, and persistence of achievement behaviors (Schunk 1995).

This article reviews the role of one type of personal cognition: self-efficacy, or one's perceived capabilities for learning or performing behaviors at designated levels (Bandura 1997). The role of self-efficacy in educational contexts is discussed to include the cues that students use to appraise their self-efficacy. A model of the operation of self-efficacy is explained, along with some key findings from educational research. The entry concludes by describing the role of teacher efficacy and suggesting future research directions.

1. *Self-efficacy Theory*

Self-efficacy can affect choice of activities, effort, persistence, and achievement (Bandura 1997, Schunk 1991). Compared with students who doubt their learning capabilities those with high self-efficacy for accomplishing a task participate more readily, work harder, persist longer when they encounter difficulties, and demonstrate higher achievement.

Learners acquire information to appraise self-efficacy from their performance accomplishments, vicarious (observational) experiences, forms of persuasion, and physiological reactions. Students' own performances offer reliable guides for assessing efficacy. Successes raise self-efficacy and failures lower it, but once a strong sense of self-efficacy is developed a failure may not have much impact (Bandura 1986).

Learners also acquire self-efficacy information from knowledge of others through classroom social comparisons. Similar others offer the best basis for comparison. Students who observe similar peers perform a task are apt to believe that they, too, are capable of accomplishing it. Information acquired vicariously typically has a weaker effect on self-efficacy than performance-based information because the former can be negated easily by subsequent failures.

Students often receive persuasive information from teachers and parents that they are capable of performing a task (e.g., 'You can do this'). Positive feedback enhances self-efficacy, but this increase will be temporary if subsequent efforts turn out poorly. Students also acquire efficacy information from physiological reactions (e.g., heart rate, sweating). Symptoms signaling anxiety might be interpreted to mean that one lacks skills.

Information acquired from these sources does not automatically influence self-efficacy; rather, it is cognitive appraised (Bandura 1986). In appraising efficacy, learners weigh and combine perceptions of their ability, the difficulty of the task, the amount of effort expended, the amount of external assistance received, the number and pattern of successes and failures, similarity to models, and credibility of persuaders (Schunk 1991).

Self-efficacy is not the only influence in educational settings. Achievement behavior also depends on knowledge and skills, outcome expectations, and the perceived value of outcomes (Schunk 1991). High self-efficacy does not produce competent performances when requisite knowledge and skills are lacking. Outcome expectations, or beliefs concerning the probable outcomes of actions, are important because students strive for positive outcomes. Perceived value of outcomes refers to how much learners desire certain outcomes relative to others. Learners are motivated to act in ways that they believe will result in outcomes they value.

Self-efficacy is dynamic and changes as learning occurs. The hypothesized process whereby self-efficacy operates during learning is as follows (Schunk 1996). Students enter learning situations with varying degrees of self-efficacy for learning. They also have goals in mind, such as learning the material, working quickly, pleasing the teacher, and making a high grade. As they engage in the task, they receive cues about how well they are performing, and they use these cues to assess

their learning progress and their self-efficacy for continued learning. Perceived progress sustains motivation and leads to continued learning. Perceptions of little progress do not necessarily diminish self-efficacy if learners believe they know how to perform better, such as by working harder, seeking help, or switching to a more effective strategy (Schunk 1996).

2. *Factors Affecting Self-efficacy*

There are many instructional, social, and environmental factors that operate during learning. Several of these factors have been investigated to determine how they influence learners' self-efficacy. For example, research has explored the roles of goal setting, social modeling, rewards, attributional feedback, social comparisons, progress monitoring, opportunities for self-evaluation of progress, progress feedback, and strategy instruction (Schunk 1995).

As originally conceptualized by Bandura, self-efficacy is a domain-specific construct. Self-efficacy research in education has tended to follow this guidance and assess students' self-efficacy within domains at the level of individual tasks. In mathematics, for example, students may be shown sample multiplication problems and for each sample judge their confidence for solving similar problems correctly. Efficacy scales typically are numerical and range from low to high confidence. After completing the efficacy assessment students are presented with actual problems to solve. These achievement test problems corresponding closely to those on the self-efficacy test, although they are not identical. Such specificity allows researchers to relate self-efficacy to achievement to determine correspondence and prediction (Pajares 1996). Other measures often collected by self-efficacy researchers include persistence, motivation, and self-regulation strategies. Following a pretest, students receive instruction complemented by one or more of the preceding educational variables. After the instruction is completed students receive a post-test; in some studies follow-up maintenance testing is done.

A general finding from much educational self-efficacy research is that educational variables influence self-efficacy to the extent that they convey to learners information about their progress in learning (Schunk 1995). For example, much research shows that specific proximal goals raise self-efficacy, motivation, and achievement better than do general goals (Schunk 1995). Short-term specific goals provide a clear standard against which to compare learning progress. As learners determine that they are making progress, this enhances their self-efficacy for continued learning. In contrast, assessing progress against a general goal (e.g., 'Do your best') is difficult; thus, learners receive less clear information about progress, and self-efficacy is not strengthened as well.

3. *Predictive Utility of Self-efficacy*

Self-efficacy research has examined the relation of self-efficacy to such educational outcomes as motivation, persistence, and achievement (Pajares 1996). Significant and positive correlations have been obtained across many studies between self-efficacy assessed prior to instruction and subsequent motivation during instruction. Initial judgments of self-efficacy have been found also to correlate positively and significantly with post-test measures of self-efficacy and achievement collected following instruction.

Multiple regression has been used to determine the percentage of variability in skillful performance accounted for by self-efficacy. Schunk and Swartz (1993) found that post-test self-efficacy was the strongest predictor of children's paragraph writing skills. Shell et al. (1989) found that although self-efficacy and outcome expectations predicted reading and writing achievement, self-efficacy was the strongest predictor.

Several studies have tested causal models. Schunk (1981) employed path analysis to reproduce the correlation matrix comprising long-division instructional method, self-efficacy, persistence, and achievement. The best model showed a direct effect of method on achievement and an indirect effect through persistence and self-efficacy, an indirect effect of method on persistence through self-efficacy, and a direct effect of self-efficacy on persistence and achievement. Schunk and Gunn (1986) found that the largest direct influence on achievement was due to use of effective learning strategies; achievement also was heavily influenced by self-efficacy.

4. *Teacher Self-efficacy*

Self-efficacy is applicable to teachers as well as students. Ashton and Webb (1986) postulated that self-efficacy should influence teachers' activities, efforts, and persistence. Teachers with low self-efficacy may avoid planning activities that they believe exceed their capabilities, may not persist with students having difficulties, may expend little effort to find materials, and may not reteach content in ways students might better understand. Teachers with higher self-efficacy might develop challenging activities, help students succeed, and persevere with students who have trouble learning. These motivational effects enhance student learning and substantiate teachers' self-efficacy by suggesting that they can help students learn.

Correlational data show that self-efficacy is related to teaching behavior. Ashton and Webb (1986) found that teachers with higher self-efficacy were likely to have a positive classroom environment (e.g., less student anxiety and teacher criticism), support students' ideas, and meet the needs of all students. High teacher self-efficacy was positively associated with use of praise, individual attention to students, checking on

students' progress in learning, and their mathematical and language achievement. Tschannen-Moran et al. (1998) discuss teacher self-efficacy in greater depth.

5. Future Research Directions

The proliferation of self-efficacy research in education has enlightened understanding of the construct but also has resulted in a multitude of measures. In developing efficacy assessments it is imperative that researchers attempt to be faithful to Bandura's (1986) conceptualization of self-efficacy as a domain-specific measure. Research will benefit from researchers publishing their instruments along with validation data to include reliability and validity.

As self-efficacy research continues in settings where learning occurs, it will be necessary to collect longitudinal data showing how self-efficacy changes over time as a consequence of learning. This focus will require broadening of self-efficacy assessments from reliance on numerical scales to qualitative data. Researchers also should relate measures of teacher self-efficacy to those of student self-efficacy to test the idea that these variables reciprocally influence one another.

Finally, research is needed on the role of self-efficacy during self-regulation. Self-regulation refers to self-generated thoughts and actions that are systematically oriented toward attainment of one's learning goals (Zimmerman 1990). Self-efficacy has the potential to influence many aspects of self-regulation, yet to date only a few areas have been explored in research. This focus will become more critical as self-regulation assumes an increasingly important role in education.

Self-esteem in Adulthood

Self-esteem refers to a global judgment of the worth or value of the self as a whole (similar to self-regard, self-respect, and self-acceptance), or to evaluations of specific aspects of the self (e.g., appearance self-esteem or academic self-esteem). The focus of this article is on global self-esteem, which has distinct theoretical importance and consequences (Baumeister 1998, Rosenberg et al. 1995). Although thousands of studies of self-esteem have been published (Mruk 1995), many central questions about the nature, functioning, and importance of global self-esteem remain unresolved (Baumeister 1998).

1. The Importance of Self-esteem

Global self-esteem is a central aspect of the subjective quality of life. It is related strongly to positive affect and life satisfaction (Diener 1984), less anxiety (Solomon et al. 1991), and fewer depressive symptoms (Crandall 1973). High and low levels of self-esteem appear to be associated with different motivational orientations. High self-esteem people focus on self-enhancement and 'being all that they can be,' whereas low self-esteem people focus on self-protection and avoiding failure and humiliation (Baumeister et al. 1989). Low self-esteem has been proposed as a cause of many social problems, such as teenage pregnancy, aggression, eating disorders, and poor school achievement. However, evidence that low self-esteem is a cause, rather than a symptom, of these problems is scarce (Baumeister 1998, Dawes 1994, Mecca et al. 1989), and some researchers have suggested that high

self-esteem may actually be the cause of social problems such as aggression (Baumeister 1998). Because of unresolved issues regarding the nature and functioning of self-esteem and how to measure it, firm conclusions about whether high self-esteem is or is not socially useful seem premature.

2. Issues in the Self-esteem Literature

2.1 Trait or State?

Psychologists assume typically that self-esteem is a psychological trait (i.e., that it is stable over time and across situations). In support of this view, self-esteem tends to be highly stable over long periods of time (see, e.g., Rosenberg 1979). Self-esteem is also a state, however, changing in response to events and experiences in the course of life (Heatherton and Polivy 1991). James (1890) suggested that self-esteem has qualities of both a state and a trait, rising and falling in response to achievements and setbacks relevant to one's aspirations. On the other hand, he recognized that people tend to have average levels of self-esteem that are not linked directly to their objective circumstances. Although research supports James' intuition, for some people self-esteem is relatively stable and trait-like across time, whereas for others it is more state-like, fluctuating daily (Kernis and Waschull 1995).

2.2 Affect or Cognitive Judgment?

Researchers disagree about whether self-esteem is fundamentally a feeling or a judgment about the self. Global self-esteem and mood are correlated strongly, leading some to conclude that affect is a component of self-esteem (e.g., Brown 1993, Pelham and Swann 1989). Others argue that self-esteem is a cognitive judgment, based on standards of worth and accessible information about how well an individual is meeting those standards (see, e.g., Moretti and Higgins 1990). Current mood may be one source of information on which judgments of self-worth are based (Schwarz and Strack 1999). It seems likely that the relationship between self-esteem and mood is complex: both mood and self-esteem may be affected independently by life events; mood may be a source of information on which judgments of self-esteem are based; and mood may also be a consequence of having high or low self-esteem.

2.3 Where Does Self-esteem Come From?

Why are some people high and others low in self-esteem? James (1890) suggested that global self-esteem is determined by successes divided by pretensions, or how well a person is doing in areas that are important. Although it might seem logical that high self-esteem results from success in life (e.g., being smart, attractive, wealthy, and popular), these objective outcomes are related only weakly to self-esteem. For example, socioeconomic status (Twenge and Campbell 1999), physical attractiveness as rated by observers (Diener et al. 1995, Feingold 1992), obesity (Miller and Downey 1999), school achievement (Rosenberg et al. 1995), and popularity (Wylie 1979) are related only weakly to global self-esteem. A stronger relationship is observed between global self-esteem and how well people *believe* they are doing in important domains, but the direction of this relationship is unclear. Believing one is doing well in important domains might cause high self-esteem, or people may think they are doing well because they have high self-esteem. Experimental studies have demonstrated that specific self-evaluations are sensitive to manipulated success or failure, but evidence that global self-esteem responds to such feedback is very scarce (Blascovich and Tomaka 1991).

Mead (1934) and Cooley (1902) proposed that self-esteem develops in social relationships. Cooley (1902) argued that subjectively-interpreted feedback from others is a main source of information about the self. The self-concept arises from imagining how others perceive and evaluate the self. These 'reflected appraisals' affect self-perceptions and self-evaluations, resulting in what Cooley (1902) described as the 'looking glass self.' Mead (1934) argued that the looking glass self is a product of, and essential to, social interaction. To interact smoothly and effectively with others, people need to anticipate how others will react to them, and so they need to learn to see themselves through the eyes of others, either the specific people with whom they interact, or a generalized view of how most people see the self, or a 'generalized other.' Research indicates that self-esteem is related only weakly to others' evaluations of the self, but is related strongly to beliefs about others' evaluations (Shrauger and Schoeneman 1979). Evidence regarding the causal direction of this effect is scarce.

A third view, which can encompass these others, is that self-esteem is a judgment of self-worth constructed on the basis of information and standards for the self that are available and accessible at the moment. People may differ in the self-standards that are chronically accessible to them (see, e.g., Higgins 1987). For example, some people may judge their self-worth chronically according to whether they are competent in important domains, whereas others judge their self-worth chronically according to whether others approve of them (Crocker and Wolfe 2001). In this view, self-esteem will be stable over time if the standards used to evaluate the self and information about how well an individual is doing relative to those standards are stable. When circumstances make alternative standards salient, or alter beliefs about how well the

individual is doing relative to those standards, then self-esteem changes (Crocker 1999, Quinn and Crocker 1999).

2.4 Defensive or Genuine?

Genuine self-esteem is usually assumed to be synonymous with self-worth, self-respect, and self-acceptance, despite awareness of one's flaws and shortcomings. Yet, many studies have demonstrated that people who are high in self-esteem are more likely to make excuses for failure, derogate others when threatened, and have unrealistically positive views of themselves (see Baumeister 1998, Blaine and Crocker 1993, Taylor and Brown 1988 for reviews), behaviors which appear to be quite defensive. These findings have fueled the suspicion that many people who are outwardly high in self-esteem inwardly harbor serious doubts about their self-worth, and have defensive, rather than genuinely high, self-esteem. Although the distinction between genuine and defensively high self-esteem has a long history in psychology, researchers have had little success at distinguishing these two types of high self-esteem empirically.

One view is that implicit, or nonconscious, evaluations of the self are dissociated from conscious self-evaluations (see, e.g., Greenwald and Banaji 1995). According to this view, genuine high self-esteem results from having high explicit (conscious) and implicit (nonconscious) self-esteem, whereas defensively high self-esteem results from having high explicit self-esteem and low implicit self-esteem. A measure of implicit self-esteem based on the Implicit Associations Test (Greenwald et al. 1998) shows the predicted dissociation between implicit and explicit measures, but to date research has not demonstrated that defensive behaviors such as blaming others for failure are associated uniquely with the combination of high explicit and low implicit self-esteem. Another view is that people who have stable high self-esteem are relatively nondefensive in the face of failure, whereas people with unstable high self-esteem are both defensive and hostile when they fail (see Kernis and Waschull 1995 for a review). According to Kernis and his colleagues, people with unstable high self-esteem have a high level of ego-involvement in everyday events, consequently their self-esteem is at stake even when relatively minor negative events occur. Considerable evidence has accumulated supporting the view that people with unstable high self-esteem are defensive, whereas people with stable high self-esteem are not. Crocker and Wolfe (2001) argue that instability of self-esteem results when outcomes in a person's life are relevant to their contingencies, or conditions, of self-worth. Consequently, Crocker and Wolfe argue that people are defensive when they receive negative or threatening information in domains in which their self-esteem is contingent. To date, however, they have not provided empirical support for their view.

In general, the issue of defensive vs. genuine self-esteem has focused attention on dimensions of self-esteem that go beyond whether it is high or low. This broader perspective on multiple dimensions of self-esteem might help resolve several issues in the self-esteem literature (Crocker and Wolfe 2001). For example, the role of self-esteem in social problems such as substance abuse and eating disorders may be linked to instability or contingencies of self-esteem as well as, or instead of, level of self-esteem.

2.5 A Cultural Universal?

Psychologists have long assumed that there is a universal need to have high self-esteem. Consistent with this view, most people have high self-esteem, and will go to great lengths to achieve, maintain, and protect this. Yet, almost all of this research has been conducted in a North American cultural context, leaving open the possibility that the need for high self-esteem is a culturally specific phenomenon (see Heine et al. 1999 for a review). Levels of self-esteem in Asians are related to how much time they have spent in the USA or Canada (Heine et al. 1999). Furthermore, Asians and Asian-Americans, on average, do not show the same self-enhancing tendencies so characteristic of North Americans. Heine et al. argue that there are fundamental cultural differences in the nature and importance of self-esteem. Taking Japan as an example, they argue that, whereas in the USA and Canada people are self-enhancing and motivated to achieve, maintain, and protect high self-esteem, in Japan people are self-critical and motivated to improve the self. This self-critical orientation in Japan, they argue, is adaptive in a culture that values self-criticism and self-improvement, and considers them to be evidence of commitment to the group. Consequently, in contrast to North America, self-criticism may lead to positive self-feelings resulting from living up to cultural standards that value self-criticism. The notion that the need for self-esteem and the motivation to self-enhance are not universal is a crucial development in self-esteem research.

3. Measurement of Self-esteem

In 1974, Wylie reviewed research on self-esteem and criticized researchers for developing idiosyncratic measures of self-esteem, rather than well-established, psychometrically valid and reliable instruments. Although measurement of self-esteem has improved somewhat since Wylie's critique (see Blascovich and Tomaka 1991 for a review), there remains a tendency

for researchers to develop idiosyncratic measures for particular studies. Issues in the measurement of self-esteem tend to reflect issues in its conceptualization. Measures of trait self-esteem assess global judgments of self-worth, self-respect, or self-regard that encourage respondents to consider how they usually or generally evaluate themselves (see, e.g., Rosenberg 1965), or assess evaluations of the self in several domains and create a composite score, on the assumption that such a composite is an indicator of global self-esteem (see, e.g., Coopersmith 1967). Measures of state self-esteem, on the other hand, focus on how the person feels at a specific moment in time. Some state measures assess momentary evaluations of the self in one or more domains such as appearance or performance (see, e.g., Heatherton and Polivy 1991). Others assess current mood or self-related affect with self-ratings on items such as feeling proud, important, and valuable (see, e.g., Leary et al. 1995). Both types of state self-esteem measures appear to be responsive to positive and negative events. Researchers interested in state self-esteem tend not to measure momentary or current self-worth, self-regard, or self-respect (i.e., global state self-esteem). Consequently, studies of state self-esteem and studies of trait self-esteem tend to measure different constructs, making results across these types of studies difficult to compare.

4. Future Directions

Several important issues remain to be addressed by research. First, additional progress is needed in measurement and conceptualization of self-esteem, and in identifying and validating different types of self-esteem (e.g., defensive vs. genuine, implicit vs. explicit, stable vs. unstable, and contingent vs. noncontingent). Possible cultural and subcultural differences in the nature and functioning of self-esteem are a very important area needing further exploration. Only after progress has been made in these areas will researchers be able to provide definitive answers to questions about the social importance of self-esteem.

Self-evaluative Process, Psychology of

This article explores some of the processes associated with evaluative response to one's own self. Evaluation refers to a response registering the idea/feeling that some aspect of one's world is good or bad, likeable or dislikable, valuable or worthless. It is one of our most fundamental psychological responses. Indeed, research on the psychology of meaning has revealed that evaluation is the single most important aspect of meaning. Evaluative responses are fast; there is evidence that we have an evaluation of some things even before we are completely able to recognize them. Evaluative responses are sometimes automatic—we do not set out to make them and we often cannot turn them off. Moreover, evaluation often colors our interpretation of situations. For example, ambiguous actions of people we like are interpreted more benevolently than the same actions of people we do not like. An evaluative response attached to the self is often termed self-esteem and we will use the terms self-esteem and self-evaluation interchangeably.

1. *Individual Differences in Self-evaluation*

There are literally thousands of studies reported since the 1950s measuring self-esteem and comparing persons who are high with persons who are low on this dimension (see *Self-esteem in Adulthood*). Most frequently, self-esteem is assessed by self-report. One of the most popular measures (Rosenberg 1965) consists of ten items like 'I am a person of worth' followed by a series of graded response options, e.g., strongly agree, agree, disagree, strongly disagree. Such measures have proven to be reliable and valid. However, they are subject to the same general criticisms of any self-report measure: Scores can be distorted by the tendency to agree with an item regardless of its content and the tendency to try to create a favorable impression. Moreover, there may be aspects of one's self-evaluation that are not easily accessible to conscious awareness. To address some of these concerns 'implicit' measures of self-esteem are currently being explored (Greenwald and Banaji 1995). Most of these measures work by priming the self, i.e., making the self salient, and then measuring the impact of self-salience on other evaluative responses. For example, when the self is primed, the more positive the self-evaluation the faster one should be in making other positive evaluative judgments. As of this writing, implicit measures of self-evaluation show great promise but it is still unclear what impact such measures will have on our ultimate understanding of self-evaluation.

Individual differences in self-evaluation have been associated with a variety of psychological traits. For example, compared to persons with low self-esteem, persons with high self-esteem tend to achieve more in school, be less depressed, better adjusted, less socially anxious and more satisfied with life, etc. Going through this research almost leads one to draw the conclusion that all the good things in life are positively associated with self-esteem. Indeed, the intuition that high self-esteem is good is so compelling that the state of California even put together a task force to promote self-esteem. There are, of course, many arguments for the positive impact of self-esteem. However, most of

the studies rely on correlational methods. Correlational methodology makes it difficult to know if self-esteem is a cause or an effect of these other variables. For example, it may be that high self-esteem leads to school achievement but it may also be that school achievement improves self-esteem. It may also be that the correlation between achievement and self-esteem is not causal at all; each may be caused by the same third variable, e.g., general health.

Recent research is beginning to correct the simple view of self-esteem as always 'good.' For example, it may be persons who are high in self-esteem rather than persons who are low in self-esteem that are most likely to be aggressive (Baumeister et al. 1996). Why? Persons high in self-esteem have more to lose when confronted by failure or a personal affront. Related to this suggestion is the observation that self-esteem may be stable in some persons but unstable in others. Stability of self-esteem is consequential (Kernis and Waschull 1995). Persons whose self-esteem is high on the average but whose self-evaluation fluctuates over time score higher on a hostility measure than persons who are high in self-esteem but whose self-evaluation is stable. Perhaps it is persons who aspire to feel positive about themselves but are unsure of themselves that tend to fluctuate in their self-evaluation and to respond aggressively to threats to self-esteem.

2. *Self Motives*

The idea that persons strive to maintain a positive self-evaluation is obvious. It is not difficult to notice that people respond positively to success and compliments and negatively to failure and insults. They tend to seek out persons who respect their accomplishments and situations in which they can do well. In spite of the obviousness and ubiquity of a self-enhancement motive, at least two other motives have captured some research attention. One is the motive for self-knowledge, i.e., a self-assessment motive, and the other is a consistency or self-verification motive.

Feeling good about ourselves can take us only so far. It is also important to have accurate knowledge about the self. Leon Festinger (1954) suggested that we have a drive to evaluate our abilities and opinions. Indeed, we seem to be fascinated by information about ourselves. We want to know what others think of us. We go to psychotherapists to learn more about ourselves. We are even curious about what the stars have to say about our lives (note the popularity of horoscopes). Systematic research has varied the diagnosticity of experimental tasks, i.e., the extent to which we believe the task is truly revealing of our abilities. Under some conditions, for example, when certainty is low or when we are in a particularly good mood, we prefer diagnostic feedback to flattering feedback. Thus, there is evidence for the self-assessment motive.

Another motive that has received some research attention is the tendency to verify one's current view of the self (Swann 1990). According to this point of view, people are motivated to confirm their self-view. They will seek out persons and situations that provide belief consistent feedback. If a person has a positive view of self, he or she will seek out others who also evaluate them positively and situations in which they can succeed. Note that this is exactly the same expectation that could be derived from a self-enhancement point of view. However, self-verification and self-enhancement predictions diverge when a person has a negative view of self. The self-verification hypothesis predicts that persons with a negative self-view will seek out others who also perceive them negatively and situations that will lead to poor performance. There is some evidence for the self-verification prediction. On the other hand, neither the self-assessment motive nor the self-verification motive appears to be as robust as the self-enhancement motive (Sedikides 1993).

3. *Self-enhancement*

As noted above, self-enhancement processes are frequent, easy to observe, and robust. William James and a host of contemporary workers have focused on particular mechanisms by which self-evaluation is affected. For example, James suggests that threats to self-esteem are stronger if they involve abilities on which the self has 'pretensions' or aspires to do well. Others have noted that feelings of success and failure that affect self-evaluation often come from comparison with other persons. Still other investigators have shown the impact of self-enhancement on cognition. For example, the kinds of causal attributions people make for their own successes and failures are often self-serving. Persons tend to locate the causes of success internally (due to my trying, ability) and the causes of failure externally (due to bad luck, task difficulty). The self-enhancement mechanisms proposed in the psychological literature have been so numerous and so diverse that the collection of them has sometimes been dubbed the 'self zoo.' However, three general classes of mechanism encompass many of the proposed self-enhancement/protection mechanisms: Social comparison, inconsistency reduction, and value expression.

3.1 *Social Comparison*

One large class of self-enhancement mechanisms concerns social comparisons. The Self-Evaluation Maintenance (SEM) model (Tesser 1988), for example, proposes that when another person does better than we do at some activity, our own self-evaluation is affected. The greater our '*closeness*' to the other person

(through similarity, contiguity, personal relationship, etc.) the greater the effect on our self-evaluation. Being outperformed by another can lower self-evaluation by inviting unflattering self-comparison, or it can raise self-evaluation, a kind of 'basking in reflected glory'. (Examples of basking are seen in statements like, 'That's my friend Bob, the best widget maker in the county.') The *relevance*of the performance domain determines the relative importance of these opposing processes. If the performance domain is important to one's self-definition, i.e., high relevance, then the comparison process will be dominant. One's self-evaluation will be threatened by a close other's better performance. If the performance domain is unimportant to one's self-definition, i.e., low relevance, then the reflection process will be dominant. One's self-evaluation will be augmented by a close other's better performance. Thus, combinations of relative performance, closeness and relevance, are the antecedents of self-esteem threat or enhancement.

The assumption that people are motivated to protect or enhance self-evaluation, combined with the sketch of how another's performance affects self-evaluation, provides the information needed to predict self-evaluation maintenance behavior. An example: Suppose Nancy learns that she made a B+ on the test. The only other person from Nancy's dormitory in this chemistry class, Kaela, made an A+. This should be threatening to Nancy: Kaela outperformed her; Kaela is psychologically close (same dormitory); and chemistry is high in relevance to Nancy who is studying to be a doctor. What can Nancy do to reduce this threat and maintain a positive self-evaluation? She can change the performance differential by working harder herself or by preventing Kaela from doing well, e.g., hide the assignments, put the wrong catalyst in Kaela's beaker. She can reduce her psychological connection to Kaela, e.g. change dorms and avoid the same classes. Alternatively, she can convince herself that this performance domain is not self-relevant, e.g., chemistry is not highly relevant to the kind of medicine in which she is most interested. Laboratory experiments have produced evidence for each of these modes of dealing with social comparison threat to self-evaluation.

3.2 Cognitive Consistency

The number of variations within this approach to self-evaluation regulation is also substantial. An example of this approach is cognitive dissonance theory (Festinger 1957). According to dissonance theory, self-esteem is threatened by inconsistency. Holding beliefs that are logically or 'psychologically' inconsistent, i.e., dissonant, with one another is uncomfortable. For example, suppose a student agrees to a request to write an essay in favor of a tuition increase at her school. Her knowledge that she is opposed to a tuition increase is dissonant with her knowledge that she agreed to write an essay in favor of a tuition increase. One way to reduce this threatening dissonance is for the student to change her attitude to be more in favor of a tuition increase.

Note that social comparison mechanisms and consistency reduction mechanisms are both self-enhancement strategies, yet they seem to have little in common. Threat from dissonance rarely has anything to do with the performance of another, i.e., social comparison. Similarly, inconsistency is generally irrelevant to an SEM threat, whereas other's performance is crucial. Attitude change is the usual mode of dissonance threat reduction; on the other hand, changes in closeness, performance, or relevance are the SEM modes.

3.3 Value Expression

The notion that expressing one's most cherished values can affect self-esteem also has a productive history in social psychology. Simply expressing who we are, affirming our important values seems to have a positive effect on self-evaluation. According to self-affirmation theory (e.g., Steele 1988), self-evaluation has at its root a concern with a sense of global self-integrity. Self-integrity refers to holding self conceptions and images that one is 'adaptively and morally adequate, that is, as competent, good, coherent, unitary, stable, and capable of free choice, capable of controlling important outcomes, and so on' (Steele 1988, p. 262). If the locus of a threat to self-esteem is self-integrity then the behavior to reduce that threat is self-affirmation or a declaration of the significance of an important self-value. Again, note that as a self-enhancement strategy, affirming a cherished value is qualitatively different from the SEM behaviors of changing closeness, relevance or performance or the dissonance behavior of attitude change.

3.4 Putting It All Together

We have briefly described three classes of self-enhancement mechanisms: Social comparison, cognitive consistency and value expression. Each of these mechanisms is presumed to regulate self-evaluation, yet they are strikingly different from one another. These differences raise the question of whether self-evaluation is a unitary system or whether there are three (or more) independent self-evaluation systems. The goal of the self-enhancement motive is to maintain positive self-esteem. If there is a unitary self-evaluation system, the various self-evaluation mechanisms should substitute for one another. For example, if behaving inconsistently reduces self-evaluation then a positive social comparison experience, being part of the same

system, should be able to restore self-evaluation. On the other hand, if there are separate self-evaluation systems then a positive social comparison experience will not be able to restore a reduction in self-evaluation originating with inconsistent behavior. One would have to reduce the inconsistency to restore one's self-evaluation. Recent research favors the former interpretation. At least under certain circumstances, the three self-enhancement mechanisms are mutually substitutable for one another in maintaining self-evaluation. In short, self-evaluation appears to be a unitary system with multiple processes for regulating itself (Tesser et al. 1996).

4. *The Origins of Self-evaluation*

Psychologists have only recently begun to think about the origins of the self-enhancement motive. One line of research suggests that the self-enhancement motive grows out of an instinct for self-preservation coupled with knowledge of our own mortality. Although we as individuals may not live on, we understand that the culture of which we are a part does live on. 'Immortality' comes from our connection with our culture. Self-evaluation is a psychological indicator of the extent to which we are connected and acceptable to our culture and, hence, an index of our own 'immortality' (Pysczynski et al. 1997). Another line of work builds on the observation that evolution has predisposed us to be social, gregarious animals who are highly dependent on group living. We wish to maintain a positive self-esteem because self-esteem is a kind of 'sociometer' that indicates the extent to which we are regarded positively or negatively by others (Leary et al. 1995). Also taking an evolutionary perspective, the SEM model builds on the sociometer idea in two ways. It suggests that groups differ in the power they have to affect self-esteem. Compared to psychologically distant groups, psychologically close groups are typically more consequential to our well being and they have greater impact on our self-esteem. The SEM model also suggests that division of labor is fundamental to groups to maximize efficiency and to avoid conflict. Consequently, self-evaluation is more sensitive to feedback regarding the self's own niche in the group. See Beach and Tesser (in press) for discussion.

5. *Summary*

Self-evaluation has a productive history in psychology. Individual differences in self-esteem tend to be correlated with a number of positive attributes such as school achievement, general happiness, and lack of depression. There is a strong tendency for people to maintain a positive self-esteem but there is also evidence of motives for self-accuracy and for self-verification. At least three processes affect self-evaluation: social comparison, cognitive consistency, and value expression. Although these processes are qualitatively different from one another, they are substitutable for one another in maintaining self-esteem. Self-enhancement is thought to have evolutionary roots in the individual's connections to groups.

Self-fulfilling Prophecies

A self-fulfilling prophecy occurs when an originally false social belief leads to its own fulfillment. The self-fulfilling prophecy was first described by Merton (1948), who applied it to test anxiety, bank failures, and discrimination. This article reviews some of the controversies surrounding early self-fulfilling prophecy research, and traces how those controversies have led to modern research on relations between social beliefs and social reality.

Self-fulfilling prophecies did not receive much attention until Rosenthal and Jacobson's (1968) Pygmalion study. Teachers were led to believe that randomly selected students would show dramatic increases in IQ over the school year. Results seemed to show that, especially in the earlier grade levels, those students gained more in IQ than other students. Thus, the teachers' initially false belief that some students would show unusual IQ gains became true.

1. *Controversy, Replication, and Meta-analysis*

Rosenthal and Jacobson's study (1968) was highly controversial. Although it seemed to explain the low achievement of disadvantaged students, it was criticized on methodological and statistical grounds. This controversy inspired attempts at replication. Only about one third of these early attempts succeeded (Rosenthal and Rubin 1978). Critics concluded that the phenomenon was unreliable. Proponents concluded that this demonstrated the existence of self-fulfilling prophecies because, if chance differences were occurring, replications would only succeed 5 percent of the time.

This controversy inspired Rosenthal's work on meta-analysis—statistical techniques for summarizing the results of multiple studies. Rosenthal and Rubin's (1978) meta-analysis of the first 345 studies of interpersonal expectancy effects conclusively demonstrated that self-fulfilling prophecies are a real and reliable phenomenon. That meta-analysis also showed that they were neither pervasive (nearly two-thirds of the studies failed to find the effect) nor powerful (effect sizes, in terms of correlation or regression coefficients, averaged 0.2–0.3).

This, however, did not end the controversy. Although few modern researchers dispute the existence of self-fulfilling prophecies in general, several do dispute the claims that teacher expectations influence student *intelligence* (Snow 1995). For example, Snow (1995) concluded that: (a) the expectancy effect disappears if one removes five students with implausible IQ increases (100 points within one year) from the Rosenthal and Jacobson (1968) study, and (b) the literature fails to demonstrate an effect of teacher expectations on IQ.

2. *Self-fulfilling Stereotypes*

Some researchers saw in self-fulfilling prophecies an explanation for social inequalities. Thus, in the 1970s, research began addressing the self-fulfilling effects of stereotypes. The main ideas were that; if most stereotypes were inaccurate and if self-fulfilling prophecies were common and powerful (as was believed) then negative stereotypes regarding intelligence, achievement, motivation, etc., may produce self-fulfilling prophecies that lead individuals from devalued groups to objectively confirm those stereotypes.

The early experimental research seemed to support this perspective:

(a) White interviewers' racial stereotypes could undermine the performance of Black interviewees.

(b) Males acted more warmly towards, and evoked warmer behavior from, female interaction partners erroneously believed to be more physically attractive.

(c) When interacting with a sexist male who was either physically attractive or who was interviewing them for a job, women altered their behavior to appear more consistent with traditional sex stereotypes.

(d) Teachers used social class as a major basis for expectations and treated students from middle class backgrounds more favorably than students from lower class backgrounds (see reviews by Jussim et al. 1996 and Snyder 1984).

3. *Widespread Acceptance and More Questions*

The role of self-fulfilling prophecies, however, in creating social problems remained unclear because many of the early self-fulfilling prophecy experiments suffered important limitations. In most, if the expectancy manipulation was successful, perceivers developed erroneous expectations. However, under naturalistic conditions perceivers may develop accurate expectations, which, by definition, do not create self-fulfilling prophecies (because self-fulfilling prophecies begin with an initially false belief). Three categories of research have addressed the limitations of the early experiments in different ways.

3.1 *Naturalistic Studies of Teacher Expectations*

Longitudinal, quantitative investigations of naturally occurring teacher expectancies addressed the accuracy problem directly. All assessed relations between

teacher expectations and students' past and future achievement. If teacher expectations predicted future achievement beyond effects accounted for by students' past achievement, results were interpreted as providing evidence consistent with self-fulfilling prophecies. These studies also provided data capable of addressing two related questions:

(a) How large are naturally occurring teacher expectation effects?

(b) Do teacher expectations predict students' achievement more because they create self-fulfilling prophecies or more because they are accurate?

The results were consistent:

(a) In terms of standardized regression coefficients, the self-fulfilling effects of teacher expectations were about 0.1–0.2.

(b) Teacher expectations were strongly based on students' past achievement.

(c) Teachers' expectations predicted students' achievement more because they were accurate than because they led to self-fulfilling prophecies.

(d) Even teachers' perceptions of differences between students from different demographic groups (i.e., stereotypes) were mostly accurate (Jussim et al. 1996).

3.2 Naturalistic Studies of Close Relationships

Recent research has begun investigating the occurrence of self-fulfilling prophecies in close relationships. Children come to view their math abilities in a manner consistent with their mothers' sex stereotypes (Jacobs and Eccles 1992). New college roommates change each others' self-perceptions of academic and athletic ability (McNulty and Swann 1994). People who feel anxious that their romantic partners will reject them often evoke rejection from those partners (Downey et al. 1998). Furthermore, the more positive the illusions one holds regarding one's romantic partner the longer that relationship is likely to continue and the more positively one's romantic partner will come to view him or herself (Murray et al. 1996). As with the teacher expectation studies, however, self-fulfilling prophecy effect sizes average about 0.2.

