One important distinction between regulation of synaptic efficacy and of other neural properties is the greater specificity that synaptic changes may exhibit. Because any given neuron may form pre- or postsynaptic contacts with thousands of other cells, the ability to modify only selected connections of a neuron confers a high degree of precision in the modification of neural pathways. In contrast, intrinsic changes such as enhanced excitability are often expressed cell-wide or nearly cell-wide, enhancing responses to virtually all inputs and enhancing virtually all outputs. In *Aplysia* siphon sensory cells, several short-term forms of synaptic plasticity, including heterosynaptic facilitation, heterosynaptic inhibition, and Hebbian facilitation, exhibit synapse specificity (Clark and Kandel 1984, Clark 2001). Synapse specificity is perhaps not surprising in short-term regulation, which involves covalent modifications of pre-existing proteins. However, long-term heterosynaptic facilitation, which depends on regulation of transcriptional and translational events, is also in part synapse-specific (Clark 2001, Martin et al. 1997). Synapse-specific long-term facilitation raises the intriguing question of how new gene products are preferentially utilized at facilitated synapses, compared with other synapses of the same neuron. An emerging answer, consistent with comparable findings in hippocampal LTP, is that synapse-specific long-term facilitation involves synaptic tagging and depends in part on local protein synthesis. According to this hypothesis, relatively short-lived, local regulatory events at treated synapses allow the subsequent capture of new gene products that are shipped cell-wide, thus conferring the specificity. Irrespective of the particular mechanistic details, long-term synapse-specific facilitation provides an additional illustrative example of the rich interplay and elegance of the multiple biological processes involved in synaptic regulation.

Synaptic Transmission

As explained in detail by J. C. Eccles in 1964, nerve cells communicate via specialized regions of close juxtaposition that were first named 'synapses' by C. S. Sherrington, who used this term to denote the anatomical region where the axon terminal of one neuron contacts another neuron. Sherrington always used synapse in its functional sense (for example, to account for the one-way conduction in the reflex arc). However, it must now be considered from an anatomical perspective as well since, despite variations, there are common structural features consistent with some of the physiological properties of synapses. For example, given that there is a high resistance gap of 200 Å width separating neuronal membranes at most synapses, as first claimed by Rámon y Cajal, current generated by one cell cannot spread significantly to the next one. Thus, it is advantageous for postsynaptic terminals to utilize a chemical mediator to secure transmission. This concept was only established after decades of controversy and efforts to distinguish between electrical and chemical models, for both excitation and inhibition. Yet, although it is beyond the scope of this overview, electrotonic interactions between nerve cells, in the periphery and in the brain, can indeed occur, due to either (a) areas of continuity between them via gap junctions (Bennett 1977); or (b) the channeling of currents in adjacent cells by an unusually high external resistance. The second case is called ephaptic or, better stated, field effect transmission (Faber and Korn 1989). These two electrical modes, which should not be confused, allow signaling to occur instantaneously, and are well suited for the mediation of rapid behaviors, such as escape. In contrast, the hallmark of chemical synapses is the irreducible delay (-1 msec) between the incoming stimulus and the postsynaptic response, which reflects activation of the presynaptic machinery involved with transmitter release (Katz 1969, Llinas 1982). Chemical synapses, however, have remarkable adaptive advantages, such as: (a) variable gain; (b) a large repertoire of polarity and kinetics, resulting in excitations and inhibitions of different durations, depending upon their specific chemistry; and (c) the ability to store information on a long-term basis, due to plastic properties which have become a paradigm for studies of learning and memory.

1. Integrative Properties of Neurons and Synaptic Correlates

Since any behavior is ultimately produced by combined activity in neuronal assemblies, it is of critical interest to understand how each individual neuron reacts to incoming signals initiated in cells connected to it through synaptic junctions, as in a simple reflex chain (Fig. 1A). In fact, information is distributed widely in the nervous system, such that a single neuron may both have many targets and receive inputs from numerous presynaptic axonal terminals, according to the principles of divergence and convergence, respectively. Recording electrodes inserted in the various

Figure 1
Integrative properties of neurons and mode of generation of action potentials

parts of a neuron (soma, dendrite, axon), in combination with anatomical studies of the synapses contacting these loci, have revealed electrical signals whose polarity reflects their function. The signals are named excitatory postsynaptic potentials (EPSPs), and inhibitory postsynaptic potentials (ISPSs). Due to nerve cell cable properties, which are determined by the membrane resistivity and capacitance, signals generated at a distance from the axon are attenuated there, but nevertheless contribute to the summation of responses at the so-called trigger zone (Fig. 1B), which decides whether or not some information will be passed on to the next neuronal relay. This essential integrative property of the cell can be quite complex, with there being multiple trigger zones (Llinas et al. 1969), and summation not always being algebraic (non-linear). Yet, whatever the rules are in a given neuronal subtype, the tonic and phasic bombardment of a cell by incoming inputs can only bring it to such a decision when excitation dominates inhibition and reaches a critical value, the threshold for generating an action potential (Fig. 1C) that will propagate along the axon towards the next synaptic relay. It can already be noted that reaching threshold is the result of the collective activity of large populations of inputs, each of which may, however, act randomly, as will be described below. This cooperative nature of the nervous system pertains whether it is viewed from a molecular, synaptic, network, or behavioral perspective.

2. *What Synapses Have in Common*

The meaning of the term 'synapse' has evolved over time, in parallel with the development of the morphological and physiological tools available for studies of the brain. Today, its strict definition requires electron microscopic demonstration of ultrastructural features associated with chemical transmission. A comparison of central synapses with the neuromuscular junction (nmj), which was the Holy Grail of pioneering studies, allows one to recognize their basic unity.

At the frog nmj, the terminals of the motor axon occupy the end plate, a specialized depression in the muscle membrane, which forms folds. Opposite the crest of each fold, where transmitter receptors are the

Figure 2
Presynaptic and postsynaptic components of quantal transmission

most abundant, the axon terminal contains dense bands and spherical organelles that package 5,000–10,000 molecules of the transmitter acetylcholine (Kuffler and Yoshikami 1975) and are called synaptic vesicles. It was later demonstrated that the opening of synaptic vesicles (exocytosis) takes place at the borders of the bands, which therefore were designated active zones (Couteaux and Pecot-Dechavassine 1970). An equivalent term for physiologists is 'release site,' as vesicle openings were observed there (Heuser et al. 1974). The motor end plate can thus be considered as a number of synaptic units, each represented by a dense band with its associated vesicles and a postsynaptic density (for review, see Peters et al. 1991).

Synapses in the central nervous system (CNS) have more restricted apposition zones. They most often consist of synaptic boutons (Fig. 2A, B) that contain the vesicles and are separated from the postsynaptic element by the 10–20 nm wide cleft. The plasma membranes on both sides exhibit marked densities which, together with the assembly of vesicles, are referred to as a synaptic complex (Palay 1958). Here the analog of the active zone is the presynaptic grid, formed by electron-opaque densities called presynaptic dense projections, which are arranged in triangular arrays and, in *en face* view, take the form of an 'egg box.' This structure is postulated to 'guide' the vesicles towards the plasma membrane (Pfenninger et

al. 1972). As at the nmj, the postsynaptic membrane facing this release apparatus contains the receptors which, however, are restricted to localized clusters (Triller et al. 1985). Thus, as further shown by physiological studies, the basic functional unit of synaptic transmission is a complex containing the presynaptic active zone and its neighboring synaptic vesicles, together with the aggregate of ligand-gated receptors in the opposing postsynaptic membrane. It thus corresponds to the synaptic complex.

At either type of chemical synapse, the depolarization of the terminals associated with a presynaptic action potential opens voltage sensitive Ca^{++} channels, with the consequent Ca^{++} influx initiating a cascade of molecular events that can culminate in the opening of a vesicle fused to the plasma membrane at the release site and the rapid discharge of its contents into the cleft (Fig. 2B). The postsynaptic receptors are thus exposed to a high concentration of transmitter, on the order of mM, albeit briefly (Fig. 2C, double arrow). Consequently, the ligand-gated channels open nearly synchronously, allowing specific ions to flow down their electrochemical gradient. However, as each individual opened channel in the postsynaptic receptor matrix closes randomly, the postsynaptic current, which is the sum of all individual channel activity, decays exponentially. This 'population' phenomenon is illustrated in Fig. 2C, where the summed current rises rapidly and relaxes slowly, a time course typical of those at the so-called fast synapses used by the brain for information processing. At the nmj, the contents of one vesicle open about 1000 receptor-channels, while at central synapses the number can be much less.

One should note that in the CNS the current flow through synaptic channels can be either inward (i.e., directed towards the cell interior) and excitatory, or outward and inhibitory, depending upon the selectivity of the channel, i.e., which ion(s) it allows to pass. Furthermore, in most neuronal systems, glycine and γ-aminobutyric acid (GABA) are inhibitory, and glutamate and acetylcholine are excitatory, although a given transmitter can have either function, depending upon the type of channel associated with that transmitter's receptor (Hille 1984).

3. *Why Synaptic Potentials Fluctuate in Integer Steps*

With a recording electrode placed at the nmj, Katz and colleagues made two related discoveries. First, at rest, spontaneous potentials of similar amplitudes occur randomly. Second, when the nerve is stimulated repeatedly, the resulting evoked endplate potentials fluctuate in amplitude in a steplike manner from trial to trial. Furthermore, amplitude histograms show that the apparently discrete size classes are integer (1, 2, 3, … n) multiples of a basic unit which corresponds in time course and average size to the spontaneous event (del Castillo and Katz 1954). These elementary 'miniature' endplate potentials were thus called 'quanta,' since they are representative of the basic unit of the evoked response. Remarkably, the underlying statistics of transmitter release, which account for the variable number of quanta issued after each impulse (based on experiments conducted in a low concentration of extracellular calcium ($[Ca^{2+}]_0$), satisfied the Poisson process. Release occurred with statistical independence at any one of a large number, n, of 'quantal units available for release' at the junction, with a low release probability (p) that was identical for each unit. Finally, it was postulated that each quantum corresponded to the action of the transmitter packaged in one synaptic vesicle, and since n is large in the Poisson equation, it was assumed to represent the total number of vesicles ready to be released (Katz 1969).

Despite difficulties inherent to the analysis of signals recorded from brain cells, such as the inability to relate any miniature response to one of the numerous junctions impinging on the neuron being investigated, and the low signal to noise ratio, the conclusion illustrated in Fig. 3A, namely that responses evoked by activating a single presynaptic neuron are quantal, was also reached for central synapses (Korn and Faber 1991, Redman 1990, see also Jonas et al. 1993). However, a statistical formulation other than the Poisson most often provides a better description of the amplitude fluctuations. Here the statistics are either a simple binomial model, where n is finite and p is relatively large, or a compound binomial, where p may be different at individual releasing units (see also below). Regardless of the mathematical details (Martin 1977 and see below), n is smaller than originally thought. Also, in experiments combining physiological recordings with anatomical reconstructions of the cells studied, the value derived for this parameter turned out to be equivalent to the number of active zones or release sites in the activated presynaptic terminals. The result lead to the 'one vesicle' hypothesis, according to which a presynaptic action potential causes the exocytosis of the contents of at most one vesicle at each active zone (reviewed in Korn et al. 1990). Despite controversies about multivesicular release, for example during development, this concept is still commonly used for interpreting experimental data (see Stevens 1993).

4. *Consequences of Quantal Transmission*

At the skeletal nmj, neurotransmission in normal Ca^{++} has a high safety factor (large n and p), such that a presynaptic impulse always leads to muscle contraction. On the other hand, the full implications and richness of the quantal nature, and hence uncertainty of transmitter release, are better exploited, albeit still puzzling, at central synapses. From a functional point

Figure 3
Binomial model of transmitter release

of view, the most novel feature is that communication across central synapses is not guaranteed systematically even when p is relatively high: after each impulse, a synapse flips a coin. This probabilistic aspect is exemplified in Fig. 3A, 3B, which stress that each synaptic unit operates in an 'all or none' manner. It also shows that over a large number of trials the average response amplitude equals the $n \cdot p \cdot q$, product, where n and p are presynaptic parameters, and q, the size of a quantum, is proportional to the number of channels opened by a single exocytotic event. This product defines the so-called synaptic weight or strength of a connection between two neurons, which is a dynamic term, as it can be modulated pre- or postsynaptically. Indeed, persistent increases in synaptic weights are considered to underlie higher-order processes such as learning and memory, from invertebrates to primates. For example, activity-dependent long-term potentiation (LTP; Bliss and Collingridge 1993) in mammalian hippocampus, which is considered a well-suited candidate for a memory mechanism, can result from an increase in any one of the three quantal parameters (Stevens 1993). The reverse form of plasticity is long-term depression (LTD; Bear and Abraham 1996) (first described in the cerebellum), which may be a cellular correlate of erasing memory traces. It presumably represents a second mechanism for allowing neurons to respond preferentially to selected subsets of their inputs.

Since a neuron may receive information from thousands of junctions, the binary mode of transmission illustrated in Fig. 2A may be better suited for computational purposes than having a graded process at each site, which would lead to excess or redundant information. Along this line, a synapse can be viewed metaphorically as a symbolic communication system with, according to the scheme of Shannon and Weaver, the encoding process localized to the release site. Knowledge of p and n then allows calculation with the classical entropy equation of the amount of information, in bits, at a connection between neurons. For example, with a given value of p, the increased reliability of neuronal connections with larger ns is counterbalanced by a decreased number of bits per quantum (Korn and Faber 1987).

5. *Diversity of Synapses*

Central synapses exhibit a great deal of structural and functional heterogeneity, which is built upon the scaffolding described above. For example, the transmitter at adjacent contacts on to a given postsynaptic could be an amino acid such as glycine or acetylcholine, a biogenic amine such as serotonin or dopamine, or a peptide such as somatostatin, substance P, or Vasoactive Intestinal Peptide (VIP), and, furthermore, combinations of these substances may be packaged in one terminal ending (Hokfelt et al. 1984). The consequences of this colocalization and of the cotransmission that is often associated with it are not yet resolved, particularly in puzzling cases where two classical transmitters with the same function can be released together (Jonas et al. 1998). In addition, there are multiple receptor subtypes for most transmitters, and more than one may be colocalized to the same postsynaptic locus (Somogyi 1998). Some are ionotropic, with binding causing channel opening or closing, while others are metabotropic, which means that the ligand-bound receptor activates an intracellular metabolic cascade which can modulate kinases or channel activity. In fact, listing the differences

Figure 4
'Latent' synapses and mechanisms of short-term modifications of synaptic efficacy

between synapses is almost an insurmountable task. One would first have to consider constitutive variations in pre- or postsynaptic parameters, namely the probability of release, the kinetics and conductances of single channels. The mechanisms for limiting the duration of action of a transmitter such as its diffusion in the synaptic cleft, its uptake by activated terminals or glia, its chemical inactivation, and receptor desensitization once the channels have opened, add another layer of complexity (Johnston and Wu 1995). One then would have to factor in the synergistic or antagonistic effects of the growing inventory of modulators (Kaczmarek and Levitan 1987), which can influence these various functions in normal and pathological conditions, as well as during development. This diversity may confer a higher degree of functional uniqueness to individual synapses and neurons than is commonly recognized. In any case, it influences the richness of animal behaviors and higher functions which result from activity in complex neuronal assemblies that are synchronized via their synaptic connectivity.

Some elements of synaptic diversity and their functional implications deserve mention. First, although most junctions are fully operational in the normal brain, some of them may remain silent, either because a presynaptic action potential does not evoke transmitter release, or because the postsynaptic receptors are unresponsive (Fig. 4A). These may be viewed as 'latent' rather than 'silent' synapses, because they may be turned on in specific circumstances, such as during learning (Malenka and Nicoll 1997). Second, by virtue of the close packing of synapses, the transmitter released at one of them can diffuse laterally and interact with the postsynaptic receptors of its neighbors (Fig. 4B). This spillover may violate the principle of independence of individual junctions and result in synergistic interactions (Korn et al. 1990), and it may contribute to phenomena such as LTP. Finally, synaptic strength can vary on a millisecond timescale when a presynaptic neuron discharges repetitively (Fig. 4C), and this plasticity can be expressed as either a facilitation or depression (Johnston and Wu 1995, Markram and Tsodyks 1996). Both processes are presynaptic in origin, due to a corresponding change in the release probability, and typically meet the functional requirements of the related networks. For example, facilitation may contribute to recruit neuronal targets that are otherwise weakly excited.

6. *Quantal Analysis and its Limitations*

A statistical dissection of postsynaptic electrical recordings, based on the quantal hypothesis, remains an unsurpassed tool for understanding how different classes of nerve cells communicate with each other. The models used, and their corresponding mathematical formulations, are the same as used in game theory and many branches of the social, behavioral and political sciences; that is, the laws of chance. Stated otherwise, the release of a packet of transmitter after an impulse is equivalent to rolling dice. Despite their apparent complexity, these laws are quite straightforward. For all models, the average number of units released over a large series of trials, which is called *mean quantal content* or m,

$$p_1 + p_2 + \ldots p_n = \sum_{i=1}^{n} p_i$$

where p_1 is the release probability at each site. This is the essence of the *compound binomial release model*, which encompasses all others that assume independent probabilities of release.

If there were no ambiguities about *quantal size*, q, i.e., the magnitude of the postsynaptic response to a quantum, amplitude distribution histograms of evoked responses would have discrete peaks corresponding to transmission *failures*, single quantum responses, doublets and so on, and these distributions could be described with one of the quantal models.

For a compound binomial:

$$\begin{aligned} p_x = {} & p_1 p_2 \ldots p_x (1-p_{x+1}) \ldots (1-p_n) \\ & + p_1 p_3 \ldots p_{x+1} (1-p_2)(1-p_{x+2}) \ldots (1-p_n) \\ & + (1-p_1) \ldots (1-p_{n-x})(p_{n-x+1}) \ldots p_n, \end{aligned}$$

where each line represents one way to get x successes and $(n-x)$ failures. For example, in the first line, units 1 to x release quanta, whereas the other units ($x+1$ to n) do not. The probability of failure for one quantal unit is $(1-p_1)$.

For a simple bionomial:

$$p_x = \left(\frac{n}{x} \right) p^x (1-p)^{(n-x)}$$

where

$$\left(\frac{n}{x} \right) = \frac{n!}{(n-x)!x!}$$

gives the number of combinations by which x quanta can be released out of an available pool of size n.

For a Poisson:

$$p_x = \frac{e^{-m} m^x}{x!}$$

with $m = np$

As developed elsewhere (Martin 1977), most investigators have relied on the two latter models and on indirect methods derived from them rather than trying to fit the distributions. These methods involve either counting the number of failures, n_0, in N trials or measuring the coefficient of variation, CV, of the amplitude distribution, since according to a Poisson:

$$\begin{aligned} m &= -\ln n_0/N \text{ (method of failures)} \\ &= \mathrm{CV}^2 \text{ (coefficient of variation method).} \end{aligned}$$

In rare cases, m can be determined directly, by counting quanta or by averaging miniature events arising from the same synapses. Corresponding expressions allow the last two methods to be applied to a binomial process if p is finite (see Martin 1977). Also, since the binomial $\mathrm{CV} = ((1-p)/np)^{1/2}$ and is independent of q, it has been used as a tool for identifying the pre- vs. postsynaptic locus of a change in synaptic strength, but this approach is liable to misinterpretations (Faber and Korn 1991).

Correct application of these tools requires the accurate identification of the quantal response, which is often difficult at central connections due to quantal variance, distortion by cable properties, and instrumental noise. As a consequence, discrete peaks in amplitude histograms are blurred and failures, single quantal responses, doublets, etc., cannot be distinguished. Various fitting algorithms have been developed, with some success (reviewed in Korn and Faber 1987; see also Stricker et al. 1994), their limitations, however, leaving some questions unresolved. One is the size of the quantum, which is related to the number of channels opened by an exocytotic event, and to their unitary conductance, and can be quite small at central contacts (Finkel and Redman 1983, Edwards et al. 1990). Another is that at some junctions there may be a mismatch between the large number of transmitter molecules released and the relatively few receptors available postsynaptically, which led to the suggestion of a saturated response (Jack et al. 1981). If so, the principles of quantal analysis would no longer hold, as quantitization would be imposed post- rather than presynaptically.

A related issue is the difficulty in determining the pre- or postsynaptic locus of the increased synaptic weight that occurs during LTP, using quantal analysis alone. Raging controversies have not yet been entirely resolved, and mechanisms on both sides of the synapse have been invoked (see Stevens 1993, Liao et al. 1995, Isaac et al. 1996). One of the most intriguing proposals is that although the induction process is postsynaptic, its maintenance can be expressed as an increased release probability, which requires signaling in the reverse direction across the synapse, by a retrograde messenger (reviewed in Bliss and Collingridge 1993). This debate could be obscuring the essential notion of the unity of the synapse where pre- and postsynaptic regulatory factors could be implicated separately or in unison, depending upon functional requirements.

7. *Other Avenues for Synaptic Studies*

Like all scientific fields, synaptic studies cannot remain confined to their historical roots, such as statistics, and need to be enriched by other approaches. The most direct is imaging of dynamic changes at the synapse, associated with the ability to tag pre- and postsynaptic structural components of activated junctions with fluorophores (Malgaroli et al. 1995). In addition, computer-aided modeling of single synapses, or of populations, is necessary to understand biophysical properties of vesicular exocytosis, the fate of the released molecules in the cleft, and their interactions with the postsynaptic receptors, all of which govern the size and kinetics of the postsynaptic response (Bartol et al. 1991, Kruk et al. 1997). Together with

Figure 5
Modulation of gene expression during learning

anatomical correlates, these techniques should not only solve issues such as those related to single vs. multivesicular release and receptor saturation, but also deepen our understanding of brain development, and learning and memory, and how synapses are affected in pathological conditions. Along this line, it can already be envisioned how synapses contribute to genetic or acquired illnesses of behavior and cognition, including psychiatric disorders (Kandel 1998). Figure 5 illustrates the manner in which expression of a gene, leading to the production of a specific protein, could be altered following synaptic activation associated with learning. Conversely, genetic alterations can lead to significant psychiatric disorders, and it can be postulated that they do not leave synapses untouched. This example shows once more that synaptic studies represent a bridge between the neural sciences, cognitive psychology, and behavioral sciences.

Syncretism

The meaning of the term 'syncretism' has changed drastically over the course of time. Currently, the term refers to the mixing together of elements from different religions. This mixing is sometimes viewed with contempt, especially by the clergy of the religions concerned. Scholarly use of the term is more objective and does not entail this kind of value judgement. In this article we shall describe the history of the term. Special attention will be given to current debates on power mechanisms in syncretism. Lastly, syncretism will be compared with fundamentalism.

1. *History of the Term 'Syncretism'*

1.1 *Earliest Uses*

The first known use of the term 'syncretism' is found in Plutarch's (46–125) *Moralia* (Morals), a treatise on moral principles. When suggesting that one should consider one's brother's enemies and friends as one's own enemies and friends, he uses the example of the inhabitants of Crete. Plutarch uses the word syncretism to refer to their habit of forgetting internal conflicts and differences when confronting a common enemy. It may be that the use of the word was inspired not only by the Cretans' example but also by a word play, since the Greek *syngkrasis* means a 'mixing together' (Stewart and Shaw 1994).

The second author known to have used the term was the humanist Erasmus of Rotterdam (1496–1536). He quoted Plutarch and, like him, recommended syncretism, although here as a way of seeking a synthesis of seemingly disparate philosophical and theological opinions and as an attempt to understand the other completely, despite differences of view.

After the Reformation, with its increase in divergent theological views, the term acquired a negative connotation for the first time. Opponents of the German Lutheran theologian George Calixtus (1586–1656), an early defendant of ecumenism and theological reconciliation, used the term pejoratively as a mixing of points of view that, in their opinion, was to be avoided. The debate became known as the 'syncretistic controversy.'

1.2 *Views from Religious Studies and Missionary Practice*

In the nineteenth century, when research on world religions began to flourish and colonialism brought cultures and religions into contact, syncretism was understood more objectively as the mixing of elements from different religions, although purity continued to be viewed implicitly as the norm (Rudolph 1979).

Christianity also reached the height of its expansion in the nineteenth century. Missionaries objected to the tendency of new converts to continue practices from their prior religion. Syncretism then became the concept used for this—condemned and combated—tendency. This meant that Christian theological use of

the term was no longer restricted to internal differences between theologians but referred to the mixing of religious elements, especially Christian and non-Christian. Unlike its usage in religious studies, syncretism was considered censurable and illegitimate. The term still retains this meaning, even though ecumenical missionary circles have become more understanding of the need to translate the Christian message into local cultural terms (so-called inculturation; see Schreiter 1993). It has also been suggested that Christianity itself is the result of a syncretistic process (Pannenberg 1970). Yet, despite this development, the theological criterion continues to be how intact the core message of Christianity remains.

For a long time scholars in religious studies have worked with the term and defined its meanings (Rudolph (1979) offers a useful summary), whereas, as will be shown in the next section, the term has a much shorter history in anthropology. Scholars in the field of religious studies, such as historians and phenomenologists of religion, view syncretism objectively and point to its general presence at the founding of new religions (even in religions that now oppose syncretism) and in their mutual contact. Scholars distinguish between symmetrical and equal relationships between religions on the one hand and asymmetrical and unequal ones on the other. Typologies of the degree to which elements can be mixed have been proposed, using terms such as identification, amalgamation, and symbiosis. It has been acknowledged that syncretism may involve elements other than religious ones, since religions are linked to cultural contexts.

The basic ambiguity of meanings in syncretistic contexts has been emphasized (Pye 1971). Sometimes syncretism is presented as the result but more often as the process itself. Syncretism is presented as part of popular religion, while the representatives of official religion generally condemn it. Correspondingly, syncretism has often been depicted as unconscious, implicit and spontaneous, as typical of what Redfield called the little tradition of the unreflective many (Rudolph 1979).

There have also been proposals to excise the term from scholarly vocabulary (Baird 1971, Schineller 1992, Van der Veer (1994) in Stewart and Shaw 1994) for being too vague, subjective, and too broad. If syncretism occurs in all religions and if borrowing and blending are universals in any event, the term seems to be insufficiently specific and therefore superfluous. Moreover, virtually no religious person sees himself or herself as syncretistic. However, terms are not easily eliminated from scholarly vocabularies. Precise definition or even redefinition may resolve this dilemma. In view of the increase in contact between believers of different religions, some term is needed to refer to the inevitable mixing of religious elements. In addition, the long history of the term has shown that its meaning may change.

1.3 Views from Cultural Anthropology

While students of religion from outside cultural anthropology focused on world religions, the first anthropological texts on syncretism referred to Latin American and Caribbean examples, especially the Afro-Christian syncretism that was followed from the presence of slaves and their descendants in the region. Of course, syncretism was present in other areas, but where the negative missionary use of the term was the norm, as in Africa, anthropologists avoided using the term, even with respect to obvious cases of syncretism, as occurred in the so-called African independent churches founded by Africans and not by missionaries (Stewart and Shaw 1994).

When the American anthropologist Melville Herskovits began using the term in anthropology, following his Brazilian student Arthur Ramos, he took his examples from Afro-American religions (Greenfield and Droogers 2001). His interest in the topic was partly ideological since he understood syncretism as a tool for promoting a unified culture in the United States, to be formed from the many cultures that immigrants, including those who had involuntarily come from Africa, had brought with them. This melting-pot idea was, of course, a way of rehabilitating the Afro-American strand in US culture over against white racism. Moreover, Herskovits saw syncretism as a half-way stage in the process of acculturation, the intermingling of cultures in contact. He was very much interested in the way people gave meanings to selected old and new elements, mixing cultural standards, and thus initiating change towards a new synthesis.

The alternative course is an emphasis on authenticity and a return to tradition and to the past, as in the case of the black consciousness movement. Nourished by the political ideal of integration the concept of acculturation may have suggested a one-sided linear evolution.

Another scholar who used the term syncretism in the Latin American context was the French ethnologist Roger Bastide (Bastide 1978). On the basis of fieldwork in Afro-Brazilian religions, he emphasized the systematic way in which analogous elements from different religious sources are mixed. He also pointed to the role of power mechanisms, especially in the contact between slaves and their masters. The structural similarity between African, Catholic, and Amerindian worldviews facilitated syncretism. Thus African gods could be identified with Catholic saints and Amerindian spirits. In the oppression that the slaves suffered, supernatural help was most welcome. This redressed the balance of power somewhat, such as when masters were the object of slave rituals intended to harm them. The redress of this balance also became clear when Catholic elements were selectively adopted through the application of African criteria, and not vice versa, as the masters wished when they baptized their slaves. In practice, as a strategic

device, identification with and differentiation from the masters' religion were both used in a double game. Thus the apparent adoption of a Catholic ritual attitude in Mass could serve as an alibi for the continuation of African ritual practices.

2. Current Issues

2.1 Power

The political use of the concept of syncretism has received more attention in the 1990s (Droogers 1989, Stewart and Shaw 1994). The negative sense of the term is an indication of a conflict between clergy and laity on the right to produce legitimate religion. Leaders of a religion whose adepts are involved in a syncretistic process will, from a purist point of view, use their power to condemn any effort to mix elements from different religions. Stewart and Shaw (1994) accordingly proposed the term antisyncretism.

As suggested above, the subjective meaning of the term could be a reason for abandoning the term in scholarly use. Yet it has the advantage of revealing the power dimension of the syncretism process. In that sense, syncretism is one of a number of terms used in anthropology despite their pejorative meanings, such as magic or popular religion.

An attitude of antisyncretism is not only held by leaders of affected religions but can also be found in representatives of religions that are the result of a process of syncretism. Thus some leaders of the very syncretistic Afro-Brazilian religions adopt an anti-syncretistic attitude, favoring a return to the African roots and the removal of all Catholic influence.

2.2 Syncretism and Fundamentalism

In various senses syncretism and fundamentalism are opposites. Whereas syncretism uses more than one religious source, fundamentalism defends the uniqueness of the one source, often codified in a sacred text. Syncretism implies that more versions of the experience with the sacred are acceptable and can be combined, whereas fundamentalists defend one exclusive version. Syncretists experiment with religious symbols, as many as seem to be applicable to their situation, whereas fundamentalists jealously guard the one central symbol of their religion. Syncretism is usually criticized by religious specialists who feel that they are losing control and who may react by defending a fundamentalist view. Syncretists interpret the opportunity offered by the growing contact between cultures and religions as a chance to combine religious repertoires for thought and action, whereas fundamentalists react to the moral side effects of this contact by retreating to the traditional repertoire, even though they may make use of modern means of communication to spread their message. Both syncretism and fundamentalism seem to flourish as a consequence of modernization and globalization but for different reasons: one embracing the new situation, the other being critical of it because it is felt to threaten cherished traditions and morals. Syncretists behave as global citizens, whereas fundamentalists divide the world into 'us' and 'them.' Syncretists are not organized and rarely present themselves as such, whereas fundamentalists tend to organize themselves and to occupy power positions.

A. Droogers

Syndromal Diagnosis versus Dimensional Assessment, Clinical Psychology of

A syndrome is a pattern of symptoms occurring in a disease; a diagnosis implies history and prognosis as well. Dimensional assessment refers to the severity of the associated symptoms or characteristics. In 1895

the countries of Europe met to define the important diseases. They could not agree, but in 1905 when they next met, they just had to agree to define diseases important to public health, if only to be able to share information about prevention and treatment. Progress is possible only when all share a common language, and definition of disorders has been as much product of practical need as the result of informed research. In clinical psychology, the dominant classifications are now the American Psychiatric Association's Diagnostic and Statistical Manual, 4th revision (DSM-IV) (1994) and the World Health Organization's International Classification of Disease, 10th revision (ICD-10) (1993). Both are lists of characteristics (symptoms and durations, and other diagnoses that preempt) but neither routinely includes history or cause. A dimensional assessment is particular to an individual, a fine grained description of symptoms and other attributes currently present. Both should inform about clinical picture and beneficial treatments: the syndromal diagnosis in respect to what is known about others with the same complaint; the dimensional assessment in respect to this individual.

Historically there was a clear distinction—when doctors made diagnoses they said this person belongs to a category, and from that category one could infer etiology, natural history, and response to treatment; whereas when psychologists completed a dimensional assessment (see Minnesota Multiphasic Personality Inventory) they could profile the person's strengths and weaknesses in respect to the normative values for the general population. A diagnosis is of value because it pulls together the ways that symptoms reflect a class phenomenon. A dimensional assessment is of value because it highlights the particular issues in an individual case. To some extent the dichotomy posed in the title of this article is an artifact, for good clinicians who make a syndromal diagnosis go on to make a formulation in which the individual characteristics are taken into account, and good clinicians who make a dimensional assessment acknowledge the syndromal information that might inform prognosis and treatment. For most, the syndromal diagnosis informs the broad choice of treatment, while the dimensional assessment is the key to measuring progress.

Syndromal diagnosis is not straight forward. It varied until the American Psychiatric Association in 1980 and the World Health Organization in 1990 published detailed diagnostic criteria for each mental disorder (see *Mental and Behavioral Disorders, Diagnosis and Classification of*). Prior to this there were significant variations between countries in the way that serious mental disorders like schizophrenia or manic depressive illness were diagnosed, and probably even more intercountry variations in the way that the nonpsychotic anxiety, depressive, substance use, and somatoform disorders were identified, although these variations were rarely studied. The current DSM (APA 1994) and ICD (WHO 1993) criteria have resulted in clinicians being able to agree much of the time. But as Meehl had originally remarked and Kendell (1989) has affirmed, two clinicians will vary in the way they ascertain the symptoms, and in the way they interpret and weight them toward the criteria, so that disagreement, even given an agreed classification, will still occur. There are no validated laboratory or x ray tests for any mental disorder and no gold standard method of determining diagnosis. Diagnosis depends solely on the pattern of illness complained of by the patient or elicited by the clinician. It is becoming increasingly clear that the present diagnostic criteria, largely based on the work of Kraepelin in Europe at the beginning of the twentieth century, are but surface markers for hypothetical underlying concepts about which clinicians agree. In Jablensky's (1999) view, we have a *nomenclature*, not a logical classification of mental disorders. The present classifications, even though sanctified by tradition, and now reliable and stable, may not even be correct.

The ICD and DSM classifications, while differing in minor ways, seem as though they should function equivalently. The advent of agreed diagnostic criteria has meant that fully structured diagnostic interviews could be developed (e.g., the Composite International Diagnostic Interview or CIDI) and as these interviews address both DSM and ICD classifications, the correspondence between the two classifications could be examined. The results are interesting (Andrews et al. 1999). Only two-thirds of people who met criteria for a diagnosis on either system met criteria on both DSM and ICD classifications, the agreement varying from a high of 85 percent for depression and dysthymia to a low of 35 percent for substance abuse and post-traumatic stress disorder. Most of the disagreements appeared to come from the way the criteria were defined and operationalized, and not from any basic disagreement about the underlying concept. Epidemiological studies show that the demographic correlates among people meeting criteria for a diagnosis of a mental disorder—age under 45, being female, currently unmarried, unemployed, and of lower socioeconomic status—were the same in both classifications, as though the cases identified by either classification shared similar underlying characteristics.

Nevertheless, such demographic correlates have lead some to question the validity of the concept of mental disorders—'Isn't it understandable that the disenfranchised have symptoms of anxiety, depression and somatic dysfunction?' Is mental illness therefore a social construct? Thomas Szasz (1961), appalled by the ease with which a supposition of psychosis could lead to involuntary hospitalization, argued that it was a social construct. The surprising feature is constancy of the syndromic nature of the disorders; psychosis has similar symptoms and natural history across cultures, in the developing and in the developed world, in people with and without the listed social correlates.

Major depressive disorder, agoraphobia, or neurasthenia are equally invariant in their symptoms and natural history across countries and across peoples. This invariant pattern is not evidence of a stereotyped response to stress, for contrary to popular belief, stress plays a very small part in mental disorders. It looks as though these are the patterns of symptoms to which we are heir.

How important are the mental disorders? The World Bank began a project to estimate the important consequences of all diseases by adding the years of life lost due to a disease to the years lived with a disability, weighted for severity. Worldwide say Murray and Lopez (1996), mental disorders, as currently defined, account for 9 percent of the total burden of disease. In established market economies like North America, Europe, and Australasia, they account for 22 percent of the total burden, not because there is an epidemic of mental disorders in those countries, but because their relative importance has increased as the burden due to infection and chronic physical disease has declined. Mortality does not contribute a great amount, the burden of mental disorders largely comes from the morbidity—the years lived with a disability. Among the mental disorders, the anxiety and depressive disorders account for half this morbidity, not so much because they are so disabling, but because they are common, whereas the psychoses, which are more disabling, are relatively rare, and so account for less of the total morbidity. In total, mental disorders are an important cause of human capital loss.

Syndromal diagnoses are important for political reasons. They are essential if epidemiological studies are to answer the usual questions asked by health planners—how many people have which disorders, how disabled are they by these disorders, what does it cost to treat them, and what services should we provide? Reliable case identification is also critical if therapeutics is to advance. Randomized controlled trials of a new remedy against placebo or established treatment are the only way that the efficacy of new treatments can be assessed. Being able to specify the diagnostic class to which the patients belong is critical, both to the scientific question, and to the marketing of the remedy once it has been shown to be efficacious. Last, funders often no longer pay for the treatment of a person, but pay on the basis of the syndromic diagnosis, i.e., a set casemix fee for a hospital to treat a new case of schizophrenia, or a set number of visits or set fee for a clinician to provide ambulatory treatment for a case of depression. Classification by syndromal diagnosis is essential to all these activities—defining the unmet need, identifying and marketing the treatments that work, and reimbursing the clinicians who provide the service. The whole edifice of mental health care would collapse were we to remove syndromal diagnosis even though we have no proof that these diagnoses are fundamentally valid.

There are a number of problems that stem from accepting the present definitions. The first problem is the seemingly arbitrary nature of the syndrome definitions themselves. In part, the diagnosis of a major depressive episode requires the presence of five of nine symptoms known to occur in depressive illness. But people with four symptoms—depression, loss of interest, inability to concentrate, feelings of worthlessness—would not meet criteria even though they could share the same demographic correlates, response to treatment, and level of disability as did some people who did meet criteria. The diagnosis of schizophrenia in part depends on a disturbance persisting for at least six months characterized by the presence of two of five symptoms of psychosis during a one month period with concomitant social/occupational dysfunction. If the disorder has been present for less than a month it is classified as Brief Psychotic Disorder, if present for one month to five months it is classified as Schizophreniform Disorder, and when it has continued for six months it becomes schizophrenia. While there are practical reasons that relate to cause and outcome that led to this division based on chronicity, it is obvious that it is an arbitrary subdivision of a spectrum of psychotic disorders. Both the ICD and the DSM classifications of mental disorders contain many more examples, of a point on a dimension of symptoms marking a criterion for a disorder.

Many presume that the existence of a specific treatment might validate a disorder, but there is a lack of specificity among current treatments for mental disorders. Given the millions of dollars spent, one would have thought that drug remedies for depression would cure depression specifically. Recent evidence suggests that three-quarters of the benefit from Prozac and other drugs sold as antidepressants is due to spontaneous remission or response to placebo and only one quarter of the observed improvement is due to the specific effects of the drug (Enserink 1999). In most jurisdictions the same drugs have won approval as being efficacious for panic disorder, social phobia, or for obsessive compulsive disorder. Clearly the drugs have little specific action and, at best, may act on some underlying brain mechanism common to depressive and anxiety disorders.

There are a number of additional reasons why the skeptic might doubt the current diagnostic systems. The first problem is that multiple diagnoses are more common than one would expect if the individual syndromes were independent, four times more common in fact (Andrews et al. 1990). At the clinical level one is surprised when a person who was hospitalized with an episode of mania—days of unnatural elation and overactivity coupled with being overtalkative and grandiose, sexually unrestrained, and careless of money and reputation—recovers and is rehospitalized two years later with a diagnosis of schizophrenia—deluded and hallucinated, with disorganized thinking and speech, coupled with a steady occupational and social role deterioration over the past months. No

one should be so unfortunate as to suffer two major mental disorders, yet clinical conferences to review the management plans of difficult to treat patients not infrequently learn that, at various times, a number of different diagnoses have been used to justify treatment. Comorbidity is to be expected if an underlying causal factor is related to both the disorders experienced, or if one disorder is a response to the other, but two or more apparently independent disorders occurring in the same person should be less common than it is.

Comorbidity should refer to the concurrence of two or more disorders (see *Comorbidity*). Structured diagnostic interviews, like the CIDI, ask whether a person has ever had the symptoms that satisfy the criterion for a disorder. Comorbidity has come to refer to people who have satisfied the criteria for more than one disorder, sometime in their lifetime. Comorbidity is common and in a number of surveys it has been shown that people who meet criteria for one disorder, will on average meet criteria for an additional disorder, which is four times the expected risk. This finding is not just due to respondents being prone to say 'yes' to any symptom question. In the anxiety and depressive disorders comorbidity has been related to the presence of a predisposing vulnerability factor of high trait anxiety and poor coping. Sequential effects are also evident, with the stress of one illness acting as a precipitant of additional disorders in vulnerable persons. For example people with agoraphobia are likely to become depressed, and people with social phobia can become dependent on the alcohol that they initially used to manage their disorder. However the comorbidity comes about, people identified as having more than two illnesses in their lifetimes to date are more likely to meet criteria for a current disorder, to be more disabled, and to be and have been very high utilizers of health services. Comorbidity is not just an artifact of measurement, it is also an indicator of severity and unmet need.

Kendell (1989) has revised the original Robins and Guze (1970) criteria for determining whether a clinical syndrome was valid as follows:

(a) identification and description of the syndrome, either by clinical intuition or by statistical analysis;

(b) demonstration of boundaries or 'points of rarity' between related syndromes by discriminant function analysis or latent class analysis;

(c) follow-up studies establishing a distinctive course or outcome;

(d) therapeutic trials establishing a distinctive treatment response;

(e) family studies establishing that the syndrome 'breeds true'; and

(f) association with some more fundamental abnormality—histological, psychological, biochemical, or molecular.

These six criteria have not been achieved in any group of mental disorders—the affective, anxiety, substance use, personality, or psychotic disorders. While identification and description of each syndrome was well advanced by the ICD and DSM classifications, clear boundaries have been difficult to establish, distinctive outcomes are rare, a unique response to one treatment is uncommon, and multiple diagnoses over time are common. The diagnostic classifications have attempted to deal with the last problem by establishing hierarchical rules as to which diagnosis precludes others, but the strategy is neither systematic nor wholly convincing. Information from studies of the human genome might go someway to resolve this impasse by showing discontinuities between genotypes and the accepted phenotypes, and so force a revision of the current classifications (Smoller and Tsuang 1998). Twenty years ago, it was believed that neurochemistry and neuroimaging studies would do this and they haven't. It is not that there are no data, it is just that reliable data are so patchy that it is not yet possible to say that disease X is distinguished by specific information addressing three or more of the Kendell criteria. Until there is, the validity of any syndrome is more a belief than a fact.

Health planners and researchers, clinicians and their patients, and funding agencies, all act as though the diagnostic categories are an established fact. Like the representatives at the International Health Conference in 1905, they have to. However, even good clinicians turn a blind eye when a depressed person has less than the required five symptoms—if, in the light of their history, the person probably will respond to the usual therapy for depression, the diagnosis will be made. Similarly, even if classic symptoms of schizophrenia have lasted for less than six months most clinicians will make the diagnosis and begin antipsychotic drugs. Most health planners will be pleased and so will most funding agencies. Good clinicians already use syndrome specific questionnaires or rating scales of thoughts, feelings and behaviors, and of global measures of disability. They know that the task is to get the person well, that is, no longer troubled by symptoms, and no longer disabled. This dimensional assessment is the key to the measurement of outcome and as outcome assessment is an increasing requirement, it is likely such dimensional assessment will soon rank in importance with the establishment of the syndromal diagnosis. Only with the personality disorders is there a strong move to discard the categories altogether and use a dimensional assessment based on measurement of personality traits as being more accurate and parsimonious.

In summary, the categories of the common mental disorders are well established and accepted and appear to represent the domains of symptoms complained of by people in both developed and developing countries. While health planners, clinicians, and funding agencies pay lip service to these categories, most realize that they are dealing with dimensions of illness on which the categories impose an artificial dichotomy and so will advise or accept the appropriate treatment even if

the person does not strictly meet the criteria. Hopes that statistical analysis of symptom patterns, or distinctions evident in treatment response, or variations in natural history would inform categorical classification have proved illusory. Some think that the advances in molecular genetics might assist in rewriting the topography of mental disorders but even if this is so, most accept that the issue will still be dimensional, 'just how much of disorder X should one cope with before seeking help,' not 'should all people with the gene for disease X be treated.' Moreover the likely response will also be dimensional and range from public education, through self-help strategies and assistance at the primary care level, to specialist mental health care (Andrews 2000). Diagnostic criteria and dimensional assessment are but two sides of the same coin. Good clinicians use both.

Syntactic Aspects of Language, Neural Basis of

Natural languages are built on three different knowledge components: the sound of words, called phonology; the meaning of words, called semantics; and the grammatical rules according to which words are put together, called syntax. This article concerns the neural mechanism underlying the knowledge and use of syntax. Three methods have been used to study the neural basis of syntax: (a) the observation of the correlation between brain lesion and behavior; (b) functional imaging approaches; and (c) event-related brain potential methods. Evidence from these three approaches with respect to syntactic processing will be reviewed and an explanatory model covering major aspects of the data will be suggested.

1. Lesion–Behavior Approaches

Lesion–behavior approaches to investigating the neural basis of language date back to the middle of the nineteenth century (Broca 1861, Wernicke 1874). Using such an approach it was observed that patients with lesions in the temporal region of the left hemisphere (the so-called Wernicke's area, Brodmann's area, BA 22/42) are characterized by poor comprehension, whereas their speech is fluent and often syntactically well structured although semantically empty. Patients with lesions in the left inferior frontal gyrus (the so-called Broca's area, BA 44), in contrast, demonstrate a selective deficit for syntactic aspects in language production and in language comprehension. Patients with lesions in Broca's area produce agrammatic speech, that is utterances containing content words, but lacking most of the grammatical morphology (function words and inflections). They fail to comprehend sentences whenever the correct interpretation depends on the full and adequate processing of the grammatical morphology. In the 1980s a central topic of discussion centered around three possible ways of understanding this behavior. A first view took this behavior to be due to a lack of grammatical knowledge as such (Caramazza and Zurif 1976, Berndt and Caramazza 1980). A second approach interpreted it as being caused by computational deficit either in accessing lexical information or in accessing the syntactic information encoded in function words and inflectional morphology (Bradley et al. 1980). A third view assumed the computational deficit to be based either on reduced memory resources (Kolk and Van Grunsven 1985) or on reduced processing resources leading to a trade-off between syntactic and semantic interpretative processes (Linebarger et al. 1983).

It has been shown that Broca's patients are able to judge a sentence's grammaticality (Linebarger et al.

Figure 1
Left hemisphere (numbers refer to Brodmann's cytoarchitectonically defined areas)

1983) and even show grammatical priming (i.e., grammatically correct context sentences enhanced the recognition of a target word compared to ungrammatical context sentences; see Haarmann and Kolk 1991). These findings lead to the assumption that Broca's area may not be the brain area where syntactic knowledge is represented, but rather that this brain tissue supports syntactic computation. While some view this brain region to be the home of very specific syntactic computations necessary to process dislocated elements (e.g., moved constituents that leave behind traces, as Grodzinsky 2000), as others consider this brain area to support on-line processes of syntactic phrase-structure building (Friederici 1995).

There is, however, evidence that might challenge these views. It has been reported that patients with lesions outside Broca's area show syntactic comprehension deficits in off-line tasks (Caplan et al. 1985, 1996). Moreover, both Broca's and Wernicke's patients display a certain similarity in their perfomance in off-line comprehension tasks (Bates et al. 1987). It was demonstrated that patients speaking a language which marks syntax by inflectional morphology are generally more deficient, irrespective of their classification, than those speaking a language marking syntax by strict word order. However, the finding that in a highly inflected language Broca's patients are more affected than Wernicke's patients suggests a particular deficit of Broca's aphasics for syntactic morphology. Thus it appears that similarities between different patient groups can be observed when using off-line comprehension tasks. As these tasks only reflect the end point of the comprehension process they may imply certain on-line operations possibly supported by Broca's area or adjacent tissue, as well as other operations possibly supported by other areas (see also Zurif et al. 1993) (see Fig. 1).

2. *Functional Neuroimaging*

New imaging techniques during the 1990s have provided additional insight into the neural basis of syntactic parsing. Positron emission tomography (PET) studies (see Sect. 4.3.3) have investigated the reading of syntactically simple and complex sentences. It was found that the regional blood flow increases in the left Broca's area as a function of syntactic complexity (Stromswold et al. 1996). A recent study using functional magnetic resonance imaging (fMRI) to register the brain's activity during the reading of sentences of different complexity found a significant increase of the hemodynamic response in the left Broca's and Wernicke's area as a function of the sentence's complexity (Just et al. 1996).

Other studies investigated the brain–syntax relationship by comparing the brain activity during the processing of word lists with that during sentence processing. In an event-related fMRI study Friederici et al. (2000) presented four different auditory stimulus types: a list of real words (nouns); a list of pseudowords; normal sentences containing function words and real content words; and sentences containing function words and pseudowords instead of real content words. Both sentence types differed from the two word lists, showing an additional activation in the anterior portion of the left superior temporal gyrus. The sentences that contained only grammatical morphemes and pseudowords instead of content words displayed an additional activation in the left frontal operculum in the vicinity of the Broca's area (i.e., medial to BA 44).

The combined imaging data suggest that parts of the left superior temporal gyrus and the left frontal operculum are the brain systems that support syntactic processes. When speculating about the specific contribution of the two brain regions one may again consult the patient data. Given the observation that Broca's patients are able to perform grammaticality judgments (Linebarger et al. 1983), but are deficient in computing syntactic information on-line (Friederici 1995), and the finding that Wernicke's patients are deficient in performing judgments (Blumstein et al. 1982), but perform similar to normals in some on-line comprehension tasks (Zurif et al. 1993), the following account may be formulated. While the left temporal region is necessary for the representation of syntactic knowledge, the left inferior frontal region supports syntactic procedures in real time.

3. Neurophysiological Approaches

The temporal course of the neural activity underlying syntax processing has been evaluated by means of electroencephalography (EEG) (see Sects. 4.3.5 and 4.3.6) and more recently also by means of magnetoencephalography (MEG) (see Sect. 4.3.7). With their seminal paper Kutas and Hillyard (1983) introduced the event-related brain potential (ERP) method to investigate language processes. They observed a particular ERP component correlated with lexical-semantic processes: a negative potential peaking around 400 msec after the onset of the critical event, called the N400 component. The critical event in their study was a sentence final word which was highly unexpected and semantically incoherent (for example: 'He spread his bread with butter and socks.'). It was shown that the amplitude of the N400 varied as a function of a word's semantic expectancy and also as a function of a word's lexical frequency. Importantly, the N400 component has been reported in a number of different languages including English, German, Dutch, French, Hebrew, and even sign language in the visual as well as in the auditory domain (for a review, see Van Petten 1995). Note that unexpected events in a non-semantic domain elicit a positivity (P300) rather than an N400 (Donchin 1981).

3.1 Syntax-related Electrophysiological Correlates

The picture is somewhat more complex for the ERP pattern correlated with syntactic processing. There are two syntax-related components that have been identified: an early left anterior negativity, and a late centroparietal positivity. While the anterior negativity is only present when processing outright violations, the late positivity is observed when processing outright violation *and* when processing violations of structural preferences.

3.1.1 The syntax-related late positivity. The late positivity is a centroparietally distributed positivity usually at around 600 msec and beyond, called P600. P600 components are observed both in correlation with outright syntactic violation and with violations of syntactic preferences. Violations of the latter kind are present in so-called 'garden path' sentences, that is sentences for which it becomes clear at a particular word that the perceiver was misguided structurally by following a simple instead of a more complex syntactic structure (for example: 'The broker hoped to sell the stock was sent to jail' vs. 'The broker persuaded to sell the stock was sent to jail,' Osterhout and Holcomb 1992). At critical points in the sentence (at the word 'to' and the word 'was') the reader/listener has to revise and reanalyze the structure initially followed. The P600 is also present in sentences containing an outright syntactic violation, be it a phrase-structure violation realized by a word category error (Neville et al. 1991, Friederici et al. 1993) or be it a morphosyntactic violation realized by an incorrect inflection (Gunter et al. 1997, Münte et al. 1997). Functionally, the P600 is taken to reflect costs of reprocessing (Osterhout et al. 1994), syntactically guided processes of reanalysis and repair (Friederici 1995), or syntactic integration difficulties in general (Kaan et al. 2000).

3.1.2 The syntax-related anterior negativity. For outright syntactic violations an anterior negativity, that is, a frontally distributed negative waveform usually with a maximum over the left, is observed. It is called ELAN (early left anterior negativity) or LAN (left anterior negativity), depending on its latency of occurrence. Before we discuss the particular appearance of this syntax-related negativity in more detail we shall recapitulate briefly that syntactic information is multiply encoded in a given language.

3.2 Domains of Syntax and their Neurophysiological Correlates

There are at least four syntactic domains that have to be considered: (a) word category information necessary to build up local syntactic structures; (b) morphosyntactic information such as verb inflections necessary to establish agreement between different elements within and across phrases or case markings allowing the assignment of thematic roles (who is doing what to whom); (c) verb argument structure information necessary to establish subcategorization relations; and (d) long-distance dependencies necessary to establish the relation between a moved element (filler: 'who') and its original position in the sentence (gap: __) in a sentence such as 'Who did Peter see __?' Some, but not all, aspects of these different domains have been investigated using neurophysiological recordings. We shall take up the different domains in turn.

3.2.1 Word category information. The anterior negativity was found in correlation with phrase-structure violations realized as word category errors and with the processing of function words. It was observed between 125 and 200 msec after the critical word's onset (italicized) in a number of studies using auditory presentation (for example: 'Der Freund wurde im *besucht*' 'The friend was in the visited' vs. for 'Der Freund wurde *besucht*'/ 'The friend was visited,' Friederici et al. 1993, Hahne and Friederici 1999). (But see Neville et al. 1991, who found an early and late negativity in the visual domain.) The distribution of the word category error related negativity is often

frontal with a maximum to the left, but has also been found to be less lateralized (Friederici et al. 1999). So far it is not yet clear what determines the distributional differences. Current research is trying to solve this issue. With respect to the possible neural generators for the anterior negativity it is interesting that left anterior cortical lesions eliminate the anterior word category related negativity whereas left anterior lesions restricted to the basal ganglia do not (Friederici et al. 1999). Functionally, the word category related negativity was interpreted as reflecting initial structure building processes (Friederici 1995), which according to syntax first models (Frazier 1987), are based on word category information only.

A comparable left anterior negativity also related to word category information was observed for the processing of function words in syntactically correct sentences (Neville et al. 1992, see also Pulvermüller et al. 1995). It was present around 280 msec post onset when reading sentences. Similar to the above discussed negativity, the function word related negativity was eliminated with left anterior lesions (Ter Keurs et al. 1999). In line with the proposal by Friederici (1995), the authors interpret the left anterior negativity to reflect processes of word category identification.

3.2.2 Morphosyntactic information. Morphosyntactic violations (for example: 'The plane took *we* to paradise' vs. 'The plane took us to paradise') usually elicit a left anterior negativity between 300 and 500 msec after the critical word's onset (italicized). It was found in the visual domain in a number of different languages (Münte et al. 1993, Gunter et al. 1997, Coulson et al. 1998), as well as in the auditory domain (although with a somewhat larger distribution, Friederici et al. 1993). Note that the types of morphosyntactic violations investigated in these studies do not alter the critical word's syntactic category, but influence the relation between the verb and its arguments (e.g., subject–verb agreement). Under the view that initial phrase-structure building is concerned primarily with word category information, and that the lexical information encoded in an inflection only becomes relevant when thematic roles are to be assigned, it is conceivable that the violation of the former information type elicits an earlier brain response than the violation of the latter information type.

3.2.3 Verb argument structure information. The processing of verb argument structure information has been investigated in a number of different studies using different types of violation. In an early study, Rösler et al. (1993) registered ERP for sentences which contained subcategorization violations (for example: 'Der Lehrer wurde gehustet'/'The teacher was coughed'). A left anterior negativity between 300 and 500 msec was found in correlation with the violation. In this study, the sentence final verb (one-place verb) does not match the thematic grid opened up by the passive construction (two-place verb). When the mismatch involved subject vs. object arguments, again a left anterior negativity was reported (Coulson et al. 1998). Thus it appears that violations concerning the relation between external (subject) and internal arguments (objects) also evoke a left anterior negativity.

Interestingly, the argument structure related negativity is present between 300 and 500 msec, that is, the time domain in which the lexical-semantic ERP component is found. This is not surprising, given that the availability of the verb argument structure information requires full access to the verb's lexical entry.

3.2.4 Long-distance dependencies. Long-distance dependencies that establish the relation between a moved constituent (filler) and its original position (gap) have been investigated by Kluender and Kutas (1993) in a number of constructions. They found a LAN at the gap position at which the previously perceived filler has to be reactivated. As it is assumed that the filler has to be kept in memory until the gap is met, they claim that the LAN is a reflection of verbal memory. The two functional interpretations of the LAN as a syntactic violation related LAN and a filler-gap related LAN has recently been solved by showing that the former is present locally (at the violation) and that the latter spans from the filler to the gap position over the sentence (Kluender et al. 1998).

In conclusion, it appears that outright syntactic violations elicit a local anterior negativity with a maximum over the left hemisphere, in addition to a P600. Moreover, the combined data suggest that word category related anterior negativities are present earlier than anterior negativities found in correlation with lexically encoded morphosyntactic information and lexically encoded verb argument information.

4. *Modeling the Neurocognition of Syntactic Processes*

The data provided by recent ERP and functional imaging studies have advanced our knowledge on the neural basis of language, and of syntax in particular. The network identified to support syntactic processes clearly includes superior temporal and inferior frontal areas dominantly in the left hemisphere. Their specific function still has to be determined in detail. It appears, however, that the left temporal region is relevant for the representation of syntactic knowledge, whereas the

inferior frontal region supports syntactic procedures. The timing of the brain's activity correlated with syntactic processes can be described to consist of different stages: an early stage during which first-pass parsing processes (based on word category information) take place, and a next stage during which lexically encoded syntactic information is processed. Both are reflected in a left anterior negativity in the ERP. A late stage of syntactic processes is reflected by a late positivity in the ERP. This component is observed whenever syntactic integration is difficult. Future research will have to determine whether different aspects of syntactic integration difficulties are correlated with distinct topographies of the late positivity which would indicate the involvement of different neural structures.

Syntactic Control

The term 'control' is usually attributed to the generative linguist Paul Postal (1970) (see *Generative Syntax*). The term expresses metaphorically the observation that the reference of an understood grammatical subject in a subordinate clause, the controllee, may depend on the reference of another constituent, the controller, in the main clause. An example illustrating the control relation is given in (1), with its relevant syntactic structure represented in (1a). In (1a) constituents with the same reference are marked by identical subscripts; the bracketed part of the sentence contains a nonfinite subordinate clause with an implicit subject symbolized as Ø (for 'empty subject'). These conventions will be followed throughout the article.

Mary convinced Billy to do her homework. (1)

Mary_i convinced Billy_j [$Ø_j$ to do her_i homework]. (1a)

In (1) the noun phrase *Billy* controls the reference of the empty subject of the infinitival complement clause. Every native speaker of English will understand (1) as meaning that Billy—and not Mary herself—will do her homework. The challenging linguistic problem is to find a principled account for why in (1) the main clause object is the controller, why the main clause subject cannot have this function, and why the empty subject cannot just refer to a third person not mentioned in the sentence at all.

Sentences such as (1) exhibit the notion of obligatory control, i.e., a case in which the empty subject must be coreferential with a main clause constituent. Obligatory control contrasts with free (also called arbitrary or nonobligatory) control as in:

[Ø to wait in the crowded airport] would be a mistake. (2)

In the subject clause in (2), the reference of the understood subject is not determined by any other noun phrase in the sentence but depends on the discourse context.

1. Some Control Phenomena

In this article, the term 'control' will be understood as meaning 'obligatory control.' The following nonexhaustive list gives some sentences that exemplify obligatory control.

(a) Infinitival Purpose Clauses

John_i bought a book_j [$Ø_i$ to amuse himself with]. (adapted from Nishigauchi 1984, p. 229) (3)

Mary_i bought the little boy_j a toy [$Ø_j$ to amuse himself with]. (adapted from Nishigauchi 1984, p. 229) (4)

(b) Infinitival Complement Clauses

John_i begged Mary_j [$Ø_j$ to leave]. (5)

Mary_i begged [$Ø_i$ to leave]. (6)

(c) Gerundial Complement Clauses

Paul_i thanked Mary_j for [$Ø_j$ writing the report]. (7)

Paul_i thanked Mary_j for [$Ø_i$ having been admitted to the tennis club]. (8)

Most work on control has been done on nonfinite complement clauses, i.e., on clauses exemplified by sentences (5) through (8). The remainder of the article will therefore be concerned with control in nonfinite complement clauses.

2. A Short History of Control

In the early days of generative grammar (see *Linguistics: Incorporation*) in the 1960s and 1970s, it was generally believed that control is a syntactic phenomenon, i.e., that the controller of the empty subject in the subordinate clause can be determined on a purely structural basis. More recently, it has become increasingly evident that semantic and pragmatic factors play an equally, if not more, important role in control.

2.1 Syntactic Approaches

The syntactic approach to control assumes that control relations can be determined on a purely structural basis. The most influential proposal along these lines was made by Peter Rosenbaum (1967, 1970). He postulated a Minimal Distance Principle (MDP), which predicts that the reference of the (empty) subject of a nonfinite complement clause depends on the closest available controller in the main clause. In sentence (1) above, the main clause noun phrase closest to the empty subject Ø is *Billy*.

Indeed, this noun phrase controls the reference of the empty subject, and the MDP thus makes the right prediction.

There are, however, many sentences for which the MDP is falsified. Difficulties emerge with constructions that display more than one potential controller in the main clause, as in (9) and (10):

Mary$_i$ persuaded Bill$_j$ [Ø$_j$ to clear her$_i$ desk]. (9)
Mary$_i$ promised Bill$_j$ [Ø$_i$ to clear her$_i$ desk]. (10)

For sentence (9) the MDP correctly selects the closest noun phrase in the main clause, *Bill*, as controller. *Persuade* belongs to the class of control verbs that normally select the main clause object as the controller. However, for sentence (10) the MDP wrongly selects *Bill* as controller; in fact, the main clause subject *Mary* is the controller. *Promise* belongs to the class of control verbs that usually select their subject as controller. Subject control verbs of the *promise* class constitute a problem for the MDP and have to be marked as exceptional in the lexicon.

Another problem that the MDP faces derives from the fact that one and the same verb may have either subject or object control:

Bill$_i$ thanked the coach$_j$ for [Ø$_j$ selecting him$_i$]. (11)
Bill$_i$ thanked the coach$_j$ for [Ø$_i$ having been admitted to the tennis club]. (12)

In (11), which can be regarded as the default case, the controller is *the coach* (object control), whereas in (12) a control switch or shift takes place: the most likely referent of the implicit subject Ø is *Bill* (subject control). The MDP wrongly predicts that in both sentences *the coach* should be the controller.

Other syntactic control theories have been proposed by Joan Bresnan (1982) (see *Lexical Functional Grammar*) and Emmon Bach (1979) in a logical framework (see *Montague Grammar*). What these theories have in common is that they regard syntactic structure as the decisive factor for determining the control relationship. However, there is a substantial body of evidence that suggests strongly the importance of semantic and pragmatic factors in the determination of control relations.

2.2 Semantic Approaches

A comparison of sentences (9) and (10), which look alike structurally, invites the conclusion that their differing control properties are caused by the meanings of the verbs *persuade* and *promise*, respectively. To persuade somebody to do something means that the addressee of an act of persuasion is led to believe that he or she should do something. This prospective action is expressed in the infinitival complement clause. Since in an active sentence such as (9) the addressee is the grammatical object of the main clause, it is not surprising that this constituent functions as controller of the empty subject of the subordinate clause. In contrast, a promise involves a commitment of the speaker to a future course of action. In an active sentence such as (10), the 'promiser' is the grammatical subject and one would therefore expect the subject to be controller of the understood subject of the complement clause.

The most complete account that acknowledges the importance of the meaning of control verbs is probably Sag and Pollard's (1991) control theory. These authors use semantic criteria to distinguish three classes of control verbs: (a) the *order/permit* class, which typically induces object control; (b) the *promise* class, which typically induces subject control; and (c) the *want/expect* class, which again induces subject control. The *order/permit* and the *promise* classes conceptually imply actions, whereas verbs of the *want/expect* class express what Sag and Pollard call an 'orientation' in their complement clause.