3.3 Nonconscious Priming of Stereotypes

Chen and Bargh (1997) avoided inducing false expectations by nonconsciously priming a stereotype, and observing its effect on social interaction. First, they subliminally presented to perceivers either African-American or White faces. Perceivers and targets (all of whom were White) were then placed into different rooms where they communicated through microphones and headphones. These interactions were recorded and rated for hostility. Perceivers primed with an African-American face were rated as more hostile, and targets interacting with more hostile perceivers reciprocated with greater hostility themselves. The expectancy effect size was 0.23.

4. Moderators

Failures to replicate and generally small effect sizes prompted some researchers to begin searching for moderators—factors that inhibit or facilitate self-fulfilling prophecies (Jussim et al. 1996). This research has identified some conditions under which powerful self-fulfilling prophecies occurred and many conditions under which self-fulfilling prophecies did not occur. Identified moderators include characteristics of perceivers, targets, and the situation.

4.1 Perceiver Moderators

(a) Perceivers motivated to be accurate or sociable are not likely to produce self-fulfilling prophecies.

(b) Perceivers motivated to confirm a particular belief about a target, or to arrive at a stable impression of a target are more likely to produce self-fulfilling prophecies.

(c) Perceivers with a rigid cognitive style or who are certain of their beliefs about targets are more likely to produce self-fulfilling prophecies.

4.2 Target Moderators

(a) Unclear self-perceptions lead people to become more vulnerable to self-fulfilling prophecies.

(b) When perceivers have something targets want (such as a job), targets often confirm those beliefs in order to create a favorable impression.

(c) When targets desire to facilitate smooth social interactions, they are also more likely to confirm perceivers' expectations.

(d) When targets believe that perceivers hold a negative belief about them, they often act to disconfirm that belief. Similarly, when their main goal is to defend a threatened identity, or express their personal attributes, they are also likely to disconfirm perceivers' expectations.

(e) Self-fulfilling prophecies are stronger among students from at least some stigmatized social groups (African-American students, students from lower social class backgrounds, and students with a history of low achievement).

4.3 Situational Moderators

(a) Self-fulfilling prophecies are most common when people enter new situations, such as kindergarten or military service.

(b) Experimental studies conducted in educational contexts were much more likely to obtain self-fulfilling prophecies if the expectancy manipulation occurred early in the school year (presumably, because teachers were more open to the information at that time).

5. Accumulation

Small self-fulfilling prophecy effects, if they accumulate over time, might lead to large differences between targets. If, for example, stereotype-based expectations lead to small differences in the intellectual achievement of students from middle class or poor backgrounds each year, those differences may accumulate over time to lead to large social class differences in achievement. This argument lies at the heart of claims emphasizing the power of self-fulfilling prophecies to contribute to social problems.

Self-fulfilling prophecies in the classroom, however, do not accumulate. All studies examining this issue have failed to find accumulation and, instead, have generally found that teacher expectation effects dissipate over time (Smith et al. 1999). Whether self-fulfilling prophecies accumulate outside of the classroom is currently unknown.

6. Future Directions

6.1 Naturalistic Studies Outside of Classrooms

Nearly all of the early naturalistic research focused on teacher expectations. Thus, the recent emergence of research on self-fulfilling prophecies in close relationships has been sorely needed, and will likely continue. The expectations that parents, employers, therapists, coaches, etc. develop regarding their children, employees, clients, athletes, etc. are all rich areas for future research.

6.2 Stereotype Threat

Stereotype threat refers to concern that one's actions may fulfill a negative cultural stereotype of one's group (Steele 1997). Such concerns may, paradoxically, lead to the fulfillment of those stereotypes. For example, African-American students who believe they are taking a test of intelligence (triggering potential concern about confirming negative cultural stereotypes regarding African-American intelligence) perform worse than White students; however, when led to believe that the same test is one of 'problem-solving,' the differences evaporate. Similar patterns have occurred for women taking standardized math tests (Steele 1997), and for middle class and poor students on intelligence tests (Croizet and Claire 1998). Stereotype threat is a relatively new concept in the social sciences, and has been thus far used primarily to explain demographic differences in standardized test performance. In addition, it helps identify how cultural stereotypes (beliefs about the widespread beliefs regarding groups) may be self-fulfilling, even in the absence of a specific perceiver with an inaccurate stereotype. As such, it promises to remain an important topic in the social sciences for some time.

7. Conclusion

Self-fulfilling prophecies are pervasive in the sense that they occur in many different contexts. They are not pervasive in the sense that self-fulfilling prophecy effect sizes are typically small, and many studies have failed to find them.

Because of the alleged power of expectancy effects to create social problems, teachers have sometimes been accused of perpetrating injustices based on race, class, sex, and other demographic categories. This accusation is unjustified. Teacher expectations predict student achievement primarily because those expectations are accurate. Furthermore, even when inaccurate, teacher expectations do not usually influence students very much; and even when they do influence students, such influence is likely to dissipate over time.

Sometimes, however, both inside and outside the classroom, self-fulfilling prophecies can be powerful. In the classroom, the effects among some groups (low achievers, African-Americans, students from lower social class backgrounds) have been quite powerful. Although self-fulfilling prophecies in the classroom do not accumulate, they can be very long lasting—detectable as many as six years after the original teacher-student relationship (Smith et al. 1999).

Outside the classroom, recent research has demonstrated the potentially important role of self-fulfilling prophecies in close relationships, and in the maintenance of socio-cultural stereotypes. Thus, self-fulfilling prophecies occur in a wide variety of contexts and are a major phenomenon linking social perception to social behavior.

Self: History of the Concept

It is often asserted that the concept of the self emerges only in early modern times in connection with the concern for subjectivity that is taken to be characteristic of modernity. While it is true that the term 'self' as a noun, describing that which in a person is really and intrinsically this person, comes into use only from the seventeenth century onwards, what can be called the question of selfhood was not unfamiliar to earlier thinkers. This is, in its core, the question whether there is—and if so, what is—some unity, or at least continuity and coherence, of a human being over the life-course beyond their bodily constitution, beyond the unity of the body.

In the history of human thought, this question has been answered in a great variety of different ways. Broadly, empirical traditions tended to doubt the existence of such unity. They could observe changes, even radical transformations, in the human mind and had thus no ground to postulate any *a priori* unity. Transcendental traditions, in contrast, tended to argue that there had to be a unity of apperception, or of consciousness. Otherwise, not even the question of the self could be asked.

In the intellectual space between these two positions, so to say, the issue could be addressed in ways that are more specific to the social and psychological sciences. Then, the faculty of memory, for instance, could be seen as enabling a sense of continuous self to emerge. Human subjects have the ability to narrate their lives. Or, selves could be seen as formed in the interaction with others, that is, in the mirroring of an image of oneself through the responses to one's own words and actions by others. In moral philosophy, the existence of a continuous self was seen as a precondition for holding human beings accountable for their past deeds. Selfhood was thus linked to moral and political responsibility.

1. *Selfhood in the Social Sciences*

In these forms, the question of the self was already posed at the historical moment when the social sciences, by and large in the contemporary understanding of the term, arose towards the end of the eighteenth century. It is noteworthy, then, that the emerging social sciences rather reduced the range of ways of exploring selfhood across the nineteenth century. In some of their fields, like liberal political philosophy and political economy/economics, they postulated a rational self, able to make choices and to be responsible for her, or rather: his deeds. In other fields, in particular in the sociological way of reasoning, the orientations and behaviors of human beings were seen as determined by their social position. This opposition has become known as the one between an under- and an oversocialized conception of the human being (Wrong 1961). More cautiously, the empirical and behavioral strands of social research restricted themselves to observing human behavior and refrained from making any assumptions about selfhood at all. Regularities emerged here only through the aggregation of observations.

All these approaches had in common, though, was that they aimed at regularizing and stabilizing human orientations and behavior. Whether human beings were under- or oversocialized or just happened to behave according to patterns, the broader question of selfhood, namely whether and how a sense of continuity and coherence in a human being forms, was rather neglected or answered *a priori* by theoretical postulate.

In this light, it seems appropriate to say that the social sciences have developed a serious interest in

questions of human selfhood only late, systematically only in the early twentieth century. Furthermore, they have largely ignored ways of representing the human self that were proposed in other areas, in philosophy for instance, but maybe even more importantly in literature. Thus, issues such as individuality and subjectivity, the possible idiosyncrasy of a life-course and life-project, have long remained outside the focus of the social sciences, which have tended to look at the question from the perspective of a fully developed, stable, personal identity, rather than making the continuity and coherence of the self an issue open to investigation.

This focus can hardly be understood otherwise than through the perceived need to expect a political stability of the world on the basis of a presupposed coherence of human orientations and actions (see *Freedom/Liberty: Impact on the Social Sciences*).

The ground for an interest in such broader issues was prepared outside of what is conventionally recognized as social science, namely by Friedrich Nietzsche, and later by Sigmund Freud. Nietzsche radically rejected the problems of moral and political philosophy and thus liberated the self from the impositions of the rules of the collective life. Freud located the drives toward a fuller realization of one's self in the human psyche and connected the history of civilization with the repression of such drives. Against such a 'Nietzschean-Freudian' background (Rorty 1989), Georg Simmel and George Herbert Mead could observe the ways in which identities are formed in social interaction and conceptualize variations of self-formation in different social contexts. From then on, a sociology and social psychology of selfhood and identity has developed which no longer relies on presuppositions about some essence of human nature and is able to connect its findings to both child psychology and phenomenology. It emphasizes the socially constructed nature of selfhood, but remains capable, at least in principle, to analyze the specific social contexts of self-formation thus working towards a comparative-historical sociology of selfhood. This broadened debate on selfhood has created a semantic space in which aspects of the self are emphasized in various ways (Friese 2001). This space can be described by connecting the concept of self to notions of modernity, of meaning, and of difference.

2. *Selfhood and Modernity*

The idea of human beings as autonomous subjects is often taken to be characteristic of modernity as an era, or at least for the self-understanding of modernity as an ethos (see *Modernity: History of the Concept*). Such a view entails a conception of the self as rather continuous and coherent, since only on such a basis is the choice of a path of action and a way of life as well as the acceptance of the responsibility for one's deeds conceivable. The concept of selfhood is here conditioned by the need to maintain a notion of human autonomy and agentiality as a basic tenet of what modernity is about, namely the possibility to shape the world by conscious human action. Such modernism, however, is not necessarily tied to the atomist and rationalist individualism of some versions of economic and political thought, most notably neoclassical economics and rational choice theory.

In the light of the twentieth century developments in sociology and (social) psychology, as mentioned above, the view that connects selfhood to modernity mostly—in all its more sophisticated forms—starts out from an assumption of constitutive sociality of the human being. Not absolute autonomy, but rather the conviction that human beings have to construct their self-identities can then be seen as characteristically modern (Hollis 1985). Unlike the concept of the rational, autonomous self, this concept is open towards important qualifications in terms of the corporeality, situatedness, and possible nonteleological character of human action (Joas 1996). Without having to presuppose the self-sustained individual of modernity, the aim is to demonstrate how autonomous selves develop through social interactions over certain phases of the life-course (Joas 1998, Straub 2001).

The commitment to autonomy and agentiality, characteristic of modernity, becomes visible rather in the fact that formation of self (or, of self-identity) is here understood as the forming and determining of the durably significant orientations in a life. It is related to the formation of a consciousness of one's own existence and thus biographically predominantly to the period of adolescence. Crises of identity occur accordingly during growing up; more precisely one should speak of life crises during the formation of one's identity. Self-identity once constituted is seen as basically stable further on. No necessary connection is presupposed between self-formation and individuality; theoretically, human beings may well form highly similar identities in great numbers. Since the very concept of identity is connected to continuity and coherence of self, however, stability is turned into a conceptual assumption.

Objections against such a conceptualization go in two different directions. On the one hand, this discourse, which often has its roots in (social) psychology, stands in a basic tension to any culturalist concept of identity, which emphasizes meaning. On the other hand, doubts about the presupposition of continuity and coherence of selfhood employ notions of difference and alterity that are not reducible to the idea that selves are formed by relating to others, by intersubjectivity.

3. *Selfhood and Meaning*

Some critics of the close connection between self-formation and modernity argue that every form of selfhood is dependent on the cultural resources that

are at hand to the particular human being when giving shape to their important orientations in life. Human beings give meaning to their lives by interpreting their situations with the help of moral-cultural languages that precede their own existence and surround them. Cultural determinism is the strong version of such theorizing, mostly out of use nowadays, but many current social theories adopt a weaker version of this reasoning which indeed sustains the notion of the continuity and coherence of the self but sees this self as strongly embedded in cultural contexts.

Such a view of the self has its modern source in romanticism (see *Romanticism: Impact on Social Thought*). Philosophically, it emerged as a response to the rationalist leanings of the Enlightenment, and politically, against the conceptions of abstract freedom in individualist liberalism. Unlike cultural determinism, however, which has a strongly oversocialized conception of the human being and thus hardly any concept of self at all, romanticism emphasizes agency and creativity in the process of self-formation and self-realization. Human beings are seen in their singularity, but the relation to others is an essential and inescapable part of their understanding of their own selves.

Charles Taylor's inquiry into *The Sources of the Self* is a most recent and forceful restatement of this conception. Taylor starts out from the familiar argument that the advent of modernity indicates that common frameworks for moral evaluation can no longer be presumed to exist. The key subsequent contention is then that the ability and inclination to question any existing such framework of meaning does not lead into a sustainable position that would hold that no such frameworks are needed at all, a view he calls the 'naturalist supposition' (Taylor 1989, p. 30). If such frameworks of meaning are what gives human beings identity, allows them to orient themselves in social and moral space, then they are not 'things we invent' and may as well not invent. They need to be seen as 'answers to questions which inescapably pre-exist for us,' or, in other words, 'they are contestable answers to inescapable questions' (Taylor 1989, pp. 38, 40). Taylor develops here the contours of a concept of inescapability as part of a moral-social philosophy of selfhood under conditions of modernity. Meaning-centered conceptions of selfhood have recently been underlined as a basis of communitarian positions in moral and political philosophy, such as Sandel's concept (1982) of the 'encumbered self.'

4. *Selfhood and Otherness*

Arguably, these two concepts of selfhood remain within the frame of a debate in which the under- and the oversocialized views of the human being occupy the extreme points. The introduction of interaction and intersubjectivity in self-formation has created intermediate theoretical positions, and, possibly more importantly, they have allowed different accentuations of selfhood without making positions mutually incompatible. Nevertheless, the modernity-oriented view still emphasizes a self that acts upon the world, whereas the meaning-oriented view underlines the fact that the self is provided the sense of their actions by the world of which they are a part. Since the mid-1970s, in contrast, theoretical and empirical developments have tended to break up the existing two-dimensional mode of conceptualization.

On the one hand, the notion of a 'decentering of the subject' has been proposed mainly from poststructuralist discussions. On the other hand, the observation of both multiple and changing basic orientations in human beings has led to the proliferation of the—infelicitously coined—term 'postmodern identity' as a new form of selfhood. In both cases, a strong concept of self has been abandoned, in the one case on the basis of philosophical reflection, in the other, grounded on empirical observation. Both the ideas of a 'decentring' and of a 'postmodern self' question some major implications of the more standard sociological view of selfhood, namely the existence of the human self as a unit and its persistence as the 'same' self over time.

In the former perspective, the philosophical maxim of thinking identity and difference as one double concept, rather than as one concept opposed to another, is translated into sociological thinking as the need to think self and other as a relation, rather than as a subject and a context or object. Such notions rather underline the nonidentitarian character of being by pointing to the issue of 'the other in me' (Emmanuel Lévinas) as a question of co-constitution rather than of interaction. While emphasized in recent poststructuralist thought, similar ideas can be found, for instance, in Arendt's (1978, pp. 183–7) insistence on the 'two-in-one,' on the relation to oneself as another, as the very precondition for thought. In a broad sense, they go back to the ancient view of the friend as an 'other self.' And Theunissen (1977/1965) had already conceptualized self-other relations on the basis of an understanding of 'the Other' as referring to all 'concepts through which philosophy interprets the presence and present of the fellow/co-human being (*Mitmensch*) or of the transcendental original form of this human being.'

In one particular formulation, Cavell's reflections provide an example for a thinking about selfhood that does not presuppose an idea of identity, coherence, or consistency (Cavell 1989, 1990). He cautions against 'any fixed, metaphysical interpretation of the idea of a self' and against the idea of 'a noumenal self as one's "true self" and of this entity as having desires and requiring expression.' In contrast, Cavell suggests that the 'idea of the self must be such that it can contain, let us say, an intuition of partial compliance with its idea

of itself, hence of distance from itself' or, in other words, he advocates the idea of 'the unattained but attainable self' (Cavell, 1990, pp. 31, 34). Cavell proposes here a relation of the unattained and the attainable as constitutive for the self, that is, he makes the very question of attainability a central feature of a theory of selfhood.

5. *Selfhood and Sociohistorical Transformations*

The development of this threefold semantic space has considerably enriched the conceptualization and analysis of selfhood in the social sciences during the twentieth century. If one considers the three fields of inquiry as explorations of the various dimensions of selfhood, rather than as mutually exclusive perspectives, the question of the constitution of the human self emerges as a *problématique* that concerns all human beings and for which there may be a variety of processes which can be determined generally only in their forms but not in their results. As a consequence, however, it becomes much more difficult to conclude from the prevailing character of selfhood on social structure and political order. This has often been seen as a 'weakness' of symbolic interactionism, for instance, which Mead's view of the self is said to have inaugurated, as a social theory that allegedly cannot address issues of societal constitution. But by the same move Mead allows for and recognizes a plurality of selves that has returned to the center of discussion today—after the renewal of a regressive synthesis of identity and society in Talcott Parsons's work (to which—what is often overlooked—Erik Erikson contributed as well). The question of the relation between selfhood and society and politics thus needs to be rephrased as a question of comparative-historical sociology rather than merely of social theory.

Some indications as to how this relation should be understood can be found when reading the historical sociology of twentieth century societies in this light. The social upheaval during the second half of the nineteenth century with industrialization, urbanization and the phrasing of 'the social question' is often seen as a first 'modern' uprooting of established forms of selfhood, as a first massive process of 'disembedding' (Giddens 1990). The development towards so-called mass societies during the first half of the twentieth century lets the question of the relation between individuation and growth of the self emerge. Totalitarianism has been analyzed in terms of an imbalance between imposed individuation and delayed self-formation, the result having been the tendency towards 'escape from freedom' and into stable collective identities (Fromm 1941, Arendt 1958). The first three decades after the Second World War are then considered as a form of re-embedding of selves into the institutional frames of democratic welfare societies. Most recently, the indications of dissolution and dismantling of the rather comprehensive set of social institutions of the interventionist welfare state are one of the reasons to focus sociological debate again on questions of selfhood and identity. During this period, as some contributions argue, no longer continuity and coherence but transience, instability, and inclination to change are said to be marks of the important life orientations of contemporary human beings (see Shotter and Gergen 1989, Lash and Friedman 1992, Kellner 1995). However, many of these analyses are challenged on grounds of the limited representativity of the empirical sample or on conceptual grounds.

Given the theoretical insights described above as the emergence of the threefold semantic space of selfhood, any attempt to offer a full-scale reformulation of the issue of the varieties of selfhood in different sociohistorical configurations would be adventurous. Forms of self-constitution and substantive orientations of human selves are just likely to be highly variable across large populations with varieties of experiences and sociocultural positions. However, the notion of recurring crises of modernity and the identification of historically distinct processes of disembedding and re-embedding could be the basis for a socially more specific analysis of the formation and stability of social selves (Wagner 1994).

The social existence of the 'modern' idea that human beings construct their selves is what many societies have in common throughout the 1800s and 1900s. As such, it does not give any guidance in defining different configurations. Therefore, three qualifying criteria have been introduced. First, the existence of the idea of construction of selfhood still leaves open the question whether all human beings living in a given social context share it and are affected by it. The social permeation of the idea may be limited. Second, human beings in the process of constructing their selves may consider this as a matter of choice, as a truly modernist perspective would have it. In many circumstances, however, though a knowledge and a sense of the fact of social construction prevails, it may appear to human beings as almost natural, as in some sense pre-given or ascribed, which social self they are going to have. Third, the stability of any self one has chosen may vary. Such a construction of selfhood may be considered a once-in-a-lifetime occurrence, but may also be regarded as less committing and, for instance, open to reconsideration and change at a later age. These criteria widen the scope of constructability of selfhood. All conditions of construction have existed for some individuals or groups at any time during the past two centuries in the West. But the widening of the scope of construction may mark the transitions from one to another social configuration of modernity. These transitions entail social processes of disembedding and provoke transformations of social selves, in the course of which not only other selves are acquired but the possibility of construction is also more widely perceived.

Self-knowledge: Philosophical Aspects

'Self-knowledge'—here understood as the knowledge a creature has of its own mental states, processes, and dispositions—has come to be, along with consciousness, an increasingly compelling topic for philosophers and scientists investigating the structure and development of various cognitive capacities. Unlike consciousness, however, the capacity for self-knowledge is generally held to be the exclusive privilege of human beings—or, at least, of creatures with the kind of conceptual capacity that comes with having a language of a certain rich complexity. Prima facie, self-knowledge involves more than simply having sensations (or sensory experiences). Many say it involves even more than having moods, emotions, and 'first-order' intentional states, paradigmatically beliefs and desires, but also hopes, fears, wishes, occurrent thoughts, and so on. Some philosophers disagree, claiming that first-order intentional states (individuated by 'propositional content') are themselves properly restricted to language-using creatures and, by that token, to self-knowing creatures. Nevertheless, it is generally agreed that self-knowledge involves, minimally, the capacity for a conceptually rich awareness or understanding of one's own mental states and processes, and hence the capacity, as it is often put, to form 'second-order' beliefs about these, a capacity that can be extended to, or perhaps only comes with, forming beliefs about the mental states and processes of others.

More generally, then, self-knowledge involves the capacity for adopting what Daniel Dennett calls the *intentional stance* (Dennett 1987)—understanding oneself (and others) as having experiences and ways of representing the world that shape agential behavior. But this capacity should not be understood in purely spectatorial terms. The more sophisticated a creature's intentional understanding, the more sophisticated it will be at acting in a world partially constituted by agential activity. Thus, the capacity for intentional understanding continually plays into, and potentially modifies, an agent's own intentionally directed activity, a point I will return to below.

1. Empirical Findings: Testing the Limits of Intentional Understanding

A number of experiments have been designed to test for the presence of such a capacity in nonhuman animals (primarily hominids) and very young children, with interestingly controversial results. Some investigators claim that the evidence for intentional understanding (including a fairly sophisticated awareness of self) is persuasively strong in the case of certain primates (chimpanzees and bonobos, though for a deflationary interpretation of this evidence based on

further empirical trials, see Povinelli and Eddy (1996)). Experiments with young children (most famously the 'false-belief task') seem clearly to indicate that intentional understanding comes in degrees, passing through fairly discernible stages. How precisely to characterize these stages and what constitutes the mechanism of change is hotly debated (Astington et al. 1988), yet there is an emerging pattern in the empirical data that is noteworthy for standard philosophical discussions of self-knowledge. First, under certain, not very unusual conditions, young children will make mistakes in attributing basic mental states to themselves (desires and beliefs) that are inconceivable from the adult point of view because of the direct first-personal awareness adults seem to have of these states. Second, the errors children make in self-attribution mirror in kind and frequency the errors they make in attributing mental states to others; there seems to be no dramatic asymmetry between self-knowledge and knowledge of other minds, at least for children (Flavell et al. 1995, Gopnik 1993). Moreover, though children become increasingly more sophisticated in their intentional self- and other-attributions, this symmetry and systematicness in kind and frequency of error seems to persist in notable ways into adulthood, with subjects 'confabulating' explanations for their actions and feelings that are purportedly based on direct introspective awareness of their own minds (Nisbett and Wilson 1977). To psychologists investigating these phenomena, this pattern of results suggests that, for both children and adults, judgments about mental states and processes are affected (perhaps unconsciously) by background beliefs about how such states are caused and how they in turn cause behavior, and these beliefs can be systematically wrong, at least in detail. There is nothing special about the capacity for self-knowledge that avoids the error-causing beliefs embedded in our 'folk-psychology.'

2. *The Philosophical Project: Explaining the Special Character of Self-knowledge*

Although judgments about our own mental states and processes are clearly not infallible, there are distinctive features of self-knowledge that require explanation. These features, and the interrelations among them, are variously presented in the philosophical literature, but they are generally held to consist in the following (Wright et al. 1998, pp. 1–2).

(a) *Immediacy*—the knowledge we have of our own sensations, emotions, and intentional states is normally not based on behavioral or contextual evidence; it is groundless or immediate, seemingly involving some kind of 'special access' to our own mind.

(b) *Saliency (or, transparency)*—knowledge of our own minds, especially with regard to sensations and occurrent thoughts, is unavoidable; if we have a particular thought or sensation, we typically know that we have it (such mental states are 'self-intimating').

(c) *(First-person) authority*—judgments about our own minds (expressed in sincere first-person claims) are typically treated by others as correct simply by virtue of our having made them. Normally, such claims require no justification and are treated as true, so long as there is no overwhelmingly defeating counter-evidence to suggest that we are wrong about ourselves.

The traditional account against which most discussions of self-knowledge react is drawn from René Descartes (Descartes 1911). Viewing the mind as a non-physical substance directly knowable only from the first-person point of view, Descartes had a ready explanation of first-person authority: we clearly and distinctly *perceive* the contents of our own minds, which are by their nature transparent to us. Alternatively, since we have no special perceptual access to the minds of others, the only way we can make judgments about them is by observing their external bodily movements and inferring from their similarities to ours that they are likewise caused by mental states and processes. Such weakly inferred third-person judgments are perforce dramatically less secure than first-person judgments, which are themselves infallible. On this view, the commonly acknowledged asymmetry between first- and third-person judgments is exaggerated in both directions.

This Cartesian account has been discredited in almost everyone's estimation—and not just empirically, but conceptually. Even the picturesque metaphor of the 'mind and its contents' was held by Gilbert Ryle to encourage such bad habits of thought that nothing worthwhile could be said in its defense. The 'metaphysical iron curtain' it introduced between knowledge of self and knowledge of others was, in Ryle's view, sufficient to show the bankruptcy of the Cartesian picture by making impossible our everyday practices of correctly applying, and being able to correct our applications of, 'mental conduct' concepts either to others or to ourselves. Since this would undermine the possibility of a coherent language containing such concepts, it undermines the possibility of our conceptualizing ourselves intentionally at all. Thus, so far from providing an explanation of our capacity for self-knowledge, Descartes' theory discredits it. We find out about ourselves in much the same way that we find out about other people, Ryle is famous for saying: 'A residual difference in the supplies of the requisite data makes some differences in degree between what I can know about myself and what I can know about you, but these differences are not all in favor of self-knowledge' (Ryle 1949, p. 155). Although Ryle exhaustively illustrated his view that the ways we find out about ourselves are as various as the kinds of things we find out, thus debarring any simple philosophical analysis of self- and other-knowledge, he is

generally thought to have promoted the doctrine of 'logical behaviorism' (not Ryle's term), according to which all talk about so-called 'mental' states and processes (our own or anyone else's) is really just talk about actual and potential displays of overt behavior. In fact, though clearly suspicious of philosophical defenses of first-person authority based on a principle epistemic privilege, Ryle is more profitably read as following Wittgenstein in trying to reveal how the 'logical (or 'grammatical) structure' of a pervasive way of thinking about the 'mind and its contents' inevitably generates self-defeating explanations of various phenomena, including our capacity for self-knowledge. Any substantial account of such phenomena must therefore exemplify a different kind of logical structure altogether (see discussions of Wittgenstein's view in McDowell 1991, Wright 1991).

3. *Current Proposals: 'Causal–Perceptual' vs. 'Constitutive' Explanations of Self-knowledge*

This proposed opposition between different 'logical types' of explanation is given more substance in contemporary work with philosophers pursuing two quite different methodological approaches to understanding the purported immediacy, saliency, and authority of self-knowledge. The first 'causal–perceptual' approach focuses on the mechanics of self-knowledge, including the nature of the states we are purportedly making judgments about, the nature of the states that constitute those judgments, and the nature of the connection between them. The second so-called 'constitutive' approach focuses on the larger implications of our capacity for self-knowledge, including what role it plays in specifying conditions for the possibility of our powers and practices of agency. Adopting either one of these approaches does not rule out addressing the questions featured by the alternative approach, although the sorts of answers given are materially shaped by which questions occupy center field.

3.1 *Causal–Perceptual Accounts of Self-knowledge*

According to some philosophers, the basic defects of the Cartesian view stem not from the idea that first-person knowledge is a form of inner perception, but from its dualistic metaphysics and an overly restricted conception of what perception involves. On Descartes's 'act-object' model of perception, mental states are objects before the mind's 'inner eye' which we perceive (as we do external objects) by the act of discerning their intrinsic (nonrelational) properties. Without mounting any radical 'grammatical' critique, problems with this view can be readily identified, especially once the mind is understood to be part of the material world (see Shoemaker 1996, Wright et al. 1998).

(a) There is no organ of inner perception analogous to the eye (but we do have a capacity for sensing the position of our bodies, by proprioception, and this does not require any specialized organ; perhaps introspection is like proprioception).

(b) Sensations could possibly count as 'objects' of inner perception, but intentional states (beliefs and desires) are less plausible candidates. First, phenomenologically, we do not seem to be aware of our intentional states as discernibly perceptible in the way that sensations are; there is no perceptual experience that precedes, or comes with, our judgments about such states—no 'qualia.' Second, intentional states are individuated by their propositional content, and their propositional content is plausibly determined by (causal) relational features these states bear to the subject's physical or social environment, rather than intrinsic features of the states themselves. If the 'externalist' view of content is right, then authoritative self-knowledge of these states cannot be based on inwardly perceiving their intrinsic properties (see Ludlow and Martin 1998).

(c) In contrast with external perception, there are no mediating perceptual experiences between the object perceived and judgments based on those perceivings. If mental states and processes are objects of inner perception, they must be 'self-intimating' objects, where the object of perception is itself a perceptual experience of that object. Taken literally, this idea is hard to make coherent, though some have found it invitingly appropriate in the case of sensations as a way of marking what is so unusually special and mysterious about them.

Many of these problems (and more) are satisfactorily addressed by adopting a 'tracking' model of inner perception (Armstrong 1968). We do have 'special access' to our own minds in so far as the second-order beliefs we form about our (ontologically distinct) first-order states and processes are *reliably caused*, perhaps *subcognitively*, by the very first-order states and processes such beliefs are about. There need be no distinctive phenomenology that characterizes such access, and no need therefore to give different accounts of our self-knowledge of intentional states versus sensations, imaginings, and other phenomenologically differentiated phenomena. Of course, if all such states are functionally defined—that is, dispositionally, in terms of their causal relations to other mental states, to perceptual inputs and to behavioral outputs—there is nothing about them that makes them in principle accessible only to the person whose states they are. But this is a strength of the approach. Such states are accessible in a *special way* to the subject (by normally and reliably causing the requisite second-order beliefs), thereby accounting for the immediacy, saliency, and authority of our first-person judgments.

Yet because causal mechanisms can break down in particular cases, first-person error may be expected (as in self-deception). Such errors may also be detected: since first-order states are constitutively related to a subject's linguistic and nonlinguistic behavior, significant evidence of noncohesiveness between the subject's sayings and doings may be used to override her self-ascriptions. Moreover, there is no inconsistency between this account of the special character of self-knowledge and psychologists' findings of systematic error in self- and other attribution. It may be just as they suggest: since the concepts in terms of which we express our second-order beliefs (about self and other) are functionally defined in terms of folk-psychological theory, systematic error may result from the theory's deficiencies.

3.2 Constitutive Accounts of Self-knowledge

The causal–perceptual approach to self-knowledge has many advantages, including, it would seem, the ontological and conceptual *independence* of first-order states from the second-order beliefs that track them in self-knowers. For this means there is no conceptual bar on attributing beliefs, desires, and so forth to creatures that lack the capacity for self-knowledge but still behave rationally enough to be well predicted from the intentional stance. Why then do some philosophers insist that having such first-order intentional states is constitutively linked to having authoritative self-knowledge—and, therefore, presumably, to a subject's forming second order beliefs about her first order states for which 'truth is the default condition' (Wright 1991)?

To begin with a negative answer: if causal–perceptualists are right in saying that the subject's status as an authoritative self-knower is merely contingently dependent on a reliable causal mechanism linking first- and second-order states, then we could not account for the special role self-knowledge plays in constituting that subject as a rational and responsible agent (Bilgrami 1998, Burge 1996, Shoemaker 1996). How so? Consider, for instance, the causal–perceptualist account of error in self-attribution: The subject forms a false second-order belief due to a breakdown in the causal mechanism normally linking that belief to the appropriate first-order state. Her lapse of rationality consists in her saying one thing (because of the second-order belief) and doing another (because of her first-order states). But why count this a lapse of *rationality* (as surely we do), rather than simply a self-misperception, analogous (except for the causal pathway) to misperceptions of others? What imperative is there for a subject's self-attributions to line up with her other sayings and doings in order for her to be a coherent subject, responsible and responsive to the norms embedded in our folk-psychological conception of rational agency?

Different authors take various tacks in answering this question, but there is a discernible common thread. An agent cannot act linguistically or nonlinguistically in ways that respond self-consciously to these norms, unless she knows in a directive sense what she is doing—i.e., unless she recognizes herself as acting in accord with certain intentional states that she knows to be hers, and knows in a way that acknowledges her own agency in producing and maintaining them.

Moreover, an agent is self-consciously responsive to norms that govern her own intentional states (such as *believing that p*), not just by recognizing what counts as norm-compliant behavior, but actually by *regulating* herself (her judgments, thoughts, and actions) in accord with such norms. On this picture, if a person's sincere claims about herself do not cohere with the (other) things she does and says, we may say she fails to know herself. But, just as importantly, we say that she acts unknowingly. That is, there is some sense (perhaps pathological) in which she acts, but without authoring her own acts as a free and responsible agent. Hence, she does not *authorize* such acts; they are out of her reflective control. To fail in self-knowledge on this account is not to be wrong in the passively spectatorial sense that one can be wrong about others; it is to fail more actively in exercising one's powers of agency.

Constitutive explanations of self-knowledge display a very different logical structure from causal–perceptual accounts. Consequently, they suggest a different way of conceptualizing the intentional capacities of self-knowers, a way that has become needlessly complicated through retaining the traditional architecture of first-order states and second-order beliefs about them that are ontologically, if not conceptually, distinct and that supposedly underlie and get expressed in first-person claims (McGeer 1996). This distinction makes sense on a causal–perceptualist account of self-knowledge; but it only confuses and obscures on the constitutive account, leading, for instance, to inappropriate descriptions of what distinguishes us from other animals. The constitutive explanation of self-knowledge focuses on what it means to be an intentional creature of a certain sort, an intentional creature that is capable of actively regulating her own intentional states, revising and maintaining them in self-conscious recognition of various norms. No doubt there are automatic mechanisms also involved in regulating intentional states in an environmentally useful way, mechanisms we may well share with nonlinguistic creatures and which explain why adopting the intentional stance towards them works as well as it does (Shoemaker 1996, essay 11). But in our own case, we increase the range and power of the intentional stance by understanding what rational, responsible agency requires of us and molding ourselves to suit. The apparatus of first- and second-order states may play some useful role in further elucidating this capacity for intentional self-regulation, but more likely

it encourages bad habits of thought—a lingering vestige of the dying, but never quite dead, Cartesian tradition in epistemology and philosophy of mind.

Self-monitoring, Psychology of

According to the theory of self-monitoring, people differ in the extent to which they monitor (i.e., observe and control) their expressive behavior and self-presentation (Snyder 1974, 1987). Individuals high in self-monitoring are thought to regulate their expressive self-presentation for the sake of public appearances, and thus be highly responsive to social and interpersonal cues to situationally appropriate performances. Individuals low in self-monitoring are thought to lack either the ability or the motivation to regulate their expressive self-presentations for such purposes. Their expressive behaviors are thought instead to reflect their own inner states and dispositions, including their attitudes, emotions, self-conceptions, and traits of personality.

Research on self-monitoring typically has employed multi-item, self-report measures to identify people high and low in self-monitoring. The two most frequently employed measuring instruments are the 25 true–false items of the original Self-monitoring Scale (Snyder 1974) and an 18-item refinement of this measure (Gangestad and Snyder 1985; see also Lennox and Wolfe 1984). Empirical investigations of testable hypotheses spawned by self-monitoring theory have accumulated into a fairly sizable published literature (for a review of the literature, see Gangestad and Snyder 2000).

1. Major Themes of Self-monitoring Theory and Research

Soon after its inception, and partially in response to critical theoretical issues of the times, self-monitoring was offered as a partial resolution of the 'traits vs. situations' and 'attitudes and behaviors' controversies in personality and social psychology. The propositions of self-monitoring theory suggested that the behavior of low self-monitors ought to be predicted readily from measures of their attitudes, traits, and dispositions whereas that of high self-monitors ought to be best predicted from knowledge of features of the situations in which they operate. Self-monitoring promised a 'moderator variable' resolution to debates concerning the relative roles of person and situation in determining behavior. These issues set the agenda for the first generation of research and theorizing on self-monitoring, designed primarily to document the relatively 'situational' orientation of high self-monitors and the comparatively 'dispositional' orientation of low self-monitors (for a review, see Snyder 1987).

In a second generation of research and theorizing, investigations moved beyond issues of dispositional and situational determination of behavior to examinations of the linkages between self-monitoring and

interpersonal orientations. Perhaps the most prominent of these programs concerns the links between expressive control and interpersonal orientations, as revealed in friendships, romantic relationships, and sexual involvements (e.g., Snyder et al. 1985). Other such programs of research concern advertising, persuasion, and consumer behavior (e.g., Snyder and DeBono 1985), personnel selection (e.g., Snyder et al. 1988), organizational behavior (Caldwell and O'Reilly 1982, Kilduff 1992), socialization and developmental processes (e.g., Eisenberg et al. 1991, Graziano and Waschull 1995), cross-cultural studies (e.g., Gudykunst 1985).

Central themes in these programs of research have been that high self-monitors live in worlds of public appearances created by strategic use of impression management, and that low self-monitors live in worlds revolving around the private realities of their personal identities and the coherent expression of these identities across diverse life domains. Consistent with these themes, research on interpersonal orientations has revealed that high, relative to low, self-monitors choose as activity partners friends who will facilitate the construction of their own situationally-appropriate images and appearances (e.g., Snyder et al. 1983). Perhaps because of their concern with images and appearances, high self-monitors have romantic relationships characterized by less intimacy than those of low self-monitors. Also consistent with these themes, explorations of consumer attitudes and behavior have revealed that high self-monitors value consumer products for their strategic value in cultivating social images and public appearances, reacting positively to advertising appeals that associate products with status and prestige; by contrast, low self-monitors judge consumer products in terms of the quality of the products stripped of their image-creating and status-enhancing veneer, choosing products that they can trust to perform their intended functions well (e.g., DeBono and Packer 1991). These same orientations manifest themselves in the workplace as well, with high self-monitors preferring positions that call for the exercise of their self-presentational skills; thus, for example, high self-monitors perform particularly well in occupations that call for flexibility and adaptiveness in dealings with diverse constituencies (e.g., Caldwell and O'Reilly 1982) whereas low self-monitors appear to function best in dealing with relatively homogeneous work groups.

It should be recognized that, although these programs of research, for the most part, have not grounded their hypotheses or interpretations in self-monitoring's traditionally fertile ground—issues concerning the dispositional vs. situational control of behavior—they do nevertheless reflect the spirit of the self-monitoring construct. That is, their guiding themes represent clear expressions of self-monitoring theory's defining concerns with the worlds of public appearances and social images, and the processes by which appearances and images are constructed and sustained. However, it should also be recognized that these lines of research go beyond showing that individual differences, in concern for cultivating public appearances, affect self-presentational behaviors. These programs of research have demonstrated that these concerns, and their manifestations in expressive control, permeate the very fabric of individuals' lives, affecting their friendship worlds, their romantic lives, their interactions with the consumer marketplace, and their work worlds.

2. *The Nature of Self-monitoring*

Despite their generativity, the self-monitoring construct and its measure have been the subject of considerable controversy over how self-monitoring ought to be interpreted and measured. The roots of this controversy are factor analyses that clearly reveal that the items of the Self-monitoring Scale are multifactorial, with the emergence of three factors being the most familiar product of these factor analyses (Briggs et al. 1980). These factor analyses, and attempts to interpret them, have stimulated a critically important question: Is self-monitoring truly a unitary phenomenon?

Although there is widespread agreement about the multifactorial nature of the items of the Self-monitoring Scale, there exist diverging viewpoints on the interpretation of this state of affairs. One interpretation is that some criterion variables represented in the literature might relate to one factor, other criterion variables to a second independent factor, and yet others to still a third factor—an interpretation which holds that self-monitoring is not a unitary phenomenon (e.g., Briggs and Cheek 1986).

Without disputing the multifactorial nature of the self-monitoring items, it is nevertheless possible to construe self-monitoring as a unitary psychological construct. Taxonomic analyses have revealed that the self-monitoring subscales all tap, to varying degrees, a common latent variable that may reflect two discrete or quasidiscrete self-monitoring classes (Gangestad and Snyder 1985). In addition, the Self-monitoring Scale itself taps a large common factor accounting for variance in its items and correlating, to varying degrees, with its subscales; this general factor approximates the Self-monitoring Scale's first unrotated factor (Snyder and Gangestad 1986). Thus, the Self-monitoring Scale may 'work' to predict diverse phenomena of individual and social functioning because it taps this general factor; this interpretation is congruent with self-monitoring as a unitary, conceptually meaningfully psychological construct.

Although much of the debate about the nature of the self-monitoring construct has focused on con-

trasting interpretations of the internal structure of the Self-monitoring Scale, it is possible to consult another source of evidence with which to address the major issues of the self-monitoring controversy—the literature on the Self-monitoring Scale's relations with criterion variables external to the scale itself (i.e., behavioral, behavioroid, and performance measures of phenomena relevant to self-monitoring theorizing). Based on a quantitative review of the literature on the Self-monitoring Scale's relations with behavioral and behavioroid external criterion variables, it appears that, with some important exceptions, a wide range of external criteria tap a dimension directly measured by the Self-monitoring Scale (Gangestad and Snyder 2000).

Based on this quantitative appraisal of the self-monitoring literature, it is possible to offer some specifications of what self-monitoring is and what it is not, specifications that may guide the next generations of theory and research on self-monitoring. That is, it is possible to identify 'exclusionary messages' about features of self-monitoring theory that should not receive the attention heretofore accorded them (e.g., delimiting the scope of self-monitoring as a moderator variable such that claims about peer-self agreement ought no longer be made, although claims about behavioral variability may yet be made), and to identify 'inclusionary messages' about features that should define the evolving agenda for theory and research on self-monitoring (e.g., focusing on the links between self-monitoring and strategic motivational agendas associated with engaging in, or eschewing, impression management tactics that involve the construction of social appearances and the cultivation of images).

3. *Conclusions*

To some extent, the productivity and generativity of the self-monitoring construct may derive from the fact that it appears to capture one of the fundamental dichotomies of psychology—whether behavior is a product of forces that operate from outside of the individual (exemplified by the 'situational' orientation of the high self-monitor) or whether it is governed by influences that guide from within the individual (typified by the 'dispositional' orientation of the low self-monitor). In theory and research, self-monitoring has served as a focal point for issues in assessment, in the role of scale construction in theory building, and in examining fundamental questions about personality and social behavior, particularly those concerning how individuals incorporate inputs from their own stable and enduring dispositions and inputs from the situational contexts in which they operate into agendas for action that guide their functioning as individuals and as social beings.

Self-organizing Dynamical Systems

Interactions, nonlinearity, emergence and context, though omnipresent in the social and behavioral sciences, have proved remarkably resistant to understanding. New light may be shed on these problems by virtue of the introduction and development of theoretical concepts and methods of self-organization and the mathematical tools of (nonlinear) dynamical systems (Haken 1996, Kelso 1995). Self-organized dynamics promises both a language for, and a strategy toward, understanding human behavior on multiple levels of description. A key problem on any given level of description is to identify the essential dynamical variables characterizing the formation and change of behavioral patterns so that the pattern dynamics, the rules governing behavior, may be found and their predictions pursued. Dynamics offers not only a concise mathematical description of different kinds and classes of behavior. Dynamical models provide new measures and predict new phenomena often not observed before in studies of individual human and social behavior. And they may help explain effects previously attributed to more static, nondynamical mechanisms. Therein lies the promise of dynamics for the social and behavioral sciences at large. Dynamics offers a new way to think about, perhaps even solve, old problems.

Here, following a brief historical introduction, the main ideas of dynamical systems are described in a nontechnical fashion. The connection between notions of self-organization and nonlinear dynamical systems is then addressed as a foundation for understanding behavioral pattern formation, flexibility, and change. A flavor of the approach, which stresses an intimate relationship between theory and experiment, is addressed in the context of a few examples from the behavioral and social sciences. Finally, some extensions of the approach are discussed briefly, including a way to include meaningful information into the self-organizing dynamics.

1. *A Short History of Dynamical Systems*

For the eighteenth century Scottish philosopher David Hume, all the sciences bore a relation to the human mind. In his *Treatise of Human Nature* (1738), Hume first divided the mind into its contents: ideas and impressions. Then he added dynamics, noting the impossibility of simple ideas forming more complex ones without some bond of union between them. Hume's three dynamical laws for the association of ideas—resemblance, contiguity, and cause and effect—were thought to be responsible for controlling all mental operations. A kind of attraction, Hume thought, existed in the mental world: the motion of the mind was conceived as analogous to the motion of a body, as described earlier by Newton. Mental 'stuff' was governed (somehow) by dynamics.

All this has a strangely contemporary ring to it. Dynamics is not only the language of the natural sciences, but has permeated the social, behavioral, and neurosciences as well (Arbib et al. 1998, Kelso 1995, Vallacher and Novak 1997). Cognitive science, whose theory and paradigms are historically embedded in the language of the digital computer, may be the most recent of the human sciences to fall under the spell of dynamics (Port and van Gelder 1995, Thelen and Smith 1994).

Which factors led to the primacy of dynamics as the language of science, whether natural or human? First, was the insight of the French mathematician Henri Poincaré to put dynamics into geometric form. Poincaré introduced an array of powerful methods for visualizing how things behave, somewhat independent of the things themselves.

Second, following Poincaré's lead, were developments in understanding nonlinear dynamical systems from a mathematical point of view. These are sets of differential equations that can exhibit multiple solutions for the same parameters and are capable of highly irregular, even unpredictable behavior.

Third, was the ability to visualize how these equations behave by integrating them numerically on a digital computer. Parameters can be varied and parameter spaces explored without doing a 'real' experiment or collecting data of any kind. In fact, computer simulation and visualization is often the only possible method of exploring complex behavior.

Finally, were quite specific examples of cooperative (or 'collective') behavior in physics (e.g., fluids, lasers), chemistry (e.g., chemical reactions), biology (e.g., morphogenesis), and later, in the behavioral sciences. The behavioral experiments (Kelso 1984) and consequent theoretical modeling (Haken et al. 1985) showed for the first time that dynamic patterns of human behavior, how behavior forms, stabilizes, and changes, may be described quite precisely in the mathematical language of nonlinear dynamical systems. Not only were new effects predicted and observed, it was possible to derive these emergent patterns and the pattern dynamics by nonlinearly coupling the component parts. Since these early empirical and theoretical developments, ideas of self-organization and dynamics have infiltrated the social, behavioral, economic, and cognitive sciences, not to speak of literature and the arts.

2. Dynamical Systems: Some Terminology

What exactly is a dynamical system? It is not possible here to do justice to the mathematics of dynamical systems and its numerous technical applications, for example, in time series analysis (e.g., Strogatz 1994). For present purposes, only the basics are considered. Fundamentally, a dynamical system pertains to anything—such as the behavior of a human being or a social group—that evolves over time. Mathematically, if $X_1, X_2, \ldots, X_n$ are the variables characterizing the system's behavior, a dynamical system is a system of equations stipulating the temporal evolution of $\vec{X}$, the vector of all permissible X-values. Therein lies the rub: in the social and behavioral sciences one has to find these Xs and identify their dynamics on a chosen level of description.

If $\vec{X}$ is a continuous function of time, then the dynamics of $\vec{X}$ is typically described by a set of first order ordinary differential equations (ODEs). The order of the equation refers to the highest derivative that appears in the equation. Thus, $\dot{X} = F(X)$ is a first order equation where the dot above the X denotes the first derivative with respect to time and $F(X)$ gives the vector field. ODEs are of greatest interest when F is nonlinear because, depending on the particular form of F, a wide variety of behaviors can arise.

Another important class of dynamical system is difference equations or maps. Maps are often useful when the behavior of a system appears to be organized around discrete temporal events. Maps and ODEs provide complementary ways to model and study nonlinear dynamical behavior, but we shall not pursue maps further here (see, however, van Geert 1995 as an example of the approach).

A vectorfield is defined at each and every point of the state or phase space of the system, defined by the values of the variables $X_1, X_2, \ldots, X_n$. As these states evolve in time they can be represented graphically as a trajectory. The state space is filled with trajectories. At any point in a given trajectory, a velocity vector can be determined by differentiation. These velocity vectors prescribe a velocity vectorfield, which is assumed to represent the flow or behavior of the dynamical system (Abraham and Shaw 1982). This flow often has characteristic tendencies particularly in dissipative systems, named thus because their state space volume decreases or dissipates over time toward attractors. In other words, trajectories converge over time (technically, as time goes to infinity) to subsets of the phase space (a given attractor's basin of attraction). One may even think of an attractor as a representation of the goal of the behaving system (Saltzman and Kelso 1987).

The term transient defines the segment of a trajectory starting from some initial condition in the basin of attraction until it settles into an attractor. Attractors can be fixed points, in which all initial conditions converge to some stable rest state. Attractors can be periodic, exhibiting preferred rhythms or orbits on which the system settles regardless of where it starts. Or, there can be so-called strange attractors; strange because they exhibit deterministic chaos, a type of irregular behavior resembling random noise, yet often containing pockets of quite ordered behavior.

The presence of chaos in physical systems is ubiquitous, and there is some evidence suggesting that it may also play an important role in certain biological systems, including the human brain and its disorders (Kelso and Fuchs 1995). Chaos means sensitive dependence on initial conditions: nudging a chaotic system by just a hair can change its future behavior dramatically. In the vernacular, human behavior certainly seems 'chaotic' sometimes. However, although an area of active interest in many research fields, it remains unclear whether chaos, and its close relative, fractals (Mandelbrot 1982) provide any essential insights in the social and behavioral sciences.

What may be rather more important to appreciate is that parameters, so-called control parameters, can move a system through a vast array of different kinds of dynamic behavior of which chaos is only one. Thus, when a parameter changes smoothly, the attractor in general also changes smoothly. In other words, sizeable changes in the input have little or no effect on the resulting output. However, when the control parameter passes through a critical point or threshold in an intrinsically nonlinear system an abrupt change in the attractor can occur. This sensitive dependence on parameters is called a bifurcation in mathematics, or a nonequilibrium phase transition in physical theories of pattern formation (Haken 1977).

3. Concepts of Self-organization

Dynamical theory, by itself, does not give us any essential insights into how patterns of behavior may be created in complex systems that contain multiple (often different) elements interacting nonlinearly with each other and their environment. This is where the concept of self-organization is helpful (Haken 1977, Nicolis and Prigogine 1977).

Self-organization refers to the spontaneous formation of pattern and pattern change in complex systems whose elements adapt to the very patterns of behavior they create. Think of birds flocking, fish schooling, bees swarming. There is no 'self' inside the system ordering the elements, dictating to them what to do and when to do it. Rather, the system, which includes the environment, literally organizes itself. Inevitably, when the elements form a coupled system with the world, coordinated patterns of behavior arise. Emergent pattern reflects the collective behavior of the elements. Collective behavior as a result of self-organization reduces the very large number of degrees of freedom into a much smaller set of relevant

dynamical variables called, appropriately enough, collective variables. The enormous compression of degrees of freedom near critical points can arise because events occur on different timescales: the faster individual elements in the system may become 'enslaved' to the slower, emergent pattern or collective variables, and lose their status as relevant behavioral quantities (Haken 1977). Alternatively, one may conceive of a hierarchy of timescales for various processes underlying human behavior. On a given level of the hierarchy are pattern variables subject to constraints (e.g., of the task) that act as boundary conditions on the pattern dynamics. At the next level down are component processes and events that typically operate on faster timescales. Notice in this scheme (Kelso 1995), the key is to chose a level of description and understand the relation between adjacent levels, not reduce to some 'fundamental' lower level.

So what causes behavioral patterns to form? And what causes pattern change? It is here that the connection between processes of self-organization and dynamical systems theory becomes quite explicit. In complex systems that are open to exchanges of information with their environment, naturally occurring environmental conditions or intrinsic, endogenous factors may take the form of control parameters in a nonlinear dynamical system. When the control parameter crosses a critical value, instability occurs, leading to the formation of new (or different) patterns.

Dynamic instability is the generic mechanism underlying spontaneous self-organized pattern formation and change in all systems coupled to their internal or external environment. The reason is that near instability the individual elements, in order to adjust to current conditions (control parameter values), must order themselves in a new or different way. Fluctuations are always present, constantly testing whether a given behavioral pattern is stable. Fluctuations are not just noise; rather, they allow the system to discover new, more adaptive behavioral patterns.

The patterns that emerge and change near instabilities have a rich and highly nonlinear pattern, or coordination dynamics. Herein lies the basis of the hypothesis that human beings and the basic forms of behavior they produce, may be understood as self-organizing dynamical systems (Kelso 1995). Humans—complex systems consisting of multiple, interacting elements—produce behavioral patterns that are captured by collective variables. The resulting dynamical rules are essentially nonlinear and thus capable of producing a rich repertoire of behaviors. By this hypothesis, all human behavior—even human cognitive development (Magnusson 1995, Thelen and Smith 1994) and learning (Zanone and Kelso 1992) which occur on very different time scales—arises because complex material systems, through the process of self-organization, create a dynamic, pattern forming system that is capable of both behavioral simplicity (such as fixed point behavior) and enormous, even creative, behavioral complexity (such as chaotic behavior). No new principles, it seems, need be introduced (but see Sect. 5).

4. *Finding Dynamical Laws in Behavioral and Social Systems*

In the social and behavioral sciences the key collective variables characterizing the system's state space are seldom known *a priori* and have to be identified. Science always needs special entry points, places where irrelevant details may be pruned away while retaining the essential aspects of the behavior one is trying to understand. Unique to the perspective of self-organized dynamical systems is its focus on qualitative change, places where behavior bifurcates. The reason is that qualitative change affords a clear distinction between one pattern and another, thereby enabling one to identify the key pattern variables that define behavioral states.

Likewise, any parameter that induces qualitative behavioral change qualifies as a control parameter. The payoff from knowing collective pattern variables and control parameters is high: they enable one to obtain the dynamical rules of behavior on a chosen level of description. By adopting the same strategy the next level down, the individual component dynamics may be studied and identified. It is the interaction between these that creates the patterns at the level above, thereby building a bridge across levels of description.

5. *The Laws that Bind Us*

It has long been recognized that social relationships are an emergent product of the process of interaction. Commonly studied relationships are the mother–infant interaction, the marriage bond and the patient-therapist relation, all of which are extremely complicated and difficult to understand. A more direct approach may be to study simpler kinds of social coordination, with the aim of determining whether such emergent behavior is self-organized, and if so what its dynamics are.

As an illustrative example, consider two people coordinating their movements. In this particular task each individual is instructed to oscillate a limb (the lower leg in this case) in the same or opposite direction to that of the other (Schmidt et al. 1990). Obviously the two people must watch each other in order to do the task. Then, either by an instruction from the experimenter or by following a metronome whose rate systematically increases, the social dyad also must speed up their movements.

When moving their legs up and down in the same direction, the two members of the dyad can remain

Figure 1
The potential, V(ϕ) of Eqn. (2) (with $\Delta\omega = 0$) and Eqn. (4) (with $\Delta\omega \neq 0$). Black balls symbolize stable coordinated behaviors and white balls correspond to unstable behavioral states (see text for details)

synchronized throughout a broad range of speeds. However, when moving their legs in the opposite direction (one person's leg extending at the knee while the other's is flexing), such is not the case. Instead, at certain critical speeds participants spontaneously change their behavior so that the legs now move in the same direction.

How might these social coordination phenomena be explained? The pattern variable that changes qualitatively at the transition is the relative phase, ϕ. When the two people move in the same direction, they are in-phase with each other, $\phi = 0$. When they move in different directions, their behavior is antiphase ($\phi = \pm\pi$ radians or ± 180 degrees).

The phase relation is a good candidate for a collective variable because it clearly captures the spatiotemporal ordering between the two interacting components. Moreover, ϕ changes far more slowly than the variables that might describe the individual components (position, velocity, acceleration, electromyographic activity of contracting muscles, etc.) Importantly, ϕ changes abruptly at the transition.

The simplest dynamics that captures all the observed facts is

$$\dot{\phi} = -a\sin\phi - 2b\sin 2\phi \tag{1}$$

where ϕ is the relative phase between the movements of the two individuals, $\dot{\phi}$ is the derivative of ϕ with respect to time, and the ratio b/a is a control parameter corresponding to the movement rate in the experiment. An equivalent formulation of Eqn. (1) is

$$\dot{\phi} = -\partial V(\phi)/\partial\phi$$
$$\text{with } V(\phi) = -a\cos\phi - b\cos 2\phi \tag{2}$$

In the literature, this is called the HKB model of coordinated behavior, after Haken et al. (1985) who formulated it as an explanation of the coordination of limb movements within a single person (Kelso 1984). Figure 1 (top) allows one to develop an intuitive understanding of the behavior of Eqn. (2), as well as to connect to the key concepts of stability and instability in self-organizing dynamical systems introduced

earlier. The dynamics can be visualized as a particle moving in a potential function, $V(\phi)$. The minima of the potential are points of vanishing force, giving rise to stable solutions of the HKB dynamics. As long as the speed parameter (b/a) is slow, meaning the cycle period is long, Eqn. (2) has two stable fixed point attractors, collective states at $\phi = 0$ and $\phi = \pm\pi$ rad. Thus, two coordinated behavioral patterns coexist for exactly the same parameter values, the essentially nonlinear feature of bistability. Such bi- and in general multistability is common throughout the behavioral and social sciences. Ambiguous figures (old woman or young girl? Faces or vase?) are well-known examples (e.g., Kruse and Stadler 1995).

As the ratio b/a is decreased, meaning that the cycle period gets shorter as the legs speed up, the formerly stable fixed point at $\phi = \pm\pi$ rad. becomes unstable, and turns into a *repellor*. Any small perturbation will now kick the system into the basin of attraction of the stable fixed point (behavioral pattern) at $\phi = 0$. Notice also that once there, the system's behavior will stay in the in-phase attractor, even if the direction of the control parameter is reversed. This is called hysteresis, a basic form of memory in nonlinear dynamical systems.

What about the individual components making up the social dyad? Research has established that these take the form of self-sustaining oscillators, archetypal of all time-dependent behavior whether regular or not. The particular functional form of the oscillator need not occupy the reader here. More important is the nature of the nonlinear coupling that produces the emergent coordination. The simplest, perhaps fundamental coupling that guarantees all the observed emergent properties of coordinated behavioral patterns—multistability, flexible switching among behavioral states, and primitive memory, is

$$K_{12} = (\dot{X}_1 - \dot{X}_2)\{\alpha + \beta(X_1 - X_2)^2\} \tag{3}$$

where X_1 and X_2 are the individual components and α and β are coupling parameters. Notice that the 'next level up,' the level of behavioral patterns and the dynamical rule that governs them (Eqns.(1) and (2)), can be derived from the level below, the individual components and their nonlinear interaction. One may call this constructive reductionism: by focusing on adjacent levels, under the task constraint of interpersonal coordination, the individual parts can be put together to create the behavior of the whole.

The basic self-organized dynamics, Eqns. (2) and (3) have been extended in numerous ways, only a few of which are mentioned here.

(a) *Critical slowing down* and *enhancement of fluctuations*. Introducing stochastic forces into Eqns. (1) and (2) allows key predictions to be tested and quantitatively evaluated. Critical slowing is easy to understand from Fig. 1 (top). As the minima at $\phi = \pm\pi$ become shallower and shallower, the time it takes to adjust to a small perturbation takes longer and longer. Thus, the local relaxation time is predicted to increase as the instability is approached because the restoring force (given as the gradient in the potential) becomes smaller. Likewise, the variability of ϕ is predicted to increase due to the flattening of the potential near the transition point. Both predictions have been confirmed in a wide variety of experimental systems, including recordings of the human brain.

(b) *Symmetry breaking*. Notice that Eqns. (1) and (2) are symmetric: the dynamical system is 2π periodic and is identical under left-right reflection (ϕ is the same as $-\phi$). This assumes that the individual components are identical, which is seldom, if ever the case. Nature thrives on broken symmetry. To accommodate this fact, a term $\Delta\omega$ is incorporated into the dynamics

$$\dot{\phi} = \Delta\omega - a\sin\phi - 2b\sin 2\phi,$$

and

$$V(\phi) = -\Delta\omega\phi - a\cos\phi - b\cos 2\phi \tag{4}$$

for the equation of motion and the potential respectively. Small values of $\Delta\omega$ shift the attractive fixed points (Fig. 1 middle) in an adaptive manner. For larger values of $\Delta\omega$ the attractors disappear entirely (Fig. 1 bottom) causing the relative phase to drift: no coordination between the components occurs. Note, however, that the dynamics still retain some curvature (Fig. 1 bottom right): even though there are no attractors there is still *attraction* to where the attractors used to be. The reason is that the difference ($\Delta\omega$) between the individual components is sufficiently large that they do their own thing, while still retaining a tendency to cooperate. This is how global integration, in which the component parts are locked together, is reconciled with the tendency of the parts to function locally, as individual autonomous units (Kelso 1995).

(c) *Information: a new principle?* Unlike the behavior of inanimate things, the self-organizing dynamics of human behavior is fundamentally informational, though not in the standard sense of data communicated across a channel (Shannon and Weaver 1949). Rather, collective variables are context-dependent and intrinsically meaningful. Context-dependence does not imply lack of reproducibility. Nor does it mean that every new context requires a new collective variable or order parameter. As noted above, within- and between-person coordinated behaviors are described by exactly the same self-organizing dynamics. One of the consequences of identifying the latter is that in order to modify or change the system's behavior, any new information (say a task to be learned, an intention to change one's behavior) must be expressed in terms of parameters acting on system-relevant collective variables. The benefit of identifying the latter is that one knows what to modify. Likewise, the collective variable dynamics—prior to the introduction of new information—influences how that information is used. Thus, information is not lying out there as mere data: information is meaningful

to the extent that it modifies, and is modified by, the collective variable dynamics.

(d) *Generalization*. The basic dynamics (Eqns. (1–4)) can readily be elaborated as a model of emergent coordinated behavior among many anatomically different components. Self-organized behavioral patterns such as singing in a group or making a 'wave' during a football game are common, yet unstudied examples. Recently, Neda et al. (2000) have examined a simpler group activity: applause in theater and opera audiences in Romania and Hungary. After an exceptional performance, initially thunderous incoherent clapping gives way to slower, synchronized clapping. Measurements indicate that the clapping period suddenly doubles at the onset of the synchronized phase, and slowly decreases as synchronization is lost. This pattern is a cultural phenomenon in many parts of Europe: a collective request for an encore. Increasing frequency (decreasing period) is a measure of the urgency of the message, and culminates in the transition back to noise when the performers reappear. These results are readily explained by a model of a group of globally coupled nonlinear oscillators (Kuramoto 1984)

$$\frac{\mathrm{d}\phi_k}{\mathrm{d}t} = \omega_k + \frac{K}{N}\sum_{j=1}^{N} \sin(\phi_j - \phi_k) \tag{5}$$

in which a critical coupling parameter, K_c determines the different modes of clapping behavior. K is a function of the dispersion (D) of clapping frequencies

$$K_c = \sqrt{\frac{2}{\pi^3}}D \tag{6}$$

During fast clapping, synchronization is not possible due to the large dispersion of clapping frequencies. Slower, synchronized clapping at double the period arises when small dispersion appears. Period doubling rhythmic applause tends not to occur in big open-air concerts where the informational coupling among the audience is small. K can also be societally imposed. In Eastern European communities during communist times, synchronization was seldom destroyed because enthusiasm was often low for the 'great leader's' speech. For people in the West, the cultural information content of different clapping patterns may be quite different. Regardless, the mathematical descriptions for coordinated behavior—of social dyads and the psychology of the crowd—are remarkably similar.

6. Conclusion and Future Directions

The theoretical concepts and methods of self-organizing dynamics are likely to play an ever greater role in the social, behavioral, and cognitive sciences, especially as the interactions among disciplines continues to grow. Up to now, the use of nonlinear dynamics is still quite restricted, and largely metaphorical. One reason is that the tools are difficult to learn, and require a degree of mathematical sophistication. Their implementation in real systems is nontrivial, requiring a different approach to experimentation and observation. Another reason is that the dynamical perspective is often cast in opposition to more conventional theoretical approaches, instead of as an aid to understanding. The former tends to emphasize decentralization, collective decision-making and cooperative behavior among many interacting elements. The latter tends to focus on individual psychological processes such as intention, perception, attention, memory, and so forth. Yet there is increasing evidence that intending, perceiving, attending, deciding, emoting, and remembering have a dynamics as well. The language of dynamics serves to bridge individual and group processes. In each case, dynamics must be filled with content, with key variables and parameters obtained for the system under study. Every system is different, but what we learn about one may aid in understanding another. What may be most important are the principles and insights gained when human brains and human behavior are seen in the light of self-organizing dynamics.

Self: Philosophical Aspects

There are two related ways in which philosophical reflection on the self may usefully be brought to bear in social science. One concerns the traditional problem about personal identity. The other concerns the distinctive kinds of social relations into which only selves can enter. Sustained reflection on the second issue reveals striking analogies between some of the social relations into which only selves can enter and certain first personal relations that only a self can bear to itself. These analogies entail two possibilities that bear on the first issue concerning personal identity, namely, the possibility that there could be group selves who are composed of many human beings and the possibility that there could be multiple selves within a single human being.

Section 1 outlines the classical problem of personal identity that was originally posed by Locke and continues to generate philosophical debate. Section 2 discusses some of the distinctive social relations into which only selves can enter. Section 3 draws several analogies between such social relations and first personal relations. Section 4 shows how these analogies point to the possibilities of group and multiple selves. It closes with some cautionary remarks about how overlooking these two possibilities can lead to confusions about methodological individualism.

1. The Philosophical Problem about Personal Identity

To have a self is to be self-conscious in roughly the sense that Locke took to be the defining mark of the person. In his words, a person is 'a thinking, intelligent being, that has reason and reflection, and can think itself as itself in different times and places' (Locke 1979). In general, all of these capabilities—for thought, reason, reflection, and reflexive self-reference—tend to be lumped together by philosophers under the common heading of self-consciousness. Except in some generous accounts of animal intelligence, it is generally assumed that the only self-conscious beings are human beings.

Locke famously disagreed. This was not because he believed that there are other species of animal besides the human species that actually qualify as persons (though he did discuss at some length a certain parrot that was reported to have remarkable conversational abilities). It was rather because he thought that the condition of personal identity should not be understood in biological terms at all; it should be understood, rather, in phenomenological terms. A person's identity extends, as he put it, exactly as far as its consciousness extends. He saw no reason why the life of a person so construed, as a persisting center of consciousness, should necessarily coincide with the biological lifespan of a given human animal. In defense of this distinction between personal and animal identity he offered the following thought experiment: first, imagine that the consciousnesses of a prince and a cobbler are switched each into the other's body and, then, consider who would be who thereafter. He thought it intuitively obvious that the identity of the prince is tied to his consciousness in such a way that he would remain the same person—would remain himself—even after having gained a new, cobbling body (similar remarks apply to the cobbler).

Many objections have been raised against Locke's argument and conclusion. It still remains a hotly disputed matter among philosophers whether he was right to distinguish the identity of the person from the identity of the human animal (Parfit 1984, Perry 1975, Rorty 1979). This philosophical dispute has not drawn much attention from social scientists who have generally assumed against Locke that the life of each individual self or person coincides with the life of a particular human being. The anti-Lockean assumption is so pervasive in the social sciences that it serves as common ground even among those who take

opposing positions on the issue concerning whether all social facts are reducible to facts about individuals or whether there are irreducibly social facts (see *Individualism versus Collectivism: Philosophical Aspects*; *Methodological Individualism: Philosophical Aspects*)). Both sides take for granted that the only individuals in question are human beings.

Prima facie, it seems reasonable that social scientists should disregard Locke's distinction between the self or person and the human being. For something that neither Locke nor neo-Lockeans have ever done is offer an *actual* instance of his distinction. All they have argued for is the *possibility* that a person's consciousness could be transferred from one human body to another and, in every case, they have resorted to thought experiments in their attempts to show this. There is a significant difference between Locke's original thought experiment about the prince and the subsequent neo-Lockean experiments. Whereas his simply stipulates that a transfer of consciousness has occurred, the latter typically describe some particular process by which the transfer of consciousness is supposed to be accomplished—as in, for example, brain transplantation or brain reprogramming. However, although this might make the neo-Lockean thought experiments seem more plausible, there is no realistic expectation that what they ask us to imagine will ever actually come to pass (Wilkes 1988). Because this is so, they have no particular bearing on the empirical concerns of social science.

Nevertheless, it is important to be clear about whether the anti-Lockean assumption that informs social science is correct. For the way in which we conceive the boundaries that mark one individual self off from another will inevitably determine how we conceive the domain of social relations that is the common subject of all the social sciences. So we need to be absolutely clear about whether it is right to assume, against Locke, that the identity of the individual is at bottom a biological fact.

As the next two sections will show, there are reasons to side with Locke. But these reasons differ from Locke's own in several respects. Unlike his, they are not derived from thought experiments. Furthermore, they support a somewhat different version of his distinction between the identity of the self or person and the human being. Finally, they invite the expectation that this version of his distinction can be realized in fact and not just in imagination—which makes it relevant to social science after all.

2. *The Sociality of Selves: Rational Relations*

Starting roughly with Hegel, various philosophers have mounted arguments to the effect that self-consciousness is a social achievement that simply cannot be possessed by beings who stand outside of all social relations (Wittgenstein 1953, Davidson 1984). The common conclusion of these arguments is overwhelmingly plausible. But even if the conclusion were shown to be false, it would remain true that many self-conscious beings are social and, furthermore, their social relations reflect their self-consciousness in interesting ways. In order to gain a full appreciation of this fact, we must shift our attention away from the phenomenological dimension of self-consciousness that Locke emphasized in his analysis of personal identity, and shift our attention to the other dimension of self-consciousness that he emphasized in his definition of the person as a 'being with reason and reflection.'

One need not cite Locke as an authority in order to see that reflective rationality is just as crucial to selfhood as its phenomenological dimension. For it obviously will not do to define the self just in phenomenological terms, as a center of consciousness, and this is so even if Locke was right to analyze the identity of the self or person in such terms. After all, some sort of center of consciousness is presupposed by all sentience, even in the case of animals that clearly do not have selves, such as wallabies or cockatoos. It also will not do to suppose that selfhood is in place whenever the sort of consciousness that goes together with sentience is accompanied by the mere capacity to refer reflexively to oneself. For, assuming that wallabies and cockatoos can represent things (which some philosophers deny (Davidson 1984)), it is very likely that some of their representations will function in ways that are characteristic of self-representation. Consider, for example, mental maps in which such animals represent their spatial relations to the various objects they perceive; such maps require a way to mark the distinction between their own bodies and other bodies, a distinction which is not inaptly characterized as the distinction between self and other (Evans 1982). Self-consciousness in the sense that goes together with selfhood involves a much more sophisticated sort of self-representation that incorporates a conception of oneself as a thinking thing and, along with it, the concept of thought itself. Armed with this concept, a self-conscious being cannot only represent itself; it can self-ascribe particular thoughts and, in doing so, it can bring to bear on them the critical perspective of reflective rationality.

Whenever selves in this full sense enter into social relations, they enter into relations of reciprocal recognition. Each is self-conscious; each conceives itself as an object of the other's recognition; each conceives the other as so conceiving itself (i.e., as an object of the other's recognition); each conceives both as having a common nature and, in so doing, each conceives both as so conceiving both (i.e., as having a common nature). Since this reciprocally recognized common nature is social as well as rational, it affords the possibility of the social exercise of rational capacities. Thus, corresponding to the capacity to ascribe thoughts to oneself, there is the capacity to ascribe

thoughts to others; corresponding to the capacity to critically evaluate one's own thoughts there is the capacity to critically evaluate the thoughts of others; and together with all this comes another extraordinary social capacity, the capacity for specifically rational influence in which selves aim to move one another by appealing to the normative force of reasons. Such rational influence is attempted in virtually every kind of social engagement that takes place among selves, including: engaging in ordinary conversation and argument; offering bribes; lodging threats; bargaining; cooperating; collaborating. In all of these kinds of engagement reasons are offered up in one guise or another in the hope that their normative force will move someone else.

3. *Analogies Between First Personal and Social Relations*

It is because selves have a rational nature that analogies arise between their first personal relations to their own selves and their social relations to one another. Here are three examples.

3.1 *Critical Evaluation*

It is a platitude that the principles of rationality are both impersonal and universal. They lay down normative requirements that *anyone* must meet in order to be rational, and they constitute the standards by which *everyone* evaluates their own and everyone else's rational performances. It follows that when we evaluate our own thoughts by these standards, we are really considering them as if they were anyone's—which is to say, as if they were not our own. We sometimes describe this aspect of critical self-evaluation with the phrase 'critical distance.' There is a specific action by which we accomplish this distancing: we temporarily suspend our commitment to act on our thoughts until after we have determined whether keeping the commitment would be in accord with the normative requirements of rationality. If we determine that it would not be in accord with those requirements, then the temporary suspension of our commitment becomes permanent, and our critical distance on our thoughts gives way to literally disowning them. But before getting all the way to the point of disowning our thoughts we must first have gotten to a point where our relations to our thoughts are rather like our relations to the thoughts of others. For, whether we decide to disown the thoughts under critical scrutiny or to reclaim them, the normative standards on the basis of which we do so are necessarily conceived by us as impersonal and universal. In consequence, there is a straightforward sense in which we are doing the same thing when we apply the standards to our own thoughts and when we apply them to the thoughts of others. There is this difference, though: whereas self-evaluation involves distancing ourselves from our own thoughts, evaluating the thoughts of others involves a movement in the opposite direction. We must project ourselves into their points of view so that we can appeal to their own sense of how the principles of rationality apply in their specific cases. This sort of criticism that involves projection is sometimes called 'internal criticism,' in contrast with the sort of 'external criticism' that proceeds without taking into account whether its target will either grasp it or be moved by it (Williams). This difference between internal criticism of others and self-criticism—the difference between projection and distancing—does nothing to undermine the analogies between them. On the contrary, for by these opposite movements two distinct selves can bring themselves to the very same place. That is, when one self projects itself into another's point of view for the purposes of internal criticism, it can reach the very same place that the other gets to by distancing itself from its own thoughts for the purposes of self-criticism. Moreover, there is a sense in which what the two selves do from that place is not merely analogous, but the very same thing. Each of the two selves brings to bear the same critical perspective of rationality on the same particular self's thoughts. The only difference that remains is that in the one case it is a social act directed at another, whereas in the other case it is a self-directed act.