2.3 Pragmatic Approaches

Since the mid-1980s, the insight has grown that, in addition to the meaning of control verbs, the context in which a sentence is uttered and world knowledge about the participants' status play a significant role in assigning the coreferential links between controller and controllee (e.g., Comrie 1984, 1985, Růžička 1999; see *Pragmatics: Linguistic*).

These additional pragmatic factors are illustrated by the following German sentences (adapted from Wegener 1989):

Der Anwalt$_i$ versprach dem Häftling$_j$ [Ø$_j$ bald aus dem Gefängnis entlassen zu werden]. (13)
'The lawyer promised the prisoner that he (= the prisoner) would be released from jail soon.'
Der Häftling$_i$ versprach seiner Frau$_j$ [Ø$_i$ bald aus dem Gefängnis entlassen zu werden]. (14)
'The prisoner promised his wife that he (= the prisoner) would be released from jail soon.'

The most plausible interpretation for both (13) and (14) is that the prisoner will be released from jail. These interpretations follow from the speech act verb *versprechen*, 'promise,' the status of the referents of the noun phrases *der Anwalt, dem Häftling*, and *seiner Frau*, and the meaning of the passive complement clause. A promise implies a promiser who is committed to a future action, and a promisee who benefits from the action of the promiser. This semantic–pragmatic scenario can be applied to the interpretation of sentences (13) and (14) and the most plausible controller can be inferred (cf. Panther and Köpcke 1993, Panther 1994).

In (13) the lawyer is the promiser; hence the lawyer is committed to some future action. However, the complement clause does not express an action explicitly. A step toward a reasonable interpretation is to assume that the complement clause expresses the result of an action performed by the promiser. The action itself has to be inferred. Furthermore, the result of the

action is beneficial to the prisoner. Therefore, the most plausible controller is the noun phrase *dem Häftling*. On this account, the assignment of the controller is not a matter of finding the noun phrase that is syntactically closest to Ø in the matrix clause, but a matter of common-sense knowledge about the roles of lawyers and prisoners.

For (14), a coherent interpretation results if it is assumed that the prisoner can behave in such a way that he causes his release from jail. Again, the complement clause is interpreted as the result of an action—an action carried out by the prisoner to the effect that he will be released from prison. His wife can be regarded as the beneficiary of this action.

The interpretations sketched above are not the only ones possible. On the assumption that the lawyer is in jail, (13) could be interpreted as conveying that the lawyer will be released from jail; and (14) could have the interpretation, 'The prisoner promised his wife that she would be released from jail soon' given the background knowledge that the prisoner's wife is in prison. It is in the nature of the pragmatic approach to control that different background assumptions have an impact on what is the most plausible controller of Ø.

Similar observations have been made for Chinese by Huang (1994, p. 153), who contrasts the following sentences (referential subscripts and bracketing have been added):

Xuesheng$_i$ daying laoshi$_j$ [Ø$_i$ mingtian jiao zuowen]. (15)
'The pupil promises the teacher that he (= the pupil) will hand in the essay tomorrow'

Laoshi$_i$ daying xuesheng$_j$ [Ø$_j$ mingtian fang yi tian jia]. (16)
The teacher promises the pupil that he (= the pupil) will have a day off tomorrow'

The control verb *daying*, 'promise,' can be used either in the 'unmarked,' i.e., normal, sense 'commitment-to-action, as in (15), or in the 'marked' sense 'commitment-to-permission,' as in (16). These senses are derived pragmatically; they constitute 'preferred' interpretations that can be inferred on the basis of the meaning of the speech act verb *daying* and world knowledge about teacher–pupil interactions in the institutional framework of a school.

To summarize, the interpretation of control sentences relies not only on syntactic and semantic information but also, to a substantial degree, on world knowledge and contextual clues about the utterance situation.

3. *Language-specific Coding Differences of Control Relations*

One might surmise that the mechanisms of control are very similar across languages, but on closer inspection it turns out that there are language-specific differences in the way that control structures are coded. A selective list of these coding differences is given below (for a detailed account, see Růžička 1999).

3.1 *Modal vs. Non-modal Coding*

For many speakers of English the following sentence is ambiguous:

Johnny$_i$ asked his mother$_j$ [Ø$_{i/j}$ to go to the movies]. (17)

Sentence (17) can mean either that Johnny wants his mother to go to the movies or that Johnny asks for permission to go to the movies himself. This latter interpretation seems to be the most likely one, assuming that Johnny's mother has authority over Johnny (see Sect. 2.3).

As Růžička (1999, p. 45) points out, the 'ask-for-permission' (subject control) reading is also available alongside the 'ask-for-action' interpretation (object control) in Spanish, although the concept of permission is not coded explicitly.

María$_i$ le$_j$ pidió a Juan$_j$ [Ø$_i$ hablar con los muchachos]. (18)
'María asked Juan that she be allowed to talk to the boys'

The 'ask-for-permission' interpretation is not possible, however, if the same sentence is translated literally into German:

Hänschen$_i$ bat seine Mutter$_j$ [Ø$_j$ ins Kino zu gehen]. (19)
'Johnny asked his mother to go to the movies'

Sentence (19) can only mean that Johnny's mother is supposed to go to the movies. In order to express the 'ask-for-permission' sense, with Johnny as controller, German speakers have to resort to an utterance that codes permission by means of the modal auxiliary dürfen:

Hänschen$_i$ bat seine Mutter$_j$ [Ø$_i$ ins Kino gehen zu dürfen]. (20)
'Johnny asked his mother to be allowed to go to the movies'

3.2 *Causative vs. Non-causative Coding*

Another important coding difference between English and languages like German, Russian, and Czech is exemplified by

Peter$_i$ persuaded his father$_j$ [Ø$_j$ to be examined by a doctor]. (21)

Sentence (21) means that Peter's father should undergo a medical examination. This sense is, however, not explicitly coded in sentence (21), but is nevertheless conventionally conveyed by it. What is coded in the subordinate clause is the result of the action, not the action itself. If sentence (21) is translated literally into German, for many speakers ungrammaticality results and, for those who accept

the sentence, an interpretation with Peter as controller is more plausible:
?Peter$_i$ überredete seinen Vater$_j$ [Ø$_i$ von einem Arzt untersucht zu werden]. (22)
'Peter persuaded his father that he (= Peter) should be examined by a doctor'

The only way of rendering the intended message of (21) in German or Russian is to code *his father* as an active participant who engages in an action which results in a medical examination by a doctor:
Peter$_i$ überredete seinen Vater$_j$ [Ø$_j$ sich von einem Arzt untersuchen zu lassen]. (23)
'Peter persuaded his father to have himself (= his father) examined by a doctor'
Petr$_i$ ugovoril otca$_j$ [Ø$_j$ podvergnut' sebja osmotru vrač]. (Růžička 1999, p. 58) (24)
'Peter persuaded father that he (= father) should undergo a medical examination'

Both German and Russian have to code the agent role of father explicitly. This is done by the causative verb *lassen* in German and the action verb *podvergnut' sebja* 'submit oneself' in Russian.

3.3 Implicit Control vs. Explicit Control

Another important difference between English and languages such as German and Russian concerns the ability for a conceptually present controller to remain unexpressed. In German it is possible to say:
Der Professor$_i$ bat Ø$_j$ [Ø$_j$ den Zeitschriftenartikel zu kopieren]. (25)
'The professor requested (of some person) that this person photocopy the journal article'

In (25) the controller of the understood subject remains unexpressed. The person or group of persons supposed to comply with the request is indeterminate. This phenomenon may be called implicit control (cf. Panther 1997).

However, a word-for-word translation of (25) would not have the same effect in English:
The professor$_i$ asked Ø$_j$ [Ø$_i$ to photocopy the journal article] (26)

As the referential subscripts indicate, the only possible interpretation of (26) is that the professor himself wants to photocopy the journal article and asks for permission to do so. In German, however, the translation of (26) requires modal coding with *dürfen* 'be allowed to' (see Sect. 3.1).

Another example of implicit control is (27):
Der Arzt$_i$ riet Ø$_j$ [Ø$_j$ den Fettanteil in meinem Essen zu verringern]. (27)
'The doctor advised (someone) that this person should reduce the amount of fat in my diet'

The literal translation of (27) in English leads to ungrammaticality (marked by an asterisk):
*The doctor$_i$ advised Ø$_j$ [Ø$_j$ to reduce the amount of fat in my diet]. (28)

These examples illustrate a general tendency in English: in obligatory infinitival control constructions the controller has to be made explicit, whereas in languages such as German and Russian it can remain unexpressed. However, sometimes there is a way to circumvent the principle in English by resorting to a gerund construction. A possible translation of (27) is:
The doctor$_i$ advised Ø$_j$ [Ø$_j$ reducing the amount of fat in my diet]. (29)

4. Conclusion

Human languages employ various means to keep track of referents on the sentence and the discourse level. Control relations can be seen in this larger framework of coreference phenomena in general (see *Anaphora*). As with other coreference relations, it turns out that the interpretation of control structures involves a complex interplay of syntactic, semantic, and pragmatic parameters.

Syntax

The linear arrangement of the words in a sentence is rarely arbitrary, and the morphological shape which words take often depends on other words they co-occur with. The part of grammar that deals with the pertinent regularities is called syntax.

1. *Functions of Syntax*

Loosely speaking, the variations in form and position that constitute syntax fulfill a number of functions: The words and phrases of a sentence stand in various meaning relations to each other, and these relations are encoded by syntactic differences. A basic function is the expression of so-called 'thematic relations' or 'argument linking': a verb such as *kill* expresses a two-place predicate KILL (x, y), a relation between an *agent* x and a *patient* y in an event of killing. Such argument roles of a predicate must be linked to the argument expressions in a sentence, and at least in the ideal case, this linking is carried out systematically in natural language, for example by word order, as in English (1), or by case, as in German (2):

(1) the tiger killed the buffalo.
agent predicate patient

(2) dass der Tiger den Büffel tötete
that the.nom tiger the.acc buffalo killed.

Argument linking is not the only semantic-pragmatic function figuring in syntax. Argument places of verbs can, for example, be questioned (*who did he see?*), and languages may require that question phrases appear in specific positions (e.g., clause initially, as in English). Information structure ('new vs. old information,' 'focus vs. topic') is a relevant dimension for sentence construction too, and may influence word order, for example. Unlike (2), German (3) seems to be fully felicitous only in a situation in which the crucial new information is the identification of the tiger as the agent of killing.

(3) dass den Büffel der Tiger tötete.

A characterization of the functions that syntax encodes must be complemented by an identification of the means of encoding. Word order and shape variation are two options. The latter comes in two varieties. The fact that a noun is the agent of a verb may be encoded by shape variation of the noun (= case), or by shape variation of the verb (agreement markers)—or a combination of both. 'Word order,' on the other hand, seems to be the result of mapping the two-dimensional hierarchical structure of a sentence onto the unidimensional sound (or letter) stream (see Sect. 4 below). Intonational differences often serve to express pragmatic and semantic functions, but they seem to be employed only rarely in argument linking.

2. *Argument Roles*

In a sentence such as (4), we can distinguish words and phrases that are linked to argument places (in italics) of the predicate (boldface), and words and phrases that are not; which have an adjunct function (underlined).

(4) *Jack* **saw** *the girl* <u>in</u> <u>the</u> <u>park</u> <u>yesterday.</u>

Let us confine our attention to argument roles. They are linked to (the meaning of) the predicate *hierarchically*. For a verb such as *kill*, the agent is higher in this hierarchy than the patient. Grammatical differences reflect these hierarchies systematically. When two arguments of a predicate refer to the same entity, the higher argument will, for example, be realized in its usual shape, whereas the lower argument takes a special form (it is, e.g., realized as a reflexive pronoun) but not vice versa.

(5) (I expect) Bill to wash himself.
(I expect) *himself to wash Bill.
[Ungrammatical strings are preceded by a*]

For prototypical instances of 'transitive' relations, that is, for verbs expressing instantaneous causation of an event affecting a patient by an agent (*kill*, *beat*), the hierarchy seems to be the same in all languages, with agents always being more prominent than patients. Potential exceptions to this (Dyirbal, Arctic Eskimo; see e.g., Marantz 1984) can presumably be explained away. For less prototypical relations—e.g., for psychological predicates—grammatical hierarchies are linked to semantics less systematically, as the difference between *like* and *please* suggests: the 'experiencer' of the psychological state is encoded as the subject (as the higher role) with *like*, but as an object (the lower role) with *please*. Languages may differ in this respect—in some, nearly all psychological predicates follow the model of *please* (Basque), in others, all relevant verbs pattern with *like* (Lezghian), and in still others (like English), both construction types occur (see Bossong 1998).

In addition to identifying their place in the hierarchy, argument roles have often been classified in terms of notions that we have already used informally, namely/thematic ('theta') roles (Gruber 1965, Dowty

1991, Jackendoff 1990; but also Hjelmslev 1972, 1935–7, Jakobson 1971, 1936) such as 'agent,' 'instrument,' 'goal,' 'experience,' 'source,' 'patient,' etc. One needs to refer to these notions in the context of selecting the proper preposition or semantic case, but for capturing core syntactic laws, the necessity of integrating theta roles (in addition to hierarchy statements) into grammatical descriptions has yet to be established (apart, perhaps, from the special role played by the agent function). At least, most if not all current grammatical models can do without them easily (Fillmore 1968 and approaches following him are notable exceptions).

3. *Grammatical Functions*

One issue of syntactic theory is whether argument roles can be linked directly to the formal means of encoding, or whether the rules of encoding crucially employ ancillary notions, namely, the grammatical functions 'subject,' 'direct object,' 'indirect object,' etc. Some grammatical models (Relational Grammar, Perlmutter (1983); Lexical Functional Grammar, (Bresnan 1982)) assume that such grammatical relations are indispensable primitive notions of syntax. Other approaches, such as the Standard Theory (Chomsky 1965), or the Government and Binding (GB) framework (Chomsky 1981) take grammatical functions (at best) to be mere classificatory concepts of little explanatory value, which can be defined in terms of structure and hierarchy: a 'direct object' is a noun phrase 'governed' by the verb, or it is a noun phrase which is a structural sister of the verb.

Thus, Lexical Functional Grammar assumes that sentences are linked to a *functional structure*, in which, e.g., the verb *kill* is linked to two abstract grammatical functions, subject and object. How these grammatical relations are spelled out is a function of language-particular rules. In English, grammatical functions are encoded by word order (more precisely, hierarchically)—the direct object has to follow the verb immediately (1). In German (2, 3), the grammatical functions seem encoded by case marking (direct objects bear accusative case). The mapping from argument structure to formal means of expression would thus proceed as in (6):

(6) kill (role 1, role 2)
kill (subject, object)
kill (nominative, accusative)

Lexical Decomposition Grammar (Wunderlich 1997) translates argument hierarchies directly into morphological markings or order relations; that is, the second step in (6) is skipped. The Standard Theory and the GB framework assume that sentences are linked to an abstract 'deep structure,' in which the words and phrases combine hierarchically, with argument role hierarchies being reflected by argument expression hierarchies in deep structure, as in (7). Such deep structures are mapped on to audible representations in various ways, e.g., by case marking, reordering, etc.

(7) $[_{\text{Infl-Phrase}}$ Infl $[_{\text{VP}}$ [the tiger] [killed [the buffalo]]]]

In other words, there is no consensus concerning the status of grammatical functions. It seems fair to say however, that no universally applicable definitional criteria for, e.g., subjecthood, have been found so far. This suggests that grammatical functions must either be considered fuzzy concepts, or that they reflect a grammatical perspective that may be adequate in some languages only.

The nature of grammatical functions has often been discussed in the context of the claim that one type of linking argument expressions to argument places, namely the hierarchical-positional ('configurational') one that we find in English, is more fundamental than the others (such as case marking) in the sense that it underlies the grammatical system of *all* languages: at deep structure level, all languages follow roughly the constructional logic of English. This is the position held by the mainstream version of the GB framework, and has been taken over in the Minimalist program (Chomsky 1995). The contrary view that there are no privileged systems has been a minority position in GB (e.g., Hale 1983), and is the position held by Lexical Functional Grammar and Relational Grammar. Debates in the 1980s primarily contrasted languages with rigid word order and little case marking (English, Chinese) with languages with a relatively elaborate case system and free constituent order (German, Japanese). One outcome is the insight that a strong hierarchy-based configurational component can be identified in the grammar of languages with a fairly rich case marking too (e.g., Haider 1993).

On the other hand, it may also be uncontroversial that polysynthetic languages (such as Mohawk) with a very rich system of verbal agreement have a grammatical system that differs radically from, say, English and Japanese. It appears as if nominal expressions in the polysynthetic languages do not show a grammatical behavior that is even remotely reminiscent of subjects and objects—rather, their grammar is comparable to what holds for adjuncts (like adverbs) in English. Argument linking and other important grammatical factors seem to be dealt with in the morphology only. Why this is so, and whether this means that there are languages without a syntax proper (a position strongly argued against by Baker 1996) is an open issue.

4. *Movement*

If more than one semantic–pragmatic relation has to be expressed, and if the same encoding mechanism is used for the different functions, the encoding rules

may impose incompatible requirements on a phrase in a sentence. In English, the positional system of identifying arguments requires that objects *follow* the verb, whereas question phrases have to appear at the *beginning* of a clause. These requirements cannot be met simultaneously:

(8) (a) *(I do not care) you like who
(b) (I do not care) who you like

One way of dealing with this problem has been the postulation of various *levels of representation*, such that different requirements have to be met at different levels. In the Chomskyian tradition (see e.g., Chomsky 1957, 1965, 1981) a level called deep structure/d-structure, representing the thematic relations among arguments and predicates has played a prominent role until quite recently. This d-structure (corresponding to (9a)) would then be *mapped* on to representations coming close to the phonetic 'surface' by a set of structure-changing operations ('transformations'), of which the movement (more precisely: fronting) of phrases has been the most important one (relative to (9a), *who* has moved to clause initial position in (9b)). The law that requires that complement questions begin with a question word applies at 'surface structure' (s-structure) only, not at deep structure.

(9) (a) you like who?
(b) who do you like?

Details changed in the 1990s, but the distinction between structure building operations encoding argument linking and structure-changing operations (movement) is still a key property of all grammatical models inspired by Chomsky. Most alternative approaches (e.g., Generalized Phrase Structure Grammar; Gazdar et al. 1985) differ at a purely technical level only. Optimality Theory borrowed from phonology (Prince and Smolensky 1993; see also Grimshaw 1997, Kager 1999, Müller 2000) allows the handling of conflicts between incompatible grammatical requirements in a quite different way: the grammatical principles are ordered, and lower principles (such as: the object appears to the right of the verb) may be violated in the interest of higher ones (such as: question phrases appear clause-initially). Whether such options will eventually reduce the importance of movement metaphors in grammatical descriptions is an open question at the time of writing.

Beginning with the seminal work of Ross (1967), investigations on syntactic movement have brought to light a new type of syntactic law. There is a set of 'locality conditions' on movement, in the sense that words and phrases cannot be moved out of certain kinds of construction. Thus, in English, simple complement clauses are transparent for movement, while complement questions or relative clauses are not. (The place where a phrase has moved from is indicated by.)

(10) (a) you think that she likes someone
who do you think that she likes _
(b) you wonder when she kissed someone
***who** do you wonder *when* she kissed _
(c) you know a man who kissed someone
***who** do you know a man *who* kissed _

In (10b) and (10c), we observe an 'intervention' effect. The phrase *who* should be placed in the position indicated by _ at d-structure (because of the laws of argument linking), and in sentence initial position at s-structure because of the laws of question formation. The 'preposing' of *who* yields ungrammaticality in (10b) and (10c) because phrases cannot cross similar phrases (like *when* in (10b)) when they move to their surface position.

A similar intervention effect can be observed in (11) when a choice must be made between different phrases that could be placed into sentence-initial position: again, a phrase of type X must not cross a phrase of the same type in this context. This is the so-called superiority effect (see Chomsky 1973, also Chomsky 1995, Rizzi 1990).

(11) (a) **who** do you expect _ to buy *what*
(b) ***what** do you expect *who* to buy _

Furthermore, only complement clauses with an object function are transparent for movement, but not subject clauses (12a) and adjunct clauses (12b):

(12) (a) *who is to kiss _ fun?
(b) *who do you weep because you met _ ?

The Chomskyan approach (in the narrower sense) tries to identify a set of purely formal and universally valid syntactic laws that characterize such 'island' effects (see Chomsky 1981, 1986). The empirical challenge is that the constraints proposed so far are not being respected in all languages in the same way.

5. *Logical Forms*

Not all languages require that constituent questions be formed by the fronting of a question word or phrase (wh-phrase). In Chinese, wh-phrases are realized in the position where they should appear according to the laws of argument linking.

(13) ni xihuan shei
you like who
'who do you like?'

Interestingly, the scope options of Chinese wh-phrases are constrained, and in a way reminiscent of what we saw in the preceding section for English. Thus, a wh-phrase which takes scope over the whole matrix clause may appear as part of an object clause (14), but cannot show up in a subject clause (15). This is identical to what we have just observed for English (10a), (12).

(14) Zhangsan xiangxin shei mai-le shu
Zhangsan believe who bought books
'who does Zhangsan believe bought books?'

(15) *Zhangsan tao-le shei zhen kexi
Zhangsan marry who real pity
'for which *x*: that Zhangsan married *x* is a real pity'

Such observations gave rise to the idea (Huang 1982), quite popular in the GB framework, that *shei* undergoes movement to the clause initial position corresponding to its semantic scope as well (so that it is clear why its scope behavior is constrained by restrictions on movement), but 'invisibly' so. There are two ways in which the relevant observations may be interpreted, one that gives priority to syntax, and one that does not.

The GB framework postulated a grammatical architecture as in (16): by putting together words from the lexicon, a deep structure arises. This d-structure undergoes a number of transformations, mainly movement, in order to reach the interface levels Phonetic Form (PF) (interface with the articulatory–perceptory system) and Logical Form (LF) (interface with the cognitive system). The first steps, so-called 'overt' syntax, are common to these two derivations targeting PF and LF; they yield surface structure (s-structure). 'After' s-structure, the two paths split. The syntactic derivation of LF proceeds in the standard way, but no longer affecting phonetic material (covert syntax).

(16)

In this model, the Logical Form of (14) is (17), i.e., question words are preposed in Chinese too—the only difference from English being that the movement of *shei* has applied 'after' s-structure, so that it lacks a phonetic effect. All languages, it is claimed, have the same Logical Form, but they may make (among other things) different decisions as to whether a certain movement operation (like the fronting of wh-phrases) applies in overt or covert syntax.

(17) shei Zhangsan xiangxin _ mai-le shu
who Zhangsan believe bought books

Note that the major argument for such a view is the empirical observation that conditions that constrain c visible movement in some languages (see (12)) restrict the scope-taking behavior of certain phrases that have not been moved visibly (see (15)) in other languages. If one presupposes or shows that the relevant constraints c are formal-syntactic in nature, the conclusion that there is a syntactic component with invisible movement is quite compelling—but one must keep in mind that the overt movement operations constrained by c serve the purpose of scope-taking too.

Thus, one can also take quite a different perspective on facts as represented by (12) and (15): language could be governed by an elaborate system of *semantic constraints* on scope taking, and apparent syntactic conditions on movement might turn out to be superficial consequences of these constraints. Such semantic constraints affect the distribution of, for example, question words quite independently of whether they are moved syntactically or not. Proposals that can be related to this idea can be found in the literature (see, e.g., Erteshik-Shir 1977, Szabolsci and Zwarts 1997), but a full semantic account of constraints on movement has yet to be developed.

6. *Structural Hierarchies*

The previous section illustrated the difficulty of disentangling syntax and semantics in the domain of constraints on movement. This difficulty reappears when one considers the role which the geometry of abstract syntactic structures plays for quite a variety of relations and processes. (18)–(20) illustrate probably universal asymmetries that are cases in point: the pronoun *he* can be bound semantically by *no one* in (18a) only, but not in (18b): (18b) cannot have the interpretation sketched in (18c). *Ever* in (19) is a so-called 'negative polarity item.' It can appear in a sentence only if there is a negating expression present in that sentence. *Nobody* manages to license the polarity element *ever* in (19a), but not in (19b). (20) illustrates the fact that question (wh-) phrases are almost always moved to the left (if at all), but not the right.

(18) (a) No one thinks that he is incompetent.
(b) *He thinks that no one is incompetent.
(c) $\neg \mathrm{V}x$ (x thinks: x is incompetent)

(19) (a) Nobody thinks he will ever have enough money.
(b) *Bill ever thinks nobody will have enough money.

(20) (a) you tell me that she likes **who**
who do you tell me that she likes?
(b) you tell **who** that she likes Mary
*you tell that she likes Mary **who**

Such asymmetries were noted very early in modern syntax theory. After several unsuccessful attempts involving crucial reference to precedence, Culicover (1976) and Reinhart (1976) discovered the relevant purely structural factor at more or less the same time. The term *c-command* goes back to Reinhart (1976). We have reformulated it here as in (21), in a way that fits easily into present-day assumptions.

(21) a *c-commands* b if b is part of the structural sister of a

Recall that argument hierarchies are mapped, e.g., on to hierarchical abstract deep-structures, which are then transformed to surface structures by further operations. For (22), one might postulate a surface

structure such as (23) in the bracket notation, and (24) in the tree notation.

(22) the dangerous tiger has killed the old buffalo

(23) [the [[dangerous] [tiger]]] [has [[killed] [the [[old] [buffalo]]]]]]

(24)

the dangerous tiger has killed the old buffalo

We have labeled the nodes in the tree (24) for ease of reference. We say that A *dominates* B iff there is a uniquely downwards directed path in the tree from A to B. Thus, *s* dominates *x*, but neither *y* nor *z* dominate *w*. A immediately dominates B iff A dominates B and there is no C that dominates B but not A. A is a sister of B if there is a C such that C immediately dominates A and B. Therefore, (21) implies that *z* c-commands *w* but not vice versa.

The following generalizations then hold for natural languages:

(25) A noun phrase A can bind a pronoun B only if A c-commands B.

(26) A negating expression A licenses a polarity element B only if A c-commands B.

(27) An element can move from position A to position B only if A c-commands B.

Let us exemplify the impact of these statements with (25) only. The examples in (18) translate into the simplified partial structural representations (28). It is easy to figure out that *no one* c-commands *he* in (28a), but not in (28b), so that (25) correctly predicts that *no one* can bind the pronoun in (18a) only.

(28) (a) [no one [thinks [that [he [is [incompetent]]]]]]

(b) [he [thinks [that [no one [is [incompetent]]]]]]

Reference to the structural notion c-command in (25) cannot be replaced by precedence, because such an account would fail to explain why *nobody* can neither bind the pronoun nor license the polarity element in (29).

(29) *a letter to nobody would ever please him

Presumably, the establishment of syntactic relations between A and B always presupposes that A c-commands B, or vice versa.

Kayne (1994) has proposed that elements α that asymmetrically c-command β precede β in all natural languages. If his approach is correct, we would understand why the basic orders subject–verb–object (SVO, English), SOV (Japanese), and VSO (Irish) predominate among the world's languages; subjects occupy a hierarchically higher position in sentence structure than objects, and should therefore precede them if Kayne is right.

7. *Operations Affecting Grammatical Relations*

That the formation of questions, relative clauses, topicalization, etc. involves a preposing operation in certain languages such as English seems to be accepted quite generally, There may even be psycholinguistic evidence suggesting that such movement dependencies are processed in a special way by the human parser (see, e.g., Frazier and Clifton 1993).

In addition to such dependencies, in which phrases are displaced in order to encode semantic or pragmatic functions (so-called A-bar-movement), there are grammatical operations such as 'passive' (as in (30)) or 'raising to subject' (as in (31)) which primarily affect the grammatical functions of arguments: in a thematic sense, *a moose* in (30c) has properties of an object (it expresses the patient role); in other respects, it behaves like a subject (in terms of position and agreement with the verb).

(30) (a) one shot a moose

(b) there was a moose shot _

(c) a moose was shot _

(31) (a) it seems that he likes Mary

(b) he seems _ to like Mary

That such operations affecting grammatical functions should be expressed in terms of movement (see (32)) is less obvious (at least for languages in which grammatical functions are not straightforwardly encoded positionally) and less widely accepted.

(32) *d-structure*

_ was shot a moose

s-structure

a moose was shot _

Although the proper analysis of these processes is still subject to some debate, a number of locality restrictions on the process have, however, been uncovered, which are illustrated in (33).

(33) (a) I shoot a moose

a moose was shot

(b) I laugh at him

he was laughed at

(c) I expect her to win

she was expected to win

(d) I expect she will win

*she was expected will win

(e) I prefer very much for you to kiss Mary

*Mary was preferred very much for you to kiss

The passive operation may map a direct object (33a), an object in a prepositional phrase (33b), and the subject of a nonfinite complement (33c) to the subject position, but fails to be able to establish such a relation for the subject of an embedded finite clause (33d), or any object in an embedded clause (33e).

The restrictions may be slightly different in other languages, as the contrast between English and German in (34) shows, but the crucial observation is that similar locality restrictions can be observed with the binding of reflexive pronouns, at least in the most restrictive subcase of this domain, as it is realized in English; see (35).

(34) (a) he forgot to repair the car
*the car was forgotten to repair

(b)

er	vergass	den Wagen
he.nom	forgot	the.acc car
zu.repaieren		
to repair		
der Wagen	wurde	zu reparieren
the.nom car	was	to repair
vergessen		
forgotten		

(35) he shot himself
he laughs at himself
he expects himself to win
*he expects himself will win
*he prefers very much for her to kiss himself

The set of constructions to which these locality restrictions common to passivization and the grammar of reflexives apply is larger: it includes quantifier scope. A quantifier s can always take scope over a quantifier t if s c-commands t at s-structure. Thus, since subjects are higher in the structural hierarchy than objects, sentence (36a) allows a reading in which the existential quantifier takes scope over the universal quantifier

(36) (a) some man loves every woman
(b) there is a man such that this man loves every woman
(c) for every woman there is a man (possibly a different one for each woman) such that that man loves the woman

In English, however, a structurally lower quantifier s in position S may additionally take scope over t in position T if S and T could interact in terms of, say, passive formation, or the binding of reflexive pronouns. Thus, (36a) allows the further interpretation indicated in (36c), in which the object quantifier takes scope over the subject quantifier. A comparison of (33), (35), and(37) exemplifies the parallelism between wide scope options for a hierarchically lower quantifier, and the possibility of passive formation/binding of reflexive pronouns. See also Hornstein (1995).

(37) some woman laughs at every man
(wide scope for *every man* **possible**)
some woman expects every man to be a loser
(wide scope for *every man* **possible**)
some woman expects every man will be a loser
(wide scope for *every man* **impossible**)
some woman prefers very much for me to kiss every man
(wide scope for *every man* **impossible**)

If formal syntax is responsible for the restrictions exemplified in (33), the binding rules for reflexives and the scope taking behavior of quantifiers must be reducible to syntactic operations too. However, it is hard to exclude the possibility that some extra-syntactic constraints governing quantifier scope or reflexive binding have side effects on passivization or raising, so that (33) would find a nonsyntactic account. Note, furthermore, that the impression that the same factor constrains the three different types of process discussed here may be spurious. Thus, in many languages (e.g., Swedish) the domain for the binding of reflexive pronouns is much larger than the domain for passive formation.

8. *A Note of Autonomy*

As a reaction to so-called Generative Semantics, the hypothesis of the autonomy of syntax governed much of the history of current syntactic theorizing (see Newmeyer 1980): syntax was considered to be the only 'generative' component, the results of which are merely *interpreted* by semantics and by phonology. The preceding sections have revealed that it is often difficult to draw a sharp boundary between syntax and semantics, and strong adherence to the autonomy hypothesis may nowadays reflect a rather parochial perspective.

The same may be true for the interaction of phonology and syntax. The laws of the placement of clitics (e.g., unstressed pronouns) as we find them in Romance and Slavic languages often make crucial reference to phonological conditions (no clitic element must appear in the initial position of an intonation phrase) and syntactic conditions (elements bearing a given case etc. must appear in the leftmost position of, say, the verbal projection) at the same time. Phonological conditions may even be responsible for the application of syntactic operations such as verb movement.

The idea of a completely autonomous and encapsulated syntactic component, in which all processes can be understood in purely formal syntax-based terms only, in which syntactic processes are driven by syntactic conditions only, which was most popular in the GB tradition, therefore has to be modified, at least.