3.2 *Joint Activities*

Just as internal criticism of another replicates what individual selves do when they critically evaluate themselves, so also, joint activities carried out by many selves may replicate the activities of an individual self. For the purposes of such activities, distinct selves need to look for areas of overlap between (or among) their points of view, such as common ends, common beliefs about their common ends, and common beliefs about how they might act together so as to realize those ends. These areas of commonly recognized overlap can then serve as the basis from which the distinct selves deliberate and act together and, as such, the areas of overlap will serve as a common point of view which is shared by those selves. Whenever distinct selves do deliberate together from such a common point of view, they will be guided by the very same principles that ordinarily govern individual deliberation, such as consistency, closure (the principle that one should accept the implications of one's attitudes), and transitivity of preferences. All such principles of rationality taken together define what it is for an individual to be fully or optimally rational. For this reason, they generally apply separately to each individual but not to groups of individuals. (Thus, different parties to a

dispute might be rational even though they disagree, but they cannot be rational if they believe contradictions.) The one exception is joint activities in which such groups of individuals deliberate together from a common point of view. To take a limited example, you and I might deliberate individually about a philosophical problem or we might do so together. If we do it individually, each of us will aim to be consistent in our reasoning because that is what the principles of rationality require of us individually. But these principles do not require us to do this together; which is to say, you and I may disagree about many things without compromising our ability to pursue our individual deliberations from our separate points of view in a completely rational manner. What would be compromised, however, is our ability to work on a philosophical problem together. We cannot do that without resolving at least some of our disagreements, namely, those that bear on the problem. This means that if we truly are committed to working on the problem together, then we should recognize a sort of conditional requirement of rationality, a requirement to achieve as much consistency between us as would be necessary to carry out our joint project. Although we needn't achieve overall consistency together in order to do this—that is, we needn't agree on every issue in every domain—nevertheless, we must resolve our disagreements about the relevant philosophical matters. When we resolve these disagreements we will be doing in degree the very same thing that individuals do when they respond to the rational requirement of consistency. The same holds for the other principles of rationality such as closure and transitivity of preferences. For, in general, whenever distinct individuals pursue ends together, they temporarily cease deliberating and acting separately from their individual points of view in order to act and deliberate together from their common point of view. They will also strive to achieve by social means within a group—albeit in diminished degree—the very sorts of rational relations and outcomes that are characteristic of the individual self (Korsgaard 1989).

3.3 Rationality over Time

Although there is some sense in which individual points of view are extended in time, the deliberations that proceed from such points of view always take place in time from the perspective of the present. The question immediately arises, why should an individual take its future attitudes into account when it deliberates from the perspective of the present? The question becomes poignant as soon as we concede that an individual's attitudes may change significantly over time. Thus, consider Parfit's Russian nobleman who believes as a young man that he should give away all of his money to the poor, but who also believes that he will become much more conservative when he is older and will then regret having given the money away. What should he do? Parfit answers as follows: if he recognizes any normative pressure toward an altruistic stance from which he is bound to take the desires of others into account, then he must extend that stance to his own future desires as well—regardless of the fact that he now disapproves of them (Parfit 1984). Other philosophers have also insisted on parity between the normative demands of prudence and altruism. Among moral philosophers, the parity is often taken in the positive way that Parfit does, as showing that we have reason to be both prudent and altruistic (Sidgewick 1981, Nagel 1970). But some philosophers have taken it in a negative way, as showing that we lack reason to be either. According to them, it follows from the fact that deliberation always proceeds from the perspective of the present that rationality does not require us to take our own future attitudes into account any more than it requires us to take the attitudes of others into account. If they are right, then the rational relations that hold within an individual over time are comparable to social relations within a group (Elster 1979, Levi 1985). However, anyone who is struck by this last suggestion—that an individual over time is, rationally speaking, analogous to a group—would do well to bear in mind what the first two analogies brought out, which is that the social exercise of rational capacities within a group, can, in any case, replicate individual rationality.

4. Group Selves and Multiple Selves

It might seem implausible that the normative analogies between first personal and social relations could ever jeopardize the metaphysical distinction between them, which is grounded in whatever facts constitute the identity and distinctness of selves. According to Locke these facts are phenomenological; according to his opponents, the facts are biological. In both cases, the metaphysical facts on offer would clearly be adequate to ground the distinction between first personal and social relations, and this is so no matter how deep and pervasive the analogies between these two sorts of relations might be at the normative level.

Yet there is a way of thinking about the self that calls this into question. It is the very way of thinking that predominated in Locke's initial definition of the person as a being with 'reason and reflection.' When we emphasize this rational dimension of the self, we will find it natural to use a normative criterion in order to individuate selves. According to this normative criterion, we have one self wherever we find something that is subject to the normative requirements that define individual rationality. There is some disagreement among philosophers about exactly what these requirements are. But, even so, we can say this much

with confidence: it is a sufficient condition for being a rational individual who is subject to the requirements of rationality that the individual have some conception of what those requirements are and is in some degree responsive to them—in the sense of at least trying to meet them when it deliberates and accepting criticism when it fails to meet them (Bilgrami 1998). Of course, such criticism might issue from without as well as within, since a rational individual in this sense would certainly have the conceptual resources with which to comprehend efforts by others to wield rational influence over it. This ensures that there is a readily available public criterion by which such rational individuals can be identified for social purposes: there is one such individual wherever there is an interlocutor whom we can rationally engage. It must be admitted that, due to the analogies between first personal and social relations, the boundaries between such individuals will not always be clear. Yet this does not mean that the normative conception of the self is inadequate or unworkable. It only means that the conception has unfamiliar and, indeed, revisionist consequences. For, if we press the analogies to their logical limit, it follows that there can be group selves comprising many human beings and, also, multiple selves within a single human being (Rovane 1998).

Take the group case first. We have seen that, for the purposes of joint activities, distinct selves must find areas of overlap between their individual points of view which can then serve as a common point of view from which they deliberate and act together. We have also seen that such joint deliberations replicate individual rationality in degree. Now, suppose that this were carried to the following extreme: a group of human beings resolved to engage only in joint activities; accordingly, they resolved to rank all of their preferences about such joint activities together and to pool all of their information; and, finally, they resolved always to deliberate jointly in the light of their jointly ranked preferences and pooled information. The overlap between their points of view would then be so complete that they no longer had separate points of view at all. They would still have separate bodies and separate centers of consciousness. But, despite their biological and phenomenological separation, they would nevertheless all share a single rational point of view from which they deliberated and acted *as one*. Consequently, they could also be rationally engaged in the ways that only individual selves can be engaged. There is good reason to regard such a group as a *bona fide* individual in its own right (Korsgaard 1989, Rovane 1998, Scruton 1989).

Now take the multiple case. Recall that it might be rational for an individual to disregard its future attitudes when it deliberates about what to do in the present, in just the way that it might be rational (though possibly immoral) to disregard the attitudes of others. If the normative demands of rationality are thus confined to one's own present attitudes, then one's future self will be no more bound by one's present deliberations than one is presently bound to take one's future attitudes into account. In other words, one's future self will be free to disregard any long-term intentions or commitments that one is thinking of undertaking now. The point is not that there are no such things as long-term intentions or commitments. The point is that when one makes them one does not thereby bind one's future self in any causal or metaphysical sense. It is always up to one's future self to comply or not as it wishes, and one could not alter this aspect of one's situation except by undermining one's future agency altogether. Although this may seem alarming, it does not follow that individual selves do not endure over time. All that follows is that the unity of an individual self over time is constituted by the same sorts of facts that constitute the unity of a group self. Just as the latter requires shared commitments to joint endeavors so too does the former, the only difference being that the latter involves sharing across bodies while the former involves sharing across time. This serves to bring out that the metaphysical facts in terms of which Locke and his opponents analyze the identity of the self over time are, in a sense, normatively impotent. The fact that there is a persisting center of consciousness, or a persisting animal body, does not suffice to bind the self together rationally over time. And, arguably (though this is more counterintuitive), such facts do not even suffice to bind the self together rationally in the present either. That is why we are able to understand the phenomenon of dissociative identity disorder, formerly labeled multiple personality disorder. Human beings who suffer from this disorder exhibit more than point of view, each of which can be rationally engaged on its own. Since none of these points of view encompasses all of the human host's attitudes, there is no possibility of rationally engaging the whole human being. At any given time one can engage only one part of it or another. Each of these parts functions more or less as a separate self, as is shown precisely by the susceptibility of each to rational engagement on its own. Although these multiple selves cannot be rationally engaged simultaneously, there is good reason to suppose that they nevertheless exist simultaneously. While one such self is talking, its companions are typically observing and thinking on their own (this generally comes out in subsequent conversation with them). Furthermore, these multiple selves who coexist simultaneously within the same body are sometimes 'co-conscious' as well—that is, they sometimes have direct phenomenological access to one another's thoughts. But their consciousness of one another's thoughts does not put them into the normative first person relation that selves bear to their own thoughts; for they do not take one another's thoughts as a basis for their deliberations and actions. Thus neither their shared body nor their shared consciousness suffices to bind multiple personalities together in the sense that is

required by the normative conception of the self. On that conception, they qualify as individual selves in their own rights (Braude 1995, Rovane 1998, Wilkes 1988).

Between these two extreme cases of group and multiple selves, the normative conception provides for a wide spectrum of cases, exhibiting differing degrees of rational unity within and among human beings. The conception says that whenever there is enough rational unity—though it is hard to say how much is enough—there is a rational being with its own point of view who can be rationally engaged as such and who, therefore, qualifies as an individual self in its own right.

5. *Implications for Methodological Individualism*

It is not the case that all of the facts about the Columbia Philosophy Department can be reduced to facts about its members atomistically described. Nor is it the case that all of the facts about that department can be explained by appealing to facts about its members atomistically described. Why? Because sometimes the members of the department stop reasoning from their own separate human-size points of view and begin to reason together from the point of view of the department's distinctive projects, needs, opportunities and so on. When the members of the department do this, they give over a portion of their human lives to the life of the department in a quite literal sense, so that the department itself can deliberate and act from a point of view that cannot be equated with any of their individual points of view. Outside the context of this article, this claim about the Columbia Philosophy Department might naturally be taken to contradict methodological individualism. This is because it is generally assumed that the only individuals there are or can be human individuals. That is what leads many to interpret the facts about the Columbia Philosophy Department—insofar as they cannot be properly described or explained by appealing to facts about its individual human members atomistically described—as irreducibly social phenomena. However, this interpretation fails to take account of the way in which the department instantiates the rational properties that are characteristic of the individual self (vs. a social whole).

Self-regulated Learning

Self-regulated learning refers to how students become masters of their own learning processes. Neither a mental ability nor a performance skill, self-regulation is instead the self-directive process through which learners transform their mental abilities into task-related skills in diverse areas of functioning, such as academia, sport, music, and health. This article will define self-regulated learning and describe the intellectual context in which the construct emerged, changes in researchers' emphasis over time as well as current emphases, methodological issues related to the construct, and directions for future research.

1. *Defining Self-regulated Learning*

Self-regulated learning involves metacognitive, motivational, and behavioral processes that are personally initiated to acquire knowledge and skill, such as goal setting, planning, learning strategies, self-reinforcement, self-recording, and self-instruction. A self-regulated learning perspective shifts the focus of educational analyses from students' learning abilities and instructional environments as fixed entities to students' self-initiated processes for improving their

methods and environments for learning. This approach views learning as an activity that students do for themselves in a proactive way, rather than as a covert event that happens to them reactively as a result of teaching experiences. Self-regulated learning theory and research is not limited to asocial forms of education, such as discovery learning, self-education through reading, studying, programmed instruction, or computer assisted instruction, but can include social forms of learning such as modeling, guidance, and feedback from peers, coaches, and teachers. The key issue defining learning as self-regulated is not whether it is socially isolated but rather whether the learner displays personal initiative, perseverence, and adaptive skill in pursuing it. Most contemporary self-regulation theorists have avoided dualistic distinctions between internal and external control of learning and have envisioned self-regulation in broader, more interactive terms. Students can self-regulate their learning not only through covert cognitive means but also through overt behavioral means, such as selecting, modifying, or constructing advantageous personal environments or seeking social support. A learner's sense of self is not limited to individualized forms of learning but includes self-coordinated collective forms of learning in which personal outcomes are achieved through the actions of others, such as family members, team-mates, or friends, or through use of physical environment resources, such as tools. Thus, covert self-regulatory processes are viewed as reciprocally interdependent with behavioral, social, and environmental self-regulatory processes.

Self-regulation is defined as a variable process rather than as a personal attribute that is either present or absent. Even the most helpless learners attempt to control their functioning, but the quality and consistency (i.e., quantity) of their processes are low. Novice learners rely typically on naive forms of self-regulatory processes, such as setting nonspecific distal goals, using nonstrategic methods, inaccurate forms of self-monitoring, attributions to uncontrollable sources of causation, and defensive self-reactions. By contrast, expert learners display powerful forms of self-regulatory processes, especially during the initial phase of learning. Student efforts to self-regulate their learning has been analyzed in terms of three cyclical learning phases. Forethought phase processes anticipate efforts to learn and include self-motivational beliefs, such as self-efficacy, outcome expectations, intrinsic interest, as well as task analysis skills, such as planning, goal setting, and strategy choice. Performance phase processes seek to optimize learning efforts and include use of time management, imagery, self-verbalization, and self-observation processes. Self-reflection phase processes follow efforts to learn and provide understanding of the personal implication of outcomes. They include self-judgment processes, such as self-evaluation and attributions, and self-reactive processes, such as self-satisfaction and adaptive/defensive inferences. Because novice learners fail to use effective forethought processes proactively, such as proximal goal setting and powerful learning strategies, they must rely on reactive processes occurring after learning attempts that often have been unsuccessful. Such unfortunate experiences will trigger negative self-evaluations, self-dissatisfaction, and defensive self-reflections—all of which undermine self-motivation necessary to continue cyclical efforts to learn. By understanding self-regulation in this cyclical interactive way, qualitative as well as quantitative differences in process can be identified for intervention.

2. *Intellectual Context for Self-regulated Learning Research*

Interest in students' self-regulated learning as a formal topic emerged during the 1970s and early 1980s out of general efforts to study human self-control. Promising investigations of children's use of self-regulatory processes like goal setting, self-reinforcement, self-recording, and self-instruction, in such areas of personal control as eating and task completion prompted educational researchers and reformers to consider their use by students during academic learning. Interest in self-regulation of learning was also stimulated by awareness of the limitations of prior efforts to improve achievement that stressed the role of mental ability, social environmental background of students, or qualitative standards of schools. Each of these reform movements viewed students as playing primarily a reactive rather than a proactive role in their own development. In contrast to prior reformers who focused on how educators should adapt instruction to students based on their mental ability, sociocultural background, or achievement of educational standards, self-regulation theorists focused on how students could proactively initiate or substantially supplement experiences designed to educate themselves.

Interest in self-regulation of learning emerged from many theoretical sources during the 1970s and 1980s. For example, operant researchers adapted the principles and technology of B. F. Skinner for personal use, especially the use of environmental control, self-recording, and self-reinforcement. Their preference for the use of single-subject research paradigms and time series data was especially useful for individuals seeking greater self-regulation of learning. During this same time period, phenomenological researchers shifted from monolithic, global views of how self-perceptions influenced learning to hierarchical, domain-specific views and began developing new self-concept tests to assess functioning in specific academic domains. The research of Hattie Marsh, Shavelson, and others was especially influential in gaining new currency for the role of academic domain self-concepts in learning. During this era, social learning researchers, such as Bandura, Schunk, and Zimmerman,

shifted their emphasis from modeling to self-regulation and renamed the approach as social cognitive. They identified a new task-specific motive for learning—self-efficacy belief, and they linked it empirically to other social cognitive processes, such as goal setting, self-observation, self-judgment, and self-reaction. During this era, researchers such as Corno, Gollwitzer, Heckhausen, Kuhls, and others, resurrected volitional notions of self-regulation to explain human efforts to pursue courses of learning in the face of competing events. In their view, self-regulatory control of action can be undermined by ruminating, extrinsic focusing, and vacillating—which interfere with the formation and implementation of an intention.

Also during the 1970s and 1980s, suppressed writings of Vygotsky were published in English that explained more fully how children's inner speech emerges from social interactions and serves as a source of self-control. Cognitive behaviorists, such as Meichenbaum, developed models of internalization training on the basis of Vygotsky's description of how overt speech becomes self-directive. During this same era, cognitive constructivists shifted their interest from cognitive stages to metacognition and the use of learning strategies to explain self-regulated efforts to learn. The research and theory of Flavell played a major role in effecting this transition by describing self-regulation in terms of metacognitive knowledge, self-monitoring, and control of learning.

Research on self-regulation was also influenced by the emergence of goal theories during the 1970s and 1980s. Locke and Lathan showed that setting specific, proximal, challenging but attainable goals greatly influenced the effectiveness of learners' efforts to learn. Theorists such as Ames, Dweck, Maehr, Midgley, and Nicholls identified individual differences in goal orientations that affected students' efforts to learn on their own. These researchers found that learning or mastery goal orientations facilitated persistence and effort during self-directed efforts to learn, whereas performance or ego goal orientations curtailed motivation and achievement. During this same period, another perspective emerged that focused on the role of intrinsic interest in learning. Deci, Harackiewicz, Lepper, Ryan, Vallerand, and others demonstrated that perceptions of personal control, competence, or interest in a task were predictive of intrinsic efforts to learn on one's own. This focus on intrinsic motivation was accompanied by a resurgence of research on the role of various forms of interest in self-directed learning by a host of scholars in Europe as well as elsewhere, such as Eccles, Hidi, Krapp, Renninger, Schiefele, Wigfield, and others. During these same decades, research on self-regulation of learning was influenced by cybernetic conceptions of how information is processed. Researchers such as Carver, Scheier, and Winne demonstrated the important role of executive processes, such as goal setting and self-monitoring, and feedback control loops in self-directed efforts to learn.

3. *Changes in Emphasis Over Time*

Before the 1980s, researchers focused on the impact of separate self-regulatory processes, such as goal setting, self-efficacy, self-instruction, volition, strategy learning, and self-management with little consideration for their broader implications regarding student learning of academic subject matter. Interest in the latter topic began to coalesce in the mid-1980s with the publication of journal articles describing various types of self-regulated learning processes, good learning strategy users, self-efficacious learners, and metacognitive engagement, among other topics (Jan Simons and Beukhof 1987, Zimmerman 1986). By 1991, a variety of theories and some initial research on self-regulated learning and academic achievement was published in special journal articles and edited textbooks (Maehr and Pintrich 1991, Zimmerman and Schunk 1989). These accounts of academic learning, which described motivational and self-reactive as well as the metacognitive aspects of self-regulation, spurred considerable research. By the mid-1990s, a number of edited texts had been published chronicling the results of this first wave of descriptive research and experimental studies of self-regulated learning (Pintrich 1995, Schunk and Zimmerman 1994). The success of these empirical studies stimulated interest in systematic interventions to students' self-regulated learning and the results of these implementations emerged in journal articles and textbooks by the end of the 1990s (Schunk and Zimmerman 1998).

4. *Emphases in Current Theory and Research*

There is much current interest in understanding the self-motivational aspects of self-regulation as well as the metacognitive aspects (Heckhausen and Dweck 1998). Self-regulated learners are distinguished by their personal initiative and associated motivational characteristics, such as higher self-efficacy beliefs, learning goal orientations, favorable self-attributions, and intrinsic motivation, as well as by their strategic and self-monitoring competence. The issue of self-motivation is of both practical as well as theoretical importance. On the practical side, researchers often confront apathy or helplessness when they seek to improve students' use of self-regulatory processes, and they need viable methods for overcoming this lack of motivation. On the theoretical side, researchers need to understand how motivational beliefs interact with learning processes in a way that enhances students' initiative and perseverance. A number of models have included motivational and learning features as interactive components, such as Pintrich's self-schema model, Boerkaert's three-layered model, Kuhl's action/state control model, and Bandura, Schunk, and Zimmerman's cyclical phase model. These models are designed to transcend conceptual barriers between

learning and motivational processes and to understand their reciprocal interaction. For example, causal attributions are not only expected to affect students' persistence and emotional reactions but also adaptations in their methods of learning. Each of these models seeks to explain how learning can become self-motivating and can sustain effort over obstacles and time.

A second issue of current interest is the acquisition of self-regulatory skills in deficient populations of learners. Study skill training programs have been instituted with diverse populations and age groups of students. These intervention programs have involved a variety of formats, such as separate strategy or study skill training classes, strategy training classes linked explicitly to subject matter classes, such as in mathematics or writing, or personal trainer services in classrooms and counseling centers. This research is uncovering a fascinating body of evidence regarding the metacognitive, motivational, and behavioral limitations of at-risk students. For example, naive learners often overestimate their knowledge and skill, which can lead to understudying, nonstrategic approaches, procrastination, and faulty attributions. Successful academic functioning requires accurate self-perceptions before appropriate goals are set and strategies are chosen. Many of these interventions are predicated on models that envision self-regulatory processes as cyclically interdependent, and a goal of these approaches is to explain how self-fulfilling cycles of learning can be initiated and sustained by students.

5. *Methodological Issues*

Initial efforts to measure self-regulated learning processes relied on inventories in which students are asked to rate their use of specific learning strategies, various types of academic beliefs and attitudes, typical methods of study, as well as their efforts to plan and manage their study time. Another method is the use of structured interviews that involved open-ended questions about problematic learning contexts, such as writing a theme, completing math assignments, and motivating oneself to study under difficult circumstances. The latter form of assessment requires students to create their own answers, and experimenters to train coders to recognize and classify various qualitative forms of self-regulatory strategies. Although both of these approaches have reported substantial correlations with measures of academic success, they are limited by their retrospective or prospective nature—their focus on the usual or preferred methods of learning. As such, they depend on recall or anticipatory knowledge rather than on actual functioning under taxing circumstances. To avoid these limitations, there have been efforts to study self-regulation on-line at various key points during learning episodes using speak-aloud, experimenter questioning, and various performance and outcome measures. Experimental studies employing the latter measures offer the best opportunity to test the causal linkage among various self-regulatory processes, but, even this approach has potential shortcomings, such as inadvertent cuing or interference with self-regulatory processes.

Two common research design issues have emerged in academic interventions with at-risk populations of students: the lack of a suitable control group, and the reactive effects of self-regulatory assessments. Educators have asked self-regulation researchers to provide assistance to students who are often in jeopardy of expulsion, and it is unethical to withhold treatment from some of these students for experimental purposes. One solution is to use intensive within-subject, time-series designs in which treatments are introduced in sequential phases. However, as students begin to collect and graph data on themselves, they become more self-observant and self-reflective—which can produce unstable baselines. This, in turn, can confound causal inferences about the effectiveness of other self-regulatory components of the intervention.

6. *Future Directions for Research and Theory*

6.1 *Role of Technology*

The computer has been recommended as an ideal instrument to study and enhance students' self-regulation. Program menus can be faded when they are no longer needed and performance processes and outcomes can be logged in either a hidden or overt fashion. Computers provide the ultimate feedback to the experimenter or the learner because results can be analyzed and graphed in countless ways to uncover underlying deficiencies. Winne is developing a specially designed computer learning environment designed to study and facilitate self-regulation by the student.

6.2 *Developmental Research*

Relatively little attention has been devoted to forms of self-regulation that can be performed by young children. Very young children have difficulty observing and judging their own functioning, are not particularly strategic in their approach to learning, and tend to reason intuitively from beliefs rather than evidence. Their self-judgments of competence do not match their teachers' judgments until approximately the fifth grade. However, there is reason to expect that simple forms of self-regulatory processes begin to emerge during the early years in elementary school. For example, there is evidence that children can make self-comparisons with their earlier performance at the outset of elementary school. These issues are con-

nected to the key underlying issue of how self-regulation of learning develops in naturalistic as well as designed instructional contexts.

6.3 Out-of-school Influences

There is increasing research showing that non-academic factors such as peer groups, families, and part-time employment strongly affect school achievement. Schunk and Zimmerman have discussed the forms of social influence that these social groups can have on students' self-regulatory development. Brody and colleagues have found that parental monitoring of their children's activities and standard setting regarding their children's performance were very predictive of the children's academic as well as behavior self-regulation, which in turn was predictive of their cognitive and social development. Martinez-Pons has recently reported that parental modeling and support for their children's self-regulation was predictive of the youngsters' success in school. More attention is needed about the psychosocial origins of self-regulatory competence in academic learning.

6.4 Role of Teachers

The recent focus on academic intervention research has uncovered evidence that teachers often conduct classrooms where it is difficult for students to self-regulate effectively. For example, teachers who fail to set specific instructional goals, are ambiguous or inconsistent about their criteria for judging classroom performance, give ambiguous feedback about schoolwork, make it difficult for students to take charge of their learning. Of course, students who enter such classes with well-honed self-regulatory skills possess personal resources that poorly self-regulated learners do not possess. Such self-regulatory experts can turn to extra-classroom sources of information, can deduce subtle unspecified criteria for success, and can rely on self-efficacious beliefs derived from earlier successful learning experiences.

Regarding the development of self-regulated learners, few teachers ask students to make systematic self-judgments about their schoolwork, and as a result, students are not prompted or encouraged to use self-regulatory subprocesses such as self-observation, self-judgment, and self-reactions. Students who lack awareness of their functioning have little reason to try to alter their personal methods of learning. Finally, teachers who run classrooms where students' have little personal choice over their goals, methods, and outcomes of learning can undermine students' perceptions of control and assumption of responsibility for their classroom outcomes.

Self-regulation in Adulthood

Self-regulation is one of the principal functions of the human self, and it consists of processes by which the self manages its own states and actions so as to pursue goals, conform to ideals and other standards, and maintain or achieve desired inner states. Many experts use self-regulation interchangeably with the everyday term self-control, although some invoke subtle distinctions such as restricting self-control to refer to resisting temptation and stifling impulses.

1. Scope of Self-regulation

Most knowledge about self-regulation can be grouped into four broad and one narrower category. The most familiar is undoubtedly impulse control, which refers to regulating one's behavior so as not to carry out motivated acts that could have harmful or undesirable consequences. Dieting, responsible sexual behavior, recovery from addiction, and control of aggression all fall in the category of impulse control.

A second category is affect regulation, or the control of emotions. The most common form of this is the attempt to bring oneself out of a bad mood or bring an end to emotional distress. In principle, however, affect regulation can refer to any attempt to alter any mood or emotion, including all attempts to induce, end, or prolong either positive or negative emotions. Affect regulation is widely regarded as the most difficult and problematic of the major spheres, because most people

cannot change their moods and emotions by direct control or act of will, and so people must rely on indirect strategies, which are often ineffective.

The third category is the control of thought. This includes efforts to stifle unwanted ideas or to concentrate on a particular line of thought. It can also encompass efforts to direct reasoning and inference processes, such as in trying to make a convincing case for a predetermined conclusion or to think an issue carefully through so as to reach an accurate judgment.

The fourth major category is performance regulation. Effective performance often requires self-regulation, which may include making oneself put forth extra effort or persevere (especially in the face of failure), avoid choking under pressure, and make optimal tradeoffs between speed and accuracy.

A narrower category of self-regulation involves superordinate regulation, which is sometimes called self-management. These processes cut across others and involve managing one's life so as to afford promising opportunities. Choosing challenges or tasks (such as college courses) that are appropriately suited to one's talents, avoiding situations that bring hard-to-resist temptations, and conserving one's resources during stressful periods fall in this category.

2. *Importance of Self-regulation*

The pragmatic importance of self-regulation can scarcely be understated. Indeed, most of the personal and social problems afflicting citizens of modern, highly developed countries involve some degree of failure at self-control. These problems include drug and alcohol abuse, addiction, venereal disease, unwanted pregnancy, violence, gambling, school failure and dropping out, eating disorders, drunk driving, poor physical fitness, failure to save money, excessive spending and debt, child abuse, and behavioral binge patterns. Experts regularly notify people that they could live longer, healthier lives if they would only quit smoking, eat right, and exercise regularly, but people consistently fail to regulate themselves sufficiently in those three areas. Longitudinal research has confirmed the enduring benefits of self-regulation. Mischel and his colleagues (e.g., Mischel 1996) found that children who were better able to exercise self-control (in the form of resisting temptation and delaying gratification) at age 4 years were more successful socially and academically over a decade later. Thus, these regulatory competencies appear to be stable and to yield positive benefits in multiple spheres over long periods of time. Self-regulation enables people to resist urges for immediate gratification and adaptively pursue their enlightened self-interest in the form of long-term goals.

Self-regulation also has considerable theoretical importance. As one of the self's most important and adaptive functions, self-regulation is central to the effective functioning of the entire personality. The processes by which the self controls itself offer important insights into how the self is structured and it operates. Higgins (1996) has analyzed the 'sovereignty of self-regulation,' by which he means that self-regulation is the master or supreme function of the self.

3. *Feedback Loops*

Psychologists have borrowed important insights from cybernetic theory to explain self-regulatory processes (e.g., Powers 1973). The influential work by Carver and Scheier (1981, 1982, 1998) analyzed self-awareness and self-regulation processes in terms of feedback loops that control behavior. In any system (including mechanical ones such as thermostats for heating/cooling systems), control processes depend on monitoring current status, comparing it with goals or standards, and initiating changes where necessary.

The basic form of a feedback loop is summarized in the acronym TOTE, which stands for test, operate, test, exit. The test phase involves assessing the current status and comparing it with the goals or ideals. If the comparison yields a discrepancy, some operation is initiated that is designed to remedy the deficit and bring the status into line with what is desired. Repeated tests are performed at intervals during the operation so as to gauge the progress toward the goals. When a test reveals that the desired state has been reached, the final (exit) step is enacted, and the regulatory process is ended.

Feedback loops do not necessarily exist in isolation, of course. Carver and Scheier (1981, 1982) explained that people may have hierarchies of such loops. At a particular moment, a person's actions may form part of the pursuit of long-term goals (such as having a successful career), medium-term goals (such as doing well in courses that will furnish qualifications for that career), and short-term goals (such as persisting to finish a particular assignment in such a course). Once a given feedback loop is exited, indicating the successful completion of a short-term act of self-regulation (e.g., finishing the assignment), the person may revert back to aiming at the long-term goals.

Emotion plays a central role in the operation of the feedback loop (Carver and Scheier 1998). Naturally, reaching a goal typically brings positive emotions, but such pleasant feelings may also arise simply from making suitable progress toward the goal. Thus, emotion may arise from the rate of change of discrepancy between the current state and the goal or standard. Meanwhile, negative emotions may arise not only when things get worse but also simply when one stands still and thereby fails to make progress. Carver and Scheier (1998) phrase this as a 'cruise control' theory of affect and self-regulation, invoking the analogy to an automobile's cruise control mechanism. Like that mechanism, emotion kicks in to regulate the process whenever the speed deviates from the prescribed rate of progress toward the goal.

Although this analysis has emphasized feedback loops that seek to reduce discrepancies between real and ideal circumstances, there are also 'negative feedback loops' in which the goal is to increase the discrepancy between oneself and some standard. For example, people may seek to increase the discrepancy between themselves and the average person.

4. *Self-regulation Failure*

Two main types of self-regulatory failure have been identified (for a review, see Baumeister et al. 1994). The more common is underregulation, in which the person fails to exert the requisite self-control. For example, the person may give in to temptation or give up prematurely at a task. The other category is misregulation, in which person exerts control over self but does so in some counterproductive manner so that the desired result is thwarted.

Several common themes and factors have been identified in connection with underregulation. One is a failure to monitor the self, which prevents the feedback loop from functioning. Thus, successful dieters often count their calories and keep track of everything they eat. When they cease to monitor how much they eat, such as when watching television or when distracted by emotional distress, they may eat much more without realizing it.

Alcohol contributes to almost every known pattern of self-control failure, including impulsive violence, overeating, smoking, gambling and spending, and emotional excess. This pervasive effect probably occurs because alcohol reduces people's attention to self and thereby impairs their ability to monitor their own behavior (see Hull 1981). Emotional distress likewise contributes to underregulation, and although there are multiple pathways by which it produces this effect, one of them is undoubtedly impairment of the self-monitoring feedback loop.

A perennial question is whether underregulation occurs because the self is weak or because the impulse is too strong. The latter invokes the concept of 'irresistible impulses,' which is popular with defense lawyers and addicts hoping to imply that no person could have resisted the problematic urge. After reviewing the evidence, Baumeister et al. (1994) concluded that most instances of underregulation involve some degree of acquiescence by the individual, contrary to the image of a valiant person being overwhelmed by an irresistible impulse. For example, during a drinking binge, the person will actively participate in procuring and consuming alcohol, which contradicts claims of having lost control of behavior and being passively victimized by the addiction. Yet clearly people would prefer to resist these failures and so at some level do experience them as against their will. Self-deception and inner conflict undoubtedly contribute to muddying the theoretical waters. At present, then, the relative contributions of powerful impulses and weak or acquiescent self-control have not been fully understood, except to indicate that both seem to play some role.

Misregulation typically involves some erroneous understanding of how self and world interact. In one familiar example, sad or depressed people may consume alcohol in the expectation that it will make them feel better, when in fact alcohol is a depressant that often makes them feel even worse. The strategy therefore backfires. By the same token, when under pressure, people may increase their attention to their own performance processes, under the assumption that this extra care will improve performance, but such attention can disrupt the smooth execution of skills, causing what is commonly described as 'choking under pressure.'

5. *Strength and Depletion*

The successful operation of the feedback loop depends on the 'operate' stage, in which the person actually changes the self so as to bring about the desired result. Recent work suggests that these operations involve a limited resource akin to energy or strength. The traditional concept of 'willpower' thus is being revived in psychological theory.

Willpower appears to be a limited resource that is depleted when people exert self-control. In laboratory studies, if people perform one act of self-regulation, they seem to be impaired afterwards. For example, after resisting the temptation to eat forbidden chocolates, people are less able to make themselves keep trying on a difficult, frustrating task (Baumeister et al. 1998). Whenever there are multiple demands on self-regulation, performance gradually deteriorates and afterwards the self appears to suffer from depletion of resources (Muraven and Baumeister 2000).

Although the nature of this resource is not known, several important conclusions about it are available. First, it appears that the same strength or energy is used for many different acts of self-regulation, as opposed to each sphere of self-control using a different facility. Trying to quit smoking or keep a diet may therefore impair a person's ability to persist at work tasks or to maintain control over emotions. Second, the resource is sufficiently limited that even small exertions cause some degree of depletion. These effects do not necessarily imply pending exhaustion; rather, people conserve their resources when partly depleted. Third, the resource is also used for making decisions and choices, taking responsibility, and exercising initiative. Fourth, there is some evidence that willpower can be increased by regular exercise of self-control. Fifth, rest and sleep seem to be effective at replenishing the resource.

The effects of ego depletion provide yet another insight into self-control failure. This helps explain the familiar observation that self-control tends to deteriorate when people are working under stress or

pressure, because they are expending their resources to coping with the stress and therefore have less available for other regulatory tasks.

6. Ironic Processes

Another contribution to understanding self-regulatory failure invokes the notion of different mental processes that can work at cross-purposes. Wegner (1994) proposed that effective self-regulation involves both a monitoring process, which remains vigilant for threat or danger (including, for example, the temptation to do something forbidden), and an operating process, which compels the self to act in the desirable fashion. When the monitoring process detects a threat, the operating process helps to prevent disaster, such as when the dieter refuses the offer of dessert. Unfortunately, the monitoring process is generally more automatic than the operating process, so the monitor may continue to notice temptations or other threats even when the operating process is not working. Upon completion of a diet, for example, the dieter may stop saying no to all tempting foods, but the monitoring process continues to draw attention to every delicious morsel that becomes available, so that the person feels constantly tempted to eat. Likewise, when people are tired or depleted, the monitoring system may continue to seek out troublesome stimuli, with disastrous results.

7. Conclusion

Effective self-regulation depends on three ingredients. First, one must have clear and unconflicting standards, such as clear goals or ideals. Second, one must monitor the self consistently, such as by keeping track of behavior. Third, one must have the wherewithal to produce the necessary changes in oneself, and that may include willpower (for direct change) or knowledge of effective strategies (for indirect efforts, such as for changing emotions). Problems in any area can impair self-regulation.

Several areas for future research on self-regulation are promising. The nature of the psychological resource that is expended must be clarified, and brain processes may shed valuable light on how self-regulation works. Interpersonal aspects of self-regulation need to be explicated. The replenishment of depleted resources will also help elucidate the nature of self-control in addition to being of interest in their own right. Individual differences in self-regulation and developmental processes for acquiring self-control need considerably more study. Applications to clinical, industrial, and relationship phenomena need to be examined.

Effective self-regulation includes the ability to adapt oneself to diverse circumstances. It is a vital aspect of human success in life.

Self-regulation in Childhood

Self-regulation has several meanings in the psychology literature, some of which have conceptual links with each other. Three definitions of self-regulation are provided below, but only the first is the theme of this article.

1. Definitions

Self-regulation refers to the development of children's ability to follow everyday customs and valued norms embraced and prescribed by their parents and others. Self-regulation is a vital constituent of the socialization process. A broad construct, self-regulation encompasses a diverse set of behaviors such as compliance, the ability to delay actions when appropriate, and modulation of emotions, motor, and vocal activities as suitable to norm-based contexts. The *self* in self-regulation is an essential feature, and involves a sentient self—one that recognizes and understands the reasons for standards and evaluates one's own actions in relation to others' feelings and needs. Thus the hallmark of self-regulation is the ability to act in accordance with various family and social values in

the absence of external monitors, across a variety of situations, but neither slavishly nor mindlessly.

A second meaning of self-regulation refers to various physiological or psychobiological processes that function adaptively to situational demands, and often do not involve normative standards. Examples include the regulation of intensity of arousal subsequent to emotion producing events, or the control of centrally regulated physiological and perceptual systems to novel events. Centrally regulated systems include electrodermal responses, vagal tone and heart rate, and attention control. Variation in these responses is often studied for links to temperament styles, control of arousal states, and emotion control and coping (e.g., Rothbart et al. 1995).

A third view of self-regulation comes from recent perspectives in motivation. Here, with an emphasis on an individual's goals and the processes that shape the person's actions, a major role is given to the self's role and to evaluation of gains and losses (e.g., Heckhausen and Dweck 1998). Autonomy, control, self-integrity, and efficacy are essential in order for the individual to be effective in the pursuit of desired goals. Within the motivational framework, substantial attention is directed to understanding how adults facilitate or inhibit the child's autonomy.

As noted earlier, this entry is concerned with the development of self-regulation to family and sociocultural standards. Related articles include *Coping across the Lifespan*; *Control Behavior: Psychological Perspectives*; and *Self-regulation in Adulthood.*

2. *Historical Contexts*

The quest to understand the origins and development of self-regulation was a late twentieth century conceptual endeavor grounded in a clinical issue: why do some children as young as two and three years of age reveal high levels of dysregulated behaviors? Examples include resistance to parental requests, difficulty with family routines, high levels of activity, and unfocused attention often associated with an inability 'to wait.'

At the time, earlier findings (e.g., impulse control, resistance to discipline) had implicated factors such as ineffective parenting, as well as distortions in the child's own cognitive or language skills. With rare exceptions, few attempts had been made to understand antecedents, age-related correlates, and consequences of early self-regulated or dys-regulated behaviors. It seemed that a more comprehensive and integrative perspective could lead to a broadened developmental model, and provide insights about multiple contributors to early-appearing problematic behaviors. This was the impetus for a new view of *self-regulation* (Kopp 1982). Family and social standards were increasingly emphasized because of their relevance for self-regulation (Kopp 1987, Gralinski and Kopp 1993).

Self-regulation is not a unique psychological construct, rather it has ideational and behavioral links to courses of action variously labeled as self-management, self-control, and will. These emphases are longstanding and can be found in biblical passages, early philosophical writings, in manuals for parents during the seventeenth century and on to the present, and in the essays of William James, Freud, and John Dewey. More recent thinking can be found in several domains of psychology: developmental, personality, social learning, psychopathology. The enduring historical importance underscores the crucial fact that *individual* adherence to behavioral norms provides essential support for the structure and function of family and sociocultural groups.

Societal norms are grounded in historical time and locale, and are reflected by caregivers' socialization practices. Changes in practices have implications for the kinds of behaviors expected of children (including those associated with self-regulation). The dramatic changes in the sociocultural scene in the USA since the mid-1900s provide an example. At the end of the twentieth century, parenting was primarily authoritarian and children were expected to conform to standards without dissent. However, a mid-century transformation in child rearing practices occurred. The change was linked to two decades of economic hardship, a devastating war, quests for family life among returning veterans, and a pediatrician (Benjamin Spock) whose counsel to mothers about trusting their own judgement would resonate with new parents. In time, as a more relaxed style of parenting emerged, there was increasing tolerance for children to assert themselves about norms. Parents began to reveal a willingness to negotiate with their children about a variety of things including how norms could be met. At the beginning of the twenty-first century, a reciprocal style of parenting (often termed authoritative; Baumrind 1967) is far more common than the more inflexible authoritarian approach.

For social scientists, this changing socialization orientation led to new or recast research topics. Studies focused on the characteristics and consequences of authoritative parenting, children's autonomy needs, and understanding how the self-determination needs of the individual balance with the value based requirements of social–cultural groups. The challenges to define and explain the balancing process continue.

3. *Socialization and Self-regulation*

3.1 *Principles*

Despite changing emphases in socialization, three principles remain a constant; these have implications for the development of self-regulation. First, most sociocultural groups expect primary authority figures such as parents to begin the active process of socialization. These individuals actively expose older infants

and toddlers to family norms and practices. Later, these socializing agents will be joined by others who typically include teachers, age mates, friends, and neighbors. New socializing agents may reinforce previous norms, expand the interpretation of norms, or introduce new ones. Children are expected to adapt their behavior accordingly.

Second, parents tend to be mindful—perhaps implicitly—of a child's developmental capabilities, the family's functional needs, and sociocultural standards when they teach norms. Protection of the child from harm seems to be the most salient *initial* child-rearing value. Then the content of parents' socialization efforts progresses to other family concerns, and from there to the broader context of neighborhood, community, and societal norms. Across sociocultural groups, there are assumptions that toddlers and preschoolers will learn a few specific family and neighborhood norms, whereas school-aged children will adopt family and cultural customs and moral standards, formal laws, and economic values. Adolescents are expected to prepare themselves for social, emotional, and economic independence using as infrastructure the norms of the family and culture.

The third principle is that socialization and self-regulation are adaptive, bidirectional processes. Children and adolescents are not passive recipients in the socialization process. With the growth of their own cognitive skills and recognition of their own self needs, children show an increasing desire to have a say in defining the everyday customs that they encounter, and the ways customs are followed. Thus each succeeding generation in modern, democratic sociocultural groups modifies the content or enactment of customs and norms in some way. An implication for children is that effective self-regulation represents thoughtful, rather than indiscriminate, adherence to family practices and social norms.

3.2 Studying Self-regulation in the Context of Socialization

Self-regulation is often used as a conceptual frame for research rather than a design element with the three themes of compliance, delay, and behavioral modulation. Rather, most research has been focused on the study of compliance during the preschool period (typically, from 3 to 5 years of age). Although this emphasis is warranted—adherence to norms is considered to be a crucial developmental task for this age (Sroufe and Rutter 1984)—important knowledge gaps exist. There is fragmented information about effective integration of compliance, delay, and behavioral modulation, and developmental trends among younger and older children.

Recent descriptive studies also reveal considerable complexity in young children's responses to parental requests. This finding has prompted efforts to refine operational definitions, expand the research contexts for the study of self-regulation, and utilize data-collection procedures that involve multiple measurement techniques and informants. These recent efforts have largely focused on children without major behavioral problems.

Lastly, considerable research has highlighted parental and child correlates of self-regulation components, albeit sometimes within a limited age period and one or two contexts. The most complete database is available for the preschool years.

3.3 Research Data: Parents, Children, and Social Norms

The timing of active socialization originates in child behaviors such as the onset of walking. When very young children locomote on their own, they discover opportunities to explore, sometimes with the potential for physical or psychological harm. Thus parents start to identify acceptable and unacceptable behaviors for the child, and attempt to obtain some measure of compliance using a variety of attention getting techniques (Schaffer 1996). These beginnings mark the dynamic and occasionally formidable interplay between parents' socialization efforts and young children's trajectory toward self-regulation.

Although parents use their child's behavior as a socializing cue, they also rely on family needs (e.g., the composition of a family, living arrangements), as well as societal norms. A toddler in a large family with limited living space is likely to be exposed to somewhat different restrictions to an only child living in spacious quarters. However, three overarching themes unite parents' initial socialization efforts: young children must be protected from harming themselves or others (LeVine 1974, Gralinski and Kopp 1993); they must not tamper with family members' possessions; and they must learn to respect others' feelings (Dunn 1988). As children become older and their social environments increase, parental cautions about normative standards extend beyond the immediate family to peers, neighbors, and teachers, and focus on conventions and moral values, among other topics.

In addition to structuring the content of socialization norms, the how of parental socialization is crucial. There is unequivocal consensus about the effect of child-rearing styles at least with Euro-American middle-class families. Sensitive and knowledgeable parenting is correlated with children's compliance to norms, across age periods (Kochanska and Aksan 1995).

3.4 A Self-regulation Developmental Trajectory

Learning to deal with parents' norm-related requests is an all-powerful challenge. Children must bring their cognitive, linguistic, social, and emotional resources to situations that demand self-regulation. The task is most difficult for young children: they have cognitive

Table 1
Self-regulation: developmental landmarks

Landmarks	Components of self-regulation		
	Compliance	Delay/waiting (object rewards, others' attention)	Modulation of emotions, vocalizations, and motor activities
Emergent: responses tend to be situation specific and unpredictable	Early 2nd year	Early 2nd year	Early PS[a]
Functional: a few predictable norm responses; some cognizance of self role	End 2nd year; early PS	Mid-PS	Mid-PS
Integrative: response coherence across two self-regulation components; nascent causal reasoning	Late PS	Late PS	Late PS
Internalized: understands, accepts others' values and self role for social norms	*Late PS*[b]; *S-A*[c]	*S-A*	*S-A*
Future oriented: planful behavior for some norm contexts	*Mid-late S-A*	*Mid-late S-A*	*Mid-late S-A*

a Preschool period. b Italics indicate presumed progression. c School age years.

and language limitations; they are inclined to explore anything that looks interesting; they long for autonomy and self-assertion. It is not surprising that self-regulation takes years to mature into an effective process.

Table 1 depicts the three components of self-regulation along with ages associated with developing behavioral landmarks. The ages represent approximations; the landmarks highlight behaviors that typify increasing maturity to parental norm-based requests.

Using compliance as an exemplar, *Emergent* signifies that responses to a parent prohibition (e.g., child does not stand on a kitchen chair) may occur sporadically. *Functional* portrays fairly regular compliance to a rule (e.g., child does not stand on chairs, whether in the living room or kitchen); children may show signs of remorse when they do not comply. *Integrative* refers to predictability (i.e., coherence) in children's behavior *across different kinds* of norm-based situations (e.g., a child does not yell in a market, respects a sibling's possessions, and waits to be served dinner).

Extant data reveal that compliance to family *do's* and *dont's* tends to be easier for young children than norm-based situations that require waiting or modulation of ongoing behaviors (also shown in Table 1). This disparity may be related to additional regulatory demands imposed on children when timing or refined behavioral nuances are critical for an effective response. In these instances, the use of strategic behaviors (e.g., self-distraction, conscious suppression efforts) may be crucial for effective self-regulation.

Despite inevitable setbacks, children become more responsive to specific family and other social rules. The growth of self-regulation is facilitated by greater understanding of people and events, widening sensitivity to everyday happenings in the family and neighborhood, and increasing ability to talk about self needs in relation to others' needs. The importance of language in self-regulation is exemplified by the transition from outright refusals common among toddlers to attempts to talk about and negotiate task demands among older preschoolers (Klimes-Dougan and Kopp 1999). Still, children of this age may have difficulty with anger control, waiting for parental attentiveness, and sharing possessions.

An extensive database on topics related to self-regulation in the preschool years suggests that correlates include gender (many girls learn behavioral controls sooner than boys), temperament characteristics such as controlled attention and inhibition of motor acts, verbal skills, effective self-distraction, and competent use of strategies (Eisenberg and Fabes 1992, Metcalfe and Mischel 1999).

Overall, continuing efforts of parents to socialize their children gradually dovetail with children's growth of their own behavioral cognitive, social, and motivational repertoire. Few details exist about how parents and children collaborate with their own resources so that children increasingly take on responsibility for self-regulation. What can be said with certainty is that self-regulation gradually emerges when children understand the reasons for values and standards, possess a cognizant self, are able to suppress an immediate goal that runs counter to family norms, and voluntarily assume responsibility for their own actions across a variety of situations.

Self-generated and self-monitored adherence to norms *is* self-regulation. This autonomous, sometimes conscious, effort to frame activities with normative values stands in contrast to early forms of compliance that do not rely on knowledge or self-awareness. Effective self-regulation is by definition an adaptive,

developmental process in that children have to discover how to meet their own self needs while in general following societal standards across many settings. The task is a changing one because each age period is associated with new socialization demands imposed by parents, teachers, other individuals, and the larger social context.

4. Self-regulation: Its Value and Directions

The construct of self-regulation has heightened awareness of dys-regulation and its long-term implications. Findings from related research point to long-standing problems when young children have difficulty with compliance, delay, and impulse control. To date, however, the developmental antecedents of these problems have been elusive. A renewed focus on the toddler years should be useful: two important developments occur in the second and third years that have relevance for the growth of self-regulation. These are emergent selfhood and the control of attention and consciousness.

It is well known that effective norm-based behaviors require reconciliation of conflicts between self-goals and social norm demands. Among mature individuals, these conflicts are often met with reflection about courses of action, informal appraisals of costs and benefits, and plans for making reparations should they be necessary. This complex cognitive strategy is not available to young children. Understanding how very young children begin to sort through competing self and social goals may provide insights into effective paths to self-regulation.

With respect to conscious learning about social norms, this almost certainly occurs, but when and how are not well understood. However, consciousness demands psychic energy, so it is in children's best interests to sort out those family and social norms that require relatively habitual responses from those that demand additional attentional or memory efforts from themselves. How children learn to differentiate and classify standards may yield understanding about strategies useful for modulating behaviors in novel norm-based contexts, and why some children falter in these situations.

Semantic Knowledge: Neural Basis of

Semantic knowledge is a type of long-term memory, commonly referred to as semantic memory, consisting of concepts, facts, ideas, and beliefs (e.g., Tulving 1983). Semantic memory is thus distinct from *episodic* or *autobiographical* memories, which are unique to an individual and tied to a specific time and place. For example, answering the question 'What does the word *breakfast* mean?' requires semantic memory. In contrast, answering the question 'What did you have for breakfast yesterday?' requires episodic memory, to retrieve information about events in our personal past, as well as semantic memory, to understand the question. Semantic memory therefore includes the information stored in our brains that represents the meaning of words and objects.

Understanding the nature of meaning, however, has proven to be a fairly intractable problem: especially

regarding the meaning of words. One important reason why this is so is that words have multiple meanings. The specific meaning of a word is determined by context, and comprehension is possible because we have contextual representations (see Miller 1999 for a discussion of lexical semantics and context). Cognitive neuroscientists have begun to get traction on the problem of meaning in the brain by limiting inquiry to concrete objects as represented by pictures, and by their names.

Consider, for example, the most common meaning of two concrete objects; a camel and a wrench. Camel is defined as 'either of two species of large, domesticated ruminants (genus camelus) with a humped back, long neck, and large cushioned feet,' the object wrench is defined as 'any number of tools used for holding and turning nuts, bolts, pipes, etc.' (Webster's New World Dictionary 1988). Two things are noteworthy about these definitions. First, they are largely about features; camels are large and have a humped back; wrenches hold and turn things. Second, different types of features are emphasized for different types of object. The definition of the camel consists of information about its visual appearance, whereas the definition of the wrench emphasizes how it is used. Differences in the types of feature that define different objects have played, and continue to play, a central role in models of how semantic knowledge is organized in the human brain.

Another point about these brief definitions is that they include only part, and perhaps only a small part, of the information we may possess about these objects. For example, we may know that camels are found primarily in Asia and Africa, that they are known as the 'ships of the desert,' and that the word camel can also refer to a color and a brand of cigarettes. Similarly, we also know that camels are larger than a bread box and weigh less than a 747 jumbo jet. Although this information is also part of semantic memory, little is known about the brain bases of these associative and inferential processes. Neuroscientists are, however, beginning to gain insights into the functional neuroanatomy associated with identifying objects and retrieving information about specific object features and attributes.

1. *Semantic Representations*

A central question for investigators interested in the functional neuroanatomy of semantic memory has been to determine how information about object concepts is represented in the brain. A particularly influential idea guiding much of this work is that the features and attributes that define an object are stored in the perceptual and motor systems active when we first learned about that object. For example, information about the visual form of an object, its typical color, its unique pattern of motion, would be stored in or near regions of the visual system that mediate perception of form, color, and motion. Similarly, knowledge about the sequences of motor movements associated with the use of an object would be stored in or near the motor systems active when that object was used. This idea has a long history in behavioral neurology. Indeed, many neurologists at the beginning of the twentieth century assumed that the concept of an object was composed of the information about that object learned through direct sensory experience and stored in or near sensory and motor cortices (e.g., Lissauer 1988, 1890).

2. *Semantic Deficits Result from Damage to the Left Temporal Lobe*

The modern era of study on the organization of semantic knowledge in the human brain began with Elizabeth Warrington's seminal paper 'The selective impairment of semantic memory' (Warrington 1975). Warrington reported three patients with progressive dementing disorders that provided neurological evidence for a semantic memory system. There were three main components to the disorder. First, it was selective. The disorder could not be accounted for by general intellectual impairment, sensory or perceptual problems, or an expressive language disorder. Second, the disorder was global, in the sense that it was neither material- nor modality-specific. Object knowledge was impaired regardless of whether objects were represented by pictures or their written or spoken names. Third, the disorder was graded. Knowledge of specific object attributes (e.g., does a camel have two, four, or six legs?) was more impaired than knowledge of superordinate category information (i.e., is a camel a mammal, bird, or insect?).

Following Warrington's report, similar patterns of semantic memory dysfunction have been reported in patients with brain damage resulting from a wide range of etiologies. These have included patients with progressive dementias such as Alzheimer's disease and semantic dementia, herpes encephalitis, and closed head injury (for review, see Patterson and Hodges 1995). Consistent with the properties established by Warrington, these patients typically had marked difficulty producing object names under a variety of circumstances, including naming pictures of objects, naming from the written descriptions of objects, and generating lists of objects that belong to a specific category (e.g., animals, fruits and vegetables, furniture, etc.). In addition, the deficits were associated primarily with damage to the left temporal lobe, suggesting that information about object concepts may be stored, at least in part, in this region of the brain.

3. Brain Damage Can Lead to Category-specific Semantic Deficits

Other patients have been described with relatively selective deficits in recognizing, naming, and retrieving information about different object categories. The categories that have attracted the most attention are animals and tools. This is because of a large and growing number of reports of patients with greater difficulty naming and retrieving information about animals (and often other living things) than about tools (and often other man-made objects). Reports of the opposite pattern of dissociation (greater for tools than animals) are less frequent. However, enough carefully-studied cases have been reported to provide convincing evidence that these categories can be doubly dissociated as a result of brain damage. The impairment in these patients is not limited to visual recognition. Deficits occur when knowledge is probed visually and verbally, and therefore assumed to reflect damage to the semantic system or systems (for review, see Forde and Humphreys 1999).

While it is now generally accepted that these disorders are genuine, their explanation, on both the cognitive and neural levels, remains controversial. Two general types of explanation have been proposed. The most common explanation focuses on the disruption of stored information about object features. Specifically, it has been proposed that knowledge about animals and tools can be disrupted selectively because these categories are dependent on information about different types of features stored in different regions of the brain. As exemplified by the definitions provided previously, animals are defined primarily by what they look like, and functional attributes play a much smaller role in their definition. In contrast, functional information, specifically how an object is used, is critical for defining tools. As a result, damage to areas where object form information is stored leads to deficits for categories that are overly-dependent on visual form information, whereas damage to regions where object use information is stored leads to deficits for categories overly-dependent on functional information. The finding that patients with category-specific deficits for animals also have difficulties with other visual-form-based categories, such as precious stones, provides additional support for this view (e.g., WarPrington and Shallice 1984).

This general framework for explaining category-specific disorders was first proposed by Warrington and colleagues in the mid- to late 1980s (e.g., Warrington and Shallice 1984). Influential extensions and reformulation of this general idea have been provided by a number of investigators, including Farah and McClelland (1991), Damasio (1990), Caramazza et al. (1990), and Humphreys and Riddoch (1987).

The second type of explanation focuses on broader semantic distinctions (e.g., animate v. inanimate objects), rather than on features and attributes, as the key to understanding category-specific deficits. A variant of this argument has recently been proposed by Caramazza and Shelton (1998) to counter a number of difficulties with feature-based formulations. Specifically, these investigators note that a central prediction of at least some feature-based models is that patients with a category-specific deficit for animals should have more difficulty in answering questions that probe knowledge about visual information about animals (does an elephant have a long tail?), than about function information (is an elephant found in the jungle?). As Caramazza and Shelton (1998) show, at least some patients with an animal-specific knowledge disorder (and, according to their argument, all genuine cases) have equivalent difficulty with both visual and functional questions about animals. As a result of these and other findings, Caramazza and Shelton argue that category-specific disorders cannot be explained by feature-based models. Instead, they propose that such disorders reflect evolutionary adaptations for animate objects, foods, and perhaps by default, tools, and other manufactured objects (the 'domain-specific hypothesis'; Caramazza and Shelton 1998).

4. Functional Brain Imaging Reveals that Semantic Knowledge about Objects is Distributed in Different Regions of the Brain

Functional brain imaging allows investigators to identify the neural systems active when normal individuals perform different types of task. These studies have confirmed findings with brain damaged subjects, and have begun to extend knowledge of the neural basis of semantic memory. Although functional brain imaging is a relatively new tool, the current evidence suggests that information about different object features is stored in different regions of the cerebral cortex. One body of evidence in support of this claim comes from experiments using word generations tasks. Subjects are presented with the name of an object, or a picture of an object, and required to generate a word denoting a specific feature or attribute associated with that object. In one study, positron emission tomography (PET) was used to investigate differences in patterns of brain activity when subjects generated the name of an action typically associated with an object (e.g., saying the word 'pull' in response to a static, achromatic line-drawing of a child's wagon), relative to generating an associated color word e.g., saying 'red' in response to the wagon) (Martin et al. 1995). Relative to generating a color word, action-word generation activated a posterior region of the left temporal lobe, called the middle temporal gyrus. This location was of particular interest because it was just anterior to sites known to be active during motion

Figure 1
Brain regions active during retrieval of color and action knowledge. **A** Ventral view of the human brain showing approximate locations of regions in the occipital cortex active during color perception (black ovals), and color word generation in response to object pictures and object names (gray ovals). This region is also active when subjects generate color imagery in response to verbal commands, and in subjects with auditory word–color synethesia (for review, see Martin 2001). **B** Lateral view of the left hemisphere showing location of the region active during motion perception (area MT; black oval), and region of the middle temporal gyrus active when subjects generated action words to object pictures, and object names (gray oval). Location of this region is based on over 20 studies encompassing nine native languages (for review, see Martin 2001). The white oval indicates the approximate location of the region of inferior prefrontal cortex implicated in selecting, retrieving, and maintaining lexical and phonological information (for review, see Martin and Chao 2001)

perception (area MT). In contrast, relative to generating action words, color-word generation activated a region on the ventral, or underside of the temporal lobe, called the fusiform gyrus. This location was of particular interest because it was just anterior to sites known to be active during color perception. Finally, the same pattern of results was found when subjects were presented with the written names of objects, rather than an object picture (Fig. 1) (for review see Martin 2001).

These findings, and findings from other studies using a wide range of semantic processing tasks, provide support for two important ideas about the neural representation of semantic knowledge. First, there is a single semantic system in the brain, rather than separate semantic systems for different modalities of input (visual, auditory) or types of material (pictures of objects, words) (e.g., Vandeberghe et al. 1996). This system includes multiple brain regions, especially in the temporal and frontal lobes of the left hemisphere (for review see Price et al. 1999, Martin 2001). Second, information about object features and attributes are not stored in a single location, but rather are stored as a distributed network of discrete cortical areas. Moreover, the locations of the sites appear to follow a specific plan that parallels the organization of sensory systems, and, as will be reviewed below, motor systems, as well.

5. *Ventral Occipitotemporal Cortex and the Representation of Object Form*

Another body of evidence that object concepts may be represented by distributed feature networks comes from studies contrasting patterns of neural activity associated with naming, and performing other types of tasks with objects from different categories. A feature common to all concrete objects is that they have physical shape or form. Evidence is accumulating that suggests that many object categories elicit distinct

Figure 2
Brain regions showing object category-related patterns of activation. Approximate location of regions in the ventral temporal cortex **A**, and lateral cortex **B**, active during viewing, naming, and retrieving information about animals (black ovals) and tools (gray ovals). Blecause of their anatomic proximity to visual object form (and form-related features like color), motion, and motor processing areas, it has been suggested that information about how an object appears, moves, and is used, is stored in these regions (see text for details). These regions interact with lower-level visual processing areas in occipital cortex (double arrows); especially when discriminating among items of similar appearance (e.g., four-legged animals, faces). 1. Superior temporal sulcus (STS). 2. Middle temporal gyrus. 3. Premotor cortex

patterns of neural activity in regions involved in object form processing (ventral occipital and temporal cortex). Moreover, the locations of these category-related activations appear to be consistent across individual subjects and processing tasks (e.g., naming object pictures, matching pictures, reading object names). This seems to be especially so for objects defined primarily by visual form-related features such as animals, faces, and landmarks.

Early reports using PET found that naming (Martin et al. 1996) and matching (Perani et al. 1995) pictures of animals resulted in greater activation of the left occipital cortex than performing these same tasks with pictures of tools. Because the occipital cortex is involved primarily in the early stages of visual processing, it was suggested that this activity reflected top-down activation from more anterior sites in the occipitotemporal object processing stream (Martin et al. 1996). This may occur whenever detailed information about visual features or form is needed to identify an object. Specifically, naming objects that differ from other members of the same category by relatively subtle differences in visual form (four-legged animals) may require access to stored information about visual detail. Retrieving this information, in turn, may require participation of early visual processing areasn the occipital cortex. A subsequent report showing that unilateral occipital lesions could result in greater difficulty in naming and retrieving information about animals than tools provided converging evidence for this view (Tranel et al. 1997).

However, most patients with semantic deficits for animals have had lesions confined to the temporal lobes (for review, see Gainotti et al. 1995). Functional brain imaging of normal individuals has now provided evidence for category-related activations in the ventral region of the temporal lobes. This has been accomplished by using functional magnetic resonance imaging (fMRI), which provides better spatial resolution than was possible using PET.

A number of investigators have found that distinct regions of the ventral temporal cortex show differential responses to different object categories. In one study, viewing, naming, and matching pictures of animals, as well as answering written questions about animals, were found to activate the lateral region of the fusiform

gyrus, relative to performing these tasks with pictures and names of tools. In contrast, the medial fusiform was more active for tools than animals. A similar, but not identical, pattern of activation was found for viewing faces (lateral fusiform) relative to viewing houses (medial fusiform) (Chao et al. 1999). Other investigators have also reported face-related activity in the lateral region of the fusiform gyrus, and house-related activity in more medial regions of the ventral temporal lobe, including the fusiform, lingual, and parahippocampal gyrus (Fig. 2) (for review, see Kanwisher et al. 2001, Martin 2001).

These findings suggest that different object categories elicit activity in different regions of ventral temporal cortex, as defined by the location of their peak activation. Moreover, the typological arrangement of these peaks was consistent across subjects and tasks. Importantly, however, the activity associated with each object category was not limited to a specific region of the ventral occipitotemporal cortex, but rather was distributed over much of the region (Chao et al. 1999).

Additional evidence for the distributed nature of object representations in the ventral temporal cortex comes from single cell recordings from intracranial depth electrodes implanted in epileptic patients (Kreiman et al. 2000a). Recordings from the regions of the medial temporal cortex (entorhinal cortex, hippocampus, and amygdala), which receive major inputs from the ventral temporal regions described above, identified neurons that showed highly selective responses to different object categories, including animals, faces, and houses. Moreover, the responses of the neurons were category-specific rather than stimulus-specific. That is, animal-responsive cells responded to all pictures of animals, rather than to one picture or a select few.

Studies reporting similar patterns of neural activity when subjects view and imagine objects provide further support that object information is stored in these regions of cortex. For example, regions active during face perception are also active when subjects imagine famous individuals (O'Craven and Kanwisher 2000). Similar findings have been reported for viewing and imagining known landmarks (O'Craven and Kanwisher 2000), houses, and even chairs (Ishai et al. 2000). In addition, the majority of category-selective neurons recorded from human temporal cortex also responded selectively when the patients were asked to imagine these objects (Kreiman et al. 2000b).

Taken together, the data suggest that the ventral occipitotemporal cortex may be best viewed, not as a mosaic of discrete category-specific areas, but rather as a lumpy feature-space, representing stored information about features of object form shared by members of a category. How this feature space is organized, and why its topological arrangement is so consistent from one subject to another, are critical questions for future investigations.

6. *Lateral Temporal Cortex and the Representation of Object Motion*

Information about how objects move through space, and patterns of motor movements associated with their use, are other features that could aid object identification. This would be especially true for categories of manufactured objects such as tools that have a more variable mapping between their name and their visual form than a category such as four-legged animals. Thus access to these additional features may be required to identify them as unique entities. Here again, evidence is accumulating that naming and identifying objects with motion-related attributes activate areas close to regions that mediate perception of object motion (posterior region of the lateral temporal lobe) with different patterns of activity associated with biological and manufactured objects.

A number of laboratories using a variety of paradigms with pictures and words have reported that tools elicit greater activity in the posterior, left middle temporal gyrus than animals and other object categories (for review, see Martin 2001). Moreover, the active region was just anterior to area MT, and overlapped with the region active in the verb generation studies discussed above. Damage to this region has been reported selectively to impair tool recognition and naming (Tranel et al. 1997). In contrast, naming animals and viewing faces elicits greater activity in the superior temporal sulcus (STS) (Fig. 2). This region is of particular interest because of its association with the perception of biological motion in monkeys as well as humans (for review, see Allison et al. 2000). As suggested for the ventral temporal cortex, neurons in the lateral temporal cortex may also be tuned to features that objects within a category share. The nature of these features is unknown; however, based on its anatomical proximity to visual motion processing areas, this region may be tuned to features of motion associated with different objects. In support of this conjecture, increased activity in the posterior lateral temporal cortex has been found when subjects viewed static pictures of objects that imply motion (Kourtzi and Kanwisher 2000, Senior et al. 2000), and when subjects focused attention on the direction of eye gaze (Hoffman and Haxby 2000). Investigation of the differences in the properties of motion associated with biological and manufactured objects may provide clues to the organization of this region.

7. *Ventral Premotor Cortex and the Representation of Use-associated Motor Movements*

If activations associated with different object categories reflect stored information about object properties, then one would expect tools to elicit activity in

motor-related regions. Several laboratories have reported this association. Specifically, greater activation of the left ventral premotor cortex has been found for naming tools relative to naming animals, viewing pictures of tools relative to viewing pictures of animals, faces, and houses, and generating action words to tools (Fig. 2). Mental imagery (e.g., imagining manipulating objects with the right hand) has also resulted in ventral premotor activation (Fig. 2) (for review, see Martin 2001).

Electrophysiological studies have identified cells in monkey ventral premotor cortex that responded not only when objects were grasped, but also when the animals viewed objects they had had experience of manipulating (Jeannerod et al. 1995). The ventral premotor activation noted in the human neuroimaging studies may reflect a similar process. These findings are consistent with reports of patients with greater difficulty in naming tools than animals following damage to the left lateral frontal cortex (for review, see Gainotti et al, 1995) and suggest that the left ventral premotor cortex may be necessary for naming and retrieving information about tools.

8. *Conclusions and Future Directions*

Evidence from functional brain imaging studies provides considerable support for feature-based models of semantic representation. However, some of the findings could be interpreted as evidence for the 'domain-specific' hypothesis as well. For example, the clustering of activations associated with animals and faces, on the one hand, and tools and houses, on the other, may be viewed as consistent with this interpretation. Other evidence suggests, however, that all nonbiological object representations do not cluster together. For example, it has been reported that activity associated with a category of objects of no evolutionary significance (chairs) was located lateral to the face-responsive region (in the inferior temporal gyrus), rather than medially where tools and houses elicit their strongest activity (Ishai et al. 1999). Both functional brain imaging and patient studies suggest that object knowledge is represented in distributed cortical networks. There do not seem to be single regions that map on to whole object categories. Nevertheless, there may be a broader organization of these networks that reflects evolutionarily adapted, domain-specific knowledge systems for biological and nonbiological kinds of object. This possibility remains to be explored.

Although progress is being made in understanding the neural substrate of some aspects of meaning, many important questions and issues remain. For example, semantic representations are prelexical. Yet, to be of service, they must be linked intimately to the lexicon. Little is known about how the lexicon is organized in the brain, and how lexical and semantic networks interact (Damasio et al. 1996).

Another important issue concerns the neural basis of retrieval from semantic memory. Semantic knowledge, like all stored information, is not useful unless it can be retrieved efficiently. Studies of patients with focal lesions have shown that the left lateral prefrontal cortex is involved critically in word retrieval, even in the absence of a frank aphasia (e.g., Baldo and Shimamura 1998). Functional brain imaging studies have confirmed this association (Fig. 2). Moreover, recent evidence suggests that different regions of the left inferior prefrontal cortex may mediate selection among competing alternatives in semantic memory, whereas other regions may be involved in retrieving, manipulating, and maintaining semantic information in working memory (for review, see Martin and Chao 2001). Much additional work will be needed to describe the role that different regions of prefrontal cortex play in semantic processing.

Another critical question will be to determine how semantic object representations are modified by experience. Some of the findings discussed here suggest that the typological arrangement among object categories in the cortex is relatively fixed. Other evidence suggests a much more flexible organization, in which the development of expertise with an object category involves a particular portion of the fusiform gyrus (Gauthier et al. 1999). Longitudinal studies tracking changes in the brain associated with learning about completely novel objects should help to clarify this issue.

There is also little known about where object information unrelated to sensory or motor properties is stored (e.g., that camels live in Asia and Africa). Similarly, little is known about the representation of abstract concepts (e.g., honor, liberty, and justice), metaphors, and the like.

Finally, questions concerning the neural systems involved in object category formation have been almost totally neglected. E. E. Smith and colleagues have shown that exemplar-based and rule-based categorization activate different neural structures (Smith et al. 1999). This finding suggests that categorization processes may be a fruitful area for future investigation. The advent of techniques to converge fMRI data with technologies such as magnetoencephalography (MEG) that provide temporal information on the order of milliseconds, should provide a wealth of new information on the neural basis of semantic knowledge.

Semantic Processing: Statistical Approaches

The development of methods for representing meaning is a critical aspect of cognitive modeling and of applications that must extract meaning from text input. This ability to derive meaning is the key to any

approach that needs to use or evaluate knowledge. Nevertheless, determining how meaning is represented and how information can be converted to this representation is a difficult task. For example, any theory of meaning must describe how the meaning of each individual concept is specified and how relationships among concepts may be measured. Thus, appropriate representations of meaning must first be developed. Second, computational techniques must be available to permit the derivation and modeling of meaning using these representations. Finally, some form of information about the concepts must be available in order to permit a computational technique to derive the meaning of the concepts. This information about the concepts can either be more structured human-based input, for example dictionaries or links among related concepts, or less structured natural language.

With the advent of more powerful computing and the availability of on-line texts and machine-readable dictionaries, novel techniques have been developed that can automatically derive semantic representations. These techniques capture effects of regularities inherent in language to learn about semantic relationships among words. Other techniques have relied on hand-coding of semantic information, which is then placed in an electronic database so that users may still apply statistical analyses on the words in the database. All of these techniques can be incorporated into methods for modeling a wide range of psychological phenomena such as language acquisition, discourse processing, and memory. In addition, the techniques can be used in applied settings in which a computer can derive semantic knowledge representations from text. These settings include information retrieval, natural language processing, and discourse analysis.

1. *The Representation of Meaning*

Definitions of semantics generally encompass the concepts of knowledge of the world, of meanings of words, and of relationships among the words. Thus, techniques that perform analyses of semantics must have representations that can account for these different elements. Because these computational techniques rely on natural language, typically in the form of electronic text, they must further be able to convert information contained in the text to the appropriate representation. Two representational systems that are widely used in implementations of computational techniques are feature systems and semantic networks. While other methods of semantic representation (e.g., schemas) also account for semantic information in psychological models, they are not as easily specified computationally.

1.1 *Feature Systems*

The primary assumption behind feature systems is that if a fixed number of basic semantic features can be discovered, then semantic concepts can be defined by their combination, or composition of these features. Thus, different concepts will have different basic semantic features or levels of these features. Concepts vary in their relatedness to each other, based on the degree to which they have the same semantic features (e.g., Smith and Medin 1981). One approach to define empirically the meaning of words using a feature system was the use of the semantic differential (Osgood et al. 1957). By having people rate how words fell on a Likert scale of different bipolar adjectives (e.g., fair–unfair, active–passive), a word could be represented as the combination of ratings. Through collecting large numbers of these ratings, Osgood could define a multidimensional semantic space in which the meaning of a word is represented as a point in that space based on the ratings on each scale, and words could be compared among each through measuring distances in the space.