9. *Approaches to Universals*

The discovery of syntactic universals and their explanation has always been the major goal of syntactic theory. The typological tradition tries to attain this goal by comparing a large and representative sample of languages with respect to specific grammatical properties. Often this presupposes that the constructions can only be looked at in less detail than in the generative tradition. In the generative approach, the idea is to uncover abstract universal laws by an in-depth analysis of a few languages only.

The GB approach (Chomsky 1981) tried to identify a small set of simple yet universally valid syntactic principles, defining a Universal Grammar. It was assumed, especially in later stages of the theory, that formal differences between languages reduce to differences in the lexical inventory. The quest for such simple yet universally valid syntactic generalization was not successful, however, so the GB framework was replaced by, essentially, two new models. The Minimalist Program (Chomsky 1995) tries to understand syntactic properties in terms of so-called interface conditions (phonology, semantics). It may have explanatory value, but its empirical coverage is sometimes limited. Optimality Theory (OT) (Prince and Smolensky 1993, Grimshaw 1997) assumes that there are universally valid and simple conditions. Phonology, syntax, and semantics are not necessarily isolated subcomponents. OT acknowledges that simple principles will be in conflict with each. Such conflicts are resolved by ordering the principles hierarchically. Hierarchies are different in various languages, the only source of grammatical differences.

In particular, the major principles assumed in OT may correspond to 'ideal types' that languages may come close to in different degrees (as a function of the ranking of the relevant principles), so OT may have moved the generative enterprise closer to typology. This may be true in yet another sense; in contrast to GB, OT declared explicitly itself as a theory of variation and its explanation.

Syntax–Phonology Interface

An individual word, pronounced in isolation, will have a characteristic pronunciation. Yet the pronunciation of a sentence, made up of a sequence of words, is not merely a stringing together of these individual pronunciations. The pronunciation of a sentence, i.e.,

its phonetic realization, is a function of the surface phonological representation of the sentence. Standard models of the organization of a grammar hold that this phonological representation interfaces with the surface syntactic representation of the sentence, the latter being made up of the sequence of the underlying phonological representations of the words and morphemes that are actually pronounced, and their organization into a syntactic word and phrase structure. This organization of the grammar permits in principle that the syntactic representation of a sentence may influence its phonological representation, and therefore allows an explanation for why sentence phonology is not simply the phonology of the individual words of the sentence strung together. Consider, for example, the sentence pairs *No people will go* vs. *No, people will go* and *People will go happily* vs. *People will go, happily*. In both cases, commas indicate a difference in syntactic structure within the pairs. That syntactic structure difference is reflected in a difference in pronunciation, specifically here in a difference in intonation. Effects like these of syntax on phonology have been studied most commonly, in part because earlier models of generative grammar sanctioned only effects in this direction. It is also possible that effects might go in the opposite direction, with phonological principles constraining the range of acceptable syntactic representations at the interface; some recent research explores this question.

Two major lines of thinking on the influence of syntax on phonology can be distinguished. The *prosodic structure hypothesis* holds that the phonological representation of a sentence is organized into a prosodic constituent structure which is independent of, but related to, the surface syntactic structure of a sentence (Selkirk 1986, 1995; Nespor and Vogel 1986; Truckenbrodt 1999). It claims, moreover, that the syntax of a sentence can impinge directly only on this prosodic structure, namely on the organization into phonological words or phrases, and on the distribution of prosodic heads (or stresses). Other apparent effects of syntax on phonology, e.g., the choice of segmental variants or the placement of certain phrasal tones, are claimed to be indirect, mediated by the prosodic structure organization. And since the phonetic interpretation of a sentence is based on surface phonological representation, it follows that there are no direct effects of syntax on phonetic form. If the prosodic structure hypothesis embodies the correct theory of the domain structure for sentence phonology, then the theory of grammar must distinguish between the surface phonological representation of a sentence (PR), which would include this prosodic structure, and its surface syntactic representation (PF). The *direct access hypothesis* (Kaisse 1985, Odden 1995), by contrast, holds that phenomena of sentence phonology and phonetics may be defined directly from the surface syntactic word and phrase structure. It does not require a theory of grammar that distinguishes the surface syntactic representation of a sentence crucially from its surface phonological representation, at least in its hierarchical structure. Evidence appears to favor the prosodic structure hypothesis.

1. *The Prosodic Structure Hypothesis*

A prosodic structure is a well-formed labeled bracketing or tree. The constituents of prosodic structure belong to distinct prosodic categories, arranged in a *prosodic hierarchy*.

(1) The Prosodic Hierarchy:
Utterance (Utt)
Intonational Phrase (IP)
Major Phonological Phrase (MaP)
Minor Phonological Phrase (MiP)
Prosodic Word (PWd)
Foot
Syllable

In the unmarked case, it is claimed, prosodic structure is *strictly layered*, in the sense that a constituent of a higher level in the hierarchy immediately dominates only constituents of the next level down in the hierarchy. In addition, within a prosodic constituent, in the unmarked case, one of the daughter constituents constitutes the *prosodic head*, the locus of prominence or stress. Compelling support for the claim that the domain structure of sentence phonology and phonetics has the formal properties of such a structure comes from evidence of *domain convergence* and *domain layering* within individual languages. Yet a direct access approach could potentially model these effects. Crucial support for the prosodic structure hypothesis comes from the fact that the constraints which define the hierarchical phonological domain structure are heterogeneous in type, including *prosodic structure markedness constraints* which are properly phonological in character, appealing only to properties of surface phonological representation, and *syntax-prosodic structure interface constraints*, which call for features of the syntactic representation to be reflected in phonological representation. Effects of prosodic markedness constraints show that the domain structure of surface phonology is not strictly determined by the syntax, only influenced by it.

1.1 *Domain Convergence*

In English declarative sentences, the right edge of a major phrase (MaP) in prosodic structure is marked by the presence of a low tone. In (1a,b) a L- marks the low target tone found on the final syllable of a MaP.

(2) (a) (No^{L-}) (animals are allowed^{L-}) =
No, animals are allowed.
[iænɨmlz]
(b) (No animals are allowed^{L-}) =
No animals are allowed.
[ænɨmlz]

We also see a segmental reflex of that same MaP organization: a glottal stop appears as the onset of the first syllable of *animals*, [ɨænɨmlz], in (2a), where it is phrase-initial, but not in (2b). This glottalization effect is arguably phonetic in character (Dilley and Shattuck-Hufnagel 1996). In (3a,b) we see an additional MaP effect: a contrast in the pronunciation of the function word *to*.

(3) (a) (They're allowed to graze there^{L-}) (by law^{L-}).
[tə]
(b) (They're allowed to^{L-}) (by law^{L-})
[tuw]

To appears in its stressless, vowel-reduced weak from [tə] in (3a), where it is medial within the MaP, but in its stressed, full vowel strong form [tuw] when it appears at the right edge of MaP in (3b) due to the ellipsis of the following verb phrase. In English, monosyllabic function words like *to* generally appear in strong form only at the right edge of MaP (or when they bear contrastive stress) (Selkirk 1995). These three different phenomena which converge on major phrase in English together show that both edges of these constituents are simultaneously relevant to defining phonetic and phonological phenomena.

In Bengali sentence phonology (Hayes and Lahiri 1991), MaP is marked at its right edge by a H- tone. The left edge of MaP is the locus of further phenomena: the word that is leftmost in a MaP is the head of that phrase, and a Low pitch accent, L*, is located on the initial syllable of this stressed word:

(4) (ʃæ^{L*}moli^{H-}) (ra^{L*} m-er bari^{H-}) (dʰu^{L*}ketʃʰil^{H-})$^{L°}$
Shamoli Ram's house entered
Shamoli entered Ram's house.

In addition, there are segmental assimilation phenomena which apply optionally both within and between words. These assimilations operate across the span of the MaP, but are blocked if the sequence of segments belongs to different phrases:

(5) (ɔ^{L*}mor^{H-}) (tʃa^{L*}dor^{H-}) (ta^{L*}ra-ke^{H-}) (díe^{L*}tʃʰe^{H-})$^{L°}$
[r] [tʃ] [r] [t]
Amor scarf Tara–to gave
Amor gave the scarf to Tara.

(6) (ɔ^{L*}mor tʃador tara-ke^{H-}) (díe^{L*}tʃʰe^{H-})$^{L°}$
[tʃtʃ] [tt]
Amor gave the scarf to Tara.

The faster pronunciation in (6) is organized into fewer MaP than in the more deliberate pronunciation of the same sentence in (5). This difference in domain organization is indicated both by the patterns of tone distribution and by the assimilation of /r/. This Bengali phrasal domain, then, shows right and left domain-edge phenomena, as well as phenomena defined on the prominent head of the domain and across the span of the domain.

1.2 Domain Layering

The edge of a clause in the syntax typically coincides with the edge of what prosodic structure theory calls the intonational phrase (IP), the prosodic constituent immediately superordinate to the MaP in the prosodic hierarchy. In English, a final rising tonal contour on the last syllable of word (notated$^{L-H°}$), sometimes referred to as the continuation rise, is taken to indicate the presence of the right edge of IP (Beckman and Pierrehumbert 1986), indicated with curly braces.

(7) {(Since herds of grazing cows^{L-})
[hrdz]
(have been allowed in her meadow^{L-})$^{H\%}$}
[əv] [ɾ]
{(her flowers have all disappeared^{L-})}
[hɾ] [əv]

The right edge of an IP typically is accompanied by a short pause or a significant lengthening of the final syllable. In English (and other languages) the left edge of IP is, moreover, the site of phonetic strengthening effects that are potentially different in kind or in degree from those seen with the major phrase (Keating et al. 1998). For example, an underlying /h/ in English will typically fail to be pronounced if it is in an unstressed syllable (compare stressed *herds* to stressless *her* in the first clause), but at the beginning of an IP /h/ must necessarily be pronounced, even in a stressless syllable (compare stressless *her* in the second clause to stressless *her* in the first). By contrast, there is the possibility of absence of /h/ in the stressless *have* which is MaP-initial in the first clause. This difference in appearance of [h] provides further testimony of the difference in the two levels of domain structure.

In Japanese, a rise (LH) in pitch which is referred to as Initial Lowering is found at the left edge of a minor phrase (MiP) (Poser 1984, Kubozono 1993), indicated with angle brackets in (8b).

(8) (a) Yamaai-no yamagoya-no uraniwa-no umagoya-ni kabi-ga hae^{H*}-ta
[[[[mountain village-GEN] hut-GEN] backyard-GEN] barn-LOC] [mold-NOM] [grow-PAST]
The barn in the backyard of a hut in a mountain village grew moldy.
(b) $^{L}<^{H}$ Yamaai-no yamagoya-no $>^{L}$ $<^{H}$ uraniwa-no umagoya-ni $>\uparrow^{L}<^{H}$ kabi-ga hae$^{H*}\downarrow$-ta $>)^{L}$

Sentence (8b) shows an organization into binary MiP. In (9b), by contrast, where all the words have a lexical accent, we see that there are as many instances of MiP, and hence of Initial Lowering, as there are of accents:

(9) (a) Yama^{H*} gata-no yama^{H*} dera-no one:^{H*} san-ga mayone:^{H*} zu-o ho:ba^{H*} tteiru-wa
[[[Yamagata-GEN] mountain temple-GEN] young-lady-NOM] [[mayonnaise-ACC] filling-her-mouth]
The young lady from a mountain temple in Yamagata was filling her mouth with mayonnaise.
(b) ($^{L}<^{H}$yama$^{H*}\downarrow$gata $>^{L}<^{H}$yama$^{H*}\downarrow$dera $>^{L}$ $<^{H}$one:$^{H*}\downarrow$san-ga $>\uparrow^{L}<^{H}$ mayone:$^{H*}\downarrow$zu-o $>^{L}<^{H}$ho:ba$^{H*}\downarrow$tteiruwa $>)^{L}$

The difference in patterns of minor phrasing seen in (8) and (9) are the result of prosodic markedness constraints, to be discussed below.

At the level of MaP, the level above MiP in the prosodic hierarchy, two tonal phenomena, are defined: catathesis (↓), and upward pitch reset (↑) (Poser 1984, Pierrehumbert and Beckman 1988). Catathesis is an accent-induced downstepping of the pitch range, while upward pitch reset returns the pitch range to a higher level. Only material within the same MaP undergoes catathesis. Upwards reset, seen in both (13) and (14), appears at the left edge of MaP. These examples, then, illustrate the basic strict layering of unmarked hierarchical prosodic structure: here a MaP is parsed into a sequence of MiP.

1.3 Nonsyntactic Determinants of Phonological and Phonetic Domain Structure

A direct access theory could model patterns of edge-sensitive phonetic and phonological phenomena as long as the edges were definable solely in syntactic terms. But demonstrably nonsyntactic factors in phonological domain organization, such as prosodic markedness constraints and speech rate, show that the influence of syntax is indirect.

1.3.1 The interaction of prosodic markedness constraints and interface constraints. In optimality theory (Prince and Smolensky 1993), phonological markedness constraints call for some ideal phonological target output shape. Of particular importance to our topic, markedness constraints compete with a class of constraints called faithfulness constraints, which call for properties of the surface phonological representation to reflect, or be identical to, properties of a related grammatical representation. Syntax–phonology interface constraints can be understood as a variety of faithfulness constraint, one of the input–output variety, if surface syntactic representation (PF) and surface phonological representation (PR) are in an input–output relation, or one of an output–output variety, if the PF and PR relation are evaluated in parallel, not serially.

In the examples of Japanese minor phrasing cited in (8) and (9), prosodic markedness constraints complement the effects of syntax–phonology interface constraints, producing phrasing where it would not be called for by the syntax. A prosodic constraint calling for a MiP to be binary in its PWd composition, call it Binary MiP, results in the binary phrasing seen in (8). Another prosodic constraint, call it MiP Accent, calls for a MiP to contain at most one accent; it is responsible for the appearance of the nonbinary MiP in (14). In Japanese, MiP Accent takes precedence over Binary MiP, as in (9), a relation that can be expressed in the grammar of Japanese with an optimality-theoretic constraint ranking: MiP Accent ≫ Binary MiP.

The ideal binary shape for MiP, which appears in (8), fails to appear in sentences with somewhat different syntactic structures, showing that certain syntax–phonology interface constraints also outrank the Binary MiP markedness constraint in the grammar of Japanese. The simple three word subject–object verb sentence (10) divides into two major phrases (MaP) at the break between subject and object, with the result that the subject consists of a nonbinary minor phrase (MiP), in violation of Binary MiP:

(10) (a) Inayama-ga yuujin-o yonda
[[Inayama-NOM] [[friend-ACC] call-PST]]
Mr Inayama called his friend.
(b) $({}^{L}<{}^{H}$Inayama-ga$>\uparrow({}^{L}<{}^{H}$yuujin-o yonda$>)^{L}$

The MaP break here is imposed by a syntax–phonology interface constraint expressible as the alignment constraint (Selkirk and Tateishi 1988, 1991):

(11) Align-L (XP, MaP)
The left edge of a maximal projection in syntactic representation (PF) corresponds to the left edge of a major phrase in surface phonological representation (PR).

The noun phrase (12), which consists of an accentless Adjective–Adjective–Noun sequence, consists of a single MaP (as shown by lack of internal upward pitch range reset), but nonetheless shows a MiP break between the two adjectives, leaving the first MiP nonbinary.

(12) (a) Amai akai ame-ga
[sweet [red [candies]]]
(b) $({}^{L}<{}^{H}$amai$>{}^{L}<{}^{H}$akai ame-ga$>)^{L}$
NOT: $*({}^{L}<{}^{H}$amai akai ame$>)^{L}$

At play here is an interface constraint sensitive to syntactic branching (Kubozono 1993):

(13) Align- L (X^{br}, MiP).
The left edge of a branching constituent in syntactic structure corresponds to the left edge of a minor phrase in prosodic structure.

These two syntax–phonology alignment constraints outrank Binary MiP in the grammar of Japanese, causing the violations of Binary MiP seen in (10) and (12):

(14) Align-L (XP, MaP), Align- L (X^{br}, MiP) ≫ Binary MiP.

It is because neither of these interface constraints is applicable in the left-branching structure of the subject noun phrase in (8) that we see the effects of the lower-ranked Binary MiP emerge there. In other words, where the lower-ranked Binary MiP is not forced to be violated by the higher ranked interface constraints, it produces effects that are *complementary* to the effects of the interface constraints.

We also find cases where an expected effect of a syntax–phonology interface constraint *fails to appear* because of pressure from a competing prosodic markedness constraint. This can be modeled by

ranking the prosodic constraint higher than the relevant interface constraint. (15) shows the expected MaP break at the left edge of VP in a neutral Focus sentence in Japanese.

(15) A neutral Focus sentence in Japanese

Sentence (16) contains a text which differs only in having a contrastive Focus on the last word of the subject NP, *ani'yome*. The phonological domain structure of this sentence shows an absence of the syntactically expected MaP break at the left edge of the VP, as well as the unexpected presence of a MaP break at the left edge of the Focus constituent (Poser 1984, Pierrehumbert and Beckman 1988, Nagahara 1994).

(16) The same sentence, except with *aniyome* as FOCUS

Truckenbrodt (1995) argues that the source of these phrasing effects in Focus sentences lies in a syntax–phonology interface constraint calling for a Focus to be more prosodically prominent than any other element within the Focus domain.

(17) Focus Prominence

The string in PR which corresponds to a string in PF dominated by Focus must contain a prosodic prominence that is greater than any other prominence contained in the Focus domain.

In the case where the domain of the Focus is the entire sentence, as in (16), respect of this constraint means that the Focus element and all the prosodic phrases that dominate it will be the head(s) of the intonational phrase corresponding to that sentence in PR (underlined). A prominent constituent is subject to a prosodic markedness constraint that calls for it to be aligned with an edge of the superordinate constituent (McCarthy and Prince 1993). The violation in (17) of the interface constraint (11) calling for a MaP edge at the left edge of VP is claimed to be driven by the higher-ranked prosodic constraint Align-R (MaP_{head}, IP).

This constraint calls for the prominent MaP in the IP that dominates the Focus in (17) to align with the right edge of the intonational phrase, and so prevents the existence of any other MaP following the Focus. This analysis is captured in the ranking in (18).

(18) Focus Prominence, Align-R (MaP_{head}, IP) $\gg$ Align-L (XP, MaP).

So, here, a syntactic effect is overridden by a prosodic effect.

1.4 Speech Rate

One additional sort of nonsyntactic factor on phonological domain structure that has been recognized for some time in the literature is speech rate. In Bengali, a faster speech rate gives rise to larger phonological phrases (see Sect. 1.1). Speech rate plays a role as well in MiP organization in Japanese; in slower speech, single words may easily constitute a MiP (Selkirk and Tateishi 1988). Since syntactic structure does not vary with speech rate, these rate-based differences in phrasing give additional evidence for an autonomous, nonsyntactic, prosodic structural representation of phonological domains.

2. The Syntax–Prosodic Structure Interface: Serialist or Parallelist?

The classic generative model of the relation between syntax and phonology is an input–output model, in which surface syntactic representation, the output of the syntactic component, is input to the phonological component, whose output is the surface phonological representation. Most approaches to modelling the syntax–prosodic structure interface have assumed this serialist, unidirectional, input–output model, with the prediction that syntax may influence phonology, but not vice versa. They have posited constraints, algorithms or rules relating the two representations which have the general form 'If the surface syntactic representation of the sentence has property S, then the surface phonological representation will have property P.'

In the Align/Wrap theory of the interface (Selkirk 1986, 1995, Truckenbrodt 1999), the demarcational Align class of constraints calls for the edge of any syntactic constituent of type C_S in the surface syntax to align with the edge of a prosodic constituent of type C_P in the surface phonology, while the cohesional Wrap class of constraints calls for a syntactic constituent of type C_S in the surface syntax to be contained within a

prosodic constituent of type C_P in the surface phonology. There have been other, relation-based, proposals concerning the nature of syntax–prosodic structure interface constraints as well, including Nespor and Vogel 1986, McHugh 1990, Kim 1997, all understood to be consistent with the prosodic structure hypothesis, and with the input–output architecture.

An input–output model of the syntax–phonology interface makes the essential claim that constraints on phonological output representation do not interact with constraints on the surface syntactic representation. Two sorts of apparent challenges for the input–output model have recurred in recent literature. One sort concerns clitics whose distribution is governed by both syntactic and prosodic constraints, such as the second position clitics of Serbo-Croatian (Inkelas and Zec 1990). Yet because the syntax itself affords options in the positioning of second position clitics, it is not necessary to construe the prosodic subcategorization of a clitic as outranking a constraint on syntactic word order. Another sort of challenge concerns the alleged dependence of word order on the positioning of focus-related prosodic prominences in the sentence, as suggested by Vallduvi (1991) for Catalan, or Zubizarreta (1998) for Spanish. However, since the latter sort of phenomenon potentially can receive a purely syntactic treatment in which the Focus properties of syntactic representation are crucial in determining word order (see, e.g., Grimshaw and Samek-Lodovici 1998), this sort of case is not yet compelling. It remains to be seen whether the syntax–phonology interface is an input–output relation or whether it is instead a two-way street.

Syntax–Semantics Interface

Anybody who speaks English knows that (1) is a sentence of English, and also has quite a precise idea about what (1) means.

(1) Every boy is holding a block.

English speakers know for infinitely many sentences that they are sentences of English, and they also know the meaning of these infinitely many sentences. A

central idea of generative syntax (see *Linguistics: Incorporation*) is that the structure of a sentence is given by a recursive procedure, as this provides the means to derive our knowledge about the infinite number of sentences with finite means. For the same reason, semanticists have developed recursive procedures that assign a meaning to sentences based on the meaning of their parts.

The syntax–semantics interface establishes a relationship between these two recursive procedures. An interface between syntax and semantics becomes necessary only if they indeed constitute two autonomous systems. This is widely assumed to be the case, though not entirely uncontroversial as some approaches (see *Grammar: Functional Approaches* and *Montague Grammar*) do not subscribe to this hypothesis.

Consider two arguments in favor of the assumption that syntax is autonomous: one is that there are apparently purely formal requirements for the well-formedness of sentences. For example, lack of agreement as in (2) renders (1) ill-formed (customarily marked by prefixing the sentence with an asterisk), though subject–verb agreement does not seem to make any contribution to the meaning of (1).

(2) *Every boy hold a block.

The special role of uninterpretable features for syntax comes out most sharply in recent work by Chomsky (1995), who regards it as one of the main purposes of syntax to eliminate such uninterpretable features before a sentence is interpreted.

On the other hand, there are also sentences that are syntactically well-formed, but do not make any sense (often marked by prefixing the sentence with a hatch mark). Chomsky's (1957, p. 15) famous example in (a) makes this point, and so does (b).

(3) (a) #Colorless green ideas sleep furiously.
(b) #She arrived for an hour.

Independent of the value of these arguments, the separation of syntax and semantics has led to tremendous progress in the field. So, at least it has been a successful methodological principle.

1. Basic Assumptions

Work on the syntax–semantics interface by necessity proceeds from certain assumptions about syntax and semantics. We are trying to keep to a few basic assumptions here. In the specialized articles on generative syntax (*Linguistics: Incorporation*), and *quantifiers* (*Quantifiers, in Linguistics*) many of these assumptions are discussed and justified in more depth.

For the syntax, we assume that sentences have a hierarchical constituent structure that groups words and subconstituents into constituents. Also, we assume that constituents can be moved from one part of the tree structure to another, subject to constraints of the kind Ross (1967) first described. The constituent structure of a sentence is captured by the kind of phrase structure tree illustrated in (4)(a). (4)(b) shows a phrase structure tree with a movement relation.

(4(a))

(4(b))

The task of semantics is to capture the meaning of a sentence. Consider first the term 'meaning.' In colloquial use, 'meaning' includes vague associations speakers may have with a sentence that do not exist for all speakers of a language: e.g., the sentence 'I have a dream' may have a special meaning in this colloquial sense to people familiar with Martin Luther King.

Semantics, however, is at present concerned only with reproducible aspects of sentence meaning. In particular, semanticists have focused on the question of whether a sentence is judged true or false in a certain situation. Part of what any speaker of English knows about the meaning of (1) is that it is true in the situation shown in picture A, but false in the situation shown in picture B.

(5) Every boy is holding a block.

Picture A Picture B

All speakers of English are equipped with certain mental mechanisms that enable them to make this truth value judgment for (1) and similar judgments for infinitely many other sentences. An explicit theory can be given using techniques similar to those used in mathematical logic. In this approach, the meaning of a constituent is modeled by a mathematical object (an individual, a function, a set, or a more complicated

object). Complete declarative sentences such as (1) correspond to functions that assign to possible situations one of the truth values True or False. The basic intuition of entailment between sentences as in (6) is captured if for every situation to which the meanings of the premises (a) and (b) assign True, the meaning of the conclusion (c) also assigns to this situation True.

(6) (a) Every boy is holding a block.
(b) John is a boy.
(c) Therefore, John is holding a block.

2. Syntax–Semantics Correspondences

Though syntax and semantics are two autonomous recursive procedures, most researchers assume that there is a relationship between the two to be captured by the theory of the syntax–semantics interface. In particular, it seems to be the case that the steps of the recursion are largely the same. In other words, two phrases that form a syntactic constituent usually form a semantic constituent as well (Partee (1975) and others).

Consider (7) as an illustration of this.

(7)	(a) A smart girl	bought	a thin book.
	(b) A thin girl	bought	a smart book.
	Subject	**Verb**	**Object**

Syntacticians have argued that the subject and the object in (6) form constituents, which we call noun phrases (abbreviated as NPs). We see in (6) that the adjective that occurs in a NP also makes a semantic contribution to that NP. This is not just the case in English: as far as we know, there is no language where adjectives occurring with the subject modify the object, and vice versa.

Further evidence for the close relation of syntactic and semantic constituency comes from so many phenomena that we cannot discuss them all. Briefly consider the case of idioms. On the one hand, an idiom is a semantically opaque unit whose meaning does not derive from the interpretation of its parts in a transparent way. On the other hand, an idiom is syntactically complex. Consider (8).

(8) (a) Paul kicked the bucket. ('Paul died.')
(b) The shit hit the fan. ('Things went wrong.')

The examples in (8) show a verb–object idiom and a subject–verb–object idiom. What about a subject–verb idiom that is then combined transparently with the object? Marantz (1984, pp. 24–28) claims that there are no examples of this type in English. Since syntacticians have argued that the verb and the object form a constituent, the verb phrase, that does not include the subject (the VP in (4)), Marantz's generalization corroborates the claim that idioms are always syntactic constituents, which follows from the close relationship between syntax and semantics.

If syntactic and semantic recursion are as closely related as we claim, an important question is the semantic equivalent of syntactic constituent formation. In other words, what processes can derive the interpretation of a syntactically complex phrase from the interpretation of its parts? Specifically, the most elementary case is that of a constituent that has two parts. This is the question to which the next two sections provide an answer.

2.1 Constituency

2.1.1 Predication as functional application. An old intuition about sentences is that the verb has a special relationship with the subject and the objects. Among the terms that have been used for this phenomenon are 'predication', which we adopt, 'theta marking,' and 'assigns a thematic role.'

(9) John gave Mary *Brothers Karamazov*.

One basic property of predication is a one-to-one relation of potential argument positions of a predicate and actually filled argument positions. For example, the subject position of a predicate can only contain one nominal: (a) shows that two nominals are two many; and (b) shows that none is not enough.

(10) (a) *John Bill gave Mary *Brothers Karamazov*.
(b) *gave Mary *Brothers Karamazov*.

Chomsky (1981) describes this one-to-one requirement between predication position and noun phrases filling this position as the theta-criterion.

The relationship between 'gave' and the three NPs in (9) is also a basic semantic question. The observed one-to-one correspondence has motivated an analysis of verbs as mathematical functions. A mathematical function maps an argument to a result. Crucially, a function must take exactly one argument to yield a result, and therefore the one-to-one property of predication is explained. So, far example, the meaning of 'gave Mary *Brothers K.*' in (10) would be captured as a function that takes one argument and yields either True or False as a result, depending on whether the sentence is true or false.

The phrase 'gave Mary *Brothers K.*' (the verb phrase) in (9) is itself semantically complex, and involves two further predication relations. The meaning of the verb phrase, however, is a function. Therefore the semantic analysis of the verb phrase requires us to adopt higher order functions of the kind explored in mathematical work by Schönfinkel (1924) and Curry (1930). Namely, we make use of functions the result of which is itself a function. Then, a transitive verb like 'greet' is modeled as a function that, after applying to one argument (the object), yields as its result a function that can be combined with the subject. The ditransitive verb 'give' is captured as a function that yields a function of the same type as 'greet' after combining with one argument.

Functional application is one way to interpret a branching constituent. It applies more generally than just in NP–verb combinations. Another case of predi-

cation is that of an adjective and a noun joined by a copula, as in (11). We assume here that the copula is actually semantically empty (i.e., a purely formal element), and the adjective is a function from individuals to truth values, mapping exactly the red-haired individuals on to True (see Rothstein 1983).

(11) Tina is red-haired.

Similarly, (12) can be seen as a case of predication of 'girl' on the noun 'Tina.' For simplicity, we assume that in fact not only the copula but also the indefinite articles in (12) are required only for formal reasons. Then, 'girl' can be interpreted as the function mapping an individual who is a girl on to True, and all other individuals on to False.

(12) Tina is a girl.

2.1.2 Predicate modification as intersection. Consider now example (13). In keeping with what we said about the interpretation of (11) and (12) above, (13) should be understood as a predication with the predicate 'red-haired girl.'

(13) Tina is a red-haired girl.

The predicate 'red-haired girl' would be true of all individuals who are girls and are red-haired. But clearly, this meaning is derived systematically from the meanings of 'red-haired' and 'girl.' This is generally viewed as a second way to interpret a branching constituent: by intersecting two predicates, and essentially goes back to Quine (1960).

2.1.3 Predicate abstraction. A third basic interpretation rule can be motivated by considering relative clauses. The meaning of (14a) is very similar to that of (13). For this reason, relative clauses are usually considered to be interpreted as predicates (Quine 1960, p. 110 f.).

(14) (a) Tina is a girl who has red hair.
(b) Tina is a girl who Tom likes.

Syntacticians have argued that the relative pronouns in (14) are related in some way to an argument position of the verb. We adopt the assumption that this relationship is established by syntactic movement of the relative pronoun to an initial position of the relative clause.

(15) who_x x has red hair
who_x Tom likes x

Looking at the representation in (15), the semantic contribution of the relative pronoun is to make a predicate out of a complete clause which denotes a truth value. An appropriate mathematical model for this process is lambda-abstraction (Church 1941). The definition in (16) captures the intuition that (14b) entails the sentence 'Tom likes Tina,' where the argument of the predicate is inserted in the appropriate position in the relative clause (see, e.g., Cresswell (1973) or Partee et al. (1990) for more precise treatments of lambda abstraction).

(16) $[\lambda_x$ XP] is interpreted as the function that maps an individual with name A to a result r where r is the interpretation of XP after replacing all occurrences of x with A.

Functional application, predicate modification and lambda abstraction are probably the minimal inventory that is needed for the interpretation of all hypothesized syntactic structures.

2.2 Scope

2.2.1 Quantifier scope. A second area where a number of correspondences between syntax and semantics have been found are semantic interactions between quantificational expressions. Consider the examples in (17) (adapted from Rodman (1976, p. 168):

(17) (a) There's a ball that every boy is playing with.
(b) Every boy is playing with a ball.

The difference between (17a) and (17b) is that only (17b) is true when every boy is playing with a different ball, as in picture B; (17a) is only judged to be true in the situation depicted in picture A, where every boy is playing with the same ball.

(18)

Picture A Picture B

The semantic difference between (17a) and (17b) correlates with a difference in syntactic structure. Namely, in (17b) 'a ball' is part of the sister constituent of 'every boy,' while it is not so in (17a).

The special role the sister constituent plays for semantic interpretation was first made explicit by Reinhart (1976) building on the work of Klima (1964) and others. She introduced the term c-command for the relationship where a phrase enters with any other phrase inside its sister constituent, and proposed that the domain of c-commanded phrases (i.e., the sister constituent) is the domain of semantic rule application. The c-command domain is then equated with what logicians call the scope.

On the recursive interpretation procedure developed in the previous section, Reinhart's generalization is captured in a straightforward manner. This can be seen without being precise about the semantics of quantifiers (see Sect. 3.1, and *Quantifiers, in Linguistics*). Consider the interpretation of the relative clause constituent in (a), which is shown with the lambda operator forming a predicate in (19). This

predicate will only be true of an object *a* if every boy is playing with *a*. Such an individual is found in picture B, but not in picture A.

(19) Every boy is playing with *x*.

For sentence (17b), however, we want to interpret the verb phrase 'is playing with a ball' as a predicate that is true of an individual *a*, if there is some ball that *a* is playing with. (Below, in Sect. 3.2, we sketch a way to derive this meaning of VP from the meanings of its parts.) Crucially, this predicate is fulfilled by every boy in both picture A and picture B.

2.2.2 Binding. A second case where c-command is important is the binding of pronouns by a quantificational antecedent. Consider the examples in (20).

(20) (a) Every girl is riding her bike.
(b) Every girl is riding John's bike.

Sentence (a) is judged true in a situation where the girls are riding different bicycles—specifically, their own bicycles. Example (b), however, is only true if John's bike is carrying all the girls. The relationship between the subject 'every girl' and the pronoun 'her' in (a) can only be made more precise by using the concept of variable binding that has its origin in mathematical logic. (Note that, for example, the relevant interpretation of (a) is not expressible by replacing the pronominal with its antecedent 'every girl,' since this would result in a different meaning.)

We assume that the interpretation of the VP in (20a) can be captured as in (21) following Partee (1975) and others.

(21) λx is riding x's bike.

The relevance of c-command can be seen by comparing (20a) with (22). Though (22) contains the NP 'every girl' and the pronoun 'her,' (22) cannot be true unless all the boys are riding together on a single bike. The interpretation that might be expected in (22) in analogy to (20a) but which is missing can be paraphrased as 'For every girl, the boys that talked with her are riding her bike.'

(22) The boys who talked with every girl are riding her bike.

The relevance of c-command corroborates the recursive interpretation mechanism that ties syntax and semantics together. Because binding involves the interpretation mechanism (16) operating on the sister constituent of the λ-operator, only expressions c-commanded by a λ-operator can be bound by it. In other words, an antecedent can bind a pronoun only if the pronoun is in the scope of its λ-operator.

3. Syntax–Semantics Mismatches

3.1 Subject Quantifiers

When we consider the semantics of quantifiers in more detail, it turns out that the view that predication in syntax and functional application in semantics have a one-to-one correspondence, as expressed above, is too simple. Consider example (23) which is repeated from (1).

(23) Every boy is holding a block.

Assume that the verb phrase 'is holding a block' is a one-place predicate that is true of any individual who is holding a block. Our expectation is then that the interpretation of (23) is achieved by applying this predicate to an individual who represents the interpretation of the subject 'every boy.' But some reflection shows that this is impossible to accomplish—the only worthwhile suggestion to capture the contribution of 'every boy' to sentence meaning by means of one individual, is that 'every boy' is interpreted as the group of all boys. But the examples in (24) show that 'every boy' cannot be interpreted in this way.

(24) (a) Every boy (*together) weighs 50 kilos.
(b) All the boys (together) weigh 50 kilos.

The interpretation of (24) cannot be achieved by applying the predicate that represents the VP meaning to any individual. It can also be seen that predicate modification cannot be used to assign the right interpretation to examples like (24a). The solution that essentially goes back to Frege (1879) and was made explicit by Ajdukiewicz (1935) is that actually the quantificational subject is a higher order function that takes the VP predicate as its argument, rather than the other way round. This interpretation is given in (25):

(25) [every boy] is a function mapping a predicate P to a truth value, namely it maps P to True if P is true of every boy.

Note that this analysis still accounts for the exactly one-argument requirement, which was observed above, because the result of combining the subject quantifier and the VP is a truth value, and therefore cannot be combined with another subject quantifier.

The Frege/Ajdukiewicz account of (23) does, however, depart from the intuition that the verb is predicated of the subject. Note that the semantic difference between quantifiers and nonquantificational NPs does not affect the syntax of English verb–subject relationships. Still in (1) the verb agrees with the subject, and the subject must precede the verb.

3.2 Object Quantifiers

Consider now (26) with a quantificational noun phrase in the object position. We argued in Sect. 2.1.1 that the interpretation of a transitive verb is given by a higher order function that takes an individual as an argument and results in a function that must take another individual as its argument before resulting in a truth value. But then (26) is not interpretable if we assume the Frege/Ajdukiewicz semantics of quantifiers.

(26) John greeted every boy.

From the partial account developed up to now, it follows that 'greet' and 'every boy' should be combined semantically to yield a predicate representing the meaning of the VP. However, the meaning of 'every boy' is a higher order predicate that takes a predicate from individuals to truth values as its argument. But the meaning of 'greet' is not such a one-place predicate.

Any solution to the interpretability problem we know of posits some kind of readjustment process. One successful solution is to assume that before the structure of (26) is interpreted, the object quantifier is moved out of the verbal argument position (see, e.g., Heim and Kratzer 1998). For example the structure shown in (27) is interpretable.

(27) John λx [every boy] λy [x greeted y]

The movement process deriving (27) from (26) is called 'quantifier movement.' Quantifier movement in English is not reflected by the order in which words are pronounced, but this has been claimed to be the case in Hungarian (Kiss 1991).

3.3 Inverse Scope

The original motivation for quantifier movement was actually not the uninterpretability of quantifiers in object position, but the observation that the scope relations among quantifiers are not fixed in all cases. In example (17a) in Sect. 2.2.1, the scopal relation among the quantificational noun phrases was fixed. But consider the following sentence:

(28) A boy held every block.

The example is judged true in the situation in picture A, though there is no single boy such that every block was held by him.

(29)

Picture A

Picture B

The truth of (28) in this situation is not predicted by the representation in (30) that in some way maintains the syntactic constituency of the verb and the object to the exclusion of the subject.

(30) [a boy] λx [every block] λy [x held y]

For this reason, May (1977) and Chomsky (1975) propose to allow also quantifier movement that creates a constituent which includes the subject and the verb but not the object (similar ideas go back to Montague (1970) and Lewis (1972)). This structure is shown in (31).

(31) [every block] λy [a boy] λx [x held y]

Hence, the hypothesis that movement of quantificational noun phrases prior to interpretation is possible (and indeed obligatory in some cases) provides a solution not only for the problem with interpreting object quantifiers, but also for the availability of inverse scope in some examples.

4. Concluding Remarks

Many of the questions reviewed above are still topics of current research. We have based our discussion on the view that syntax and semantics are autonomous, and that there is a mapping from syntactic structures to interpretation. However, recent work by Fox (2000) argues that in some cases properties of interpretation must be visible to the syntax of quantifier movement. As the basic inventory of interpretation principles, we have assumed functional application, predicate modification, and lambda abstraction over variables. Other approaches, however, make use of function composition and more complex mathematical processes to eliminate lambda abstraction (Jacobson and others). In a separate debate, Sauerland (1998) challenges the assumption that movement in relative clauses should be interpreted as involving binding of a plain variable in the base position of movement. While the properties of scope and binding reviewed in Sect. 2.2 are to our knowledge uncontroversial, current work extends this analysis to similar phenomena such as modal verbs, tense morphemes, comparatives and many other topics (Stechow and Wunderlich (1991) give a comprehensive survey).

Research activity on the syntax–semantics interface is currently expanding greatly, as an increasing number of researchers become proficient in the basic assumptions and the formal models of the fields of both syntax and semantics. Almost every new issue of journals such as *Linguistic Inquiry* or *Natural Language Semantics* brings with it some new insight on the questions raised here.

System: Social

A system is a set of differentiated and interdependent components. With such an abstract definition, the notion of system explicitly or implicitly underlies all or most of the theories of the social sciences. It is therefore useful to distinguish three ways of conceptualizing social systems, each one corresponding to a major paradigm. First, the *historicist* paradigm, according to which society constitutes a global system subject to a necessary law of historical evolution; this paradigm was mainly represented by Comte and Marx in the nineteenth century. Second, the *structural-functional* paradigm, according to which a society is a system whose components are the social institutions (the family, religion, etc.); this approach was developed in anthropology by Radcliffe-Brown and Malinowski in the 1930s, and then imported into sociology by Merton and Parsons. Third, the *actionist* paradigm, in which the social systems are constituted by actors and their interactions; one of the main sources of this paradigm is the subjectivist and marginalist revolution that happened in the 1870s in economics.

1. *The Historicist Conception of Social Systems*

According to the historicist conception, society is destined to go through a necessary succession of great historical stages, each of which is a social system. The aim of sociology, then, is to determine the nature of these systems, and especially the historical 'law' governing their succession. Thanks to this historical 'law,' it becomes possible to know the nature of the social system that will appear in the future, the nature of the next great historical stage. What is the use of knowing in advance an inescapable future? Comte and Marx have the same answer: it gives us the power to facilitate and accelerate the advent of the ideal future society, since according to them the future social system will be the ultimate stage in the progress of humanity.

1.1 *Comte and Marx*

In his *positivist* theory, Comte (1824) analyzes the past and future evolution of society as the succession of three great social systems. The *theological* system, first, was represented by the European absolute monarchies: social phenomena were then interpreted in the frame of the Christian religion, the spiritual power was held by the priests and the temporal power by the aristocracy (the sword). Then came the *metaphysical* system ushered in by the French Revolution: social phenomena were interpreted in the frame of the philosophy of the Enlightenment, the spiritual power gave way to freedom of conscience, and the temporal power came into the hands of the people (democracy). According to Comte, this metaphysical system is only transitional. It has a destructive nature and is thus unable to constitute a lasting social order. It will be replaced in the future by the *positive* system, in which sociology will become a 'positive' science (founded, just like modern physics and chemistry, upon observation and invariable natural laws), and in which the spiritual power will be held by the scientists and the temporal power by the producers (the manufacturers). Each social system is thus defined by its 'civilization' (the state of our understanding of social phenomena) and by its 'social organization' (as defined by who holds the spiritual and of the temporal powers). Social organization is here supposed to be determined by the state of civilization, and the latter is determined by scientific progress. Comte believed that this progress obeyed the *law of the three stages*: he thought that

sociology, like the other positive sciences, would appear at the end of a three-stage process ('theological,' 'metaphysical,' and 'positive') through which knowledge is progressively liberated from its animistic and anthropomorphic bias. In this way, the components of each social system and social evolution itself are determined by the progress of knowledge, and this progress is in turn determined by the law of the three stages.

Marx's historicism (1859), or *dialectical materialism*, describes a succession of four 'modes of production' (or social systems), antique, feudal, capitalistic, and socialistic. Each one of these systems is made up of two major components: the 'material productive forces' (techniques, tools, machinery) and the 'production relations' (property laws). The productive forces are supposed to determine the production relations, and also all the other ideological features of society (politics, religion, esthetics, philosophy). Marx illustrated this idea with a famous sentence: 'the hand mill gives you feudal society, the steam mill industrial capitalism' (*Misère de la philosophie* 1847). In a watered-down version of his historicism, Marx (1859, Preface) explains that the succession of these systems is a historical necessity arising from the development of the productive forces (i.e., of the technical capacities of production). Technical and economic progress end up being incompatible with existing production relations. When this contradiction reaches its climax, the production relations are unshackled, and a great social revolution takes place, marking the transition between two modes of production. In *Das Kapital* (1867, Vol. 1), Marx attempts to study in a much more detailed way, with an actionist methodology, the necessary future succession between capitalism and socialism (see Sect. 3 for actionism).

The historicist view was widely held in the nineteenth century. It is to be found in Tocqueville's analysis of the secular transition between aristocratic and democratic society (*De la Démocratie en Amérique*, Vol. 1, 1835). Durkheim, greatly influenced by Comte, attempts to explain in *De la Division du Travail Social* (1893) the necessary transition between the primitive societies, where social cohesion is 'mechanical' (cohesion comes from the similarity between individuals), and modern society, where social cohesion is 'organic' (cohesion arises from the differences between and the complementarity of individuals). In Spencer's historicism (*The Principles of Sociology*, 1891), the historical law of succession between the primitive and modern societies is a law of evolution from a simple to a complex organization, based in part on the biological principles of Darwinism.

1.2 Limits and Errors of Historicism

It is easy today to perceive the limits of historicist theories. From a static point of view, social systems are represented in an oversimplified way, and their internal causal relations are debatable (the alleged primacy of 'civilization' over 'social organization' in Comte, and of 'productive forces' over 'production relations' in Marx). But these theories are especially questionable from a dynamic point of view: regardless of the obvious errors of prediction of a Comte or a Marx, the historicist project may be conclusively refuted with the help of an epistemological argument. Historicist 'laws' are supposed to be the equivalent in the field of social phenomena of physical laws in the field of natural phenomena. But physical laws (for instance, the law of falling bodies) explain *reproducible* phenomena, i.e., phenomena that may be repeatedly observed because they recur a great number of times. Historicist 'laws,' on the other hand, try to explain a *unique* phenomenon, human history. This phenomenon, which happens only once and is definitely not reproducible, cannot be explained by a scientific law in the sense of the natural sciences (Popper 1957). In other words, the claim of historicism to possess a scientific character is completely unfounded. Historicist authors are unable to establish, in a convincing way, the causal relations that are supposed to determine the necessary succession between the great social systems or historical stages (for an analysis of other deep contradictions in the positivism of Comte see Hayek 1952, and in the dialectical materialism of Marx see Mises 1957).

2. The Structural-functional Conception of Social Systems

In the structural-functional paradigm, social institutions are the components of society considered as a system. On the one hand, these institutions play a role in the functioning of society (*functionalism*) and on the other hand are held together by relationships of complementarity that constitute a structure (*structuralism*). The historicist sociologists of the nineteenth century were immersed in a vast process of sociological, economic, and political change. This process seemed to be explainable in terms of a necessary succession of great social systems. The structural-functional paradigm was born in a totally different intellectual context. It originated from the anthropological study of primitive societies, whose long-term history was unknown. As a consequence, this paradigm was completely severed from the most questionable aspect of historicism, namely the search for a global historical 'law' of succession between great social systems.

2.1 Society as a Functional System

As formulated by anthropologist Radcliffe-Brown (1935), the basic idea of functionalism is that in a given society, every institution, every social process, every

cultural form possesses a 'function,' i.e., it plays a definite and even indispensable role in the survival and perpetuation of this system. This reasoning is borrowed from biology, where each organ plays a necessary role in the survival of the organism. Faced with a social institution, whatever it may be, the social scientist is supposed to establish its function from the standpoint of the global system constituted by society. For instance, Radcliffe-Brown explains the existence of ancestor worship in traditional societies by the function of strengthening solidarity: thanks to these rites, individuals learn that they can count on the magical help of their forebears, and also that they must submit to the traditional rules. A narrower conception of functionalism was offered by Malinowski (1944). According to him, the economic, educational and political institutions of a society have the function of satisfying—directly or indirectly—the 'primary' needs related to the biological survival of individuals (food, medical care, reproduction). These primary needs give birth to 'derivative' needs. Satisfying the need for food, for instance, implies a cooperation between the members of society. Since this cooperation requires rules of conduct, these rules themselves become a need, but an 'indirect' one in the sense that it is derived from a primary need.

Functionalism was then imported into the sociology of complex societies by Merton (1949). His *functional analysis* is more qualified than the basic or 'absolute' functionalism developed by the anthropologists of traditional societies. Merton begins by distinguishing the functions that are 'manifest' (i.e., deliberately sought for or designed by the actors taking part in the system) and the functions that are 'latent' (i.e., those that play a role unknown to the participants in the system). The function of the cult of the ancestors according to Radcliffe-Brown is an example of a latent function. Merton then observes that in modern societies some institutions can be functional for a given group, and at the same time dysfunctional for another group (a technical advance, for instance, can increase the average productivity of labor, but also create a redundancy in some branches of production and compel some workers to search for a new job). A modern society, considered as a system, shares none of the 'functional unity' of biological organisms. Furthermore, some institutions or customs may not have any function. Finally, Merton criticizes the idea that there exist a certain number of functions that are necessary to the survival of any society, and that the same specific institutions would be indispensable to perform these functions across all societies.

2.2 The Structure of Social Systems

The conception of society as a functional system of institutions leads quite naturally to an analysis of *social structure*, that is, to an analysis of the complementarity of these institutions. A famous illustration is given by Parsons (1951). He observes that a highly industrialized society requires actors to be socially and geographically mobile. But this mobility is possible only if the actors are not too closely connected to their parents: there must be a clear-cut separation between an actor's 'orientation' family (where he or she was born) and the 'procreation' family (the one created by his or her marriage). If we follow this reasoning to its logical conclusion, industrialization is seen to be incompatible with powerful and extensive traditional family ties. Those two components—industrialization on the one hand and the separation between orientation and procreation families on the other—constitute a consistent social structure typical of modern societies. Conversely, the absence of industrialization and extensive and powerful family ties are the components of another stable social structure, typical of traditional societies. This example shows how the existence of one institution can imply the existence of another institution, their combination representing a stable and coherent social structure.

In anthropology, with Lévi-Strauss (1958), the study of social structure became a *structuralism* based largely upon linguistics. Lévi-Strauss realized that in traditional societies kinship relations (brother/sister), (husband/wife), (uncle/nephew), (father/son) constitute a system characterized by a law of opposition. If, in a given society, the relations between a brother and his sister are generally 'good' (friendly), then (husband/wife) relations are 'bad' (reserved or hostile); in the same way, if (uncle/nephew) relations are 'good,' then (father/son) relations are 'bad,' or vice versa. The system of kinship (brother/sister)(husband/wife)/(uncle/nephew)(father/son) can thus exist in only four structures in the different societies: '+ −/+ −,' '+ −/− +,' '− +/+ −,' or '− +/− +.' The first of these structures, '+ −/+ −,' means that (brother/sister) relations are good, as symbolized by the '+' sign, (husband/wife) relations are bad, '−' sign, (uncle/nephew) relations are good, and (father/son) relations are bad.

This law of opposition, in which relations take precedence over the components they relate, is perfectly similar to the law that had been previously discovered by the linguists N. S. Troubetzkoy and R. Jakobson in the area of structural phonology (these authors showed that language as a communication system rests on a law of opposition between the phonemes).

2.3 The Explanatory Limits of Structural-functional

This paradigm has been criticized mainly for its lack of explanatory power. In principle, the 'absolute' functionalism of a Radcliffe-Brown or a Malinowski permits us to explain the existence of an institution by the role it plays in the working and thus in the

existence of a given society. But the more qualified conception of functionalism to be found in Merton does not enable us to explain the existence of an institution by its latent function, since this institution or function is not considered as a functional requisite of the society anymore. The existence of an institution, then, can only be explained with the help of a 'genetic' analysis consisting of the study of the historical origin of this institution. Two important criticisms have been aimed at structural-functional from an actionist viewpoint by Homans (1987): first, this paradigm takes for granted the actors' obedience to social rules, and does not explain why the actors choose to follow these rules; second, the existence of social structures is also taken for granted, and no explanation is offered as to how these structures emerge from social interaction.

3. *The Actionist Conception of Social Systems*

The actionist paradigm aims at discovering the causes of social phenomena in the *actions* of individuals, and more precisely in the combination of these actions (e.g., see *Action, Theories of Social*; *Methodological Individualism in Sociology*). Social systems are defined as systems of actions or of interactions, from the smallest (two actors) to the largest ones (for instance, the international division of labor). In this paradigm, individual actions are generally considered as rational. This rationality may be utilitarian (appropriateness of means to ends), cognitive (rationality of positive beliefs, i.e., of factual propositions), or axiological (rationality of normative beliefs). The focus of attention, here, is neither on the global evolution of society (historicism), nor on social institutions seen from the standpoint of their functional role and of their mutual relationships (structural-functional), but on human action: social phenomena are considered as emergent and possibly unintentional effects whose causes are actions constituting a system. The actionist paradigm is widely used in economics as well as in sociology. It is quite old since it implicitly underlies, for instance, the works of a classical economist like A. Smith (*An Inquiry into the Nature and Causes of the Wealth of Nations*, 1776). Its importance was reinforced in the 1870s by the marginalist and subjectivist revolution that took place in economics. This revolution consisted of a much more rigorous analysis of human choices and actions in an environment characterized by the scarcity of goods, and made possible the development of really satisfying theories of prices and interest rates.

3.1 *The Systems of Economic Exchange*

The most simple system of exchange is composed of two actors, either of which possesses a good and decides or refuses to exchange it against the other good, according to his or her subjective preferences. For an exchange to take place, the good supplied must have less subjective value than the good demanded (and this is true of each of the two actors). This system can be generalized to a market comprising many sellers and buyers trading one good for another. It may then be generalized to a whole economic system made up of a great numbers of markets. In the tradition originating in L. Walras (*Éléments d'Économie Politique Pure*, 1874), the representation of a global economic system rests on the concept of *general equilibrium*. In a situation of general equilibrium, all the actions of all the actors on all the markets are compatible with one another: they can all be carried out without any actor feeling any regret or disappointment. Thanks to a mathematical formalization of the subjective preferences of the consumers and the possibilities of production of the producers, the existence of a general equilibrium can be logically demonstrated: under some conditions, there exists a set of prices of consumer goods and factors of production such that all the actions of buying and selling are compatible (Arrow and Hahn 1971). This theory is rather complex from a mathematical point of view, and it suffers from two main defects: it does not demonstrate that the system converges towards a general equilibrium, and it does not take into account the radical uncertainty of the future.

In another school of thought, the Austrian school (Mises 1949), the focus is on *market processes*. Economic analysis here focuses on the consequences in the economic system of a change in one of its elements. If, for instance, the consumers change their preferences and decide to spend more than before on good *A* and less on good *B*, the demand for *A* rises and its price tends to rise. The rate of profit also tends to rise in the branch of production of good *A* (since the price of this product rises when its costs of production remain the same). If this rate of profit becomes higher than the current rate of profit, more resources will be invested in the production of good *A*. Two consequences follow: first, the demand for the factors of production of *A* will rise and thus the prices of these factors will tend to rise; and second, the supply of *A* will increase and thus its price will tend to diminish. In this way, the rate of profit in the branch of production of *A* is brought down to the current level (since the price diminishes and the costs rise). Conversely, as the demand for *B* and its price are lowered, the rate of profit falls below the current level, and a disinvestment occurs. Demand for the factors of production of *B* decreases, resulting in lower prices. As a consequence, the supply of *B* tends to drop and its price to rise. As a consequence, the rate of profit in the production of *B* is brought back to the current level (the price rises and the costs diminish). A first adaptation of the economic system to the change of demand is thus achieved: the branch of production of *A* expands and the branch of *B* contracts. But the changes are not restricted to these

two branches of production. To the extent that the demand for the factors of production of *A* or *B* (and for the factors of production of these factors) is also changed, the changes diffuse throughout the system and a new balance between the various branches of industry is established. It is possible to study in the same way the diffusion of the effects of a technical advance, or of a variation in the supply of a natural resource, in the quantity of money, in savings, and so on.

3.2 The Actionist Systems in Sociology

The actionist tradition in sociology was born in Germany at the end of the nineteenth century. Weber (1956), for instance, developed a 'comprehensive' method, which consists of trying to understand actions from the point of view of the actors themselves. This method constitutes a generalization of the analysis of human choices derived from the subjectivist revolution of the 1870s in economics. The German sociological tradition had a major influence on sociology in the twentieth century, for instance through the 'interactionist' approach (e.g., see *Interactionism, Symbolic*). The use of actionist systems enables us to explain in a convincing way a number of important and puzzling phenomena. Boudon (1973) has thus explained 'Anderson's paradox' in the field of sociology of education. From the 1960s on, an important democratization of schooling took place, as the proportion of children of low socioeconomic status increased in the colleges and universities. Since future social status is strongly related to academic achievement, vertical social mobility was expected to increase in developed countries. But, and this is the paradox, it didn't. In spite of a reduction of this inequality, social mobility was not greater than before. Boudon showed that this paradox could be explained due to an actionist system based on the motivations and choices of individuals. Many other examples could be taken from the various fields of sociology (see Boudon 1979 for a survey).

4. The General System Theory

In the 1940s, Bertalanffy (1968) began to develop a 'general system theory,' aiming at transcending the frontiers between a wide range of disciplines—physics, chemistry, biology, psychology, and the social sciences. His basic idea was that the systems analyzed in these different branches of learning share a number of features that can and should be the subject of a science of systems as such. But if it is admitted that the aim of science is to find satisfactory explanations of important phenomena, then the analogies that can be discovered between the systems originating from different branches of science do not matter very much. These analogies can constitute genuine scientific contributions only if they suggest new ways of explaining phenomena, or if they improve the existing explanations. Structural anthropology (Lévi-Strauss 1958) is a good example of a set of theories that originated from an abstract theory of the structure of systems (see Sect. 2 above), but it is an exception. Most of the time, the study of social systems can dispense with a general science of systems (obviously, the opposite is not true).

Systems Modeling

The term 'system' has many uses. Within the social sciences, one finds it used in several combinations such as: behavioral system, response system, neural system, social system, structural system, functional system, systems therapy, developmental system, cognitive system, etc. It is difficult to provide a general definition of 'system' which would be clear and distinct, covering the manifold uses of the term. The definition given in Klir (1991) is: a system is comprised of a set of things, together with a set of relations defined between these things. According to Klir, the traditional sciences can be understood as being concerned with things, whereas general systems science is concerned with systemhood as reflected by generalized relationships between things. Klir adds an important qualification—a system is not to be considered as a natural category but as a convenient cognitive construction.

A number of fundamental characteristics of systemhood in the social and biological sciences will be discussed. These characteristics concern general types of relationships, in conformance with Klir's (1991) definition. In contrast, specific relationships can be of any kind, like semantic relationships in cognitive systems, associative relationships in behavioral systems, synaptic relationships in neural systems, etc. From a general perspective, such specific relationships can each be conceived as a mapping in an abstract space, where this space is spanned up by generalized coordinates indexed by location and time. In this abstract setting, location-like relationships involve geometrical patterns and forms, timelike relationships involve dynamic regimes, and relationships involving both location and time pertain to spatiotemporal patterns. In this article, only timelike relationships can be considered in detail. However, much of the discussion generalizes rather straightforwardly to spatial and spatiotemporal aspects of systemhood.

Perhaps the most basic characteristic of systemhood is stability. Stability is a multifaceted characteristic. On the one hand, it pertains to the relationships of a system with its environment, how a system reacts to external inputs. This is the more classical variant of stability in which various types of equilibrium are distinguished, associated with distinct dynamic responses to environmental perturbations. On the other hand, stability characterizes the internal relationships between components of a system, how these relationships accommodate to endogenous changes. This more modern variant of stability concerns the changes in within-system types and number of equilibria under slow (so-called adiabatic) variation of system parameters. In between these classical and modern variants of stability we find equilibrium concepts associated with dynamic game theory.

In what follows the focus will be on a modern conceptualization of stability. That is, a consideration of qualitative changes in the equilibria of systems due to slow continuous variation of system parameters. Modern approaches to stability include much more than this; for instance, the recently discovered new equilibrium types (strange attractors associated with deterministic chaotic dynamic regimes). But attention will be restricted to qualitative changes in equilibria, because this has more definite implications for the social and behavioral sciences. A general theory of sudden qualitative changes, including methodological guidelines and some applications, will be outlined.

Another important characteristic of systemhood, closely related to stability, is homeostasis. The reason why it is considered separately is because in theoretical treatises the ubiquity of homeostatic processes in neurological and physiological systems is often emphasized, yet in actual empirical research it is equally often neglected. It will be shown, to the best of our knowledge for the first time in the social scientific literature, what are the expected consequences of homeostasis for empirical studies of, for instance, the biological bases of personality and behavior.

The final characteristic of systemhood to be considered is difficult to summarize with a single label. The characteristic concerned is related to the well-known slogan: 'The whole is more than its parts.' This slogan could be elaborated as a new logic of part–whole relationships for general systems, but that is not our present endeavor. Yet the possibility of a whole transcending its constituent parts also bears on a number of fundamental issues such as unity, individuality, and other questions concerning the lack of comparability of systems that are composed of the same parts, but may differ at some higher level. In the closing sections it will be shown that taking the individuality of systems seriously leads to entirely new psychometric concepts and to a vindication of the so-called Developmental Systems paradigm.

1. *Statistical Systems Modeling*

To provide a proper setting for the discussion of characteristics of systemhood, a preliminary overview of statistical systems modeling will be given. For this purpose a canonical representation of systems, the so-called state–space model, is introduced. This canonical

state–space model will only be used for the purpose of clarification. There exists an extensive literature on system identification, parameter estimation and hypothesis testing (cf. Elliott et al. 1995) which can be consulted for further details.

The state–space model concerned is defined as:

$$\mathbf{s}_i(t+1) = \mathbf{f}_i[\mathbf{s}_i(t), \boldsymbol{\theta}_i(t), t] + \mathbf{w}_i(t+1) \quad (1a)$$

$$\mathbf{y}_i(t) = \mathbf{h}_i[\mathbf{s}_i(t), \boldsymbol{\theta}_i(t), t] + \mathbf{v}_i(t) \quad (1b)$$

In Eqn. (1a) $\mathbf{s}_i(t)$ denotes the state of system i at time t, a vector-valued (hence bold-faced) latent (i.e., not directly observed) process. The difference equation (1a) expresses the dynamics of the state process of system i: $\mathbf{s}_i(t+1)$ is related to $\mathbf{s}_i(t)$ by some function $\mathbf{f}_i$, where $\mathbf{f}_i$ also may depend on time t as well as on a vector-valued parameter $\boldsymbol{\theta}_i(t)$. The latter parameter $\boldsymbol{\theta}_i(t)$ itself may vary in time. The remaining term $\mathbf{w}_i(t+1)$ in Eqn. (1a) denotes random variation in $\mathbf{s}_i(t+1)$ which cannot be predicted on the basis of $\mathbf{f}_i$. In Eqn. (1b) $\mathbf{y}_i(t)$ denotes the observed (manifest) vector-valued process of system i at time t. The function $\mathbf{h}_i$ expresses the dependence of $\mathbf{y}_i(t)$ on the state $\mathbf{s}_i(t)$, where $\mathbf{h}_i$ also may depend on time t as well as on the parameter $\boldsymbol{\theta}_i(t)$. The remaining term $\mathbf{v}_i(t)$ in Eqn (1b) denotes random measurement error.

The state–space model Eqn. (1) is quite general, although an even more general definition could be given. But for our present purposes Eqn. (1) suffices. Through additional specifications, many well-known types of process models are obtained as special instances of Eqn. (1). These specifications mainly concern the measurement scales of the state process $\mathbf{s}_i(t)$ and manifest process $\mathbf{y}_i(t)$, which each can be metrical or categorical; the forms of $\mathbf{f}_i$ and $\mathbf{h}_i$, which can be linear or nonlinear, and the distributional assumptions characterizing $\mathbf{w}_i(t)$ and $\mathbf{v}_i(t)$. Furthermore, the time index in Eqn. (1) can be defined as real-valued instead of integer-valued. Some well-known process models which can be obtained as special instances of Eqn. (1) are the hidden Markov model, the generalized linear state–space model, and the doubly stochastic Poisson model. Statistical analysis of Eqn. (1), in particular parameter estimation of $\boldsymbol{\theta}_i(t)$, can be accomplished according to a uniform Maximum Likelihood technique involving a combination of recursive filtering and the Expectation-Maximization algorithm (cf. Molenaar 1994).

In what follows we will often consider the linear state–space model, a special case of Eqn. (1). Let $\mathbf{s}_i(t)$ and $\mathbf{y}_i(t)$ be metrical processes, $\mathbf{f}_i$ and $\mathbf{h}_i$ be linear functions, and $\mathbf{w}_i(t)$ and $\mathbf{v}_i(t)$ be Gaussian processes. Denoting the linear functions $\mathbf{f}_i$ and $\mathbf{h}_i$ by, respectively, the (q, q) dimensional matrix $\mathbf{F}_i[\mathbf{s}_i(t), \boldsymbol{\theta}_i(t), t]$ and the (p, q) dimensional matrix $\mathbf{H}_i[\mathbf{s}_i(t), \boldsymbol{\theta}_i(t), t]$ yields:

$$\mathbf{s}_i(t+1) = \mathbf{F}_i[\boldsymbol{\theta}_i(t), t]\mathbf{s}_i(t) + \mathbf{w}_i(t+1);$$
$$\mathbf{y}_i(t) = \mathbf{H}_i[\boldsymbol{\theta}_i(t), t]\mathbf{s}_i(t) + \mathbf{v}_i(t) \quad (2)$$

where $\mathbf{s}_i(t)$ is the q-variate factor or state process of system i at measurement occasion t, $\mathbf{F}_i$ is the matrix of autoregression coefficients relating $\mathbf{s}_i(t+1)$ to $\mathbf{s}_i(t)$, and $\mathbf{H}_i$ is the matrix of loadings at t. Specific version of this linear model underlie both longitudinal factor analysis (Jöreskog 1979) and dynamic factor analysis of time series (Molenaar 1994). Statistical analysis of Eqn. (2) proceeds as for Eqn. (1), although the linear state–space system Eqn. (2) allows for an analysis using standard structural equation modeling techniques.