Feature representations have been widely used in psychological models of memory and categorization. They provide a simple representation for encoding information for input into computational models, most particularly connectionist models (e.g., Rumelhart and McClelland 1986). While the representation permits assigning concepts based on their features, it does not explicitly show relations among the concepts. In addition, in many models using feature representations, the dimensions are hand-created; therefore, it is not clear whether the features are based on real-world constructions, or are derived psychological constructions developed on the fly, based on the appropriate context. Some of the statistical techniques described below avoid the problem of using humanly defined dimensions by automatically extracting relevant dimensions.

1.2 *Semantic or Associative Networks*

A semantic network approach views the meaning of concepts as being determined by their relations to other concepts. Concepts are represented as nodes with labeled links (e.g., IS-A or Part-of) as relationships among the nodes. Thus, knowledge is a combination of information about concepts and how those concepts relate to each other. Based on the idea that activation can spread from one node to another, semantic networks have been quite influential in the development of models of memory. Semantic networks and spreading activation have been widely used for modeling sentence verification times and priming, and have been incorporated into many localist connectionist models.

Semantic networks permit economies of storage because concepts can inherit properties shared by other concepts (e.g., Collins and Quillian 1969). This basis has made semantic networks a popular approach for the development of computer-based lexicons, most particularly within the field of artificial intelligence.

Nevertheless, many of the assumptions for relatedness among concepts must still be based on handcrafted networks in which the creator of the network uses their knowledge to develop the concepts and links.

2. *Statistical and Human Approaches to Deriving Meaning*

No matter what type of representation is used for meaning, some form of information must be stored within the representation for it to be useful. There are two primary techniques to derive representations and fill in the lexical information. The first is to handcraft the information through human judgments about definitions, categorization, organization, or associations among concepts. The second is to use automated methods to extract information from existing on-line texts. The former approach relies on human expertise, and it is assumed that humans' introspective abilities and domain knowledge will provide an accurate representation of lexical relations. The latter approach assumes that the techniques can create a useful and accurate representation of meaning from processing natural language input.

2.1 *Human Extraction of Meaning for Knowledge Bases*

Long before the existence of computing, humans developed techniques for recording the meaning of words. These lexical compilations include dictionaries, thesauri, and ontologies. While not strictly statistical techniques for deriving meaning, human-based methods deserve mention for several reasons. Many of these lexical compilations are now available on-line. For example, there are a number of machine readable dictionaries on-line (e.g., Wilks et al. 1996), as well as projects to develop large ontologies of domain knowledge. Because of this availability, statistical techniques can be applied to these on-line lexicons to extract novel information automatically from a lexicon, for example to discover new semantic relations. In addition, the information from existing lexical entries can be used in automatic techniques for categorizing new lexical items.

One notable approach has been the development of WordNet (see Fellbaum 1998). WordNet is a handbuilt on-line lexical reference database which represents both the forms and meanings of words. Lexical concepts are organized in synonym sets (synsets) which represent semantic and lexical relations among concepts including synonymy, antonymy, hyponymy, meronymy, and morphological relations. Automated techniques (described in Fellbaum 1998) have been applied to WordNet for a number of applications including discovering new relations among words, performing automated word-sense identification, and applying it to information retrieval through automated query expansion.

Along with machine-readable dictionaries and ontologies, additional human-based approaches to deriving word similarity have collected large numbers of word associations to derive word-association norms (e.g., Deese 1965) and ratings of words on different dimensions (e.g., Osgood et al. 1957). The statistics from these collections are incorporated into computational cognitive models. In human-generated representations, however, there is much overhead involved in collecting the set of information before the lexical representation can be used. Because of this, it is not easily adapted to new languages or new domains. Further, handcrafted derivations of relationships among words do not provide a basis for a representational theory.

2.2 *Automatic Techniques for Deriving Semantics*

'You shall know a word by the company it keeps' (Firth 1957). The context in which any individual word is used can provide information about both the word's syntactic role and the semantic contributions of the word to the context. Thus, with appropriate techniques for measuring the use of words in language, we should be able to infer the meaning of those words. While much research has focused on automatically extracting syntactic regularities from language, there has been a recent increase in research on approaches to extracting semantic information. This research takes a structural linguistic approach in its assumption that the structure of meaning (or of language in general) can be derived or approximated through distributional measures and statistical analyses.

In order automatically to derive a semantic representation from analyzing language, several assumptions must be fulfilled. First it is assumed that information about the cooccurrence of words within contexts will provide appropriate information about semantic relationships. For example, the fact that 'house' and 'roof' often occur in the same context or in similar contexts informs that there must be a relationship between them. Second, assumptions must be made about what constitutes the context in which words appear. Some techniques use a moving window which moves across the text analyzing five to 10 words as a context; others use sentences, paragraphs, or complete documents as the complete context in which words appear. Finally, corpora of hundreds of thousands to millions of words of running text are required so that there are enough occurrences of information about how the different words appear within their contexts.

A mathematical overview of many statistical approaches to natural language may be found in Manning and Schütze (1999), and a review of statistical techniques applied to corpora may be found in

Boguraev and Pustejovsky (1996). Below, we focus on a few techniques that have been applied to psychological modeling, have shown psychological plausibility, and/or have provided applications that may be used more directly within cognitive science. The models described all use feature representations of words, in which words are represented as vectors of features. In addition, the models automatically derive the feature dimensions rather than having them predefined by the researcher.

2.2.1 The HAL model. The HAL (Hyperspace Analog to Memory) model uses lexical cooccurrence to develop a high-dimensional semantic representation of words (Burgess and Lund 1999). Using a large corpus (320 million words) of naturally occurring text, they derive vector representations of words based on a 10-word moving window. Vectors for words that are used in related contexts (within the same window) have high similarity. This vector representation can characterize a variety of semantic and grammatical features of words, and has been used to investigate a wide range of cognitive phenomena. For example, HAL has been used for modeling results from priming and categorization studies, resolving semantic ambiguity, modeling cerebral asymmetries in semantic representations, and modeling semantic differences among word classes, such as concrete and abstract nouns.

2.2.2 Latent Semantic Analysis. Like HAL, Latent Semantic Analysis (LSA) derives a high-dimensional vector representation based on analyses of large corpora (Landauer and Dumais 1997). However, LSA uses a fixed window of context (e.g., the paragraph level) to perform an analysis of cooccurrence across the corpus. A factor analytic technique (singular value decomposition) is then applied to the cooccurrence matrix in order to derive a reduced set of dimensions (typically 300 to 500). This dimension reduction causes words that are used in similar contexts, even if they are not used in the same context to have similar vectors. For example, although 'house' and 'home' both tend to occur with 'roof,' they seldom occur together in language. Nevertheless, they would have similar vector representations in LSA. In LSA, vectors for individual words can be summed to provide measures of the meaning of larger units of text. Thus, the meaning of a paragraph would be the sum of the vectors of the words in that paragraph. This basis permits the comparison of larger units of text, such as comparing the meaning of sentences, paragraphs, or whole documents to each other.

LSA has been applied to a number of different corpora, ranging from large samples of language that children and adults would have encountered to specific corpora on particular domains, such as individual course topics. For the more general corpora, it derives a generalized semantic representation of knowledge similar to that general knowledge acquired by people in life. For the domain-specific corpora, it generates a representation more similar to that of people knowledgeable within that domain area.

LSA has been used both as a theoretical model and as a tool for the characterization of semantic relatedness of units of language (see Landauer et al. 1998 for a review). As a theoretical model, LSA has been used to model the speed of acquisition of new words by children, its scores overlap those of humans on standard vocabulary and subject matter tests, it mimics human word sorting and category judgments, it simulates word-word and passage-word lexical priming data, and it accurately estimates textual coherence and the learnability of texts by individual students. The vector representation in LSA can be applied within other theoretical models. For example, propositional representations based on LSA-derived vectors have been integrated into the Construction-Integration model, a symbolic connectionist model of language (see Kintsch 1998). As an application, LSA has been used to measure the quality and quantity of knowledge contained in essays, for matching user queries to documents in information retrieval, and for performing automatic discourse segmentation.

2.2.3 Connectionist approaches. Connectionist modeling uses a network of interacting processing units operating on feature vectors to model cognitive phenomena. It has been widely used to model aspects of language processing. Although in some connectionist models words or concepts are represented as vectors in which the features have been predefined (e.g., McClelland and Kawamoto 1986), recent models have automatically derived the representation. Elman (1990) implemented a simple recurrent network that used a moving window analyzing a set of sentences from a small lexicon and artificial grammar. Based on a cluster analysis of the activation values of the hidden units, the model could predict syntactic and semantic distinctions in the language, and was able to discover lexical classes based on word order. One current limitation, however, is that it is not clear how well the approach can scale up to much larger corpora. Nevertheless, like LSA, due to the constraint satisfaction in connectionist models, the pattern of activation represented in the hidden units goes beyond direct cooccurrence, and captures more of the contextual usage of words.

3. Conclusions

Statistical techniques for extracting meaning from online texts and for extending the use of machine-readable dictionaries have become viable approaches

for creating semantic-based models and applications. The techniques go beyond modeling just cooccurrence of words. For example, the singular value decomposition in LSA or the use of hidden units in connectionist models permits derivation of semantic similarities that are not found in local cooccurrence but that are seen in human knowledge representations. The techniques incorporate both the idea of feature vectors, from feature-based models, and the idea that words can be defined by their relationships to other words found in semantic networks.

3.1 Advantages and Disadvantages of Statistical Semantic Approaches

Compared to many models of semantic memory, statistical semantic approaches are quite parsimonious, using very few assumptions and parameters to derive an effective representation of meaning. They further avoid problems of human-based meaning extraction since the techniques can process realistic environmental input (natural language) directly into a representation. The techniques are fast, requiring only hours or days to develop new lexicons, and can work in any language. They typically need large amounts of natural language to derive representation; thus, large corpora must be obtained. Nevertheless, because they are applied to large corpora, the lexicons that are developed provide realistic representations of tens to hundreds of thousands of words in a language.

3.2 Theoretical and Applied Uses of Statistical Semantics

Within cognitive modeling, statistical semantic techniques can be applied to almost any model that must incorporate meaning. They can therefore be used in modeling in such areas as semantic and associative priming, lexical ambiguity resolution, anaphoric resolution, acquisition of language, categorization, lexical effects on word recognition, and higher-level discourse processing. The techniques can provide useful additions to a wide range of applications that must encode or model meaning in language; for example, information retrieval, automated message understanding, machine translation, and discourse analysis.

3.3 The Future of Statistical Semantic Models in Psychology

While it is important that the techniques provide effective representations for applications, it is also important that the techniques have psychological plausibility. The study of human language processing can help inform the development of more effective methods of deriving and representing semantics. In turn, the development of the techniques can help improve cognitive models. For this to happen, strong ties must be formed between linguists, computational experts, and psychologists. In addition, the techniques and lexicons derived from them are not widely available to all researchers. For the techniques to succeed, better distribution, either through Web interfaces or through software, will allow them to be more easily incorporated into a wider range of cognitive models.

Semantic Similarity, Cognitive Psychology of

Semantic similarity refers to similarity based on meaning as opposed to form. The term is used widely throughout cognitive psychology and related areas such as psycholinguistics, memory, reasoning, and neuropsychology. For example, semantically similar words are confusable with each other, and can prime each other, with the consequence that verbal memory performance is heavily dependent on similarity of meaning (see *False Memories, Psychology of*; *Priming, Cognitive Psychology of*). In the context of reasoning, people draw inductive inferences on the basis of semantic similarity, for example, inferring that properties of cows are more likely to be true of horses than to be true of hedgehogs (Heit 2001)

But what is semantic similarity? In experimental work, semantic similarity is often estimated directly from participants' explicit judgments. However, there are several advantages to representing semantic similarity within a standardized framework or model. These advantages include the greater consistency and other known mathematical properties that can be imposed by a formal model, and the possible benefits of data reduction and the extraction of meaningful dimensions or features of the stimuli being analyzed. The history of research concerning semantic similarity can be captured in terms of the succession of models that have been applied to this topic. The models themselves can be divided into generic models of similarity and a number of more specialized models aimed at particular aspects of semantic similarity.

1. General Models of Similarity

Although the following accounts are meant to address similarity in general terms, they can be readily applied to semantic similarity. The two classical, generic approaches to modeling similarity are spatial models of similarity and Tversky's (1977) contrast model. More recently, structured approaches have addressed limitations of both of these classical accounts.

1.1 Spatial Representations

Spatial models seek to represent similarity in terms of distance in a psychological space (Shepard 1980). An item's position is determined through its coordinate values along the relevant dimensions; nearby points thus represent similar items, whereas distant items are psychologically very different. For example, a spatial representation of mammal categories might represent different animals on dimensions of size and ferocity, with lions and tigers being close on both of these dimensions (Fig. 1). The relevant space is derived using the technique of multidimensional scaling (MDS), a statistical procedure for dimensionality reduction. MDS works from experimental participants' judgments, typically in matrices of proximity data such as pairwise confusions or similarity ratings between items. Spatial models have been used widely for visualization purposes and as the heart of detailed cognitive models, e.g., of categorization and recognition memory (Nosofsky 1991). Less widely used are related statistical procedures such as hierarchical clustering (Shepard 1980) although they have also been used in the context of semantic similarity.

1.2 The Contrast Model

The traditional alternative to spatial models is Tversky's (1977) contrast model. This account was developed to address perceived limitations of spatial models which bring these into conflict with behavioral data (but also see Nosofsky 1991). Chief among these are violations of the so-called metric axioms that underlie any spatial scheme, such as asymmetries in human similarity judgments that are not well captured by spatial distance which should be symmetrical. For example, people judged the similarity of North Korea to China to be greater than the similarity of China to North Korea. In the contrast model (Eqn. (1)), the similarity between items a and b is a positive function of the features common to both items and a negative function of the distinctive features of a and also the distinctive features of b. Each of these three feature sets is governed by a weighting parameter which allows the model to capture asymmetries according to the nature of a particular task. According to the focusing hypothesis, greater attention is given to distinctive features of the first item in a comparison than of the second item, hence $\alpha > \beta$. When China is more familiar than North Korea, having more known distinctive features, then the similarity from China to North Korea should be lower than the similarity of North Korea to China.

$$S(a, b) = \theta f(A \cap B) - \alpha f(A - B) - \beta f(B - A) \quad (1)$$

Although applications of the contrast model to the modeling of specific cognitive tasks are fewer than those of spatial models, an application to semantic similarity can be found in Ortony (1979), who applied the model to distinctions between literal and metaphorical similarity.

Figure 1
Multidimensional scaling representation of mammals

1.3 Structured Representations

Despite the efforts aimed at establishing the superiority of either the contrast model or spatial models, it has been argued that both approaches share a fundamental limitation in that they define similarity based on oversimplified kinds of representations: points in space or feature sets. Arguably most theories of the representation of natural objects, visual textures, sentences, etc., assume that these cannot be represented in line with these restrictions (see *Feature Representations in Cognitive Psychology*). Instead, they seem to require structured representations: complex representations of objects, their parts and properties, and the interrelationships between them. Descriptions such as SIBLING-OF (Linus, Lucy) and SIBLING-OF (Lucy, Linus) cannot be translated in an obvious way to either lists of features or points in space that represent the similarity between these two items as well as their differences from BROTHER-OF (Linus, Lucy). (See also Fodor and Pylyshyn (1988) for a critique of attempts in connectionist networks to represent relational structure in a featural framework.)

The perceived need for accounts of similarity to work with structured representations has given rise to the structural alignment account (see Markman (2001) for an overview) which has its roots in research on analogical reasoning (see *Mental Models*, *Psychology of*). Structural alignment operates over structured representations such as frames (see *Schemas*, *Frames*, *and Scripts in Cognitive Psychology*) consisting of slots and fillers. The comparison process requires that at least some of the predicates, that is relations such as ABOVE (x, y), are identical across the comparison. These identical predicates are placed in correspondence. The alignment process then seeks to build maximal structurally consistent matches between the two representations.

Structural alignment has been implemented in a variety of computational models (e.g., Falkenhainer et al. 1990, Goldstone and Medin 1994) that have been used to capture behavioral data, especially similarity judgments and analogical reasoning. Experimental results have supported an important prediction of the structural alignment account, that there will be a greater impact of alignable differences compared with nonanalignable differences. Nonalignable differences between two representations are elements of one object that have no correspondence in the other. In contrast, alignable differences refer to representational elements that have corresponding roles in the two representations but fail to match exactly. For example, imagine two tables, one with a flower on top and the other with a bowl on top in addition to a chair beneath it. Comparing the two scenes, flower vs. bowl would be an alignable difference, whereas the chair would be a nonalignable difference.

2. Specialized Models of Semantic Similarity

2.1 Semantic Differentials

Leaving behind generic models of similarity, semantic similarity has also been captured through a variety of specially built models and approaches. The first of these is Osgood et al.'s (1957) semantic differential.

This approach used psychometric techniques to compute the psychological distance between concepts. Participants were required to rate concepts on 10–20 bipolar scales for a set of semantically relevant dimensions, such as positive–negative, feminine–masculine. The ratings of words on these dimensions would essentially form their coordinates in semantic space. The approach is thus related to spatial models of similarity with the difference primarily in the way that the semantic space is derived. Whereas models based on multidimensional scaling require pairwise proximity data for all concepts of interest, the semantic differential approach requires that all concepts of interest are rated on all relevant dimensions. Therefore, the semantic differential method suffers from the difficulty that the relevant dimensions must be stipulated in advance. Still, semantic differentials have been widely used, largely because the data are straightforward to collect, analyze, and interpret.

2.2 Semantic Networks and Featural Models

Osgood et al.'s work motivated the semantic feature model of Smith et al. (1974) which addressed how people verify statements such as 'a robin is a bird' and 'a chicken is a bird,' considering the defining and characteristic features of these concepts. Verifying the latter statement would be slower owing different characteristic features for chicken vs. bird. The semantic feature model was developed in contrast to Collins and Quillian's (1969) semantic network model. In this model semantic meaning is captured by nodes that correspond to individual concepts. These nodes are connected by a variety of links representing the nature of the relationship between the nodes (such as an IS-A link between robin and bird). Semantic similarity (or distance) is captured in terms of the number of links that must be traversed to reach one concept from another. Although the semantic network model was a groundbreaking attempt at capturing structured relations, it still suffered from some problems. For example, the model correctly predicts that verifying 'a robin is an animal' is slower than verifying 'a robin is a bird' owing to more links being traversed for the first statement. However, this model does not capture typicality effects such as the difference between robin and chicken.

2.3 High-dimensional Context Spaces

Osgood et al.'s semantic differential can also be seen as a predecessor of contemporary corpus-derived measures of semantics and semantic similarity. For example, Burgess and Lund's (1997) hyperspace analogue to language model (HAL) learns a high-dimensional context from large-scale linguistic corpora that encompass many millions of words of speech or text. The model tracks lexical co-occurrences throughout the corpus and from these derives a high-dimensional representational space. The meaning of a word is conceived of as a vector. Each element of this vector corresponds to another word in the model, with the value of an element representing the number of times that the two words co-occurred within the discourse samples that constitute the corpus. For example, the vector for dog will contain an element reflecting the number of times that the word 'bone' was found within a given range of words in the corpus. These vectors can be viewed as the coordinates of points (individual words) in a high-dimensional semantic space. Semantic similarity is then a matter of distance between points in this space.

Several other such usage-based models have been proposed to date; similar in spirit to HAL, for example, is Landauer and Dumais's (1997) latent semantic analysis (see also *Semantic Processing*: *Statistical Approaches*). The basic approach might be seen to be taking to its logical consequence Wittgensteir's famous adage of 'meaning as use.' Its prime advantage over related approaches such as spatial models of similarity and the semantic differential lies in the ability to derive semantics and thus measures of semantic similarity for arbitrarily large numbers of words without the need for any especially collected behavioral data. The ability of these models to capture a wide variety of phenomena, such as results in semantic priming and effects of semantic context on syntactic processing, has been impressive.

2.4 Connectionist Approaches

The final approach to semantic similarity to be discussed shares with these context-based models a statistical orientation, but connectionist modeling has been popular particularly in neuropsychological work on language and language processing. In connectionist models, the semantics of words are represented as patterns of activations, or banks of units representing individual semantic features. Semantic similarity is then simply the amount of overlap between different patterns, hence these models are related to the spatial accounts of similarity. However, the typically nonlinear activation functions used in these models allow virtually arbitrary re-representations of such basic similarities. The representation schemes utilized in these models tend to be handcrafted rather than derived empirically as in other schemes such as multidimensional scaling and high-dimensional context spaces. However, it is often only very general properties of these semantic representations and the similarities between them that are crucial to a model's behavior, such as whether these representations are 'dense' (i.e., involve the activation of many semantic features) or 'sparse,' so that the actual semantic features chosen are not crucial. For example, this distinction between dense and sparse representation has been used to capture patterns of semantic errors

associated with acquired reading disorders (Plaut and Shallice 1993) and also patterns of category specific deficits following localized brain damage (Farah and McClelland 1991).

3. Conclusion

There is a wide variety of models of semantic similarity available. Underlying this array of approaches is a fundamental tension that is as yet unresolved. Many of the models reviewed can be classed as loosely spatial in nature. These models have all been applied extensively to behavioral data, yet there are fundamental limitations to spatial approaches with respect to their representational capacity, made clear by the successes of the contrast model and the structural alignment approach. The behavioral evidence that relational structure is important to similarity seems particularly compelling. This leaves this area of research with two contrasting and seemingly incompatible strands of models, each of which successfully relates to experimental data. It is possible only to speculate on how this contradiction might ultimately be resolved. One possibility is that spatial models and structured representations capture different aspects or types of semantic similarity: one automatic, precompiled, effortless, and in some ways shallow, and one the result of more in-depth, or line, or metacognitive processing. Such a distinction between types of processing of similarity would be compatible with the success of models based on, for example, context spaces in capturing phenomena such as semantic priming, and the success of models such as those based on structural alignment in capturing phenomena such as analogy, or the understanding of novel concept combinations. Whether such a distinction will take shape or whether there will one day be a single, all-encompassing account remains for future research.

Semantics

Semantics is the study of meaning communicated through language, and is usually taken to be one of the three main branches of linguistics, along with phonology, the study of sound systems, and grammar, which includes the study of word structure (morphology) and of sentence structure (syntax). This entry surveys some of the main topics of current semantics research.

1. Introduction

Traditionally, the main focus of linguistic semantics has been on word meaning, or lexical semantics. Since classical times writers have commented on the fact, noticed surely by most reflecting individuals, that the meaning of words changes over time. Such observa-

tions are the seeds of etymology, the study of the history of words. Over longer stretches of time, such changes become very obvious, especially in literate societies. Words seem to shift around: some narrow in meaning such as English 'queen,' which earlier meant 'woman, wife' but now means 'wife of a king.' Others become more general, while still others shift to take on new meaning or disappear altogether. Words are borrowed from language to language. The study of such processes is now part of historical semantics (Fisiak 1985). Another motivation for the study of word meaning comes from dictionary writers as they try to establish meaning correspondences between words in different languages, or, in monolingual dictionaries, seek to provide definitions for all the words of a language in terms of a simple core vocabulary. In lexicology similarities and differences in word meaning are a central concern.

The principled study of the meaning of phrases and sentences has only become established in linguistics relatively recently. Thus it is still common for descriptive grammars of individual languages to contain no separate section on semantics other than providing a lexicon. Nonetheless it has always been clear that one can identify semantic relations between sentences. Speakers of English know from the semantics of negation that nominal negation has different effects than sentence negation, so that 'No-one complained' may aptly be used to answer 'Who complained?,' while 'Someone did not complain' may not. Two sentences may seem to say essentially the same thing, even be paraphrases of each other, yet one may be more suited to one context than another–like the pair 'Bandits looted the train' and 'The train was looted by bandits.' A single sentence may be internally inconsistent, such as 'Today is now tomorrow,' or seem to be repetitive or redundant in meaning, such as 'A capital city is a capital city.' Another feature of sentence meaning is the regularity with which listeners draw inferences from sentences, and often take these to be part of the meaning of what was said. Some inferential links are very strong, such as entailment. Thus we say that 'Bob drank all of the beer' entails 'Bob drank some of the beer' (assuming the same individual Bob, beer, etc.), because it is hard to think of a situation where acceptance of the second sentence would not follow automatically from acceptance of the first. Other inferential links are weaker and more contextually dependent: from the utterance 'Bob drank some of the beer' it might be reasonable to infer 'Bob didn't drink all of the beer,' but it is possible to think of situations where this inference would not hold. We might say that a speaker of the first sentence is implying the second, in a certain context. Speakers of all languages regularly predict and use such inferential behavior to convey their meaning, such that often more meaning seems to be communicated than is explicitly stated. All these aspects of sentence meaning are under study in various semantic frameworks.

Semanticists share with philosophers an interest in key issues in the use of language, notably in reference. We use this term to describe the way in which speakers can pick out, or name, entities in the world by using words as symbols. Many scholars, especially formal semanticists, accept Frege's distinction between reference (in German, *Bedeutung*) and sense (*Sinn*); see Frege (1980). Reference is the act of identifying an entity (the referent) while sense is the means of doing so. Two different linguistic expressions such as 'the number after nine' and 'the number before eleven' differ in sense but they both share the same referent, 'ten.' For semanticists it is particularly interesting to study the various mechanisms that a language offers to speakers for this act of referring. These include names such as 'Dublin,' nouns such as 'cat,' which can be used to refer to a single individual, 'your cat,' or a whole class, 'Cats are carnivorous,' quantified nominals such as 'many cats,' 'some cats,' 'a few cats,' etc. Linguists as well as philosophers have to account for language's ability to allow us to refer to nonexistent and hypothetical referents such as 'World War Three,' 'the still undiscovered cure for cancer,' 'the end of the world.'

Semanticists also share interests with psychologists, for if sense is the meaning of an expression, it seems natural to many semanticists to equate it with a conceptual representation. Cognitive semanticists, in particular, (for example Lakoff 1987, Talmy 2000), but also some generative linguists (Jackendoff 1996), seek to explore the relationship between semantic structure and conceptual structure. One axis of the debate is whether words, for example, are simply labels for concepts, or whether there is a need for an independent semantic interface that isolates just grammatically relevant elements of conceptual structure. As Jackendoff (1996) points out, many languages make grammatical distinctions corresponding to the conceptual distinctions of gender and number, but few involve distinctions of colour or between different animal species. If certain aspects of concepts are more relevant to grammatical rules, as is also claimed by Pinker (1989), this may be justification for a semantic interface.

2. *Approaches to Meaning*

Even in these brief remarks we have had to touch on the crucial relationship between meaning and context. Language of course typically occurs in acts of communication, and linguists have to cope with the fact that utterances of the same words may communicate different meanings to different individuals in different contexts. One response to this problem is to hypothesize that linguistic units such as words, phrases, and sentences have an element of inherent meaning that does not vary across contexts. This is sometimes called inherent, or simply, sentence meaning. Language

users, for example speakers and listeners, then enrich this sentence meaning with contextual information to create the particular meaning the speaker means to convey at the specific time, which can then be called speaker meaning. One common way of reflecting this view is to divide the study of meaning into semantics, which becomes the study of sentence meaning, and pragmatics, which is then the study of speaker meaning, or how speakers use language in concrete situations. This is an attempt to deal with the tension between the relative predictability of language between fellow speakers and the great variability of individual interpretations in interactive contexts. One consequence of this approach is the view that the words that a speaker utters underdetermine their intended meaning.

Semantics as a branch of linguistics is marked by the theoretical fragmentation of the field as a whole. The distinction between formal and functional approaches, for example, is as marked in semantics as elsewhere. This is a large subject to broach here but see Givón (1995) and Newmeyer (1998) for characteristic and somewhat antagonistic views. One important difference is the attitude to the autonomy of levels of analysis. Are semantics and syntax best treated as autonomous areas of study, each with its own characteristic entities and processes? A related question at a more general level is whether linguistic processes can be described independently of general psychological processes or the study of social interaction. Scholars in different theoretical frameworks will give contradictory answers to these questions of micro- and macro-autonomy. Autonomy at both levels is characteristic of semantics within generative grammar; see, for example, Chomsky (1995). Functionalists such as Halliday (1996) and Harder (1996) would on the other hand argue against microautonomy, suggesting that grammatical relations and structure cannot be understood without reference to semantic function. They also seek motivation for linguistic structure in the dynamics of communicative interaction. A slightly different external mapping is characteristic of cognitive semantics, for example Lakoff (1987) and Langacker (1987), where semantic structures are correlated to conceptual structures.

Another dividing issue in semantics is the value of formal representations. Scholars are divided on whether our knowledge of semantics is sufficiently mature to support attempts at mathematical or other symbolic modeling; indeed, on whether such modeling serves any use in this area. Partee (1996), for example, defends the view of formal semanticists that the application of symbolic logic to natural languages, following in particular the work of Montague (1974), represents a great advance in semantic description. Jackendoff (1990), on the other hand, acknowledges the value of formalism in semantic theory and description but argues that formal logic is too narrow adequately to describe meaning in language. Other scholars, such as Wierzbicka (1992), view the search for formalism as premature and distracting.

There has been an explosive increase in the research in formal semantics since Montague's (1974) proposal that the analysis of formal languages could serve as the basis for the description of natural languages. Montague's original theory comprised a syntax for the natural language, say English, a syntax for the logical language into which English should be translated (intensional logic), rules for the translation, and rules for the semantic interpretation of the intensional logic. This and subsequent formal approaches are typically referential (or denotational) in that their emphasis is on the connection of language with a set of possible worlds, including the real, external world and the hypothetical worlds set up by speakers. Crucial to this correspondence is the notion of truth, defined at the sentence level. A sentence is true if it correctly describes a situation in some world. In this view, the meaning of a sentence is characterized by describing the conditions which must hold for it to be true. The central task for such approaches is to extend the formal language to cope with the semantic features of natural language while maintaining the rigor and precision of the methodology. See the papers in Lappin (1996) for typical research in this paradigm.

Research in cognitive semantics presents an alternative strategy. Cognitive semanticists reject what they see as the mathematical, antimentalist approach of formal semantics. In their view meaning is described by relating linguistic expressions to mental entities, conventionalized conceptual structures. These semanticists have proposed a number of conceptual structures and processes, many deriving from perception and bodily experience and, in particular, conceptual models of space. Proposals for underlying conceptual structures include image schemas (Johnson 1987), mental spaces (Fauconnier 1994), and conceptual spaces (Gärdenfors 1999). Another focus of interest is the processes for extending concepts, and here special attention is given to metaphor. Lakoff (1987) and Johnson (1987) have argued against the classical view of metaphor and metonymy as something outside normal language, added as a kind of stylistic ornament. For these writers metaphor is an essential element in our categorization of the world and our thinking processes. Cognitive semanticists have also investigated the conceptual processes which reveal the importance of the speaker's perspective and construal of a scene, including viewpoint shifting, figure-ground shifting, and profiling (Langacker 1987).

3. *Topics in Sentence Semantics*

Many of the semantic systems of language, for example tense (see *Tense, Aspect, and Mood, Linguistics of*), aspect, mood, and negation, are marked

grammatically on individual words such as verbs. However, they operate over the whole sentence. This 'localization' is the reason that descriptive grammars usually distribute semantic description over their analyses of grammatical forms. Such semantic systems offer the speaker a range of meaning distinctions through which to communicate a message. Theoretical semanticists attempt to characterize each system *qua* system, as in for example Verkuyl's (1993) work on aspect and Hornstein's (1990) work on tense. Typological linguists try to characterize the variation in such systems across the world's languages, as in the studies of tense and aspect by Comrie (1976, 1985), Binnick (1991), and Bybee et al. (1994). We can sketch some basic features of some of these systems.

3.1 Situation Type and Aspect

Situation type and aspect are terms for a language's resources that allow a speaker to describe the temporal 'shape' of events. The term situation type is used to describe the system encoded in the words of a language, while aspect is used for the grammatical systems which perform a similar role. To take one example, languages typically allow speakers to describe a situation either as static, as in 'The bananas are ripe,' or as dynamic, as in 'The bananas are ripening.' Here the state is the result of the process but the same situation can be viewed as more static or dynamic, as in 'The baby is asleep' and 'The baby is sleeping.' As these examples show, this distinction is lexically marked: in English, for example, adjectives are typically used for states, and verbs for dynamic situations. There are, however, a group of stative verbs, such as 'know,' 'understand,' 'love,' 'hate,' which describe static situation types. There are a number of semantic distinctions typically found amongst dynamic verbs, for example the telic/atelic (bounded/unbounded) distinction and the punctual/durative distinction. Telic verbs describe processes which are seen as having a natural completion, which atelic verbs do not. A telic example is 'Matthew was growing up,' and an atelic example is 'Matthew was drinking.' If these procsses are interrupted at any point, we can automatically say 'Matthew drank,' but not 'Matthew grew up.' However, atelic verbs can form telic phrases and sentences by combining with other grammatical elements, so that 'Matthew was drinking a pint of beer' is telic. Durative verbs, as the term suggests, describe processes that last for a period of time, while punctual describes those that seem so instantaneous that they have no detectable internal structure, as in the comparison between 'The man slept' and 'The light flashed.' As has often been observed, if an English punctual verb is used with a durative adverbial, the result is an iterative meaning, as in 'The light flashed all night,' where we understand the event to be repeated over the time mentioned.

Situation type typically interacts with aspect. Aspect is the grammatical system that allows the speaker choices in how to portray the internal temporal nature of a situation. An event, for example, may be viewed as closed and completed, as in 'Joan wrote a book,' or as an ongoing process, perhaps unfinished, as in 'Joan was writing a book.'

The latter verb form is described as being in the progressive aspect in English, but similar distinctions are very common in the languages of the world. In many languages we find described a distinction between perfective and imperfective aspects, used to describe complete versus incomplete events; see Bybee et al. (1994) for a survey. As mentioned above, aspect is intimately associated both with situation type and tense. In Classical Arabic the perfective is strongly associated with past tense (Comrie 1976, Binnick 1991). In English, for example, stative verbs are typically not used with progressive aspect, so that one may say 'I know some French' but not 'I am knowing some French.' Staying with the progressive, when it is used in the present tense in English (and in many other languages) it carries a meaning of proximate future or confident prediction as in 'We're driving to Los Angeles' or 'I'm leaving you.' The combination of the three semantic categories of tense, situation type, and aspect produces a complex system that allows speakers to make subtle distinctions in relating an event or describing a situation.

3.2 Modality

Modality is a semantic system that allows speakers to express varying attitudes to a proposition. Semanticists have traditionally identified two types of modality. One is termed epistemic modality, which encodes a speaker's commitment to, or belief in, a proposition, from the certainty of 'The ozone layer is shrinking' to the weaker commitments of 'The ozone layer may/might/could be shrinking.' The second is deontic modality, where the speaker signals a judgment toward social factors of obligation, responsibility, and permission, as in the various interpretations of 'You must/can/ may/ ought to borrow this book.' These examples show that similar markers, here auxiliary verbs, can be used for both types. When modality distinctions are marked by particular verbal forms, these are traditionally called moods. Thus many languages, including Classical Greek and Somali, have a verb form labeled the optative mood for expressing wishes and desires. Other markers of modality in English include verbs of propositional attitude, as in 'I know/believe/think/doubt/ that the ozone layer is shrinking,' and modal adjectives, as in 'It is certain/probable/likely/possible that the ozone layer is shrinking.'

A related semantic system is evidentiality, where a speaker communicates the basis or source for present-

ing a proposition. In English and many other languages this may be done by adding expressions like 'allegedly,' 'so I've heard,' 'they say,' etc., but certain languages mark such differences morphologically, as in Makah, a Nootkan language spoken in Washington State (Jacobsen 1986, p. 10):
wiki·caxaw: 'It's bad weather' (seen or experienced directly);
wiki·caxakpi·d: 'It looks like bad weather' (inference from physical evidence);
wiki·caxakqad/I: 'It sounds like bad weather' (on the evidence of hearing); and
wiki·caxakwa·d: 'I'm told there's bad weather' (quoting someone else).

3.3 Semantic Roles

This term describes the speaker's semantic repertoire for relating participants in a described event. One influential proposal in the semantics literature is that each language contains a set of semantic roles, the choice of which is partly determined by the lexical semantics of the verb selected by the speaker. A characteristic list of such roles is:

agent: the initiator of some action, capable of acting with volition;

patient: the entity undergoing the effect of some action, often undergoing some change in state;

theme: the entity which is moved by an action, or whose location is described;

experiencer: the entity which is aware of the action or state described by the predicate but which is not in control of the action or state;

beneficiary: the entity for whose benefit the action was performed;

instrument: the means by which an action is performed or something comes about;

location: the place in which something is situated or takes place;

goal: the entity towards which something moves;

recipient: the entity which receives something; and

source: the entity from which something moves.

In an example like 'Harry immobilized the tank with a broomstick,' the entity Harry is described as the agent, the tank as the patient, and the broomstick as the instrument. These roles have also variously been called deep semantic cases, thematic relations, participant roles, and thematic roles.