2. System Stability

Modern concepts of system stability characterize the ways in which the internal relationships between the components of a system react to endogenous parametric changes in $\boldsymbol{\theta}_i(t)$. The analysis of this so-called structural stability constituted a milestone in the nonlinear dynamics paradigm which was initiated by three scientific theories: catastrophe theory, non-equilibrium thermodynamics, and synergism. Despite differences between the three theories, they share a basic focus on the explanation of structural stability and self-organization in nonlinear systems.

Consider a system S that can vary along n dimensions. Take, for instance, a network of n artificial neurons, where the activity of each neuron constitutes a dimension along which the network can vary in time. Then the state of S at each time point is described by an n-dimensional vector $\mathbf{s}_S(t)$ composed of the configuration of activity values along the n dimensions. Moreover the set of all possible values of the state across all time points constitutes the state space. Some states, i.e., some locations in state space, are special in that the system stays there if there are no perturbations. These special states are the equilibrium states of the system. From a geometrical point of view each equilibrium state acts as an attractor for those fluctuating states that are located in its domain of attraction in state space. Hence the set of equilibrium states yields a qualitative characterization of S in that it induces an organization of the state space in the form of a geometrical structure of domains of attraction.

The time-dependent changes of S are described by an n-dimensional evolution equation like Eqn. (1) in which the parameter $\boldsymbol{\theta}_S(t)$ is associated with the strength of the connections between each pair of neurons. It is a defining characteristic of $\boldsymbol{\theta}_S(t)$ that it changes in time at a much slower rate than the rate of change of the state $\mathbf{s}_S(t)$. Moreover the standard assumption is that the slow time-dependent changes of $\boldsymbol{\theta}_S(t)$ are smooth, i.e., without sudden jumps.

The equilibrium states of S are defined as the states for which the rate of change as described by Eqn. (1) is zero. Consequently, the equilibrium states constitute the roots of Eqn. (1). As Eqn. (1) depends upon $\boldsymbol{\theta}_S(t)$, it follows that the equilibrium states of S also depend

upon $\boldsymbol{\theta}_S(t)$. Hence it is evident that the set of equilibrium states will change if $\boldsymbol{\theta}_S(t)$ changes. The important question in assessing structural stability is, in what way these equilibria will change. More specifically, given that $\boldsymbol{\theta}_S(t)$ changes in a slow and smooth way, does this cause the set of equilibrium states to change in a similar slow and smooth way? It turns out that this depends upon the functional form of Eqn. (1): if $\mathbf{f}_S[\mathbf{s}_S(t), \boldsymbol{\theta}_S(t), t]$ is a linear function than smooth variation of $\boldsymbol{\theta}_S(t)$ always causes smooth changes in the set of equilibria of S (i.e., smooth changes in the topological pattern of domains of attraction in its state space). But if $\mathbf{f}_S[\mathbf{s}_S(t), \boldsymbol{\theta}_S(t), t]$ is a nonlinear function then smooth variation of $\boldsymbol{\theta}_S(t)$ can give rise to abrupt qualitative changes in the set of equilibria of S which can be likened to sudden earthquakes that completely reorganize the existing topological pattern of domains of attraction in its state space. That is, existing equilibria may disappear or change in character, and new types of equilibria may suddenly emerge. Such abrupt qualitative changes in the equilibria as a result of smooth parameter changes are called bifurcations (in mathematics), phase transitions (in physics), or stage transitions (in biology and psychology).

It might seem that a bifurcation originates from the smooth variation of the system parameter $\boldsymbol{\theta}_S(t)$. But that can only be so in a restricted sense because smooth parameter variation belongs to a different category than the sudden qualitative changes characterizing a bifurcation. Smooth parameter variation is necessary for a bifurcation to occur, but it is not sufficient. Moreover, the action of the parameter variation in $\boldsymbol{\theta}_S(t)$ is nonspecific in that the process according to which it varies does not determine the kind of qualitative changes of the equilibria of S during a bifurcation. Hence parameter variation is not a formative cause of the ensuing bifurcation. In contrast, it is the dynamical behavior of S, described by $\mathbf{f}_S$, that constitutes the true formative cause of the abrupt qualitative changes in its equilibrium states. The dynamical behavior of S defines a trajectory in the same state space to which also the equilibrium states of S belong. Hence the reorganization of the topographical pattern of domains of attraction in state-space associated with a bifurcation constitutes self-organization, i.e., it is due to the formative action of the dynamics of S itself.

Analysis of structural stability of systems like S shows that nonlinear dynamical systems have the capacity to self-organize: the existing organization of their dynamical behavior transforms into qualitatively new organizations with emergent properties. This is a general mathematical result that in principle applies to any nonlinear dynamical system. In the context of developmental systems it is evident that the mathematical theory of structural stability and self-organization matches the characteristics of epigenetic processes. Epigenesis is the context-dependent unfolding of genetic control of development. In theoretical accounts this context-dependent unfolding of genetic control gives rise to stagewise developmental processes (cf. Molenaar and Raijmakers 2000, for elaboration of this point).

In mathematical analyses of bifurcations it is taken for granted that the details in Eqn. (1) describing a system are known. While this requirement will usually be met in applications in physics, it should be acknowledged that at present such detailed knowledge is lacking for most biological, behavioral and social systems. However, for a class of bifurcations called elementary catastrophes (Gilmore 1981) the analysis can proceed without specification of Eqn. (1). This makes catastrophe theory of unique importance to the analysis of structural stability, self-organization and epigenesis in biology and psychology. Van der Maas and Molenaar (1992) discuss in detail the application of catastrophe theory to the detection and classification of cognitive stage transitions. They present a set of inductive criteria, the so-called catastrophe flags, which provide the necessary methodological tools to establish empirically the presence of genuine stage transitions and to distinguish these from alternative developmental scenarios like sudden changes (spurts) in the level of equilibrium states due, for instance, to changes in environmental influences or the switching on or off of genetic influences. Some applications and elaborations of catastrophe analysis can be found in van der Maas and Molenaar (1992) and Raijmakers et al. (1996).

3. *Homeostasis*

Homeostasis refers to a general principle that safeguards the stability of natural and artificial systems, where stability is understood in its more classical sense of robustness against external perturbations. Homeostasis is a fundamental concept in neuropsychology, psychophysiology and neuroscience (Cannon's thesis). In the behavioral sciences, however, the concept of homeostasis is acknowledged, but it rarely fulfils a prominent role in actual analyses. A noteworthy exception is the monograph by McFarland (1971). Yet the mathematical-statistical theory of homeostasis, in particular optimal control theory of systems with feedback (e.g., Goodwin and Sin 1984), shows that homeostasis has important effects on system behavior and hence should be taken into account in statistical system modeling and analysis. Molenaar (1987) gives an application of optimal control theory to the optimization of a psychotherapeutic process.

A concise illustration is given of some of the effects of homeostasis in applied systems modeling. Homeostasis will be defined as negative feedback control (McFarland 1971). It is shown by means of a simple computer simulation that the presence of homeostasis has profound effects on measured intercorrelations

between the behavior of coupled systems. Although the systems are strongly coupled, the manifest intercorrelations between their behavior approaches zero as a direct function of the strength of homeostasis. This has noteworthy implications for applied behavioral systems analysis. Consider, for instance, the long-standing research tradition investigating the biological basis (a physiological system) of personality (a behavioral system). Both systems are assumed to be coupled, but both have also to be considered as being homeostatic. The homeostatic nature of the coupled physiological and behavioral systems investigated in this research tradition therefore can be expected to yield biased measures of their coupling (i.e., intercorrelations close to zero), whereas the actual strength of this coupling may be considerable.

The illustrative simulation study is based on a simple instance of the linear state–space model in Eqn. (2). Only a single set of two coupled systems is considered, hence the subscript i can be dropped in the defining equations. To simplify matters further, it is assumed that the state $\mathbf{s}(t)$ is observed directly, hence the matrix $\mathbf{H}$ is taken to be the identity matrix and the measurement noise $\mathbf{v}(t)$ is absent. Denoting the unidimensional state process of system 1 (e.g., the behavioral system) by $s_1(t)$ and the unidimensional state process of system 2 (e.g., the physiological system) by $s_2(t)$, this yields:

$$\begin{aligned} s_1(t+1) &= f_{11}s_1(t)+f_{12}s_2(t)+w_1(t+1) \\ s_2(t+1) &= f_{21}s_1(t)+f_{22}s_2(t)+w_2(t+1) \end{aligned} \tag{3a}$$

In Eqn. (3a) $f_{12}s_2(t)$ denotes the influence of the physiological system on the behavioral state process $s_1(t+1)$, where f_{12} is the strength of this coupling; $f_{21}s_1(t)$ denotes the reverse influence of the behavioral system on the physiological state process $s_2(t+1)$.

The system Eqn. (3a) does not include homeostasis. In contrast, the following analogue of Eqn. (3a) includes homeostasis:

$$\begin{aligned} s_1(t+1) &= f_{11}s_1(t)+f_{12}s_2(t)+c_1[s_1(t)]+w_1(t+1) \\ s_2(t+1) &= f_{21}s_1(t)+f_{22}s_2(t)+c_2[s_2(t)]+w_2(t+1) \end{aligned} \tag{3b}$$

In Eqn. (3b) $c_1[s_1(t)]$ and $c_2[s_2(t)]$ denote optimal feedback functions which depend on a number of additional parameters that are not displayed explicitly. Molenaar (1987, and references therein) presents a complete description of the computation of these optimal feedback functions.

To assess the effects of homeostasis on the manifest correlation between $s_1(t)$ and $s_2(t)$, time series are generated according to Eqns. (3a) and (3b). This requires that numerical values are assigned to the system parameters in both Eqns. (3a) and (3b). For instance: $f_{11} = 0.6$, $f_{12} = 0.4$, $f_{21} = 0.4$, and $f_{22} = 0.7$. In addition, $c_1[s_1(t)]$ is taken to be zero (only the physiological system 2 in (3b) includes homeostasis). It is then found that the manifest instantaneous intercorrelation between $s_1(t)$ and $s_2(t)$, as determined for a realization of $T = 100$ time points, is 0.85 for Eqn. (3a) and 0.15 for Eqn. (3b). This shows clearly that the intercorrelation for Eqn. (3b), that is when homeostasis is present in the physiological system 2, is substantially biased towards zero and does not reflect the strength of the coupling between the two systems without homeostasis present.

The same result (substantial underestimation of the actual coupling strength by the manifest intercorrelation between coupled systems in case homeostasis is present) is found under all other possible scenarios (negative coupling between systems without homeostasis, homeostasis present in both systems, etc.). This general result also can be proven by means of mathematical-statistical methods. It is concluded that homeostasis has substantial biasing effects on manifest measures of system coupling, even in simple linear systems such as considered above.

4. *Wholeness and Individuality*

The slogan that the whole is more than its parts implies that distinct systems may each be composed of the same set of components, yet still be different from each other in their global characteristics of systemhood. Another way to state this point of view is that the unity characterizing each system gives rise to emergent characteristics, and thus to individuality.

To investigate the individuality of a given system i, it is required to observe its time-dependent behavior $\mathbf{y}_S(t)$, $t = 1, 2, \ldots, T$, at T consecutive time points (where, to simplify the discussion, consecutive time points are taken to be equidistant). Hence S is fixed and the time interval from $t = 1$ to $t = T$ is conceived of as a sample from the time axis. With regard to Eqn. (1) and Eqn. (2), this implies that $i = S$ is taken to be fixed, whereas statistics and parameter estimates are determined by taking appropriate averages over time points, and consecutively are generalized to the whole time axis (prediction and retrodiction). Henceforth this ($N = 1$ time series) design will be called an analysis of intra-individual variation (IAV).

If a set (population) of systems can be taken to be homogeneous in all relevant aspects, then their time-dependent behavior can be analyzed in the following way: take a sample of N systems from the set and observe the time-dependent behavior $\mathbf{y}_i(t_j)$, $i = 1, \ldots, N$ of this sample at a fixed set of time points t_j, $j = 1, \ldots, J$. Hence, with regard to Eqns. (1) and (2) the J time points are fixed, whereas statistics and parameter estimates are determined by taking appropriate averages over systems, and consecutively are generalized to the whole set or population of systems. Henceforth this (longitudinal) design will be called an analysis of inter-individual variation (IIV).

The particular aspect of wholeness and individuality of systems which will concern us in this section can now be stated more specifically as: under which circumstances and conditions will a longitudinal analysis of IIV yield results that are qualitatively the same as a time series analysis of IAV? This question can be raised with respect to all known techniques of statistical analysis, like analysis of variance, regression analysis, factor analysis, etc. In what follows, only factor analysis is considered in the context of the linear model in Eqn. (2), leading to the particular question: given that $\mathbf{y}$ consists of a fixed set of manifest variables (e.g., psychological test scores), under which circumstances will a longitudinal factor analysis of $\mathbf{y}_i(t_j)$ yield results that are qualitatively the same (same number of latent factors, same pattern of factor loadings, etc.) as a dynamic factor analysis of $\mathbf{y}_S(t)$? For more extensive elaboration of this issue, the reader is referred to Molenaar et al. (2001).

The mathematical-statistical ergodicity theory is of direct relevance to this question. Ergodicity is a basic concept in statistical mechanics and equilibrium thermodynamics (e.g., Cornfield et al. 1982). Consider a closed domain containing a pure gas, where each gas molecule traverses a path or trajectory according to standard dynamical laws. The totality of these time-dependent trajectories of all gas molecules within the domain constitutes an ensemble (comparable with the concept of population in statistics). The dynamics of this ensemble is called ergodic if statistics like the mean velocity determined by following a single molecule in time is (asymptotically) the same as the mean velocity determined by averaging across all molecules at a fixed point in time. Notice that this closely parallels the basic issue under consideration: a process is ergodic if analysis of its IAV yields the same results as an analysis of its IIV. In contrast, if a process is nonergodic then this equivalence no longer holds. A heuristic criterion for ergodicity which applies in many cases is that the mean, variance and covariance associated with an ergodic process are invariant in time. With respect to Eqn. (2) this ergodicity criterion implies that $\mathbf{F}_i[\boldsymbol{\theta}_i(t), t] = \mathbf{F}_i[\boldsymbol{\theta}_i]$ and $\mathbf{H}_i[\boldsymbol{\theta}_i(t), t] = \mathbf{H}_i[\boldsymbol{\theta}_i]$, i.e., these matrices (as well as the parameter vector $\boldsymbol{\theta}_i$) have to be invariant in time.

The ergodicity question is an important issue in theoretical discussions in developmental psychology (cf. Molenaar et al. 2001). If developmental psychology is conceived of as the study of ontogenetic trajectories across the lifespan, then the life history of each individual subject constitutes a path in some high-dimensional state–space, while a population of subjects defines an ensemble of such age-dependent paths. The theoretical debate concerns the question whether the pattern of IIV within such an ensemble of life histories at some point in time contains sufficient information to arrive at valid causal explanations of the pattern of IAV characterizing the time course of each individual life history (cf. Wohlwill 1973).

The ergodicity question also is relevant to the foundations of psychometrics. Standard (longitudinal) factor analysis is the classical method to construct psychological tests (Lord and Novick 1968). Now suppose that it has been concluded in a longitudinal factor analysis that a particular psychological test obeys a 1-factor model at each measurement occasion, that the factor loadings stay invariant across measurement occasions, and that the intercorrelations of factor scores between measurement occasions are high. Hence the structure of interindividual variation of the scores on this test is simple: it stays qualitatively the same across measurement occasions and is characterized by high stability. If this particular test is used in a clinical or counseling setting to predict the scores of a single subject belonging to the population from which the longitudinal sample was drawn, can we be sure that this simple structure also characterizes this subject's IAV? More specifically, can we expect to find in a dynamic factor analysis of this single subject's scores also a 1-dimensional dynamic factor which stays qualitatively invariant in time and has high stability? If the test is measuring a nonergodic process then the answer will be negative.

The consequences of nonergodicity can be observed clearly in classical test theory. Lord and Novick (1968) define the basic concept of true score as the mean of the intraindividual distribution of scores of a fixed subject. Then they remark (Lord and Novick 1968, p. 32): 'The true and error scores defined above are not those primarily considered in test theory. They are, however, those that would be of interest to a theory that deals with individuals rather than with groups (counseling rather than selection).' Next, instead of defining true and error scores for a single fixed person tested an arbitrarily large number of times, true and error scores are defined for an arbitrarily large number of persons tested at one or more fixed times. Hence, instead of focusing on IAV as stipulated by the initial definition of true score, classical test theory is based on IIV. The quote from Lord and Novick given above clearly indicates the restricted nature of results thus obtained in classical test theory.

The standard longitudinal factor model is a special instance of Eqn. (2) in which $\mathbf{F}_i[\boldsymbol{\theta}_i(t), t] = \mathbf{F}[\boldsymbol{\theta}(t), t]$ and $\mathbf{H}_i[\boldsymbol{\theta}_i(t), t] = \mathbf{H}[\boldsymbol{\theta}(t), t]$. That is, these matrices as well as the parameter vector are taken to be invariant across systems (subjects), but may vary in time. Comparison with the heuristic criterion for ergodicity given earlier (i.e., $\mathbf{F}_i[\boldsymbol{\theta}_i(t), t] = \mathbf{F}_i[\boldsymbol{\theta}_i]$ and $\mathbf{H}_i[\boldsymbol{\theta}_i(t), t] = \mathbf{H}_i[\boldsymbol{\theta}_i]$), it is immediately evident that the possible time-dependency of $\mathbf{F}[\boldsymbol{\theta}(t), t]$, $\mathbf{H}[\boldsymbol{\theta}(t), t]$ and $\boldsymbol{\theta}(t)$ in the longitudinal factor model implies the possibility of nonergodicity. Hence in general the structure of IIV as determined in standard longitudinal factor analysis (e.g., test–retest designs) will differ from the structure of IAV as determined in dynamic factor analysis. In particular, psychological tests which have been constructed and normed by means of test–retest factor

analysis will in general yield invalid assessments and predictions in individual counseling. This is a straightforward consequence of classical theorems in ergodicity theory.

It also is evident that the assumptions underlying standard (longitudinal) factor analysis regarding the invariance of the **F** and **H** matrices across systems (subjects) would seem to be a odds with the individuality and wholeness of systems as considered in this section. There is strong theoretical and empirical evidence that in many circumstances systems (subjects) do not obey these strong homogeneity assumptions and instead are heterogeneous, i.e., $\mathbf{F}_i$, $\mathbf{H}_i$ and $\boldsymbol{\theta}_i$ vary across systems i. It can be proven that (longitudinal) factor analysis is in general insensitive to this kind of heterogeneity, despite its incompatibility with the homogeneity assumptions underlying this analysis. This insensitivity has been corroborated in several simulation studies using the following design. An ensemble of individual time-dependent trajectories (life histories) $\mathbf{y}_i(t)$, $t = 1, 2, \ldots, T$, $i = 1, 2, \ldots, N$, is generated according to dynamic factor models with heterogeneous system matrices and parameter vectors varying across systems (subjects). Then (longitudinal) factor analysis is carried out on a sample from this ensemble at one or more fixed time points. The consistent finding then is, that 1-factor (longitudinal) models yield satisfactory fits to these data, while the structure and parameter estimates in the fitted models do not match any of the structures and parameters in the dynamic factor model used to generate the data (cf. Molenaar et al. 2001, for details and references).

5. *Conclusion*

Aspects of systemhood can have profound implications for the modeling and analysis of social, behavioral and biological systems. This has been illustrated by a consideration of three such aspects: structural stability (emergent changes in the geometry of (strange) attractors in state–space), homeostasis (negative feedback inducing underestimation of system coupling), and wholeness (nonergodicity inducing a lack of relationship between analyses of IAV and IIV). Each of these aspects can be underpinned by powerful mathematical-statistical theories and has been studied in extensive simulation studies, showing their manifold effects on system modeling. It is concluded that to accommodate the effects of systemhood in valid ways, advanced time series analysis techniques will prove to be indispensable.

Taboo

A concept assumed in the Victorian period to be central to the religions of supposedly less evolved societies, the term taboo today generally is used to refer to prohibitions grounded in custom or religion rather than in bureaucratic law or common sense and hence bearing some moral weight. Taboos can be widespread, observed over the long term, internalized, and deeply felt, as in the case of incest taboos, or applied temporarily with respect to specific persons, acts, conditions, and objects. This article reviews the history of the concept which can be seen to reflect the development of anthropological theory more generally.

1. Taboos, Social Order, and Moral Persons

The word taboo is originally Polynesian. Via the writings of explorers like Cook and missionaries like Ellis it rapidly entered ordinary usage in Victorian England. In 1842 the 7th edition of the *Encyclopaedia Britannica* defined taboo succinctly as, 'A word used by the South Sea islanders, and nearly of the same import as prohibited or interdicted. It applies equally to persons and things, and is also expressive of anything sacred, devoted, or eminent' (quoted in Steiner 1999, p. 164). In the hands of Robertson Smith and Frazer, taboo came to epitomize the essence of primitive thought, distinguishing it from civilized religion (i.e., the Judaeo–Christian tradition) in the way it combined holiness with defilement. In a deconstructive work equivalent to that which Lévi-Strauss performed for totemism, Steiner admirably summarized and critiqued the use of the term through the first half of the twentieth century, demonstrating the problems with applying a culturally particular concept in a comparative and evolutionary fashion. Steiner showed that it was impossible to separate defilement from the sacred in any consistent manner. Steiner's critique of the abstraction and reification of taboo has been pursued by MacIntyre, while his insights into its significance in Polynesia have been considerably enlarged by Gell, Sahlins, and Valeri.

The most profound reflections on taboo have concerned its universal social basis. Both Freud and Lévi-Strauss have seen the incest taboo as fundamental to the constitution of society. For Freud, internalizing prohibitions against intra-familial violence and sexual relations establishes the conditions for the emergence of kinship and moral conscience. Lévi-Strauss argued that the incest taboo generates inter-familial relations, providing the basis for the exchange of women (or marriage partners of either sex) that in effect constitutes society. Whereas Freud in *Totem and Taboo* emphasized the temporal significance of the incest taboo (whose phylogenetic origin in actual historical events is largely dismissed by anthropologists) and the implications for intrapsychic and intrafamilial relations (which finds broader though not unanimous support), Lévi-Strauss argued that the incest taboo forms the logical basis of society and is rooted in the universal mental capacity to make categorical binary distinctions, notably those between self and other, culture and nature. In an ambitious attempt to unify and critique the theory, Rubin added the injunction against homosexual relations.

It is Lévi-Strauss's emphasis on classification that has most influenced subsequent analyses of taboos and has proved fruitful in understanding their varied and often ostensibly trivial content. Drawing on their common heritage of Durkheim, both Douglas and Leach emphasized the role of taboos in protecting systems of social classification by banning anomalous or marginal words, objects, and practices that might violate the order of the categories or blur their distinctions. The title of Douglas's major work, *Purity and Danger* (1966), captures the crux of her argument perfectly. Dirt, or that which is viewed with revulsion and hence tabooed, is 'matter out of place' and hence always relative to a system of classification but also dangerous for it. Building on Steiner, Douglas argued convincingly that individual taboos can only be understood as parts of larger social wholes; that taboos are not false or failed attempts at science; that Western lives are replete with taboos which are no more or less rational than those of other societies; and that without principles of restriction, conceptual and moral discrimination would be compromised and the ensuing freedom of both thought and action would be hopelessly chaotic.

Douglas's argument has inspired much subsequent work, especially on gender, the body, and food. Among the merits of her approach is the ability to show structural similarities in taboos, whatever their specific content, both within a given society, between societies, and across both ostensibly secular (e.g., hygiene, courtesy) and sacred realms. Somewhat more controversial have been attempts both to illustrate how taboos in various orders of phenomena (notably

diet) reflect concerns with the maintenance of social boundaries and divisions and, at a greater level of abstraction, to plot the degree of general interest in maintaining the purity of classificatory orders against the underlying nature of the social relations (the type of society, relatively defined). Following one strain of Durkheim's thought, Douglas gives primacy to the form and integration of social groupings and thus, despite her radical demonstration of the contingent nature of particular taboos, the argument appears rather conservative. Purity and impurity are not only relative to a system of categories, but this system may also be arranged with respect to a hierarchy of sanctity within a holistic universe, as epitomized by Dumont's account of the South Asian caste system. Ensuing questions about the relationship of sanctity and encompassment to power have been much debated.

While the presence of taboos is universal, their substance and direction are not, giving rise to culturally specific social orders. In some parts of the world, like eastern Indonesia, prescriptive rules are emphasized, while in others, like Madagascar, proscriptions are pervasive (Lambek 1992). Lévi-Strauss demonstrated that specific positive rules of marriage—made possible by the underlying incest taboo—generate certain patterns of relationship over time. Taboos, by contrast, in that they do not specify what must or should be done, allow greater degrees of freedom. Yet, as Fortes argued, they are also grasped more easily and internalized more deeply than positive injunctions.

While taboos usually are analyzed as discursive elements, it is important to understand that they become realized in practice. Often the most consequential taboos are the least explicit. If in a structural model the semantic contents of taboos distinguish who or what one is not, from a practice perspective it is the observance of the taboo that substantiates who one is. Van Gennep saw taboos as acts of obligation, creating both continuity and separation. Fortes emphasized the morally binding quality of taboos and the personal significance of observing them for the internalization of an enduring identity and the acknowledgment of dependence on, and obligation to, higher authorities or values. Moreover, taboos 'crystallize these abstract norms in concrete objects and precise rules of conduct which are the more effective because they are of no utilitarian or rational value' (Fortes 1987, p. 129).

Fortes observed both the essentially inward orientation of taboos, especially with respect to eating, and their continuous nature. An important consequence of the fact that taboos are phrased in the negative is that their observance is a relatively continuous and private form of action, whereas carrying out a positive order is a discontinuous and relatively discrete and public act. Hence while the power entailed in observing a taboo may be less explicit and forthright than a direct command, the implications may be more profound. Defiance of taboo may challenge subjection, identity, and value at quite a deep level.

Taboos, then, are not merely imposed, lifted, or carried out in discrete acts but observed continuously. As practical disposition the observance of taboos exemplifies Mauss's and Bourdieu's notion of the habitus and Aristotelian virtue that underlies it. Although not always accepted happily, taboos index personal dignity and (self-)respect, and insofar as they are embodied statements, they may be understood as acts which performatively establish and maintain moral states of social commitment and individual conscience. Moreover, in the visceral reactions to the violation of taboos (nausea, disgust, etc.), underlying social conventions are naturalized. Hence, as Douglas also intuits, taboos do not merely signify social or cosmological order but, in acts of separation, commitment, and principled refusal, they constitute it.

Taboos may be understood phenomenologically with respect to a dialectic of subject and object. Gell argues that it is through taboos, applied at varying levels of specificity across social categories, and operating as intentional, if negative, engagement with the world, that the ego or self is constituted. 'To observe a taboo is to establish an identifiable self by establishing a relationship (negative in this case—*not* eating) with an external reality such that the "self" only comes into existence in and through this relationship' (1979, p. 136). 'Taboos on eating, on killing, on sexual intercourse, on looking at, touching, etc., together circumscribe a "hole" in the texture of shareable intersubjective reality which, privileged with respect to a specific individual, constitutes his soul, or ego, or personality. Taboo does more than express the self: it constitutes the self' (1979, p. 137). When Gell's argument that taboos carve out the self is combined with Lévi-Strauss' argument that taboos generate exchange and hence society, it is clear that the self is relationally constituted, simultaneously held apart from and connected to others, simultaneously social and itself. There is a dynamic quality here: Umeda of Papua New Guinea alternate phases of taboo and consumption; in Gell's analysis the taboo phase restores the integrity of the ego by 'reconstituting it as a closed system' (1979, p. 146). Elsewhere Gell (1995) generalizes the logic of taboo in its original Polynesian locus where it produced differentiation in a cosmos in which sacredness was immanent rather than transcendental.

2. *Transgression*

One of Freud's central arguments concerned the essential ambivalence of taboos, understood as the coalescence of the conflict between a desire and its refusal, attraction, and repression. It is clear that anticipation or suspicion of the violation of taboos often produces visceral reactions—whether laughter, lust, or queasiness—disgust rather than mere indig-

nation. Moreover, because the embodied practice of powerful taboos goes without saying, their pervasive presence is only highlighted by the observance of violation. That is to say, taboos are often indicated through instances of their transgression, in effect, a double negation. As Douglas, Gluckman, and Turner showed, suitably framed transgressions may provide central episodes in religious experience, moral education, and social transition, but otherwise they are perceived as highly threatening. Transgressions may establish political dissent or domination, but they are also the source and substance of neurotic illness, social panic, and much fantasy.

Stallybrass and White (1986) conjoined these ideas with Bakhtin's notion of the carnivalesque and Elias's history of manners to explore the significance of taboos in the historical constitution of the European middle class. The rigorous expulsion of what was perceived as disorderly, low, and carnal has produced, in their view, various 'returns of the repressed.' These include nostalgia, longing, fascination, and even the academic preoccupation with the body.

While some people continue to argue for a biological basis to the incest taboo (and possibly certain other widespread prohibitions), the increased acknowledgment of the prevalence of actual incestuous relations supports those theories that find the source of taboos in culture or society and human ambivalence. Indeed, the question has been raised whether incest taboos are any longer necessary and whether they have been *de facto* lifted, or at least limited. On another front, the violence and rape characteristic of twentieth-century warfare, and the torture carried out by repressive political regimes, must be recognized. Indeed, these might be viewed as deliberate and state-sanctioned liftings of taboos in order to maximize personal violation. However, due in part to fears of contamination that accompany any discussion of transgression, research has focussed more on the condition of victims than the acts of perpetration.

Of course, the presence of taboos has always generated fantasies of transgression. These are often difficult to distinguish from actual transgressions and at the same time may produce transgressive acts of their own, as in the 'de-repression' characteristic of accusations of witchcraft and child abuse prevalent in recent years in North America and northern Europe but also globally (Comaroff 1997, LaFontaine 1998). The need for moral discernment is not always matched by epistemological clarity, yet the fantasies and acts, characteristic of sites and moments of moral vertigo and vacuum, underline the near universality of disgust in the face of certain kinds of physical and sexual brutality and invasiveness, the universal need for avenues for the exercise of dignified moral agency, and the place of taboos among such means.

Conversely, it could be argued that the preceding discussion suffers from an overly socialized, moralistic, and tame conception of taboos; that negation and excess are central to religious experience; and that transgression be recognized as 'the ultimate sacred act' (Taussig 1998, p. 361).

Tacit Knowledge, Psychology of

Tacit comes from the Latin *tacitus* and translates roughly as *silent*, or *unspoken* and, indeed, the sense of the unverbalized, the unuttered, is still carried by contemporary usage. Usually the Hungarian/British

scholar Michael Polanyi is credited with importing the notion of tacit knowledge into the social sciences and the credit is deservedly his (Polanyi 1962, 1966, Reber 1993a). In Polanyi's framework, tacit knowledge was information that was intensely personal, introspectively opaque, and communicatively unresponsive. It was also, importantly, complex knowledge, abstract in nature, and deeply causal. He wrote of knowing more about familiar conceptual domains than we can tell and characterized his own early life as a creative scientist as being largely a struggle to make tacit knowledge available to consciousness and open to introspection and communication.

Within psychology, this notion of a rich, personal knowledge base with direct causal links to behavior has been around for a long time, surfacing and resurfacing in various forums from the psychoanalytic to the neurocognitive, from the study of perception and learning to models of memory and information storage. The flurry of interest in these issues has spawned a host of synonyms, so much so that Polyani's original term *tacit* is actually rather rare. Preferred lexical entries refer to knowledge that is *implicit* or *unconscious*, occasionally to mental processes that are *nonconscious*, *unaware*, *procedural*, *covert*, and, from time to time, to functions which are *incidental* or *automatic*. However, no matter what cover term is employed, the focus remains on the cluster of perceptual and cognitive processes that function largely independently of awareness of both the processes by which such knowledge was acquired and of the mental representations that result from such learning. In short, *tacit knowledge*, by whatever name enjoys momentary currency, is knowledge that is acquired and used with little in the way of the top-down, modulating control of consciousness. And herein lie the big psychological puzzles. How is complex knowledge acquired largely outside of consciousness? How are memories encoded so that their impact on behavior is manifested by indirect measures while their contents remain largely unavailable to recall and recognition? Is the tacit system merely functionally distinguishable from the more cognitively familiar, consciously modulated systems? Or, as many suspect, are the observed dissociations reflective of deeper neurocognitive systems? Is it possible that explicit, retrievable knowledge systems are linked with biological systems that are evolutionarily distinct from the tacit, implicit systems? Is knowledge that was acquired implicitly superficial knowledge that is tied to the specific form of the stimulus displays, or can such knowledge also be abstract and symbolic?

While work on these questions since the 1970s has touched on virtually every area in modern psychology, it is not unreasonable to distill it down to four classical problems. Not surprisingly, these four are the classical topics that have dominated psychological thought since the nineteenth century: perception, learning, memory, and motivation. The difference is that here an exclusionary clause is invoked, the tacit dimension includes only those processes and mechanisms that operate while remaining more or less impenetrable to top-down, conscious access and control.

As noted above, the cover term *tacit knowledge*, despite its currency in earlier work and its central position in Polanyi's writings, no longer appears in many 'keyword' lists. This is too bad. One of the difficulties with much recent work on the cognitive unconscious is that connotatively loaded terms such as *awareness* and *consciousness* pepper the field and fuel disputes that are often unproductive and unsatisfying. In the following, synonyms will be freely interchanged and attempts will be made to resurrect the core term *tacit*. So, with lexicographic inclusiveness in place, the following are the four primary areas of research.

1. *The Four Primary Areas of Research*

1.1 *Tacit or Implicit Perception*

For the most part, the existence of information pick-up that occurs when the stimulus materials are presented under nonoptimal conditions is a generally accepted phenomenon. The last serious critique of the effect (Holender 1986) was countered by a large number of effective rebuttals and it seems safe to conclude that the acquisition of information about stimulus displays that participants are unaware of perceiving is a robust phenomenon. There is also good evidence that such subliminally perceived representations have emotive elements (Kunst-Wilson and Zajonc 1980). For more detail on this issue, see *Perception without Awareness, Psychology of*.

1.2 *Implicit or Tacit Memory*

Implicitly held memories are, in effect, those memorial residues of experience whose contents affect behavior while remaining largely unavailable for recall or recognition. Such memories show up primarily in indirect tests such as word-stem completion tasks (fill in the blank with the first word that comes to mind: MOT_) where participants reliably complete the task using items previously encountered even though they are unable consciously to recall them. One of the more intriguing findings is that implicit memory is relatively intact in amnesic patients who manifest severely disordered explicit memories. For additional information on this issue, see *Implicit Memory, Cognitive Psychology of*.

1.3 *Implicit or Tacit Learning*

Implicit learning is the process whereby knowledge about complex stimulus domains is acquired largely

without involvement of top-down, conscious control (Reber 1993b). Naturally occurring examples of the operation of implicit learning are language acquisition and the process of socialization. Implicit learning yields implicit or tacit knowledge in that not only is the learner unaware of the process of learning, the very knowledge itself is highly resistant to explication.

This notion that deep, abstract knowledge about a complex stimulus domain can be acquired and represented outside of consciousness is the one that is closest to Polanyi's original use of the term. In Polanyi's framework, tacit, personal knowledge played a critical role in everyday life. Moreover, such communicatively resistant knowledge was also viewed as lying at the very core of creativity. In Polyani's epistemology, to engage in a creative act to struggle to make tacitly acquired and held knowledge conscious and communicable. Doing science, in his mind, was following the urging of one's carefully crafted intuitions and slowly shaping the reservoir of initially unavailable, tacit knowledge out into a communicable form.

1.4 Implicit or Tacit Motivation

The focus here is the exploration of unconsciously held representations. The essential argument, which derives from the classical, Freudian approach, is that unconsciously held knowledge plays its primary role by modifying and adjusting perceptions and memories. This approach goes one step further than the above in that the unconsciously held knowledge in assumed actually to change conscious representations in accordance with deeply held knowledge systems. This use is found primarily in analytically and psychodynamically oriented research where unconsciously held knowledge is presumed to have its impact on behavior through disguised, hidden routes (e.g., Horowitz 1988) although hints of it emerge in more recent work on the development of preferences and aesthetic judgment (Manza and Bornstein 1995).

2. Disputes and Controversies

Perhaps not surprisingly, many of the issues raised in these contexts have proven controversial. It is important to appreciate that most of modern experimental psychology is built on a foundation that goes back to Locke and other British empiricists. This approach, which favored introspection as the primary method of inquiry, equated *mental* with *conscious* and rejected out of hand the notion of a cognitively sophisticated unconscious. Although few appreciate (consciously?) these Lockean roots, many of the arguments being waged over the characteristics of the tacit dimension appear to hinge on the notion that the unconscious, as Polanyi maintained, is just flat-out smart. Specifically, we can consider the following.

2.1 Methodological

It has been argued that the observed implicit–explicit distinction is not an ontological one but merely results from the procedures used to measure participants' awareness of held knowledge (Holender 1986, Shanks and St. John 1994). This argument turns on two points: first, that the measures used to evaluate tacit knowledge are more sensitive than those used to evaluate consciously held knowledge, and second, that no other independent evidence exists to support the distinction. There are good reasons for suspecting that the former is (or was) correct. When more effective methods of inquiry are employed, participants often have shown more awareness of held knowledge than first suspected. Contemporary researchers are much more careful to use more sensitive measures of knowledge held by participants in these studies. The argument, however, appears weaker on the second point. There is a large and growing body of evidence that shows that distinct neuroanatomical substrata are involved in the acquisition and storage of tacit knowledge, specifically structures in the medial temporal lobes. Patients with severe damage in these cortical regions show often devastating episodic memory dysfunctions with little or no disruption in the pick-up and acquisition of tacit knowledge. In addition, there are good reasons for suspecting that the two systems have emerged under distinct evolutionary pressures and have very different evolutionary biological histories (Sherry and Schacter 1987, Reber 1992).

2.2 Functional

The point is often made that there is no 'true' cleavage between tacit knowledge and knowledge held at the edges of consciousness, that the observed dissociations are mere functional adjustments made to particular contexts (Whittlesea and Dorken 1993). The argument here is that participants in standard experimental settings shift from conscious to unconscious modes depending upon the constraints placed upon them and the contexts in which they are required to function. Neither system is the default system and, in fact, they should probably not even be thought of as separate systems but as poles on a continuum running from the deeply tacit to the poignantly conscious. From a functionalists point of view, there is much to recommend in this contention. In all likelihood, most of the interesting things that human beings do on a

routine basis involve a synergistic blend of the conscious and the unconscious, the explicit and the tacit, the overt and the implied. However, recognizing this truth of a complex mind operating in a world of flux misses a basic point. The tacit dimension still needs to be viewed as neurologically and evolutionarily distinct from those processes that are modulated by consciousness. Human consciousness is a late arrival on the evolutionary scene and was preceded by a sophisticated unconscious that functioned without benefit of top-down controlling mechanisms that were open to introspection. They may function interdependently but they are almost surely distinct systems.

2.3 Representational

The dispute here concerns the underlying form of tacit knowledge. Beginning with Polanyi's (strictly nonempirical) work, the presumption was that unconsciously held knowledge had all the rich abstract and symbolic features of knowledge that resided within the spotlight of consciousness. However, many theorists have maintained that the evidence tends to support a more concrete and nonsymbolic representational system (Brooks 1978, Perruchet et al. 1990). Ironically, the problem turns on methodological and functional issues. As has been noted (Manza and Reber 1997), the conditions under which the stimuli are presented seems to be the strongest predictor of the nature of the mental representation. When the inputs consist of large numbers of complex stimuli, participants invariably set up abstract memorial systems which reflect rule-governed qualities. When they consist of simple displays or of small numbers of exemplars, concrete representations abound. Tacit knowledge, like conscious knowledge, most likely can take any of a variety of epistemic forms. The critics of the symbolic are almost certainly correct in that much knowledge held tacitly is concrete and tied to the form of the input stimulus. They are also almost certainly wrong that all tacit knowledge has these features.

2.4 Causal

The dispute here stems from the psychoanalytically motivated claim that tacit knowledge can affect behavior through covert means by disguising the meaning of stimulus displays or adjusting the symbolic content of thoughts, dreams, and fantasies. Of all the purported characteristics of the tacit knowledge system, this one is the most controversial, so much so that it is rarely even mentioned in the cognitive literature (see Erdelyi 1985, 1996 for a singular exception). The problems stem from the assumption of a second level of causal action. Not only must the tacit system be capable of representing complex, symbolically rich knowledge, it must also be capable of making adjustments in its representational form and of disguising its functional meaning. Even theorists who are comfortable with the notion of a cognitively sophisticated and abstractly represented tacit knowledge base resist this extension.

3. Conclusion

The intriguing state of affairs at the start of the twenty-first century is that virtually no one in the social sciences doubts the existence of and the importance of a tacit epistemic dimension, and virtually no two can agree on the nature and mechanisms that underlie it. The future looks interesting.

Tactile Maps in Geography

People gather geographic information mainly through sight. Maps and graphics are important in this process and the visually impaired user needs them in tactual format. Types of tactile maps are presented in this article. The design, production, and use of tactile maps are also discussed, including new computer technologies and current research.

1. *Tactile Maps: the Concept and its Relevance in Geography*

Maps are graphic representations of space, and as abstractions of reality, they belong to the world of images. Most maps are not available for the visually impaired person and they need to be translated to a tactual language using raised symbols. Maps are called tactile maps when they are in a format that lets them be 'seen' by touch.

People acquire and develop the concept of space mainly through the eye. Visual perception is fundamental for understanding the environment. People deprived of vision, either totally or partially, depend on the other senses to gather information on the real world and its geography. Tactile maps have raised symbols on a flat surface. They differ from models, which are three-dimensional, though both are perceptible by touch. Tactual perception works with movement (kinesthetic force), feeling raised images, surfaces, and objects by moving the fingers. This is called haptic perception and it allows visually impaired persons to explore the tangible, world. Besides tactile, other terms such as haptic, tangible, and raised relief maps are currently applied to the same concept.

Tactile maps have been used since Egyptian times where they first appeared as stones set in sand. Since then, many materials have been used, including wood, plaster, and even embroidery. With the invention of Braille in the mid-nineteenth century, it became possible to describe map features using a font that blind people could understand. Embossed images and Braille text have been used for 150 years in maps.

2. *Types of Tactile Maps*

Blind people learn about geographical space through direct exploration, verbal explanations, sounds, smell, gestures, models, and tactile images. Tactile maps are essential to navigate, to develop space perception, and to gather geo-spatial data. There are two main groups of tactile maps, based on their purpose, scale, and features:

2.1 *Orientation and Mobility Maps*

These maps are directed only to blind and severe low-vision people who need to be aware of the physical environment in order to navigate in space. An orientation map gives an overview of the area. Mobility maps, as the name suggests, provide the kind of detailed information that is needed if the person is to move safely through the environment. Mobility maps show obstacles to be avoided, as well as elements to use such as sidewalks, or elevators. They can depict indoor and outdoor environments and both are always large-scale representations of buildings, routes, streets, transportation networks, neighborhoods, and recreation areas. Verbal maps, also called sequential maps, can replace tactile mobility maps to explain routes to blind people.

2.2 *Geographical Maps*

Geographical maps represent larger areas in much smaller scale than mobility maps. They are classified as follows:

General reference maps include political and physical tactile maps, ranging from cities, states, and countries to the whole globe. Tactile topographical maps are relief models, also produced in colored plastic for the sighted user, which need adaptation for the blind by having all symbols in raised format.

Thematic maps portray qualitative and quantitative geographical information in tactile form. They show location, pattern, and structure of geo-spatial data on a wide variety of themes such as population, industry, climate, distribution of vegetation, and at all scales from local and regional to global.

3. *Tactile Map Design, Production, and Use*

Many authors have contributed significantly to tactile cartography. Research on tactile map design, production, and use has been carried out by a large number of specialists (e.g., Barth 1987, Edman 1992, Ishido 1989, James 1982, Kidwell and Greer 1973, Tatham and Dodds 1988, Schiff and Folke 1982, Vasconcellos 1996, Wiedel 1983, and Wiedel and Groves 1972). Guidelines for map design, production, and use can be found in the suggested bibliography, including issues like scale, standardization, degree of generalization, and choice of symbols.

3.1 Tactile Map Design

The design of a tactile map involves a cartographic language with tactile symbols such as raised lines, points, and textures. Visual variables studied by graphic semiology have to be translated into tactual form to construct tactile maps. The nature of geographical data, either quantitative or qualitative, has to be considered when selecting the correct variable to represent the particular data element. Graphic variables (e.g., size, value, texture, color, orientation, and shape) can be expressed in point, linear, and area modes. Color is not part of the tactual graphic language, but elevation (height) can be used alone or combined with other variables in multiple ways, to represent features in addition to height of the terrain.

Clarity and simplicity are important qualities in tactile mapping, as is the use of a map legend or key. A collection of maps or a multi-layered tactile map can help avoid complexity and excessive clutter, making tactual perception easier. Tactile maps when designed for low vision users should combine visual and tactile symbols, preferably in color. Many studies have been done on the legibility and discriminative capability of symbols from the perspective of the visually impaired as map users. In general, choice of symbols, scale, and degree of generalization greatly depend on the production method to be used, including master construction and reproduction techniques.

3.2 Production Methods and Materials

There are many techniques and materials used in the construction and reproduction of tactile maps. The advantages and limitations of these production methods might include, for example, cost, available technology, number of copies needed, or the user's ability to read maps. The most common methods are:

(a) hand-made collage maps using a large variety of inexpensive materials, usually prepared by non-specialists;

(b) molded plastic maps done in vacuum forming machines (e.g., Thermoform with Brailon plastic), and made from a master map prepared in a variety of materials such as embossed aluminum, collage, paper, or plaster carved manually or driven by computers;

(c) embossed paper maps done by Braille printing machines, using conventional or digital methods;

(d) silk-screen maps using puff ink, usually printed on paper;

(e) microcapsule paper maps compatible with conventional printers and raised by heat, largely used with digital maps.

Collage has very good discriminatory properties because of its varied textures, and low precision and low-cost reproduction capability. On the other hand, silk-screen and microcapsule paper maps have low discriminatory properties, but high reproduction capabilities. Besides these more common techniques, there are others such as German film, virktyping, or thermocraft. Each has its advantages and disadvantages depending on a variety of factors including costs.

3.3 Tactile Map Use: the Need for Training

There are some rules to be followed regarding tactile map use. In general, more training is necessary for all producers and users. Before using maps, it is advisable to teach basic geographical concepts such as scale, point of view, relative positioning, orientation, location, and distance. Tactual graphic language has to be introduced to the users before tactile map reading exercises that help them to understand physical space and its representation.

It is important to consider the user's degree of sensory impairment, previous experience, knowledge about the environment, and cartographic skills. Tactual sense is coarser and it works by bringing pieces together to form a map. It is different from sight, which is synthetic with high resolution. Despite some limitations, blind people can have an excellent ability to decode map keys by using both hands simultaneously, one on the legend and the other on the map. In most cases, the visually impaired user needs personal assistance or good instructions to understand the message conveyed in a tactile map. Successful cartographic communication depends on different approaches and efficient training since many of the problems this group may encounter in map reading differ from those identified for sighted users.

4. New Technologies and Future Directions

New technologies have introduced great changes and improvements in the area of tactile map production and use. Tactile maps with Braille text have been produced and used in many countries, but only a minority of blind people read Braille. In the late 1980s, a tactile–audio system called Nomad was developed. This system combined touch and sound so that a tactile map, when touched, spoke the information under the finger. Now, much more information can be placed on a tactile map and Braille is no longer required. Other problems related to map size, low resolution, and shape interpretation are removed.

Since the mid-1980s, there have been refinements of the Nomad system, and in the late 1990s a system called Tactile Graphics Designer or TGD, also by the Australian inventors of the original Nomad system, was developed. This new system allows the blind and visually impaired to draw their own maps and graphics using a combination of software and hardware, printer and embosser (Parkes 1998). Research in Japan, the United States, and Germany has also been focusing on dynamic refreshable surfaces using a matrix of solenoid driven pins, piezoelectric cells, and the possible use of dynamic shape memory to create tactile surfaces.

Thus far, these approaches have proved prohibitively expensive and no commercial products are available. This is an exciting field where computers, telecommunications, geographical position systems, and even phone and fax machines connected to the Internet will work together, facilitating the production of multisensory maps combining sounds, images, and tactile graphics. Both visually impaired and sighted users will appreciate this.

Design and production of tactile maps is a task usually done by other specialists. Concepts such as generalization and standardization can facilitate design and use, but they are not easy to deal with and are still a challenge for geographers and cartographers. Orientation and mobility maps are more likely to have a system of conventions established at the international level. In any case, it is important to prepare users and mapmakers to deal with tactile cartography. There is a need to produce and disseminate tactile graphics, especially maps, not only for the blind but also as teaching materials for all schools.

The International Cartographic Association has supported this initiative and a Commission on Tactile and Low Vision Maps was formed in 1984, aimed at the study and dissemination of tactile cartography. It has members from over 20 countries and has organized four major international conferences in the USA, the UK, Japan, and Brazil, and several regional meetings on all continents.

Tactile cartography helps to overcome informational barriers for those who cannot see, facilitating their access to a world dominated by images. It is very important to design, reproduce, and distribute tactile maps, and to teach how to use them. All kinds of maps and graphics should become available in tactual form, promoting graphic literacy and integration of the visually impaired. Future research should move from tactile cartography to a broader field of special needs cartography with maps reaching more people.

Talk Show in Media

Talk shows can be defined as televised broadcasts of conversation. Usually a host and several guests discuss a topic in a studio. In TV guides a wide variety of programs are listed as talk shows, ranging from outrageous shows like *Ricki Lake* to serious political discussion programs such as BBC's *Question Time* and from therapeutically inclined programs like the *Oprah Winfrey Show* to the light hearted *David Letterman Show*. Talk shows are a hybrid genre, which contains both journalistic and entertainment elements in different combinations. Looking at talk shows one can trace a number of conversational techniques (interview, debate, informal conversation), varying subject matters (news related issues, entertainment, lifestyle, victims of human tragedy, personal relationships and family matters), and different types of guests (experts, politicians, celebrities, lay people). A broad distinction can be made between the night-time talk shows and the daytime talk shows. The night-time shows generally are entertainment shows or political discussions and broadcast once a week. The daytime talk shows are often broadcast more than once a week, aimed at women and deal with issues from people's private lives.

1. History

The precursors of the television talk show are the listener–participation radio shows of the 1930s and 1940s and the 1960s talk radio with its emphasis on political debate, loud controversy, and shock. On radio the talk show still is a popular format. In the US there are radio stations that only broadcast live talk shows such as NBC's Talknet and ABC's Talkradio Network. Earlier roots can be traced back to public traditions like the nineteenth century literary circles, lyceums, and coffee houses where citizens gathered to discuss matters of common interest. Other influences

come from working class public leisure and spectacular mass entertainment such as the carnival, vaudeville, circus sideshows, and tabloids.

Like many television genres, the talk show format originates in the US. Other countries adopted the genre and adapted the format to their own culture. In many countries commercial channels also broadcast several of the popular American shows. Due to a stronger public broadcasting system, West European talk shows, especially those on public channels, are often less extravagant, slightly more serious, and journalistically inclined than their American counterparts. Cheering audiences are mostly lacking as well as staged confrontations between opponents. In newly democratized countries, where state censorship used to prevent open discussions between ordinary people in the media, talk shows are a new, but often immensely popular phenomenon. Talk shows (and other tabloid media) have in many countries had an influence in reshaping the norms of public discourse in other spheres like politics. In some countries talk shows have taken over prime time and it has even been claimed that their conversational style has become the standard of public discourse (Liebes and Katz 1998).

2. *Host and Participants*

The key to most talk shows is the personality of the hosts. Many hosts acquire celebrity status and often shows are named after their presenters. Hosts can take on several roles, such as stand-up comedian (Steve Allen on *Tonight*! Jack Paar in *The Tonight Show*, David Letterman in the *David Letterman show*), therapist (Oprah Winfrey, Jack Kilroy, Donahue), confrontational interviewer (in some political discussion programs), or promoter of ordinary people's interests. Sometimes their role is a more modest one as the moderator of the discussion. In all cases hosts, to a large extent, control the course of the debate.

Guests on shows are celebrities, actors, authors, and politicians promoting new plays, films and books, or defending a cause. Characteristic is the participation of ordinary people as live, cheering, and applauding audiences but also as the main guests on the panel.

Talk shows often break with traditional roles of experts and lay people. In news programs, politicians, academics, and other public figures are the main spokespeople. In talk shows on the contrary, lay people who disclose personal experiences are the most prominent participants. In some talk shows the contribution of experts is used to substantiate, amplify, or balance the contributions of lay people. In others expert knowledge is confronted with real life experiences of ordinary people. The contribution of the latter is often valued better because their informal performance and straightforward vocabulary is better suited to television codes than the more formal attitude of experts.

Talk shows, especially the more extravagant daytime shows, have been accused of misleading the audience because they are said to stage actors instead of real people. This may be true for some guests on some shows; there are also numerous guests who are not actors. In fact, some claim that the production logic of the shows blurs the boundary between actors and real people, since there is so much coaching of the 'real people' to play themselves or to play the most outrageous version of themselves (Gamson 1998). There has also been criticism on the exploitative character of shows and its potentially harmful effects on the talk shows guests. Guests cannot determine the conditions of their appearance on television and generally cannot foresee its consequences. Their interests do not always coincide with those of staff and producers of the talk shows. Nevertheless, research into people's motivations to appear on talk shows indicates that most participants feel positive about appearing on talks shows and feel that their contribution has been valuable and worthwhile. Promoting a cause, sharing experiences with others in similar situations, or trying to get recognition from relatives, friends, or authorities are mentioned most often as motivations for participating (Priest 1995, Gamson 1998).

3. *Audiences*

The composition of talk show audiences varies with the type of talk show. Late night talk shows hosted by the stand-up comedian type of host are aimed at a predominantly male audience. Subject matter and style of daytime talk shows on the other hand are often aimed at housewives. In the late 1990s a shift has taken place in which daytime shows turned to a younger, racially mixed, and urban audience (*Ricki Lake*, *Jessy Jones*, *Jerry Springer*) (Gamson 1998).

Ratings are rarely very high, but considering that many of the daytime talk shows are broadcast daily, they still attract large numbers of viewers over the week and their market share can be relatively high.

Apart from some quantitative data concerning sociodemographic characteristics of viewers, little is known about the meaning of talk shows for their audiences. There is some evidence however that viewers approve of the genre—even though they are often critical about guests, hosts, or topics discussed. It offers them an opportunity to check their own experiences and knowledge against the statements of the guests on the show (Livingstone and Lunt 1994). For people belonging to groups that are socially marginalized such as handicapped people or sexual minorities it is one of the few television genres in which they are visible. Their experiences are acknowledged, even if they are not always approved of. Often talk show hosts and studio audiences adopt a liberal attitude that at least underlines peoples right to express

themselves. For viewers belonging to a social minority the shows thus offer more than just voyeuristic pleasures.

4. Production

Talk shows are a popular and relatively cheap television format. With the economic pressure of ever expanding numbers of channels and broadcast time to fill, the genre has proved to be a versatile and flexible format that can be adapted to all program slots and target audiences. It has been found particularly suitable to fill less favorable time slots in the mornings, late afternoon, or late night. Talk shows are also often used as a channel to promote books, films, plays, shows, and new releases of CDs and are thus an important marketing outlet for the entertainment industry.

Despite their emphasis on lively, spontaneous, and revealing conversations, most talk shows are carefully orchestrated through pre-interviewing guests and preparing questions for the host. Participants are called upon through screened phone numbers and ads in newspapers. Often the quest for guests involves an active search by editors.

Guests are guided in what to say during the interview, audiences are told when to applaud by a master of ceremony, and camera work is cleverly coordinated. However, debates cannot be completely controlled. Especially the shows that are broadcast live still offer space for genuine audience interruptions and unexpected turns in the debate.

Talk shows are regularly accused of being harmful to society. They have been accused of allowing and even provoking the use of indecent language, physical violence among guests or members of the studio audience, and offering a platform for all sorts of freaks. In their attempt to attract large audiences through staging entertaining and controversial subject matters and guests, they are said to violate moral standards, often leading to confrontations among the participants or to mental and verbal abuse.

5. Theoretical Approaches to Talk Shows

The study of talk shows is relatively new and has expanded with their growing share in program schedules. At the same time these studies reflect more general concerns in mass communication research. In the 1950s psychologists studied the effects of talk shows on the emotional well being of supposedly alienated and isolated members of the audience (Horton and Wohl 1956). In the 1960s and 1970s, talk shows were analyzed from an economic perspective. They were considered to exemplify the commercialization of television and its corruption of morals and the public sphere. In the 1980s and 1990s, in the wake of the growing popularity and academic status of media and cultural studies, more serious attention is being paid to the study of popular culture in general and popular television genres such as the talk show in particular. Currently a number of different approaches can be distinguished. An important strand of research looks at talk shows as an alternative public sphere that provides a platform for citizens to communicate about public affairs among themselves or with representatives of government institutions (Livingstone and Lunt 1994, Liebes and Katz 1998, Munson 1993, Gamson 1998). It is considered 'alternative' because it encompasses social groups that are usually excluded or under-represented in the public sphere. In particular, daytime talk shows in which studio audiences participate in the discussion offer opportunities for the participation of marginalized social groups (women, blacks, 'ordinary people') which are not normally heard in the traditional news genres. They deal with issues and perspectives that are usually excluded from the public sphere, but are nonetheless relevant in many people's lives, especially the lives of less powerful groups in society. Another contribution comes from research into the motivation of guests on talk shows (Priest 1995, Gamson 1998, Hoffmann 1998) and into audience gratification and interpretation (Livingstone and Lunt 1994). An in-depth study of certain characteristics of talk shows is a sociolinguistic analysis of the forms of speech in talk shows (Carbaugh 1988).

Finally the genre is labeled as a postmodern genre *par excellence* because of its extreme intertextuality, its ambiguity and incoherence, its combination of both information and entertainment, personal and public experiences, lay people and experts (Munson 1993). Relatively unexplored is the place of talk shows in the media systems of non-Western countries.

Taste and Smell, Psychology of

Taste and smell are separate senses anatomically: taste is mediated by receptors in the oral cavity, smell by receptors high in the nasal cavity; their receptors, too, connect to the brain by different nerves. In perception, however, they function in intimate connection with each other and also with a third sense, the 'common chemical sense' (CCS). The CCS is mediated by receptors in both cavities and in the eyes, throat, and larynx, and gives sensations of irritation and pungency. These three 'chemical senses' are indispensable to feeding, sexual, and predatory behavior in most organisms. In human beings they function mainly to promote the intake of healthy substances and to reject harmful ones.

In everyday perception, sensations aroused via the chemical senses are often blended with one another. Eating and drinking stimulate taste and smell together, but both sensations are localized in the mouth, and in everyday parlance we call the complex 'taste' or flavor. Touch, temperature, pungency (as in pepper), even sound (as in crunchy foods) may also participate in the complex 'taste.' The neural (brain) mechanism underlying this referral and melding of disparate sensations is largely unknown, but the phenomenon is nonetheless central to understanding eating and drinking.

In addition, substances like salt and vinegar that stimulate taste may simultaneously trigger pungency as well as true taste. Likewise 'odors,' e.g., ammonia, may trigger pungency as well as true smell.

To evaluate the separate roles of the chemical senses it is useful to compare their psychological and psychophysical properties in several categories, as follows.

1. *Quality*

The number of taste qualities is small, the classical view being four: sweet, sour, salty, and bitter. Occasionally others are debated, such as the savory taste of monosodium glutamate (called '*umani*' in Japan). A complication here is the potential confusion of true taste with other sensations localized in the mouth as mentioned above.

Qualitative discrimination is a hallmark of smell, but the number of qualities is even harder to settle. One can discriminate among hundreds of thousands of odorous compounds, but the roles of quality, intensity, and CCS are hard to disentangle. Descriptive terms for qualities abound, but none of the various schemes for their classification commands general acceptance. When it comes to CCS, little, if any, quality discrimination is to be discerned.

2. *Hedonic Tone*

Tastes and smells are very often experienced as pleasant or unpleasant, even at moderate intensity levels. This characteristic is not surprising given their roles in monitoring intake of foods and airborne substances. Acceptance of sweet and rejection of bitter appear already in neonates, but odor preferences develop over the first decade. Compelling as they are, preferences are modifiable, dramatically by conditioned aversion (pairing of chemical sensation with nausea) or gradually by repeated experience. Even CCS sensations, initially unpleasant, can become appetizing, as in peppered food concoctions. The contexts in which sensations occur help determine their hedonic tone. For example, sour and bitter alone are unpleasant, but in lemonade or chocolate medium, agreeable.

3. *Intensity*

The strength of tastes, smells, and CCS sensations all increase with increasing stimulus concentration, but in strikingly different ways. The following example illustrates these differences. To 'double' subjectively rated taste intensity requires roughly doubling of the concentration. To 'double' subjective smell intensity requires 3 to 100 times (or more) increase in concentration, depending on the particular compound. (This property of smell is called psychophysical compression, and no other sense exhibits compression more impressively.) To 'double' a CCS sensation (nasal irritation from inhaled CO_2) may require only a 50 percent increase in concentration (psychophysical expansion). Thus, as a function of increasing stimulus concentration, odor sensation grows slowly, CCS sensation fast, and taste sensation roughly proportionally to concentration.

4. *Absolute Sensitivity*

Smell exhibits exquisite sensitivity. That is, just-detectable physical threshold levels are often amazingly low. Some compounds, notably the sulphurous mercaptans, require for detection only about one part per trillion of air. This approximates a theoretical limit of only a few molecules absorbed by a few receptors. Across compounds, however, sensitivity varies by over a trillion-fold. To account for this in terms of chemical structure is a challenge for olfactory science, so far met only for limited families of organic compounds. For the same compound, the detection threshold in CCS (evaluated in persons lacking smell) is higher than in

smell, but everyday intensities often stimulate both senses simultaneously.

Taste sensitivity is less remarkable and, like smell, also varies among compounds. Some bitter compounds are notable for high sensitivity. Genetic differences account for large differences among persons' sensitivity to some bitter compounds, such as those known as PTC and PROP.

5. *Differential Sensitivity*

In contrast to their impressive absolute sensitivity, taste and smell exhibit poor differential sensitivity. By this is meant that to make a just-noticeable increase in supra-threshold strength requires a relatively large percentage increase in concentration: estimates range between 15 percent and 60 percent, as compared with 1 percent for vision and 10 percent for hearing. One investigation of factors limiting olfactory discrimination blames random fluctuations in stimulus concentration rather than the sense of smell itself. Discounting stimulus fluctuation, Cain (1988) concluded that smell rivals hearing in differential sensitivity.

6. *Reaction Time*

Relative to hearing, touch, and vision, whose reaction times to moderate stimulus levels are of the order of one or two tenths of a second, the chemical senses respond sluggishly. Weak odors give reaction times longer than a second, and even strong odors rarely less than half a second. CCS reaction times may be even longer. Reaction times to taste are also slow, of the order of half a second, and appear to be quality-specific, with bitter giving the longest reaction times.

7. *Adaptation*

Most if not all of the senses exhibit adaptation, which means that the detection, magnitude, and quality of a given stimulus depend on prior history of stimulation. The chemical senses are no exception. In general, in a chemical-free world, whether of taste or smell stimuli, sensitivity increases with time, that is to say one can detect progressively weaker stimuli, and supra-threshold stimuli appear progressively more intense. In contrast, as these senses are exposed to taste or smell stimuli, detection suffers and supra-threshold sensations decline. An interesting example is the perception of salt. The tongue is normally adapted to saliva, which contains salt. Bathing the tongue with water removes the salt and thereby increases salt sensitivity (i.e., reduces absolute threshold) by about a hundredfold.

When a taste stimulus lies undisturbed on the tongue the sensation will fade with time and often disappear altogether. Smell sensations, too, fade with prolonged exposure, not altogether, but to a steady state of roughly a third of their initial subjective magnitude.

Both smell and taste can exhibit cross-adaptation. This means that adaptation to a given compound can often affect sensitivity to another compound. Sourness exhibits cross-adaptation with the sourness of all compounds that elicit sourness, consistent with the idea that sourness is mediated by a common mechanism. The same is true of saltiness. In contrast, some sweet compounds cross-adapt, but other do not; and some bitter compounds cross-adapt, but others do not. This is consistent with the belief that sweet and bitter have multiple stimuli (and perhaps multiple receptor mechanisms), unlike sourness and saltiness.