One concern is to explain the matching between semantic roles and grammatical relations. In many languages, as in the last example, there is a tendency for the subject of the sentence to correspond to the agent and for the direct object to correspond to a patient or theme; an instrument often occurs as a prepositional phrase. Certain verbs allow variations from this basic mapping, for example the we find with English verbs such as 'break': 'The boy broke the window with a stone' (subject = agent); 'The stone broke the window' (subject = instrument); 'The window broke' (subject = patient). Clearly verbs can be arranged into classes depending on the variations of mappings they allow, and not all English verbs pattern like 'break.' We can say 'The admiral watched the battle with a telescope,' but 'The telescope watched the battle' and 'The battle watched' sound decidedly odd.

From this literature emerges the claim that certain mappings are more natural or universal. One proposal is that, for example, there is an implicational hierarchy governing the mapping to subject, typically such as: agent > recipient/benefactive > theme/patient > instrument > location. In such a hierarchy each left element is more preferred than its right neighbor, so that moving rightward along the string gives us fewer expected subjects. The hierarchy also makes certain typological claims: if a language allows a certain semantic role to be subject, it will allow all those to its left. Thus if we find that a language allows the role instrument to be subject, we predict that it allows the roles to the left, but we do not know if it allows location subjects.

One further application of semantic roles is in lexical semantics, where the notion allows verbs to be classified by their semantic argument structure. Verbs are assigned semantic role templates or grids by which they may be sorted into natural classes. Thus, English has a class of transfer, or giving verbs, which in one type includes the verbs 'give,' 'lend,' 'supply,' 'pay,' 'donate,' 'contribute.' These verbs encode a view of the transfer from the perspective of the agent and may be assigned the pattern <*agent*, theme, recipient>, as in 'The committee donated aid to the famine victims.' A second subclass of these transfer verbs encodes the process from the perspective of the recipient. These verbs include 'receive,' 'accept,' 'borrow,' 'buy,' 'purchase,' 'rent,' 'hire,' and have the pattern <*recipient*, theme, source>, as in 'The victims received aid from the committee.'

3.4 Entailment, Presupposition, and Implication

These terms relate to types of information a hearer gains from an utterance but which are not stated directly by the speaker. These phenomena have received a lot of attention because they seem to straddle the putative divide between semantics and pragmatics described above, and because they reveal the dynamic and interactive nature of understanding the meaning of utterances. Entailment describes a relationship between sentences such that on the basis of one sentence, a hearer will accept a second, unstated sentence purely on the basis of the meaning of the first. Thus sentence A entails sentence B, if it is not possible to accept A but reject B. In this view a sentence such as 'I bought a dog today' entails 'I bought an animal today'; or 'President Kennedy was assassinated yesterday' entails 'President Kennedy is now dead.' Clearly these sentential relations depend on lexical relations: a speaker who understands the meaning of

the English word 'dog' knows that a dog is an animal; similarly the verb 'assassinate' necessarily involves the death of the unfortunate object argument. Entailment then is seen as a purely automatic process, involving no reasoning or deduction, but following from the hearer's linguistic knowledge. Entailment is amenable to characterization by truth conditions. A sentence is said to entail another if the truth of the first guarantees the truth of the second, and the falsity of the second guarantees the falsity of the first.

Presupposition, on the other hand, is a more complicated notion. In basic terms, the idea is simple enough: that a speaker communicates certain assumptions aside from the main message. A range of linguistic elements communicates these assumptions. Some, such as names, and definiteness markers such as the articles 'the' and 'my,' presuppose the existence of entities. Thus 'James Brown is in town' presupposes the existence of a person so called. Other elements have more specific presuppositions. A verb such as 'stop' presupposes a preexisting situation. So a sentence 'Christopher has stopped smoking' presupposes 'Christopher smoked.' If treated as a truth-conditional relation, presupposition is distinguished from entailment by the fact that it survives under negation: 'Christopher has not stopped smoking' still presupposes 'Christopher smoked,' but the sentence 'I didn't buy a dog today' does not entail 'I bought an animal today.'

There are a number of other differences between entailment and presupposition that cast doubts on the ability of a purely semantic, truth-conditional account of the latter. Presuppositions are notoriously context sensitive, for example. They may be cancelled without causing an anomaly: a hearer can reply 'Christopher hasn't stopped smoking, because he never smoked' to cancel the presupposition by what is sometimes called metalinguistic negation. This dependency on context has led some writers to propose that presupposition is a pragmatic notion, definable in terms of the set of background assumptions that the speaker assumes is shared in the conversation. See Beaver (1997) for discussion.

A third type of inference is Grice's conversational implicature (1975, 1978). This is an extremely context-sensitive type of inference which allow participants in a conversation to maintain coherence. So, given the invented exchange below,

A: Did you give Mary the book?
B: I haven't seen her yet.

It is reasonable for A to infer the answer 'no' to her question. Grice proposed that such inferences are routinely relied on by both speakers and hearers, and that this reliance is based on certain assumptions that hearers make about a speaker's conduct. Grice classified these into several different types, giving rise to different types of inference, or, from the speaker's point of view, what he termed implicatures. The four main maxims are called Quality, Quantity, Relevance, and Manner (Grice 1975, 1978). They amount to a claim that a listener will assume, unless there is evidence to the contrary, that a speaker will have calculated their utterance along a number of parameters: they will tell the truth, try to estimate what their audience knows, and package their material accordingly, have some idea of the current topic, and give some thought to their audience being able to understand them. In our example above, it is A's assumption that B's reply is intended to be relevant that allows the inference 'no.'

Implicature has three characteristics: first, that it is implied rather than said; second, that its existence is a result of the context i.e., the specific interaction. There is no guarantee that in other contexts 'I haven't seen her' will be used to communicate 'no.' Third, implicature is cancelable without causing a contradiction. Thus the implicature 'no' in our example can be cancelled if B adds the clause 'but I mailed it to her last week.'

These three notions—entailment, presupposition, and implicature—can all be seen as types of inference. They are all produced in conversation, and are taken by participants to be part of the meaning of what a speaker has said. They differ in a number of features and crucially in context sensitivity. The attempt to provide a unified analysis of them all is a challenge to semantic and pragmatic theories. See Sperber and Wilson (1995) for an attempt at such a unified approach.

4. *Future Developments*

Although semantics remains theoretically a very diverse field it is possible to detect some shared trends which seem likely to develop further. One is a move away from a static view of sentences in isolation, detached from the speaker/writer's act of communication, toward dynamic, discourse-based approaches. This has always been characteristic of functional approaches to meaning but has also been noticeable in formal approaches as they move away from their more philosophical origins. Among examples of this we might mention discourse representation theory (Kamp and Reyle 1993) and dynamic semantics (Groenendijk et al. 1996).

Another development which seems likely to continue is a closer integration with other disciplines in cognitive science. In particular, computational techniques seem certain to make further impact on a range of semantic inquiry, from lexicography to the modeling of questions and other forms of dialogue. A subfield of computational semantics has emerged and will continue to develop; see Rosner and Johnson (1992) for example.

Semiotics

Semiotics is an interdisciplinary field that studies 'the life of signs within society' (Saussure 1959, p. 16). While 'signs' most commonly refers to the elements of verbal language and other vehicles of communication, it also denotes any means of representing or knowing about an aspect of reality. As a result, semiotics has developed as a close cousin of such traditional disciplines as philosophy and psychology. In the social sciences and humanities, semiotics has become an influential approach to research on culture and communication particularly since the 1960s. This article describes the classical origins of semiotics, exemplifies its application to contemporary culture, and outlines its implications for the theory of science.

1. Origins: Logic and Linguistics

Two different senses of 'signs' can be traced in the works of Aristotle (Clarke 1990, p. 15) (see *Aristotle (384–322 BC)*). First, the mental impressions that

people have, are signs which represent certain objects in the world to them. Second, spoken and written expressions are signs with which people are able to represent and communicate a particular understanding of these objects to others. The first sense, of mental impressions, points to the classical understanding of signs, not as words or images, but as naturally occurring evidence that something is the case. For example, fever is a sign of illness, and clouds are a sign that it may rain, to the extent that these signs are interpreted by humans. The second sense of signs as means of communication points towards the distinction that came to inform most modern science between conventional signs, especially verbal language, and sense data, or natural signs. Modern natural scientists could be said to study natural signs with reference to specialized conventional signs.

Given the ambition of semiotics to address the fundamental conditions of human knowledge, it has been an important undercurrent in the history of science and ideas. The first explicit statement regarding natural signs and language as two varieties of one general category of signs came not from Aristotle, but from St. Augustine (c. AD 400). This position was elaborated throughout the medieval period with reference, in part, to the understanding of nature as 'God's Book' and an analogy to the Bible. However, it was not until the seventeenth century that the term semiotic emerged in John Locke's *An Essay concerning Human Understanding* (1690). Here, Locke proposed a science of signs in general, only to restrict his own focus to 'the most usual' signs, namely, verbal language and logic (Clarke 1990, p. 40).

1.1 Peircean Logic and Semiotics

Charles Sanders Peirce (1839–1914) was the first thinker to recover this undercurrent in an attempt to develop a general semiotic. He understood his theory of signs as a form of logic, which informed a comprehensive system for understanding the nature of being and of knowledge. The key to the system is Peirce's definition of the sign as having three aspects:

> A sign, or *representamen*, is something which stands to somebody for something in some respect or capacity. It addresses somebody, that is, creates in the mind of that person an equivalent sign, or perhaps a more developed sign. That sign which it creates I call the *interpretant* of the first sign. That sign stands for something, its *object*.

An important implication of this definition is that signs always serve to mediate between objects in the world, including social facts, and concepts in the mind. Contrary to various skepticist positions, from Antiquity to postmodernism, Peirce's point was not that signs are what we know, but how we come to know what we can justify saying that we know, in science

Figure 1
The process of semiosis

and in everyday life. Peircean semiotics married a classical, Aristotelian notion of realism with the modern, Kantian position (see *Kant, Immanuel (1724–1804)*) that humans necessarily construct their understanding of reality in the form of particular cognitive categories.

A further implication is that human understanding is not a singular internalization of reality, but a continuous process of interpretation, what is called semiosis. This is witnessed, for example, in the process of scientific discovery, but also in the ongoing coordination of social life. Figure 1 illustrates the process of semiosis, noting how any given interpretation (interpretant) itself serves as a sign in the next stage of an unending process which differentiates the understanding of objects in reality. Although Peirce's outlook was that of a logician and a natural scientist, semiosis can be taken to refer to the processes of communication by which cultures are maintained and societies reproduced and, to a degree, reformed.

One of the most influential elements of Peirce's semiotics outside logic and philosophy has been his categorization of different types of signs, particularly icon, index, and symbol. Icons relate to their objects through resemblance (e.g., a realistic painting); indices have a causal relation (e.g., fever as a symptom of illness); and symbols have an arbitrary relation to their object (e.g., words). Different disciplines and fields have relied on these types as analytical instruments in

order to describe the ways in which humans perceive and act upon reality.

1.2 Saussurean Linguistics and Semiology

Compared with Peirce, the other main figure in the development of semiotics, Ferdinand de Saussure (1857–1913), placed a specific focus on verbal language (see *Saussure, Ferdinand de (1857–1913)*), what Peirce had referred to as symbols. Probably the main achievement of Saussure was to outline the framework for modern linguistics (see *Linguistics: Overview*). In contrast to the emphasis that earlier philology had placed on the diachronic perspective of how languages change over time, Saussure proposed to study language as a system in a synchronic perspective. Language as an abstract system (*langue*) could be distinguished, at least for analytical purposes, from the actual uses of language (*parole*). The language system has two dimensions. Along the syntagmatic dimension, letters, words, phrases, etc., are the units that combine to make up meaningful wholes, and each of these units has been chosen as one of several possibilities along a paradigmatic dimension, for example, one verb in preference to another. This combinatory system helps to account for the remarkable flexibility of language as a medium of social interaction.

To be precise, Saussure referred to the broader science of signs, as cited in the introduction to this article, not as semiotics, but as semiology. Like Locke, and later Peirce, Saussure relied on classical Greek to coin a technical term, and the two variants are explained, in part, by the fact that Peirce and Saussure had no knowledge of each other's work. Moreover, in Saussure's own work, the program for a semiology remained undeveloped, appearing almost as an aside from his main enterprise of linguistics. It was during the consolidation of semiotics as an interdisciplinary field from the 1960s that this became the agreed term, overriding Peirce's 'semiotic' and Saussure's 'semiology', as symbolized by the formation in 1969 of the International Association for Semiotic Studies. It was also during this period that Saussure's systemic approach was redeveloped to apply to culture and society.

One important legacy of Saussure has been his account of the arbitrariness of the linguistic sign. This sign type is said to have two sides, a signified (concept) and a signifier (the acoustic image associated with it), whose relation is conventional or arbitrary. While this argument is sometimes construed in skepticist and relativist terms, as if sign users were paradoxically free to choose their own meanings, and hence almost destined to remain divorced from any consensual reality, the point is rather that the linguistic system as a whole, including the interrelations between signs and their components, is arbitrary, but fixed by social convention. When applied to studies of cultural forms other than language, or when extended to the description of social structures as signs, the principle of arbitrariness has been a source of analytical difficulties.

2. Applications: Media, Communication and Culture

It was the application of semiotics to questions of meaning beyond logic and linguistics which served to consolidate semiotics as a recognizable, if still heterogeneous field from the 1960s. Drawing on other traditions of aesthetic and social research, this emerging field began to make concrete what the study of 'the life of signs within society' might mean. The objects of analysis ranged from artworks to mass media to the life forms of premodern societies, but studies were united by a common interest in culture in the broad sense of worldviews that orient social action. The work of Claude Lévi-Strauss (1963) on structural anthropology was characteristic and highly influential of such research on shared, underlying systems of interpretation which might explain the viewpoints or actions of individuals in a given context. It was Saussure's emphasis on signs as a system, then, which provided a model for structuralist theories (see *Structuralism*) about social power (e.g., Louis Althusser) and about the unconscious as a 'language' (e.g., Jacques Lacan) (see *Psychoanalysis: Overview*).

Of the French scholars who were especially instrumental in this consolidation, Roland Barthes, along with A. J. Greimas, stands out as an innovative and systematic theorist. His model of two levels of signification, reproduced in Fig. 2, has been one of the most widely copied attempts to link concrete sign vehicles, such as texts and images, with the 'myths' or ideologies which they articulate. Building on Louis Hjelmslev's formal linguistics, Barthes (1973) suggested that the combined signifier and signified (expressive form and conceptual content) of one sign (e.g., a picture of a black man in a French uniform saluting the flag) may become the expressive form of a

Figure 2
Two Levels of Signification (reproduced by permission of Roland Barthes [Random House Group Ltd (Jonathan Cape)] from *Mythologies*, p. 115, first published in French by de Seuil in 1957)

further, ideological content (e.g., that French imperialism is not a discriminatory or oppressive system). Barthes' political agenda, shared by much semiotic scholarship since then, was that this semiotic mechanism serves to naturalize particular worldviews, while oppressing others, and should be deconstructed (see *Critical Theory: Contemporary*).

In retrospect, one can distinguish two ways of appropriating semiotics in social and cultural research. On the one hand, semiotics may be treated as a methodology for examining signs, whose social or philosophical implications are interpreted with reference to another set of theoretical concepts. On the other hand, semiotics may supply also the theoretical framework, so that societies, psyches, and images are understood not just in procedural, but also in actual conceptual terms as signs. The latter position is compatible with a variant of semiotics, which assumes that also biological and even cosmological processes are best understood as semioses. This ambitious and arguably imperialistic extension of logical and linguistic concepts into other fields has encountered criticism, for example, in cases where Saussure's principle of arbitrariness has been taken to apply to visual communication or to the political and economic organization of society.

A semioticization of, for instance, audiovisual media (for example, see *Visual Images in the Media*) can be said to neglect their appeal to radically different perceptual registers, which are, in certain respects, natural rather than conventional (e.g., Messaris 1994) (for example, see *Cognitive Science: Overview*). Similarly, a *de facto* replacement of social science by semiotics may exaggerate the extent to which signs, rather than material and institutional conditions, determine the course of society, perhaps in response to semioticians' political ambition of making a social difference by deconstructing signs. In recent decades, these concerns, along with critiques of Saussurean formalist systems, have led to attempts to formulate a social semiotics, integrating semiotic methodology with other social and communication theory (e.g., Hodge and Kress 1988, Jensen 1995). On the relations between semiotics and other fields, see Nöth 1990.

A final distinction within semiotic studies of society and culture arises from the question of what is a 'medium'. Media research has drawn substantially on semiotics to account for the distinctive sign types, codes, narratives and modes of address of different media such as newspapers, television or the Internet (for example, see *Mass Media: Introduction and Schools of Thought*). A particular challenge has been the film medium, which was described by Christian Metz (1974) not as a language system, but as a 'language' drawing on several semiotic codes. Beyond this approach to media as commonly understood, semioticians, taking their inspiration from Lévi-Strauss' anthropology, have described other objects and artifacts as vehicles of meaning. One rich example is Barthes' study of the structure of fashion (see *Fashion, Sociology of*), as depicted in magazines (Barthes 1985). The double meaning of a 'medium' is another indication both of the potential theoretical richness of semiotics and of the pitfalls of confusing different levels of analysis.

3. *Theory of Signs and Theory of Science*

It is this double edge which most likely explains the continuing influence of semiotic ideas since Antiquity, mostly, however, as an undercurrent of science. The understanding articulated in Aristotle's writings of signs as evidence for an interpreter of something else which is at least temporarily absent, or as an interface which is not identical with the thing that is in evidence to the interpreter, may be taken as a cultural leap that has made possible scientific reflexivity as well as social organization beyond the here and now. Further, the sign concept has promoted the crucial distinction beginning with Aristotle between necessary and probable relations, as in logical inferences. Returning to the examples above, fever is a sure sign that the person is ill, since illness is a necessary condition of fever. But clouds are only a probable sign of rain. Empirical social research is mostly built on the premise that probable signs can lead to warranted inferences.

The link between a theory of signs and a theory of science has been explored primarily from a Peircean perspective. For one thing, Peirce himself made important contributions to logic and to the theory of science generally, notably by adding to deduction and induction the form of inference called abduction, which he detected both in everyday reasoning and at the core of scientific innovation. For another thing, the wider philosophical tradition of pragmatism (for example, see *Pragmatism: Philosophical Aspects*), which Peirce inaugurated, has emphasized the interrelations between knowledge, education, and action, and it has recently enjoyed a renaissance at the juncture between theory of science and social theory (e.g., Bernstein 1991, Joas 1993). By contrast, the Saussurean tradition has often bracketed issues concerning the relationship between the word and the world (Jakobson 1981, p. 19), even if critical research in this vein has recruited theories from other schools of thought in order to move semiology beyond the internal analysis of signs.

For future research, semiotics is likely to remain a source of inspiration in various scientific domains, as it has been for almost 2500 years. In light of the record from the past century of intensified interest in theories of signs, however, the field is less likely to develop into a coherent discipline. One of the main opportunities for semiotics may be to develop a meta-framework for understanding how different disciplines and fields conceive of their 'data' and 'concepts'. The semiotic heritage offers both systematic analytical procedures

and a means of reflexivity regarding the role of signs in society as well as in the social sciences.

Semiparametric Models

Much empirical research in the social sciences is concerned with estimating conditional mean functions. For example, labor economists are interested in estimating the mean wages of employed individuals, conditional on characteristics such as years of work experience and education. The most frequently used estimation methods assume that the conditional mean function is known up to a set of constant parameters that can be estimated from data, possibly by ordinary least squares. Models in which the only unknown quantities are a finite set of constant parameters are called 'parametric.' The use of a parametric model greatly simplifies estimation, statistical inference, and interpretation of the estimation results but is rarely justified by theoretical or other *a priori* considerations. Estimation and inference based on convenient but incorrect assumptions about the form of the conditional mean function can be highly misleading. Semiparametric statistical methods reduce the strength of the assumptions required for estimation and inference, thereby reducing the opportunities for obtaining misleading results. These methods are applicable to a wide variety of estimation problems in economics and other fields.

1. Introduction

A conditional mean function gives the mean of a dependent variable Y conditional on a vector of explanatory variables X. Denote the mean of Y conditional on $X = x$ by $\boldsymbol{E}(Y|x)$. For example, suppose that Y is a worker's weekly wage (or, more often in applied econometrics, the logarithm of the wage) and X includes such variables as years of work experience and education, race, and sex. Then $\boldsymbol{E}(Y|x)$ is the mean wage (or logarithm of the wage) when experience and the other explanatory variables have the values specified by x. As an illustration, the solid line in Fig. 1 shows an estimate of the mean of the logarithm of weekly wages, $\log W$, conditional on years of work experience, EXP, for white males with 12 years of education who work full time and live in urban areas of the North Central USA. The estimate was obtained by applying a nonparametric method (explained in Sect. 2) to data from the 1993 Current Population Survey (CPS). The estimated conditional mean of $\log W$ increases steadily up to approximately 30 years of experience and is flat thereafter.

In most applications, $\boldsymbol{E}(Y|x)$ is unknown and must be estimated from data on the variables of interest. In the case of estimating a wage function, the data consist of observations of individuals' wages, years of experience, and other characteristics. The most widely used method for estimating $\boldsymbol{E}(Y|x)$ is not the nonparametric method mentioned previously, but rather a method that assumes that $\boldsymbol{E}(Y|x)$ is known up to finitely many constant parameters. This gives a 'parametric model' for $\boldsymbol{E}(Y|x)$. Often, $\boldsymbol{E}(Y|x)$ is assumed to be a linear function of x, in which case the parameters can be estimated by ordinary least squares (OLS), among other ways. A linear function has the form $\boldsymbol{E}(Y|x) = \beta' x$, where β is a vector of coefficients. For

Figure 1
Estimates of $\boldsymbol{E}(\log W \mid EXP)$

example, if x consists of an intercept and the two variables x_1 and x_2, then β has three components, and $\beta' x = \beta_0 + \beta_1 x_1 + \beta_2 x_2$. OLS estimators are described in many textbooks. See, for example, Goldberger (1998).

The OLS estimator of $\boldsymbol{E}(Y \mid x)$ can be highly misleading if $\boldsymbol{E}(Y \mid x)$ is not linear in the components of x, that is if there is no β such that $\boldsymbol{E}(Y \mid x) = \beta' x$. This problem is illustrated by the dashed and dotted lines in Fig. 1, which show two parametric estimates of the mean of the logarithm of weekly wages conditional on years of work experience. The dashed line is the OLS estimate that is obtained by assuming that $\boldsymbol{E}(\log W \mid EXP)$ is the linear function $\boldsymbol{E}(\log W \mid EXP) = \beta_0 + \beta_1 EXP$. The dotted line is the OLS estimate that is obtained by assuming that $\boldsymbol{E}(\log W \mid EXP)$ is quadratic: $\boldsymbol{E}(\log W \mid EXP) = \beta_0 + \beta_1 EXP + \beta_2 EXP^2$. The nonparametric estimate (solid line) places no restrictions on the shape of $\boldsymbol{E}(\log W \mid EXP)$. The linear and quadratic models give misleading estimates of $\boldsymbol{E}(\log W \mid EXP)$. The linear model indicates that $\boldsymbol{E}(\log W \mid EXP)$ steadily increases as experience increases. The quadratic model indicates that $\boldsymbol{E}(\log W \mid EXP)$ decreases after 32 years of experience. In contrast, the nonparametric estimate of $\boldsymbol{E}(\log W \mid EXP)$ becomes nearly flat at approximately 30 years of experience. Because the nonparametric estimate does not restrict the conditional mean function to be linear or quadratic, it is more likely to represent the true conditional mean function.

The opportunities for specification error increase if Y is binary. For example, consider a model of the choice of travel mode for the trip to work. Suppose that the available modes are automobile and transit. Let $Y = 1$ if an individual chooses automobile and $Y = 0$ if the individual chooses transit. Let X be a vector of explanatory variables such as the travel times and costs by automobile and transit. Then $\boldsymbol{E}(Y \mid x)$ is the probability that $Y = 1$ (the probability that the individual chooses automobile) conditional on $X = x$. This probability will be denoted $\boldsymbol{P}(Y = 1 \mid x)$. In applications of binary response models, it is often assumed that $\boldsymbol{P}(Y \mid x) = G(\beta' \mathrm{x})$, where β is a vector of constant coefficients and G is a known probability distribution function. Often, G is assumed to be the cumulative standard normal distribution function, which yields a 'binary probit' model, or the cumulative logistic distribution function, which yields a 'binary logit' model (see *Multivariate Analysis: Discrete Variables (Logistic Regression)*). The coefficients β can then be estimated by the method of maximum likelihood (Amemiya 1985). However, there are now two potential sources of specification error. First, the dependence of Y on x may not be through the linear *index* $\beta' x$. Second, even if the index $\beta' x$ is correct, the 'response function' G may not be the normal or logistic distribution function. See Horowitz (1993, 1998) for examples of specification errors in binary response models and their consequences.

Many investigators attempt to minimize the risk of specification error by carrying out a 'specification search' in which several different models are estimated and conclusions are based on the one that appears to fit the data best. Specification searches may be unavoidable in some applications, but they have many undesirable properties and their use should be minimized. There is no guarantee that a specification search will include the correct model or a good approximation to it. If the search includes the correct model, there is no guarantee that it will be selected by the investigator's model selection criteria. Moreover, the

search process invalidates the statistical theory on which inference is based.

The rest of this entry describes methods that deal with the problem of specification error by relaxing the assumptions about functional form that are made by parametric models. The possibility of specification error can be essentially eliminated through the use of nonparametric estimation methods. These are described in Sect. 2. They assume that $\boldsymbol{E}(Y|x)$ is a smooth function but make no other assumptions about its shape or functional form. However, nonparametric methods have important disadvantages that seriously limit their usefulness in applications. Semiparametric methods, which are described in Sect. 3 offer a compromise. They make assumptions about functional form that are stronger than those of a nonparametric model but less restrictive than the assumptions of a parametric model, thereby reducing (though not eliminating) the possibility of specification error. In addition semiparametric methods avoid the most serious practical disadvantages of nonparametric methods.

2. Nonparametric Models

In nonparametric estimation $\boldsymbol{E}(Y|x)$ is assumed to satisfy smoothness conditions such as differentiability, but no assumptions are made about its shape or the form of its dependence on x. Härdle (1990) and Fan and Gijbels (1996) provide detailed discussions of nonparametric estimation methods. One easily understood and frequently used method is called 'kernel estimation.' This method was used to produce the solid line in Fig. 1. To describe the kernel method simply, assume that X is a continuously distributed, scalar random variable. Let $\{Y_i, X_i : i = 1, \ldots, n\}$ be a random sample of n observations of (Y, X). Let K be a probability density function that is bounded, continuous, and symmetrical about zero. For example, K may be the standard normal density function. Let $\{h_n\}$ to be a sequence of positive numbers that converges to 0 as $n \to \infty$. For each $n = 1, 2, \ldots$ and $i = 1, \ldots, n$ define the function $w_{ni}(\cdot)$ by

$$w_{ni}(x) = \frac{K[(x - X_i)/h_n]}{\sum_{i=1}^{n} K[(x - X_i)/h_n]} \tag{1}$$

Then the kernel nonparametric estimator of $\boldsymbol{E}(Y|x)$ is

$$H_n(x) = \sum_{i=1}^{n} w_{ni}(x) Y_i \tag{2}$$

$H_n(x)$ is a weighted average of the observed values of Y. Observations Y_i for which X_i is close to x get higher weight than do observations for which X_i is far from x. It can be shown that if $h_n \to 0$ and $nh_n/(\log n) \to \infty$ as $n \to \infty$, then $H_n(x) \to \boldsymbol{E}(Y|x)$ with probability 1. Thus, if n is large, $H_n(x)$ is likely to be very close to $\boldsymbol{E}(Y|x)$. Härdle (1990) provides a detailed discussion of the statistical properties of kernel nonparametric estimators.

Nonparametric estimation minimizes the risk of specification error, but the price of this flexibility can be high. One important reason for this is that the precision of a nonparametric estimator decreases rapidly as the number of continuously distributed components of X increases. This phenomenon is called the 'curse of dimensionality.' As a result of it, impracticably large samples are usually needed to obtain acceptable estimation precision if X is multidimensional, as it often is in social science applications. For example, a labor economist may want to estimate mean log wages conditional on years of work experience, years of education, and one or more indicators of skill levels, thus making the dimension of X at least 3. See *Exploratory Data Analysis: Multivariate Approaches (Nonparametric Regression)* for further discussion of the curse of dimensionality.

Another problem is that nonparametric estimates can be difficult to display, communicate, and interpret when X is multidimensional. Nonparametric estimates do not have simple analytic forms, so displaying and interpreting them can be difficult. If X is one- or two-dimensional, then the estimate of $\boldsymbol{E}(Y|x)$ can be displayed graphically as in Fig. 1, but only reduced-dimension projections can be displayed when X has three or more components. Many such displays and much skill in interpreting them can be needed to fully convey and comprehend the shape of the estimate of $\boldsymbol{E}(Y|x)$.

Another problem with nonparametric estimation is that it does not permit extrapolation. That is, it does not provide predictions of $\boldsymbol{E}(Y|x)$ at points x that are outside of the support (or range) of the random variable X. This is a serious drawback in policy analysis and forecasting, where it is often important to predict what might happen under conditions that do not exist in the available data. Finally, in nonparametric estimation, it can be difficult to impose restrictions suggested by economic or other theory. Matzkin (1994) discusses this issue.

Semiparametric methods permit greater estimation precision than do nonparametric methods when X is multidimensional. In addition, semiparametric estimates are easier to display and interpret than nonparametric ones and provide limited capabilities for extrapolation and imposing restrictions derived from economic or other theory models.

3. Semiparametric Models

The term 'semiparametric' refers to models in which there is an unknown function in addition to an unknown finite dimensional parameter. For example, the binary response model $\boldsymbol{P}(Y = 1|x) = G(\beta' x)$ is

semiparametric if the function G and the vector of coefficients β are both treated as unknown quantities. This section describes two semiparametric models of conditional mean functions that are important in applications. The section also describes a related class of models that have no unknown finite-dimensional parameters but, like semiparametric models, mitigate the disadvantages of fully nonparametric models.

In addition to the estimation of conditional mean functions, semiparametric methods can be used to estimate conditional quantile and hazard functions, binary response models in which there is heteroskedasticity of unknown form, transformation models, and censored and truncated mean- and median- regression models, among others. Space does not permit discussion of these models here. Horowitz (1998) and Powell (1994) provide more comprehensive treatments in which these models are discussed.

3.1 Single Index Models

In a semiparametric single index model, the conditional mean function has the form

$$\boldsymbol{E}(Y \mid x) = G(\beta' x) \tag{3}$$

where β is an unknown constant vector and G is an unknown function. The quantity $\beta' x$ is called an 'index.' The inferential problem is to estimate G and β from observations of (Y, X). G in (3.1) is analogous to a link function in a generalized linear model, except in Eqn. (3) G is unknown and must be estimated.

Model (3) contains many widely used parametric models as special cases. For example, if G is the identity function, then Eqn. (3) is a linear model. If G is the cumulative normal or logistic distribution function, then Eqn. (3) is a binary probit or logit model. When G is unknown, Eqn. (3) provides a specification that is more flexible than a parametric model but retains many of the desirable features of parametric models, as will now be explained.

One important property of single index models is that they avoid the curse of dimensionality. This is because the index $\beta' x$ aggregates the dimensions of x, thereby achieving 'dimension reduction.' Consequently, the difference between the estimator of G and the true function can be made to converge to zero at the same rate that would be achieved if $\beta' x$ were observable. Moreover, β can be estimated with the same rate of convergence that is achieved in a parametric model. Thus, in terms of the rates of convergence of estimators, a single index model is as accurate as a parametric model for estimating β and as accurate as a one-dimensional nonparametric model for estimating G. This dimension reduction feature of single index models gives them a considerable advantage over nonparametric methods in applications where X is multidimensional and the single index structure is plausible.

A single-index model permits limited extrapolation. Specifically, it yields predictions of $\boldsymbol{E}(Y \mid x)$ at values of x that are not in the support of X but are in the support of $\beta' X$. Of course, there is a price that must be paid for the ability to extrapolate. A single index model makes assumptions that are stronger than those of a nonparametric model. These assumptions are testable on the support of X but not outside of it. Thus, extrapolation (unavoidably) relies on untestable assumptions about the behavior of $\boldsymbol{E}(Y \mid x)$ beyond the support of X.

Before β and G can be estimated, restrictions must be imposed that insure their identification. That is, β and G must be uniquely determined by the population distribution of (Y, X). Identification of single index models has been investigated by Ichimura (1993) and, for the special case of binary response models, Manski (1988). It is clear that β is not identified if G is a constant function or there is an exact linear relation among the components of X (perfect multicollinearity). In addition, (3.1) is observationally equivalent to the model $\boldsymbol{E}(Y \mid X) = G^*(\gamma + \delta\beta' x)$, where γ and $\delta \neq 0$ are arbitrary and G^* is defined by the relation $G^*(\gamma + \delta v) = G(v)$ for all v in the support of $\beta' X$. Therefore, β and G are not identified unless restrictions are imposed that uniquely specify γ and δ. The restriction on γ is called 'location normalization' and can be imposed by requiring X to contain no constant (intercept) component. The restriction on δ is called 'scale normalization.' Scale normalization can be achieved by setting the β coefficient of one component of X equal to one. A further identification requirement is that X must include at least one continuously distributed component whose β coefficient is nonzero. Horowitz (1998) gives an example that illustrates the need for this requirement. Other more technical identification requirements are discussed by Ichimura (1993) and Manski (1988).

The main estimation challenge in single index models is estimating β. Given an estimator b_n of β, G can be estimated by carrying out the nonparametric regression of Y on $b_n X$ (e.g., by using the kernel method described in Sect. 2). Several estimators of β are available. Ichimura (1993) describes a nonlinear least squares estimator. Klein and Spady (1993) describe a semiparametric maximum likelihood estimator for the case in which Y is binary. These estimators are difficult to compute because they require solving complicated nonlinear optimization problems. Powell et al. (1989) describe a 'density-weighted average derivative estimator' (DWADE) that is noniterative and easily computed. The DWADE applies when all components of X are continuous random variables. It is based on the relation

$$\beta \propto \boldsymbol{E}[p(X)\partial G(\beta' X)/\partial X] = -2\boldsymbol{E}[Y\partial p(X)/\partial X] \tag{4}$$

where p is the probability density function of X and the second equality follows from integrating the first by

parts. Thus, β can be estimated up to scale by estimating the expression on the right-hand side of the second equality. Powell et al. (1989) show that this can be done by replacing p with a nonparametric estimator and replacing the population expectation $\boldsymbol{E}$ with a sample average. Horowitz and Härdle (1996) extend this method to models in which some components of X are discrete. They also give an empirical example that illustrates the usefulness of single index models. Ichimura and Lee (1991) investigate a multiple index generalization of Eqn. (3).

3.2 Partially Linear Models

In a partially linear model, X is partitioned into two nonoverlapping subvectors, X_1 and X_2. The model has the form

$$\boldsymbol{E}(Y \mid x_1, x_2) = \beta' x_1 + G(x_2) \tag{5}$$

where β is an unknown constant vector and G is an unknown function. This model is distinct from the class of single index models. A single index model is not partially linear unless G is a linear function. Conversely, a partially linear model is a single index model only in this case. Stock (1989, 1991) and Engle et al. (1986) illustrate the use of Eqn. (5) in applications. Identification of β requires the 'exclusion restriction' that none of the components of X_1 are perfectly predictable by components of X_2. When β is identified, it can be estimated with an $n^{-1/2}$ rate of convergence regardless of the dimensions of X_1 and X_2. Thus, the curse of dimensionality is avoided in estimating β.

An estimator of β can be obtained by observing that Eqn. (5) implies

$$Y - \boldsymbol{E}(Y \mid x_2) = \beta'[X_1 - \boldsymbol{E}(X_1 \mid x_2)] + U \tag{6}$$

where U is an unobserved random variable satisfying $\boldsymbol{E}(U \mid x_1, x_2) = 0$. Robinson (1988) shows that under regularity conditions β can be estimated by applying OLS to Eqn. (6) after replacing $\boldsymbol{E}(Y \mid x_2)$ and $\boldsymbol{E}(X_1 \mid x_2)$ with nonparametric estimators. The estimator of β, b_n, converges at rate $n^{-1/2}$ and is asymptotically normally distributed. G can be estimated by carrying out the nonparametric regression of $Y - b_n' X_1$ on X_2. Unlike b_n, the estimator of G suffers from the curse of dimensionality; its rate of convergence decreases as the dimension of X_2 increases.

3.3 Nonparametric Additive Models

Let X have d continuously distributed components that are denoted $X_1, \ldots X_d$. In a nonparametric additive model of the conditional mean function,

$$\boldsymbol{E}(Y \mid x) = \mu + f_1(x_1) + \cdots + f_d(x_d) \tag{7}$$

where μ is a constant and $f_1, \ldots, f_d$ are unknown functions that satisfy a location normalization condition such as

$$\int f_k(v) w_k(v)\, \mathrm{d}v = 0, \quad k = 1, \ldots, d \tag{8}$$

where w_k is a non-negative weight function. An additive model is distinct from a single index model unless $\boldsymbol{E}(Y \mid x)$ is a linear function of x. Additive and partially linear models are distinct unless $\boldsymbol{E}(Y \mid x)$ is partially linear and G in Eqn. (5) is additive.

An estimator of $f_k (k = 1, \ldots, d)$ can be obtained by observing that Eqn. (7) and (8) imply

$$f_k(x_k) = \int \boldsymbol{E}(Y \mid x) w_{-k}(x_{-k})\, \mathrm{d}x_{-k} \tag{9}$$

where x_{-k} is the vector consisting of all components of x except the kth and w_{-k} is a weight function that satisfies $\int w_{-k}(x_{-k})\, \mathrm{d}x_{-k} = 1$. The estimator of f_k is obtained by replacing $\boldsymbol{E}(Y \mid x)$ on the right-hand side of Eqn. (9) with nonparametric estimators. Linton and Nielsen (1995) and Linton (1997) present the details of the procedure and extensions of it. Under suitable conditions, the estimator of f_k converges to the true f_k at rate $n^{-2/5}$ regardless of the dimension of X. Thus, the additive model provides dimension reduction. It also permits extrapolation of $\boldsymbol{E}(Y \mid x)$ within the rectangle formed by the supports of the individual components of X. Hastie and Tibshirani (1990) and *Exploratory Data Analysis: Multivariate Approaches (Nonparametric Regression)* discuss an alternative estimation procedure called 'backfitting.' This procedure is widely used, but its asymptotic properties are not yet well understood.

Linton and Härdle (1996) describe a generalized additive model whose form is

$$\boldsymbol{E}(Y \mid x) = G[\mu + f_1(x_1) + \cdots + f_K(x_d)] \tag{10}$$

where $f_1, \ldots, f_d$ are unknown functions and G is a known, strictly increasing (or decreasing) function. Horowitz (2001) describes a version of Eqn. (10) in which G is unknown. Both forms of Eqn. (10) achieve dimension reduction. When G is unknown, Eqn. (10) nests additive and single index models and, under certain conditions, partially linear models.

The use of the nonparametric additive specification (7) can be illustrated by estimating the model

$$\begin{aligned}\boldsymbol{E}(\log W \mid EXP, EDUC) \\ = \mu + f_{EXP}(EXP) + f_{EDUC}(EDUC)\end{aligned}$$

where W and EXP are defined as in Sect. 1, and $EDUC$ denotes years of education. The data are taken from the 1993 CPS and are for white males with 14 or fewer

Figure 2
(a) Estimate of f_{EXP} in additive nonparametric model of $\boldsymbol{E}(\log W \mid EXP, EDUC)$. (b) Estimate of f_{EDUC} in additive nonparametric model of $\boldsymbol{E}(\log W \mid EXP, EDUC)$

years of education who work full time and live in urban areas of the North Central US. The results are shown in Fig. 2. The unknown functions f_{EXP} and f_{EDUC} are estimated by the method of Linton and Nielsen (1995) and are normalized so that $f_{EXP}(2) = f_{EDUC}(5) = 0$. The estimates of f_{EXP} (Fig. 2a) and f_{EDUC} (Fig. 2b) are nonlinear and differently shaped. Functions f_{EXP} and f_{EDUC} with different shapes cannot be produced by a single index model, and a lengthy specification search might be needed to find a parametric model that produces the shapes shown in Fig. 2. Some of the fluctuations of the estimates of f_{EXP} and f_{EDUC} may be artifacts of random sampling error rather than features of $\boldsymbol{E}(\log W \mid EXP, EDUC)$. However, a more elaborate analysis that takes account of the effects of random sampling error rejects the hypothesis that either function is linear.

4. *Conclusions*

This article has described several semiparametric methods for estimating conditional mean functions. These methods relax the restrictive assumptions made by linear and other parametric models, thereby reducing (though not eliminating) the likelihood of

seriously misleading inference. The value of semiparametric methods in empirical research has been demonstrated. Their use is likely to increase as their availability in commercial statistical software packages increases.

Senescence: Genetic Theories

Senescence is the progressive deterioration of vitality that accompanies increasing age. Like other features of organismal life histories, patterns of senescence vary between individuals within populations, between populations of the same species, and between species, suggesting that they are modifiable by genetic factors and subject to evolutionary change. In this article, the various evolutionary forces that might direct genetic modifications of senescence are considered, and a theoretical framework for understanding the evolution of life histories is presented. The secondary problem of the maintenance of genetic variation for life history traits is also reviewed.

1. Medawar's Principle

The modern evolutionary theory of senescence begins with Medawar who argued that '…the efficacy of natural selection deteriorates with increasing age' (1952, p. 23). A simple hypothetical example similar to a case considered by Hamilton (1966) illustrates the principle. Consider two genetic variants in humans, both having age-specific effects as follows: each variant confers complete immunity against a lethal disease, but only for one particular year of life. The first variant gives immunity to 12 year-olds, while the second variant confers immunity at the age of 60 years.

What are the relative selective advantages of the genetic variants? If, for simplicity, the effects of parental care are ignored and it is also assumed that menopause always comes before 60 years, then it is immediately obvious that the second variant is selectively neutral, having no effect at all on the ability of carriers to transmit genes to the next generation, whereas the first variant has a significant selective advantage. This example illustrates the general principle that natural selection is most effective in the

young. To obtain a more exact and quantitative understanding of the relation between organismal age and the force of selection, it is necessary to develop a description of selection in age-structured populations.

2. *Age-structured Populations*

Some organisms, such as annual plants, complete their life cycles in discrete fashion, exhibiting no overlap of parental and offspring generations. However, most higher organisms, including humans, have overlapping generations. Under the latter circumstances, the description of population composition and growth requires two kinds of information: age-specific survival, and age-specific fertility. Survivorship, denoted $l(x)$, is defined as the probability of survival from birth or hatching until age x. A survivorship curve is a graph of $l(x)$ versus x, where x ranges from zero to the greatest age attained in the population. The survivorship is initially 100 percent at birth and then declines to zero at the maximum observed age; it cannot increase with increasing age. If a cohort of 1,000 age-synchronized individuals are followed throughout their lives, then 500 of them will be alive at the age when $l(x)$ is 0.50, 100 will be alive when $l(x)$ is 0.10, and so on. Age-specific fertility, represented as $m(x)$, is defined as the average number of progeny produced by a female of age x.

One of the fundamentals of demography is that, under a wide range of conditions, a population having fixed $l(x)$ and $m(x)$ schedules will eventually attain a stable age-structure. That is, after a period of time the proportions of the population in each age-class will reach unchanging values. If the survivorship or fertility schedules are altered, then a different age-structure will evolve.

Prior to attaining the stable age distribution, population growth is likely to be erratic, but once the stable age distribution is reached, then, under the assumption of unlimited resources, the population will grow smoothly. In particular, the population will exhibit exponential growth described by the following equation:

$$N(t) = N(0)\,\mathrm{e}^{rt} \tag{1}$$

where $N(t)$ is population size as a function of time t, $N(0)$ is initial population size, e is the natural exponential, and r is the Malthusian parameter, also known as the intrinsic rate of increase of the population. The parameter r combines the effects of age-specific survival and fertility and translates them into a population growth rate. The value of r is the implicit solution to the following equation, known as the Euler–Lotka equation:

$$\int \mathrm{e}^{-rx}\, l(x)\, m(x)\, \mathrm{d}x = 1 \tag{2}$$

The significance of the Malthusian parameter is that it reflects fitness, in the Darwinian sense, in an age-structured population. If there are several genotypes in a population, and if those genotypes differ with respect to age-specific survival or fertility patterns, then each genotype will have a particular r value. Those r's specify the rate at which a population consisting of only that genotype would grow, once the stable age distribution has been attained. The r's also specify the relative fitnesses of the genotypes in a genotypically mixed population. The genotype with the highest r has the highest fitness and will be favored by natural selection under conditions that allow population growth. Much of the evolutionary theory relating to senescence and life histories uses the Malthusian parameter r as a surrogate for Darwinian fitness, essentially asking what changes in the $l(x)$ and $m(x)$ schedules would maximize the intrinsic rate of increase.

There is one other quantity that arises as a measure of fitness in populations with overlapping generations. Fisher (1930) defined 'reproductive value,' which is the expected number of progeny that will be produced by an individual of age x over the rest of its lifetime, given that it has survived to age x. Reproductive value is not the same as fitness, because it does not take into account the chances of surviving to age x.

3. *Hamilton's Perturbation Analysis*

Hamilton (1966) asked the following question: What sorts of small genetic changes in the $l(x)$ or $m(x)$ schedules will be favored by natural selection? To answer this question he employed the Malthusian parameter r as a measure of fitness, assuming that the modifications of $l(x)$ and $m(x)$ that lead to the highest value of r will be the ones to evolve. He also approximated the continuous functions described above with their discrete-time counterparts. The discrete-time rate of population increase is:

$$\lambda = \mathrm{e}^{r} \tag{3}$$

The discrete-time version of the Euler–Lotka equation is

$$\sum l_x m_x \lambda^{-x} = 1 \tag{4}$$

Age-specific survival is expressed in descrete time as:

$$l_x = p1\; p2\; p3 \ldots p_x \tag{5}$$

where p_x is the probability of surviving the duration of the xth age class given that one has survived to the beginning of age class x.

Now consider the evolutionary fate of a mutation which causes a small change in the ability to survive at some particular age a. The new mutation will be favored by natural selection if it causes an increase in r, or, what is equivalent in the discrete-time case, an increase in $ln\ \lambda$. The effect of the perturbation is studied by examining the partial derivative of λ with

respect to p_a. Hamilton obtained a closed form of this derivative and was able to conclude the following:

(a) The force of selection, as indicated by the partial derivative is highest at the youngest pre-reproductive ages, begins to decline when reproduction commences and drops to zero when reproduction ceases.

(b) If a mutation causes a gain in survival at a particular age a_1 and an equal loss in survival at age a_2, then such a mutation will increase in the population only if $a_1 < a_2$.

(c) If a mutation causes a gain in fertility at a particular age a_1 and an equal loss of fertility at age a_2, then such a mutation will increase in the population only if $a_1 < a_2$.

(d) If a mutation causes a loss in survival at a particular age and an increase in fertility at that same age, then the limits of the loss in survival that can be tolerated are set by the inverse of the reproductive value. That is, if the reproductive value at age x is large, then only a small reduction of survival can be exchanged for a gain in fertility, but if the remaining reproductive value is small, then a large reduction in survival can evolve.

(For further explication of these results, see Roughgarden 1996, p. 363.)

Hamilton's general conclusion is that 'for organisms that reproduce repeatedly senescence is to be expected as an inevitable consequence of the working of natural selection' (1966, p. 26). This is a view that is clearly consistent with Medawar (1952). For a technical discussion of the validity of the assumption that the Malthusian parameter is equivalent to fitness in age-structured populations, see Charlesworth (1980), whose models extend the early results of Haldane (1927) and Norton (1928).

4. *Pleiotropy*

Pleiotropy means that a single gene affects two or more characters. In the context of life history evolution, pleiotropy means that a single gene affects the fitness of the organism at two or more ages. It is convenient to categorize the combinations of age-specific pleiotropic effects as shown in Table 1. If a new mutation improves fitness in both young and old animals, then it is likely to be favored by natural selection, and will increase in the population. Conversely, a gene that decreases fitness in both young and old organisms will be eliminated by natural selection. The more interesting cases in Table 1 are those in which the fitness effects on young and old organisms are negatively correlated, a condition referred to as 'negative pleiotropy' or 'antagonistic pleiotropy.' Medawar's principle suggests that mutations that improve early fitness at the expense of late fitness will be favored by natural selection, while those with the converse effects will be eliminated.

Table 1
Pleiotropic effects of mutations affecting life history

Effect on fitness in the young	Effect on fitness in the old	Evolutionary fate
+	+	Increase
−	−	Decrease
−	−	Decrease
−	+	Decrease
+	−	Increase

Table 2
Fitness parameters for a one-locus model of antagonistic pleiotropy

Genotype:	A1A1	A1A2	A2A2
Fitness in young:	High	Medium	Low
Fitness in old:	Low	Medium	High

The possibility that genes might increase fitness at one age and also decrease it at another was mentioned by early theorists, but the first strong advocate of this mechanism of the evolution of senescence was Williams (1957), who noted that natural selection will tend to maximize vigor in the young at the expense of vigor later in life. An example of negatively pleiotropic gene action of the sort that Williams proposed is shown in Table 2. Williams argued that, in the course of selecting for the allele A1 which is beneficial at young ages, the deleterious effects of allele A2 on the old are brought along; in this scenario, senescence evolves as an incidental consequence of adaptation at earlier ages. The exact mathematical conditions for the increase of antagonistic, pleiotropic mutations have been derived (Charlesworth 1980), verifying that such mutations can indeed increase in populations.

While the theoretical basis for antagonistic pleiotropy is sound and widely accepted, it is unclear whether there exists the special sort of genetic variation that this mechanism requires. While it is easy to imagine physiological situations in which there could occur trade-offs between the fitness of the young and the old, there are few, if any, actual cases of such variation identified (Finch 1990, p. 37), even though a half century has passed since Williams' proposal. Negative correlations between life history characters are sometimes construed as evidence for pleiotropy, but this interpretation overlooks the fact that phenotypic correlations arise from factors other than pleiotropy, including the correlation of environmental factors and the correlation of alleles at genetically linked loci (linkage disequilibrium). What is required for the antagonistic pleiotropy model is not just evidence of trade-offs in life history traits, which is abundant, but a demonstration that there exist trade-offs in life history characters that are mediated by alternative alleles at specific polymorphic loci. Until such genes are characterized and shown to play a role

in life history evolution, the antagonistic pleiotropy model will remain an interesting theoretical construct, but one of unknown, and possibly negligible, biological significance.

5. *Mutation Accumulation*

Germ-line mutations, which are changes in the DNA sequence in sperm and egg cells, occur at low but nonzero rates, largely as a result of proof-reading errors in the enzymes that replicate DNA. This slow, steady input of genetic variants has the potential to corrupt the gene pool, since almost all of the novel variants that have some effect are deleterious. However, natural selection works against the corrupting effect by removing carriers of deleterious mutations. A balance is reached between the steady input of deleterious genes through mutation and their removal by natural selection. One of the characteristics of the equilibrium balance state is that, for any particular gene, the deleterious alleles are present at low frequencies, usually much less than 1 percent. The low rate of occurrence of each of many hereditary human diseases is thought to reflect the mutation-selection balance operating at many genes, each of which is capable of being mutated to produce a deleterious condition (Hartl and Clark 1997).

The classical mutation-selection balance model is appropriate for mutations that have deleterious effects early in life, but what happens when the disability is expressed only late in life? Medawar (1952) suggested that natural selection will be unable to counteract the feeble pressure of repetitive mutation if the mutant genes make their effects known at advanced ages, either post-reproductively or at ages not attained by most of the members of the species. This follows naturally from his proposal that the force of selection declines with increasing age. Under such conditions, the deleterious mutations would gradually accumulate, unchecked by natural selection. In this view, senescence is a process driven entirely by mutation. This mechanism for the evolution of senescence is distinct from, but not mutually exclusive of, antagonistic pleiotropy. While the pleiotropy process suggests that senescence is the incidental consequence of adaptation, the mutation accumulation model invokes deterioration without adaptation (Partridge and Barton 1993).

Charlesworth (1980) has analyzed a deterministic model of an age-structured population with recurrent mutation. He derived an approximation for the frequency of heterozygous carriers of deleterious alleles and found that the equilibrium frequency is inversely proportional to the selection intensity. The significance of this result is that when there is only very weak selection pressure, as at advanced ages, then mutant alleles can attain high frequencies under the influence of recurrent mutation. This result verifies the earlier conjectures of Medawar and Williams. In contrast to the situation with antagonistic pleiotropy, there is experimental evidence for the kinds of genetic variation that the model requires, namely spontaneous mutations with age-specific effects on vital rates (Mueller 1987, Pletcher et al. 1998, 1999).

6. *Postponement of Deleterious Effects*

Medawar (1952) also considered the case of Huntington's chorea, a grave and ultimately fatal nervous disorder that usually manifests itself in middle-aged patients. He suggested that there could be selection in favor of genetic modifiers which have as their main effect the postponement of the effects of the Huntington's gene or other genes causing hereditary disorders. This suggestion, which very much resembles an earlier proposal of R. A. Fisher concerning the evolution of dominance, is unlikely to be correct. While it makes sense that there would be some selection in favor of delaying the mutant effect, Charlesworth (1980, p. 219) has shown that the selection pressure exerted on such a hypothetical modifier gene would be exceedingly small, on the order of the mutation rate. This is because the modifier has an effect on fitness only when it co-occurs with the Huntington's or other disease gene, which is at mutation-selection balance and present in only a small fraction of the population. Under such conditions the evolutionary fate of the modifier is likely to be determined by genetic drift or other stochastic factors rather than the minuscule selective pressure.

7. *The Variation Problem*

While the primary concern of theorists has been to explain the degeneration of vitality associated with old age, there is a secondary problem that can also be addressed with these models. Genetic variation is the raw material upon which natural selection operates to produce adaptations and new species. The mechanisms by which variation is maintained in populations are therefore of considerable interest to evolutionary geneticists. To what extent do genetic models of senescence tend to maintain variation in life histories within populations? Several authors have addressed the question and come to two different answers depending upon the theoretical construct employed. Curtsinger et al. (1994) analyzed deterministic one- and two-locus models of antagonistic pleiotropy and asked under what conditions polymorphisms would be maintained. The conditions for stable polymorphism were found to be rather restrictive, especially with weak selection. The conditions were also found to be very sensitive to dominance parameters; in particular, reversal of dominance properties with respect to the two traits is often required for polymorphism, but seems improbable on biochemical grounds.

Tuljapurkar (1997) gives an overview of modeling strategies and describes some of his own models in which mortality is assumed to depend on both organismal age and random variables in the environment. In these models, the relative fitnesses are measured by a stochastic growth rate, which reflects average vital rates and environmental variability. Results from several related models show that phenotypic combinations that differ in age-specific fertility can be equally fit in a range of stochastic environments. The paper concludes that polymorphisms for length of reproductive life can be readily maintained by selection in temporally varying environments.

8. *Future Directions*

Two important challenges to the genetical theories of senescence arise from recent experimental work. The first challenge concerns mortality rates at advanced ages. Observations of survival in experimental organisms are usually presented in terms of age-specific survivorship, as defined in Sect. 2, but if sample sizes are sufficiently large then the survival data can also be analyzed in terms of hazard functions, which define the instantaneous risk of death as a function of age. Unlike survivorship, the hazard function can be nonmonotonic. Many experimental studies of moderate sample size have documented that the hazard increases approximately exponentially with age, a dynamic generally referred to as the Gompertz law (Finch 1990). Recent experiments have been done on an unusually large scale, making it possible to estimate hazards at very advanced ages. For Drosophila, nematode worms, and Med-flies, hazard functions increase exponentially in the early part of the life history, as expected, but at the most advanced ages the hazard functions decelerate, bending over and producing unexpected 'mortality plateaus' (see Vaupel et al. 1998, for a review of the experimental evidence and data on human populations).

The existence of mortality plateaus at advanced, post-reproductive ages poses a challenge for mutation accumulation models, which predict, under a wide range of assumption, a 'wall' of high mortality at the age when reproduction is completed. A preliminary attempt to accommodate mortality plateaus into antagonistic pleiotropy models has failed (Pletcher and Curtsinger 1998, Wachter 1999). One possible solution is that the mortality plateaus are caused by population heterogeneity of both genetic and nongenetic origin (Pletcher and Curtsinger 2000, Service 2000). It has so far proved very difficult to measure the relevant heterogeneity and determine whether it is of sufficient magnitude to produce the plateaus. A second possibility that can explain some features of the plateaus is a model of positive pleiotropy, which causes late-life mortality rates to avoid inflation because of the positively correlated effects of alleles selected for early survival (Pletcher and Curtsinger 1998). Models of positive pleiotropy merit further investigation.

The second experimental challenge to current theory concerns genetic variance. The mutation accumulation model predicts that genetic variance for mortality should increase at advanced ages. Recent experiments document instead a decline of genetic variance at advanced ages in experimental populations of Drosophila (Promislow et al. 1996). Hughes and Charlesworth (1994) initially reported that genetic variance for mortality increases with age in their Drosophila populations, but a re-analysis of the data show close concordance with the Promislow result (Shaw et al. 1999). At present no one knows why genetic variance declines at advanced ages; it could be related to the mortality plateaus described above.

Three other lines of research appear to hold promise. Group selection is a process by which collections of organisms succeed or fail as a collective, either becoming extinct or spawning new groups in competition with other groups. Groups selection arguments are sometimes invoked to explain altruistic behaviors, but evolutionary biologists typically disdain group selection, because the process tends to be much weaker than selection between individuals, and also seems to work only in very small populations (Williams 1966). However, group selection might play a role in shaping post-reproductive mortality rates, when individual-level selection is essentially inoperative. This type of model could be particularly relevant to human evolution, and is essentially unexplored. A related type of model that needs further development involves the evolution of vital rates in combination with kin selection, taking into account the effects of post-reproductive survival, parental care, and fitness effects mediated through relatives in the kin group (Roach 1992). Finally, as noted by Tuljapurkar (1997), the theoretical methods are limited to small perturbations and local analyses, under which conditions the population is always close to demographic equilibrium. There does not exist at present a theory that can accommodate large mutational changes in vital rates in combination with non-equilibrium demographics.

Sensation and Perception: Direct Scaling

One aim of psychophysics is to measure the subjective intensity of sensation. We easily hear that a tone of given intensity has a particular loudness, and that a tone of higher intensity sounds louder still. The measurement problem lies in the question 'How much louder?' Direct scaling is a particular way of answering that question: the observer is asked to assign numbers corresponding to the subjective magnitudes of given stimulus intensities, thus providing the capability of saying that, for example, one tone sounds twice or ten times as loud as another.

1. *History*

1.1 *Fechner's Solution*

G. Fechner first proposed a solution, albeit an indirect one, in 1860 (Boring 1950). He accepted Weber's law—that the difference threshold (the physical size of a difference in intensity needed to tell one signal from another) grows in proportion to signal intensity, determining a constant of proportionality, the Weber fraction, unique to each sensory continuum. Fechner assumed that all difference thresholds are subjectively constant and therefore can serve as the unit of measurement for scales of sensation. He concluded that subjective magnitude grows by constant differences as stimulus magnitude grows by constant ratios, a logarithmic relation now known as Fechner's law.

1.2 *Category Rating and Magnitude Scaling*

In Fechner's laboratory, there also evolved a direct approach to measuring sensation magnitude. This was the method of absolute judgment (later called category rating), in which the subject assigns stimuli to categories according to some subjective aspect. Originally designed to study esthetic judgment, it was adapted by 1920 to studying sensation magnitude; early findings using this method supported Fechner's law.

In the 1950s, S. S. Stevens refined another and related direct scaling procedure in which the subject estimates the apparent magnitude of a signal by assigning to it a numerical value—hence, magnitude estimation. Data from this method were better fitted by a power law.

2. Methods

All the direct scaling methods require an observer to judge a series of stimuli varying along (at least) one dimension. For instance, the experimenter might present a pure tone at several sound pressure levels covering a 1000:1 range and request judgments of loudness, or present a light disk at several luminanoes covering a 10:1 range and request judgments of brightness.

2.1 Category Rating

The observer is instructed to assign each stimulus to a category, which may be designated descriptively (very soft, soft, … very loud) or numerically (1, 2, … , 7); the assignments should create subjectively equal category intervals. The allowable response values, including the extreme values, are specified by the experimenter. Usually the number of categories ranges from 5 to 11, although smaller and larger values are sometimes used. Typically, the stimulus range does not exceed 10:1, although it may do so.

2.2 Magnitude Estimation and Production

In magnitude estimation, the observer is instructed to assign to each stimulus a (positive) number so that the number reflects its apparent intensity. There are no limits on allowable response values. Originally, one stimulus value was designated as standard and a numerical value assigned to it as modulus. Later, however, the use of designated standard and assigned modulus was abandoned and the observer instructed to choose any numbers appropriate to represent apparent magnitudes. Typically the stimulus range is at least 100:1 and is often greater.

In magnitude production, stimulus and judgmental continua are interchanged; the experimenter presents a set of numbers, and the observer produces values on some intensive continuum to effect a subjective match for each presented number.

2.3 Cross-modal Matching

The use of numbers, which has provoked many objections, can be avoided by instructing the observer to match intensities on one physical continuum directly to intensities on another. For example, the observer may produce luminances to match sound pressure levels so that brightness of a light disk is equivalent to loudness of a tone, or the observer may produce handgrip forces to match odor intensities so that perceived effort is equivalent to strength of smell.

3. Achievements of Direct Scaling

3.1 A Quantitative Phenomenology

These methods made possible a quantitative phenomenology of the various sensory systems. For example, in hearing, the importance of salient variables, such as frequency and intensity, to the ability of the observer to detect a sound or to tell the difference between two sounds, had long been known. Furthermore, by having the observer match tones of varying frequency and intensity to a fixed reference tone, equal loudness contours were established. What remained unknown were the loudness relations among these contours. Magnitude estimation, by providing a numerical reference scale, permits the observation that one tone sounds twice, or ten times, or half as loud as another. Thus, magnitude estimation has been used to map the effects of variables known to influence perception for loudness, brightness, tastes and smells, and tactile sensations, as well as internal states such as perceived effort, fatigue, and satiety (Stevens 1975). It has also been used to study continua without a physical measure (e.g., seriousness of crime, severity of punishment, and their relationship) (Sellin and Wolfgang 1964). Category rating has been employed to study the cognitive integration of perceptual dimensions (Anderson 1981).

3.2 Intermodal Comparisons

Direct scaling also provides the capability to compare and contrast phenomena that occur in several modalities, such as temporal and spatial summation, sensory adaptation and recovery, and spatial inhibition (brightness contrast and auditory masking), at levels above absolute threshold (Marks 1974). For example, a persisting olfactory stimulus of constant intensity produces a smell intensity that diminishes in strength over time. That diminution can be assessed by asking an observer to assign numbers to the apparent magnitude of the smell at different elapsed times, e.g., after 5 s, 10 s, 30 s, 60 s, … ; in this way, the course of sensory adaptation can be traced for this stimulus and for others of differing initial intensities. When the procedure is repeated in a different modality, the parameters of the adaptation curves can be compared.

3.3 Stevens' Power Law

The third major achievement of direct scaling is the discovery that, to at least a first approximation, equal stimulus ratios produce equal judgmental ratios. This nearly universal relation is called Steven's power law, after S. S. Stevens who established it: subjective

magnitude is proportional to intensity raised to some power. Further, that exponent takes distinctive values for each stimulus continuum, ranging from 0.3 for luminance to 2.0 or more for electric shock.

Later experiments showed that the magnitude exponents predicted cross-modal matching exponents: if continua A and B had magnitude exponents a and b, and if a cross-modal match of B to A was obtained, the resulting exponent was a/b. Indeed, the cross-modal exponents for a variety of continua are connected in a transitive network (Daning 1983), a finding with important theoretical implications.

4. Problems of Direct Scaling

4.1 Use of Numbers as Responses

Critics questioned treating the numbers that subjects assigned to stimulus magnitudes as if they were measurements. However, the practice was validated by the discovery that the results obtained with number as the matching continuum are in agreement with the results obtained with cross-modal matching (Stevens, 1975). Furthermore, in cross-modal matching, some other stimulus continuum can substitute for number, since the choice of a reference continuum is, for most purposes, arbitrary. Whether the numbers used by an observer constitute a direct measure of sensation is an unresolved, and perhaps unresolvable, question (Teghtsoonian 1974).

4.2 The Psychophysical Regression Effect

Since magnitude estimation (assigning numbers to physical intensities) and magnitude production (assigning physical intensities to match numbers) are inverses of each other, they should produce the same exponent. However, this is not the case. The size of the difference in exponents may be quite large, with the result that a precise value of the exponent for a given stimulus continuum cannot be specified; no satisfactory combination rule has been agreed upon. The size, and indeed the direction, of the difference depends on the range of physical intensities (or numbers) presented; for practical purposes, the smallest effect is exhibited when the range is large. Some portion, at least, of this regression effect depends on sequential effects, the influence exerted by previous stimuli and judgments on subsequent judgments.

4.3 Category vs. Ratio Scales

Although both category rating and magnitude estimation purport to give scales of sensation magnitude, they do not, in general, agree with each other: both scales can be characterized as power functions, but the exponents are not the same. Much discussion has centred on whether subjects can make two kinds of judgments or whether the experimenter transforms a single kind of magnitude judgment by treating it as ratio or interval. However, an experimental determination of the sources of variance in the type of scale produced shows that instructions to judge either ratios or intervals account for almost none of the variance; much more important are such methodological variables as whether judgmental end-points are assigned or free and whether the range of stimuli is small or large. With free end-points and a large range, category judgment and magnitude estimation produce the same results; the obtained power functions have stable exponents characteristic of magnitude estimation (Montgomery 1975).

4.4 Local vs. Global Psychophysics

A long-standing conundrum in psychophysics has been the relation between the local (thresholds, both absolute and difference) and the global (measurements of subjective magnitude at levels above absolute threshold) (Luce and Krurnhansl (1988). Fechner believed he had combined the two by using difference thresholds as subjective units to yield a logarithmic scale of sensation. Stevens (1961) proposed, while honoring Fechner, to repeal his law and to substitute a power scale of sensation; he believed that one could not derive measures of sensation magnitude from threshold determinations. An early attempt to reconcile these two positions was R. Teghtsoonian's argument (1973) that both difference thresholds and power law exponents are indices of dynamic range. He proposed that there is a common scale of sensory magnitude for all perceptual continua and that the observer's dynamic range for each continuum maps completely onto that common scale. For example, the least sound intensity experienced has the same subjective magnitude as the least luminance, and the greatest sound intensity to which the auditory system responds has the same subjective magnitude as the greatest luminance. Thus the mapping of widely divergent dynamic ranges for the several perceptual continua onto a single subjective magnitude range determines their power law exponents, and the mapping of widely divergent difference thresholds onto a single subjective difference threshold determines their Weber fractions.

Sensation Seeking: Behavioral Expressions and Biosocial Bases

Sensation seeking is a personality trait defined as the tendency to seek varied, novel, complex, and intense sensations and experiences and the willingness to take risks for the sake of such experience (Zuckerman 1979, 1994). The standard measure of the trait is the Sensation Seeking Scale (SSS). In the most widely used version (form V) it consists of four subscales: (a) Thrill and Adventure Seeking (through risky and unusual sports or other activities); (b) Experience Seeking (through the mind and senses, travel, and an unconventional lifestyle); (c) Disinhibition (through social and sexual stimulation, lively parties, and social drinking); (d) Boredom Susceptibility (aversion to lack of change and variety in experience and people). Form V uses a total score based on the sum of the four subscales. More recently a single scale called 'Impulsive Sensation Seeking' has been developed which is a combination of items measuring the tendency to act impulsively without planning ahead, and adaptations of items from the SSS which assess the general need for excitement without mention of specific interest or activities (Zuckerman 1993).

Similar constructs and measures have been developed by other researchers including: change seeking, stimulus variation seeking, excitement seeking, arousal seeking, novelty seeking and venturesomeness. Most of these scales correlate very highly with the SSS and usually have the same kind of behavioral correlates.

Novelty seeking, a construct and scale devised by Cloninger (1987), not only correlates highly with Impulsive Sensation Seeking, but is based on a similar kind of biobehavioral model. Individuals high on novelty seeking are described as impulsive, exploratory, fickle, and excitable. They are easily attracted to new interests and activities, but are easily distracted and bored. Those who are low on this trait are described as reflective, rigid, loyal, stoic, frugal, orderly, and persistent. They are reluctant to initiate new activities and are preocccupied with details, and think very carefully and long before making decisions.

1. *Theoretical and Research Origins of the Construct*

The first version of the SSS was an attempt to provide an operational measure of the construct 'optimal levels of stimulation and arousal' (the level at which one feels and functions best). The author was conducting experiments on sensory deprivation (SD) in which participants volunteered to spend some length of time (from 1 to 24 hours in the author's experiments and up to two weeks in those of other investigators) in a dark soundproof room. It was theorized that persons with high optimal levels of stimulation would be most deprived by the absence of stimulation. Experiments show that the high sensation seeker became more restless over the course of an eight-hour experiment but did not experience more anxiety than the low sensation seekers (defined by the first version of the SSS). The construct changed as research using the SSS was extended to the broader domain of life experience.

2. *Behavioral Expressions*

Contrary to what we expected, the volunteers for the SD experiments were more commonly high sensations seekers than lows. This was because they had heard that people had weird experiences in SD, like hallucinations. High sensation seekers volunteered for any kind of unusual experiments, like hypnosis or drug studies. They did not volunteer for more ordinary experiments. The concept of sensation seeking centered more around the need for novel stimulation or inner experiences rather than stimulation *per se*. Surveys of drug use and preferences showed that high sensation seekers tended to be polydrug users of both stimulant and depressant drugs whereas lows did not use any drugs (Segal et al. 1980). It was the novel experience of drugs, not their effect on arousal, that

attracted high sensation seekers. Of course hallucinatory drugs had a particular attraction for those who scored high on this trait. They were not deterred by the legal, social, or physical risks entailed in drug use. Sensation seeking in preadolescents predicts their later alcohol and drug use and abuse.

Similarly sensation seekers proved to be attracted to risky sports that provided intense or novel sensations and experiences, like mountain climbing, parachuting, scuba diving, and car racing. They were not found in ordinary field sports or among compulsive exercisers. Outside of sports the high sensation seekers were found to drive their cars faster and more recklessly than lower sensation seekers.

High sensation seekers are attracted to exciting vocations such as firefighting, emergency room work, flying, air-traffic control, and dangerous military assignments. When they are stuck in monotonous desk jobs they report more job dissatisfaction than low sensation seekers.

In interpersonal relationships high sensation seekers tend to value the fun and games aspects rather than intimacy and commitment (Richardson et al. 1988). They tend to have more premarital sexual experience with more partners and engage in 'risky sex.' There is a high degree of assortative mating based on sensation seeking, i.e., highs tend to marry highs and lows tend to marry lows. Couples coming for marital therapy tend to have discrepant scores on the trait. Divorced persons are higher on the trait than monogamously marrieds.

Not all expressions of sensation seeking are risky. High sensation seekers like designs and works of art that are complex and emotionally evocative (expressionist). They like explicit sex and horror films and intense rock music. When watching television they tend to frequently switch channels ('channel surfing'). High sensation seekers enjoy sexual and nonsense types of humor (Ruch 1988). Low sensation seekers prefer realistic pastoral art pictures, media forms like situation comedies, and quiet background music.

3. *Psychopathology*

Sensation seeking is an essentially normal trait and most of those who are very high or low on the trait are free from psychopathology. However, persons with certain kinds of disorders involving a lack of impulse control tend to be high sensation seekers. Sensation seeking is a primary motive for those with antisocial personality disorder; their antisocial behavior involves great risks where the only motive is sometimes the increase of excitement. Other disorders with a high number of sensation seekers include those with conduct disorders, borderline personality disorders, alcohol and drug abusers, and bipolar (manic-depressive) disorders. It has been discovered that there are genetic and biological trait links between many of these disorders and sensation seeking. For instance, as yet unaffected children of bipolars tend to be high sensation seekers as well as showing similar differences on an enzyme to be discussed.

4. *Genetics*

Studies of twins raised in intact families show a relatively high degree of heritability (60 percent), compared to other personality traits that are typically in the range 30–50 percent. Analyses show no effects for the shared family environment; the environment that is important is that outside of the family which affects each twin differently. A study of twins separated shortly after birth and adopted into different families confirms these results (Hur and Bouchard 1997).

A specific gene has been found to be related to novelty seeking (Ebstein et al. 1996). The gene produces one class of receptors for the neurotransmitter dopamine. One of the two major forms of the gene is found more often in high sensation seekers. This form of the gene has also been found in high percentages of heroin abusers, pathological gamblers, and children with attention deficit hyperactivity disorder. The neurotransmitter dopamine as well as the other two monoamines in the brain, norepinephrine and serotonin, are theorized to underlie the three behavioral mechanisms involved in sensation seeking: strong approach, and weak arousal and inhibition.

5. *Biochemistry*

Males who are high in sensation seeking trait have high levels of the hormone testosterone compared to average levels in lower sensation seekers (Daitzman and Zuckerman 1980). This finding is consistent with the difference between men and women in the trait and the finding that sensation seeking peaks in the late teens and declines with age in both sexes.

The enzyme monoamine oxidase (MAO) type B is lower in high sensation seekers than in those who score low on the trait. This is also consistent with age and gender differences since women are higher than men on MAO at all ages and MAO rises in the brain and blood platelets with age. Type B MAO is a regulator of the monoamines, particularly dopamine, and low levels imply a lack of regulation perhaps related to the impulsivity characteristic of many high sensation seekers. Low levels of MAO are also found in disorders characterized by poor behavioral control: attention deficit hyperactivity disorder, antisocial and borderline personality disorders, alcoholism, drug abuse, pathological gambling disorder, and mania (bipolar disorder). MAO is part of the genetic predisposition for these disorders as shown by the finding that the enzyme is low in as yet nonaffected children of alcoholics and those with bipolar disorder. Evidence

of behavioral differences in newborn infants related to MAO levels also show the early effects on temperament. MAO differences are also related to behavioral traits in monkeys analogous to those of high and low sensation seeking humans.

6. Psychophysiology

Differences in the psychophysiological responses of the brain and autonomic nervous system as a function of stimulus intensity and novelty have been found and generally replicated (Zuckerman 1990). The heart rate response reflecting orienting to moderately intense and novel stimuli is stronger in high sensation seekers than in lows, perhaps reflecting their interest in novel stimuli (experience seeking) and disinterest in repeated stimuli (boredom suceptibility).