As in taste, some smell compounds cross-adapt with each other, others do not, but the data so far suggest no clear-cut underlying receptor mechanisms. Contrary to naive expectation, a pair of similar-smelling compounds may (or may not) exhibit less cross-adaptation than a pair of dissimilar-smelling compounds. And adaptation by one member of a pair on the other may greatly exceed adaptation in the reverse direction.

From time to time it has been suggested that distilled water can have a definite taste. It is now known that water can take on any quality, depending on the stimulus to which the tongue is previously adapted. For example, after adaptation to salt, distilled water tastes bitter–sour.

8. *Stimulus Mixtures*

A single chemical compound of the taste or smell laboratory serves only rarely as a stimulus in everyday tasting or smelling. In eating, especially, normal stimuli are mixtures, often comprising thousands of compounds. Such complexes are difficult to study, so scientists have usually employed mixtures of a few components. Even so, the picture is complicated and much remains to be learned.

Two important phenomena can emerge simultaneously when two or more chemical compounds are tasted or sniffed in mixture. (a) *Masking*. A compound may mask another, either totally (if the masker is sufficiently strong) so as to eliminate any perceptual trace of the second, or partially so as to reduce but not eliminate the perceptual intensity of the second. Masking may be reciprocal so that the second may also mask the first. (b) *Integration*. A compound may add its effect to the effect of another compound so that the mixture of the two is more detectable than either alone, or have somewhat greater overall strength than either alone.

A mixture of taste compounds may be detectable even though all components are below their thresholds measured separately. Contrary to earlier belief, such integration occurs whether the constituents are of like or unlike quality. One can detect taste mixtures even when their components are qualitatively unrecogniza-

ble. Supra-threshold mixtures behave differently. The subjective intensity of a complex is usually less than predicted by simple addition of the intensities of the constituents assessed separately. Nevertheless, much remains to be learned about the rules of integration and masking in such mixtures.

As for taste, the rules governing olfactory mixtures are only partly known. Integration appears to characterize detection of smell in much the way that it does taste, with generous integration across many constituents. Less is known about supra-threshold mixtures but, similar to taste, mixtures smell weaker than the sum of their unmixed components. Also as in taste, smells are able to mask one another, partly or wholly, depending on their relative strengths.

Integration across compounds in the CCS has been shown to be generous. This finding has important implications for understanding air pollution. A mixture of many compounds that unmixed are all below the threshold of perceived irritation (of the nose, throat, eyes) can nevertheless cause significant irritation. Thus, mixtures may constitute a nuisance or danger, even when each constituent by itself is deemed acceptable.

9. *Aging*

All of the senses undergo changes throughout the life span, the chemical senses included. By middle to older age the ability to detect smells and tastes appears to be slightly to moderately impaired in nearly everybody, and more markedly in smell than in taste. Supra-threshold intensity losses are clearly more pronounced in smell than in taste.

In evaluating aging of the sense of smell one must emphasize the cognitive richness of this sense. Of special interest is the ability to identify and remember, over long stretches of time, a large number of different odors. It is not surprising, therefore, that aging takes a toll on odor identification and memory, independent of its effect on sensitivity and magnitude.

Taste and Taste Culture

Taste is the ability to make discriminating judgments about aesthetic and artistic matters. It is one component of symbolic systems of classification whose content and structure both reflect and shape particular states of social relations. Taste is part of the process by which social actors construct meaning about their social world, classifying people, practices, and things into categories of unequal value. It is displayed in conversation, habits, manners, and in the possession of goods, which signal co-membership into communities of wealth or knowledge. Taste serves as an identity and status marker, being used simultaneously as 'fences or bridges' (Douglas and Isherwood 1979, p. 12) in processes of exclusion and inclusion. Displays of taste contribute to the creation of networks and shared identities within groups, but they also allow for the identification and exclusion of outsiders whose standards of taste differ and who do not belong. Taste cultures are clusters of cultural forms which embody similar values and aesthetic standards.

1. *Taste and the Emergence of the Modern Self*

In his 1757 *Essai sur le Goût* [*An Essay on Taste*] written for the *Encyclopédie* published under the direction of Diderot, Montesquieu defined taste as 'the faculty of discovering with quickness and delicacy the degree of pleasure which we should receive from each object that comes within the sphere of our perception' (Montesquieu 1970, p. 260). Montesquieu's definition of taste has a double meaning. Taste refers both to the feelings of pleasure one experiences when confronted with beautiful objects and to the intrinsic standards of beauty embodied in these objects. Taste is an individual and subjective sentiment, but it is also a discriminating faculty, through which individuals *discover* the amount of pleasure that things *ought* to give them by virtue of their objective properties. According to Ferry (1990), the eighteenth-century invention of taste as a subjective faculty mediating the perception of objective beauty represents a radical break with the past, since aesthetic standards are no longer seen as immediately given by nature, tradition, or other principles transcending human experience. It is emblematic of the emergence of the modern self. The individual's ability to feel and to think rationally became the foundation of aesthetic experience at the

same time that it became the basis of political legitimacy, economic life, and scientific truth.

Attempts to reconcile the subjectivity of aesthetic experience with objective standards of taste remained a central problem of modern aesthetics through the eighteenth and late nineteenth centuries. The classical Cartesian view maintained that art imitates nature according to principles which are discovered through reason, much in the same way that science uncovers the eternal laws of nature. In an argument which resonated well with the Romantic spirit, others argued that beauty does not rest on objective properties of nature, but in immutable and eternal characteristics of the human soul. The mid-eighteenth century controversy on the sources of beauty in music, for example, opposed composer Jean-Philippe Rameau, who argued that music is beautiful because its rules of harmony and melody reflect mathematical properties of sound, to philosopher Jean-Jacques Rousseau, who argued that music is beautiful because sounds mirror humanity's primitive passions (see Ollivier 1987). Moving away from both of these positions, Immanuel Kant's groundbreaking *Kritik der Urteilskraftwork* [*Critique of Judgement*], published in 1790, maintained that taste is an autonomous realm independent from external influences, be they rationality or passions, as well as from considerations of utility, morality, or economy. This position paved the way for theories of art for art's sake, according to which art reflects the genius of the artist and should be allowed to develop unfettered by social and economic constraints. Throughout the twentieth century, art increasingly came to be seen as an extension of subjective experience, reflecting the artist's personal interpretation of the outside world rather than mirroring some preexisting and eternal cosmological order. Aesthetic experience thus lost its objective foundations, and the search for universal and immutable standards of taste appeared increasingly illusory.

2. *Taste in the Social Sciences*

The abandonment of the search for objective standards of taste in aesthetic theory is contemporary with the rise of the social sciences, whose purpose is not so much to understand the universality of aesthetic experience, but rather to analyze how tastes are shaped by ever-changing social conditions. Social science perspectives on taste thus stand in sharp contrast both to theories of taste as a direct reflection of universal principles and to neo-Kantian theories of aesthetic experience as entirely detached from external constraints. Rather than speaking of the discriminating faculty of taste, in the singular, social scientists nowadays also refer to tastes, in the plural form, acknowledging the changing, diverse, and often incommensurable standards of taste that co-exist in complex stratified and multicultural societies.

2.1 *Taste and Pecuniary Emulation*

One of the first modern analyses of tastes in the social sciences is Thorstein Veblen's study of conspicuous consumption (Veblen 1939). Veblen argued that invidious distinction and emulation are driving motives of social interaction. The accumulation of wealth is driven not only by a need to ensure basic subsistence, but primarily by the honor attached to its possession. In order to confer honor, Veblen argued, wealth must be displayed either through conspicuous leisure (abstention from work or from tasks considered demeaning) or through conspicuous consumption of costly goods. Standards of taste do not reflect autonomous and eternal standards of beauty, but a 'sense of costliness masquerading under the name of beauty' (Veblen 1939, p. 128). It is the honor attached to the appropriation and consumption of costly objects which determines our standards of taste, even when honorific considerations are not present in the consciousness of the valuer.

2.2 *Taste and Class Domination*

The most influential treatment of taste in the social sciences over the last decades has been Bourdieu's (1984) theory of distinction. Like Veblen, Bourdieu argues that taste is shaped by status competition: 'good taste' is a mark of distinction, in the double sense of setting apart from, and conferring honor to, those who claim to possess it. 'Taste classifies, and it classifies the classifier' (Bourdieu 1984, p. 6). As opposed to Veblen, however, Bourdieu argues that taste confers honor not because it is a signal of economic wealth, but rather as an expression of wealth which is cultural in nature. Taste is an unequally distributed capacity for appropriating, both symbolically and materially, classes of objects and practices. Along with attitudes, preferences, manners, know-how, and educational credentials, it is a component of cultural capital, which is transmitted by a complex process of socialization through the family and the education system. As part of class habitus, it is one element of a set of dispositions and preferences which are perceived as freely-embraced by social actors but which thoroughly reflect their objective class position.

In spite of appearances, taste is thus a cultivated rather than an innate disposition. In a society divided into antagonistic classes and class fractions, class membership determines both the position of actors in social space and the perceptual framework through which they make sense of their world. Since members of the dominant class experience few material constraints in everyday life, their aesthetic outlook reflects an attitude of detachment, an appreciation for abstract ideas, and a concern for formal properties of objects. Distance from economic necessity imposes a style of life and a legitimate way of perceiving the world. By virtue of its closeness to material constraints, popular

culture is oriented towards the practical and functional. It is defined negatively, as the flip side of legitimate taste.

Because it is misperceived as spontaneous and disinterested, taste functions as an effective instrument of class domination and reproduction. The definition of 'good taste' is part of struggles for the monopolization of symbolic violence, which arbitrarily imposes as natural and legitimate the evaluative standards and perceptual categories of the dominant class. Mastering the complex and subtle nuances of good taste requires a long process of familiarization. Since this process is carried out primarily within the family and in elite schools, good taste only comes 'naturally' to upper-class children who have long been exposed to it. In everyday interaction, displays of a taste for 'difficult' objects signal membership in the privileged class while a taste for common, vulgar, or less refined ones betrays membership in the dominated class.

While Bourdieu's theory of taste as a key mechanism of class reproduction has had a major impact in the social sciences, it has also come under intense criticism. Most importantly, Bourdieu has been criticized for postulating the existence of a single, objective space of distinction, in which cultural capital operates as a universally recognized currency of exchange. Although Bourdieu recognizes that cultural distinctions are expressed differently in various fields, he maintains that a unique organizing principle ultimately accounts for these variations. Bourdieu postulates a strict homology between class position and class dispositions. He subsumes under the concept of class the entire spectrum of status distinctions based, for example, on race, ethnicity, gender, language, and age (Hall 1992). As a result, he pays scant attention to non-class-based struggles for distinction in local status markets, where upper-class tastes may be entirely irrelevant. Similarly, Bourdieu has been criticized for treating popular culture as a negative image of dominant culture rather than as an autonomous space of symbolic production, with its own logic and characteristics (Cingolani 1984). Bourdieu's model is thus seen as giving analytical primacy to processes of distinction which most closely reflect the experience and world view of the French upper classes.

2.3 Taste and Symbolic Classification

An interesting extension of Bourdieu's model, designed for understanding how and why tastes vary over time and place, was proposed by DiMaggio (1987). Tastes, he argues, are one component of symbolic systems of classification. These systems are shaped by structural features of societies but they vary along four distinct dimensions: differentiation (the extent to which tastes are separated into few or several taste cultures); hierarchy (the extent to which tastes are arranged hierarchically as opposed to being considered of equal value); universality (the degree to which specific standards of taste are universally recognized and accepted as legitimate); and symbolic potency (the relative strength and permeability of boundaries between tastes).

The degree to which tastes are segmented, are arranged hierarchically as opposed to being considered of equal value, are universally recognized as legitimate rather than being contested, and have strongly bounded rather than permeable boundaries—these features of classification systems vary over time and place according to changing social and historical conditions. If tastes are homologous with certain characteristics of social structure, it is because they are shaped by a complex interplay of social forces, including the extent of social differentiation and inequality in a community, the cohesiveness and capacity for mobilization of status groups and classes, state policy towards the arts and popular culture, the degree of centralization of cultural authority, and the types of organizational structures through which art and culture are produced and distributed. For example, DiMaggio (1982) has shown that the emergence of a sharp differentiation between high and popular culture in nineteenth-century Boston was the result of class action on the part of urban elites, whose status claims were reinforced by exclusive access to high culture. The differentiation and stratification of tastes was sustained through specific organizational structures, including upper-class patronage for the arts and a system of upper education which transmitted canons of taste to upper-class youth. Similarly, Lamont and Lareau (1988) argue that Bourdieu's conception of tastes as highly hierarchized, differentiated, and universally recognized cultural capital more accurately represents France than North America, where social and geographic mobility, ethnic and racial diversity, and political and cultural decentralization account for more fluid and less stable boundaries between tastes.

3. Taste Cultures: Highbrow, Lowbrow, Nobrow

One of the most ubiquitous and ritually potent classification of tastes in modern times is the distinction between high culture, based on formal aesthetic standards and displayed in museums, theaters and symphony halls, and low or popular culture, in its commercialized and folk versions. The ritual strength and universality of the high/low boundary, however, has varied over time, in different societies, and across cultural genres. In the USA, several observers have noted that after a period of relatively low differentiation and hierarchization through much of the nineteenth century, tastes became more sharply polarized at the turn of the twentieth century. In a process whose pace varied in different geographical locations and across cultural genres, high and low culture

became more strongly differentiated and the boundary between them gained in ritual potency (DiMaggio 1982, Kammen 1999).

The debate about mass culture, which culminated in the 1950s, may be understood as one manifestation of the polarization between high and low culture. Critiques of mass culture reflected anxieties about the coming of mass society, in which traditional hierarchies were seen as rapidly tumbling down. Mass society was perceived as an aggregate of atomized and depoliticized individuals, whose passive consumption of standardized cultural goods made them easy preys for totalitarian ideologies. The commercialized forms of popular culture, produced for mass consumption by profit-driven cultural industries, were seen as aesthetically worthless and socially dangerous. Radical (Horkheimer 1986) and more conservative (MacDonald 1964) critics of mass culture cast a pessimistic look at social relations, arguing that declining standards of taste were evidence of a degradation in individual autonomy and independent judgement, capacities seen as essential for participation in an egalitarian and democratic society.

It is in this context that Herbert Gans (1974) developed the concept of taste cultures. In explicit contrast to much of the literature on mass culture, Gans wishes to go beyond any sharp distinction between high and low culture. He identifies several taste levels within high and low culture and encompasses them all within a single theoretical framework. As stated above, taste cultures are clusters of cultural forms (e.g., in art, entertainment, architecture, consumer goods, etc.) which embody similar values and aesthetic standards. The concept of taste cultures applies as much to classical symphonies performed by the best orchestras as to garish landscapes printed on black velvet. Gans thus rejects the negative connotations associated with low, mass, and popular culture. He advocates what he calls 'cultural pluralism,' arguing that all cultures should be considered of equal value and be placed on an equal footing, at least from the point of view of social analysis and public policy. Taste cultures correspond to a diversity of taste publics, defined as unorganized aggregates of people sharing similar aesthetic standards. Gans acknowledges that the conditions for appreciating works of art associated with different taste cultures are unequally distributed across taste publics, but he does not examine how these inequalities both reflect and reinforce social processes of domination and exclusion.

4. *Postmodern Tastes*

The degree to which discrete and homogeneous taste cultures actually exist as empirical categories has long been a topic of debate among social scientists. In spite of disagreements, a strong consensus has emerged that there has been, in the last decades of the twentieth century, an erosion of boundaries between taste cultures. Evidence of a convergence between high and popular culture is found in all aspects of cultural production and consumption, from content and aesthetic standards to organizational structures and publics. With regard to taste publics, surveys of cultural preferences do not support the picture of societies stratified into sharply differentiated and class-based taste levels. Rather, surveys show that high socio-economic status respondents report preferences for, and participation in, the broadest range of cultural genres and activities, while low-status respondents display more restricted tastes and practices (Peterson and Kern 1996).

The erosion of high/low boundaries parallels a series of social transformations which have increased the breadth and anonymity of social relations: high levels of geographic mobility, made possible by the development of means of transportation and communication; the declining significance of physical place and the concurrent extension of loose networks associated with the new communication technologies; high levels of intragenerational and horizontal occupational mobility under the joint effect of technological change and economic globalization; greater accessibility to higher education beyond the restricted circles of traditional elites; and the extraordinary increase in the amount and diversity of information in circulation, as print and electronic media bombard us with images which are used in strategies of self-presentation in everyday life.

Greater breadth and anonymity, in turn, affect processes of identity formation and status competition, as more people come into more frequent and fleeting contact with others in a wide diversity of social situations. In relatively small and stable communities, status and identity are linked to personal knowledge of fixed categories such as family name, reputation, kinship, and place of residence. In enlarged and anonymous social spaces, individuals typically participate in a multiplicity of groupings which do not necessarily coincide. Combined with the availability of a wide range of styles conveyed by mass communications, this expands the possibilities of experimenting with self-construction in various social circles. Elites no longer form cohesive and tightly bounded status groups but more diffuse networks of well-educated and geographically mobile professionals and upper managers. In this context, the ability to manipulate a diversity of cultural symbols becomes a crucial resource in social interaction. Knowledge of the cultural codes appropriate in various social milieus and the ability to culture-switch according to circumstances become more useful than knowledge of a restricted range of high culture symbols.

While the case for a convergence between high and popular culture is well documented, the meaning of this convergence is open to conflicting interpretations.

At one extreme, the erosion of cultural boundaries and the proliferation of aesthetic hierarchies, none of which can claim absolute legitimacy, is taken as an indication that tastes are now strictly an expression of individual preferences and private choices (Lipovetsky 1983). Taste-based inequalities may persist, but they are individual in nature rather than an expression of class domination. A less extreme but related position is that tastes, along with other cultural resources, remain linked to status competition among groups and classes. Contemporary societies, however, are characterized by multiple, heterologous, and incommensurable status markets rather than by a single, objective space of distinction dominated by a legitimate elite culture (Hall 1992, Erickson 1996). Taste-based domination is constantly challenged, as no one group succeeds in imposing as legitimate its own standards of taste. This leads to the co-existence of multiple spaces of distinction anchored in constantly shifting identities and hierarchies.

Without contesting the co-existence of multiple status markets in contemporary societies, still others argue the blurring of boundaries between taste cultures signals a transformation rather than the end of taste-based class domination (Peterson and Kern 1996). The celebration of cultural diversity expressed by high-status respondents does not mean that tastes no longer serve as a means of distinction, but rather that new rules of distinction are emerging. Upper-class position is no longer expressed as an exclusive taste for a limited range of high-status cultural objects. It is above all characterized by an openness to an array of multicultural objects and practices, which include high culture but are not restricted to it. The omnivore/univore pattern is thus consistent with a new class division which separates high-status omnivores, who prefer and consume a wide range of cultural products, from low-status univores, whose tastes and activities are more restricted.

Regardless of the specific patterns and meanings attached to them, it is clear that tastes are no longer considered an expression of universal and eternal standards of beauty originating outside social experience. Tastes are part of symbolic systems of classification which both express and shape social interaction. They are linked closely to processes of identity formation and status exclusion. Tastes are instrumental to the creation of symbolic boundaries (Lamont and Fournier 1992), whose degree of differentiation, hierarchization, universalization, and ritual potency varies over time and space. Whether this social conception of taste necessarily leads to cultural relativism remains an open question. If there are no objective criteria of evaluation and if aesthetic hierarchies simply reflect the arbitrary values of the dominant classes, nothing distinguishes a Shakespeare play from a comic strip or a pair of boots (Finkielkraut 1987). Whether the equalizing of all hierarchies should be celebrated as the triumph of democracy and the end of all cultural domination, whether it should be lamented as a failure to reach beyond cultural particularities and to tap into truly universal aspects of human existence, or whether these questions are outside the reach of social sciences, remains a pressing issue in societies increasingly shaped by economic and cultural globalization.

Taste, Neural Basis of

The sense of taste is located at the interface between the uncontrolled chemical environment beyond the body and the highly regulated biochemical environment within. It serves to select, from among a vast array of candidates, those chemicals that satisfy the biochemical needs while identifying for rejection those that have proven toxic. This is accomplished through transduction mechanisms at the receptor level that permit the recognition of sugars, salts, acids, alkaloids, amino acids, fats, and starches. Peripheral taste nerves carry the signal to the brain stem where it activates reflexes for swallowing nutrients or rejecting toxins, then on to the cortex for recognition, and to the lower forebrain for an analysis of pleasure or disgust.

1. *Sensitivity to Chemicals*

The skin is only a crude chemical detector of deviations from pH 7 or certain plant irritants. The exceptions to this insensitivity occur at the points where chemicals enter the body: the nose and mouth. Here, chemical sensitivity is refined, complex, and subtle, for decisions must be made about which substances to admit. Taste may be viewed as the beginning of a long chemosensory tube that extends through the intestines, with receptors along its length that are sensitive to the products released by digestion. Thus, taste should be, and is influenced by the visceral signals that are a continuation of its own function. Together, taste and visceral sensations represent a core of chemical sensitivity that permits an animal to detect a subset of nutrients from an array of toxic or useless chemicals that surround them. What distinguishes taste is not that it recognizes chemicals—glucose is detected in the pancreas, sodium in the kidneys, and amino acids in the duodenum by similar mechanisms to those in the mouth—but that it does so before the irrevocable decision to swallow has been made. While preliminary assessments are made by other senses, notably vision and smell, and through familiarity and cultural norms, nonetheless, taste is the final arbiter of what is taken into the body. Every chemical that enters the mouth goes on trial, and the only verdicts are swallow or not swallow.

2. *Taste Projections into the Nervous System*

Taste input is carried through peripheral nerves to the hindbrain of the central nervous system, from which it projects to at least four locations to mediate distinct functions.

2.1 *Somatic Reflexes to Swallow or Reject*

Clusters of taste cells in the brain stem send projections to local motor nuclei that coordinate acceptance–rejection reflexes. These are based on a preliminary analysis of the chemical composition of a potential food, and elicit swallowing if the substance is deemed nutritious or rejection if it is toxic. The reflexes are fully integrated in the brain stem and are stereotypical for each basic taste. Consequently, they are not altered even by the loss of all neural tissue above the level of the midbrain (Grill and Norgren 1978). This chemical monitor is intact in humans by the seventh gestational month (Steiner 1979).

2.2 *Visceral Reflexes to Aid Digestion*

A second set of projections passes to motor nuclei that initiate digestive reflexes. There are several of these 'cephalic phase' reflexes whereby the brain elicits a preemptory digestive response to prepare for the food that it is simultaneously ordering to be swallowed. These reflexes are mediated by the *vagus* (Lat: wandering) nerve that ramifies throughout the viscera.

2.3 *Discrimination of Quality and Intensity*

A third projection from brain stem taste areas passes up to the thalamus and cortex of the forebrain. Neurophysiological recordings from macaques indicate that taste quality and intensity are represented most accurately in primary taste cortex (Scott and Plata-Salamán 1999). Therefore, the capacity to identify a substance in the mouth most likely derives from cortical activity.

2.4 *Hedonic Appreciation*

The degree to which a taste is appealing or repulsive—its hedonic tone—is determined by projections from primary taste cortex to other cortical and subcortical sites. Prominent among these are secondary taste

cortex in the orbitofrontal region, the amygdala, and the hypothalamus. In macaques, neurons in these areas respond briskly to the taste of glucose when the animal is hungry. As he feeds and becomes satiated, the neurons show progressively less response. The appeal of glucose declines in parallel, finally to turn to rejection as these hedonic neurons fail to respond (Rolls 1995). Even then, however, other tastes may activate these cells and restore the macaque's eagerness to eat. Similarly, humans may be surfeited by a main course, yet show renewed enthusiasm as dessert arrives. It is this enduring sense of pleasure that extends the reflexive bite to a meal; a meal to a diet.

3. Basic Taste Qualities

It remains controversial whether there are basic taste qualities, though most scientists accept the notion at least as a convenient means of organizing the system. The number and identity of the basic tastes is also at issue. Criteria for acceptance include (a) having a specialized transduction mechanism for recognition at the receptor level, (b) eliciting a pattern of neural activity that is distinct from, and does not cross-adapt with, those of other basic taste stimuli, and (c) evoking a taste perception that is unique (in humans) and which does not generalize to those of other tastes (in lower animals). Sweet (glucose, sucrose), salty (NaCl), sour (HCl, citric acid), and bitter (quinine) arouse little debate, and are held by some to comprise the complete range of taste perceptions. Others argue for the inclusion of the amino acid taste *umami* (Japanese, roughly translated as *savory*, represented by monosodium glutamate), which they deem to satisfy the criteria above. Less well-developed cases are presented for the taste of fats and for complex carbohydrates or starches.

4. Taste Receptors

4.1 Anatomy

Humans have about 300,000 taste receptor cells, though the number may vary by a factor of 100 across individuals. They are gathered in groups of about 50 into goblet-shaped structures called taste buds, which number some 6,000. Two-thirds of the buds are located on the surface of the tongue, housed in groups of 3 to 250 in small mounds called papillae (Lat: nipple). Each of the three types of papillae covers a discrete area of the tongue. At the front are 200 fungiform (Lat: mushroom-shaped) papillae, each containing from 0–36 taste buds with an average of three. On each side are about six foliate (Lat: leaf-shaped) papillae, each housing some 100 buds. Toward the back are typically nine circumvallate (Lat: surrounded by a trench) papillae each containing 250 buds. This brings the total number of buds on the tongue to about 4,000. Another 2,000 are not gathered into papillae, but are embedded in the epithelium of the soft palate, pharynx, larynx, and epiglottis (Fisher and Scott 1997).

4.2 Transduction Mechanisms

4.2.1 Sweet taste. Sweetness signals the availability of immediate energy. While sugars are not as dense a caloric source as are fats, they are useful to the brain and muscles only minutes after consumption, and so play a crucial role in survival. Consequently, sweetness has a powerful hedonic appeal, and the word itself has become synonymous with pleasure.

Sugars and most other sweet molecules bind with specific—though as yet unidentified—proteins on taste receptor cells. Once activated, these receptors stimulate G-proteins to amplify the signal. This activates the enzyme adenylate cyclase (AC) which converts ATP to cAMP. It is cAMP that serves as the second messenger, causing protein kinase A (PKA) to close the potassium (K) channels of the cell's membrane. The positively-charge K ions that would otherwise exit through the membrane are instead sequestered within it, depolarizing the cell and causing calcium ion channels to open. This is the event that releases neurotransmitter from the taste receptor onto the peripheral nerve terminals, initiating the signal that is carried to the central nervous system.

4.2.2 Salt taste. Sodium (Na, Lat: natrium) is the crucial ion for controlling movement of body fluids by means of the osmotic force it exerts, and for carrying electrical currents through its positive charge. Its loss devastates normal physiological function. As sodium concentration declines from 140 to below 115 mM, cardiovascular and muscular processes are compromised, and with them the animal's speed and endurance. With further loss, sodium is unavailable to carry electrical potentials resulting in neurological symptoms of stupor, convulsions, and coma. The management of sodium stores is, thus, central to an animal's existence. Accordingly, there is a powerful selection pressure to detect sodium, and reward associated with its taste up to isotonic concentrations.

Sodium enters and activates taste cells simply by passing through ion channels along its concentration gradient. The positive charge the ion carries serves to depolarize the cell and so generates action potentials and transmitter release. These ions are then extruded by Na/K transporters to re-establish the resting state of the receptor.

This occurs readily at the top of the cell where its membrane is exposed to saliva. Access to sodium channels along its side is more controversial. There are tight junctions between taste cells that have been

thought to prevent molecules from passing down their sides. This turns out not to be the case for the small, mobile sodium ion. However, the degree to which sodium can gain access to side channels depends on the anion with which it is paired. Chloride is nearly as small as sodium, passes through the tight junction with it, and allows sodium extensive contact with side channels. Larger anions such as acetate or gluconate are blocked by the tight junction. The negative charge that builds up at this barrier holds the positively charged sodium ion close and prevents it from reaching side channels. Accordingly, the larger the anion, the weaker the salt taste.

4.2.3 Sour (acid) taste. Sourness is the recognition of protons (H^+). These ubiquitous ions participate in many physiological processes. They are also plentiful in unripe fruit and spoiled food, and so serve to warn the animal of danger. These two roles make the recognition of protons a central feature of all chemosensory systems, from protozoans to humans.

The small, mobile proton can penetrate ion channels on all parts of the receptor, and once inside they can affect cellular processes in several ways. Thus, the mechanisms of acid transduction should be varied and subtle. One path has been established and another hypothesized. In amphibians, protons block leaky potassium channels, restricting potassium to the cell and so causing depolarization. In mammals, it is hypothesized that protons enter and so depolarize the cell via sodium channels. This raises an issue of sensory coding that has not yet been addressed, namely, how the animal can discriminate between sour and salty tastes if protons and sodium—both monovalent cations—activate the same receptors by means of the same mechanism. The implication is that other transduction processes for acids remain to be discovered.

4.2.4 Bitter taste. Plants defend themselves against foragers with toxins. Some 10 percent of plant species contain alkaloids, and toxic glycosides are still more common. Animals counter by developing detectors of toxins which, when activated, usually generate a bitter taste and rejection response.

Toxins comprise a variety of molecular structures and disrupt animal physiology in many ways. The taste system cannot focus on a particular molecule, but rather must attend to the common physiological outcome of toxicity. Thus, there will be multiple transduction mechanisms for bitter stimuli. Since most toxic molecules are organic, specialized protein receptors and second messenger systems are likely.

Three mechanisms for bitter molecules have been identified. First, like protons, bitter salts and quinine block leaky potassium channels, restricting potassium to the cell and causing depolarization. How the animal can discriminate bitter from sour when protons use the same mechanism is not known. Second, alkaloids are thought to bind with an undiscovered protein receptor whose activation is amplified by a G-protein. This stimulates the enzyme phosphodiesterase to block cAMP production, a process that could disinhibit calcium channels that are normally held in check by cAMP. The entry of calcium would depolarize the cell and cause transmitter release. Third, bitter stimuli are transduced through the inositol triphosphate (IP_3) second messenger system. The protein receptor, coupled through a G-protein, activates phopholipase C (PLC), the enzyme that produces IP_3. This second messenger then causes the release of calcium from stores sequestered within the cell, resulting in depolarization and release of transmitter. Most toxins are transduced by more than one of these mechanisms. Animals build redundancy into their capacity to detect poison (Lindemann 1996).

5. *Neural Coding*

Once transduced, taste information must be encoded in a neural signal that travels to the central nervous system for processing and interpretation. The nature of that code and the organization of the neurons that generate it have been sources of debate for decades.

5.1 *Gustatory Neuron Types*

Most researchers accept that taste neurons may be divided into three or four discrete types according to the profiles of activity they give in response to a battery of stimuli. Sweet cells and salt cells are clearly identifiable. Acid cells and quinine cells overlap more, and whether they are discrete from one another is doubtful. The centrist position is that taste neurons are of three types: sweet, salt, and generalist, with the last showing almost equal sensitivity to all qualities except sweetness (Smith and Shepherd 1999).

5.2 *The Code for Taste Quality*

The nature of the neural code for taste has been the central controversy of the field for decades. The two positions have come to be called labeled-line and across-fiber patterning.

5.2.1 Labeled-line theory. Proponents of labeled-line theory contend that there is a small number of discrete basic tastes, each served by an associated neuron type. All neurons of one type are dedicated to and responsible for the recognition of their assigned basic taste. Hence, their communication

channels—their lines—may be labeled with that quality. In this view, there are four independent systems whose transduction mechanisms, structures, connections, functions, and very reasons for being may be studied in isolation.

5.2.2 Across-fiber patterning. Neuroscientists had anticipated a labeled-line code for taste from the work of nineteenth century psychophysicists, who concluded that taste was reducible to a small number of independent qualities. The first electrophysiological recording from taste nerve fibers violated that anticipation (Pfaffmann 1941). Single fibers of taste nerves were broadly responsive across the basic taste stimuli, rendering it unlikely that any one fiber would bear responsibility for signaling one taste. A code that involved a pattern of activity across fibers emerged as a more reasonable alternative. In its pure form, patterning theory holds that all neurons contribute equally to the code for each taste. A neuron makes its contribution to the code by filling one place in the activity pattern whose shape represents the taste.

While the theoretical distinctions between labeled-line and patterning are clear, the empirical differences are not. Both accommodate most data. Similar taste stimuli elicit highly correlated patterns of activity, but they do so from a common set of neurons. A patterning theorist does not recognize the need for a channel in this scheme, while a labeled-line proponent sees need for *only* the appropriate channel and nothing else. Still, the same set of neurons, channel or not, is generating most of the activity.

The original finding of breadth of sensitivity in individual taste cells is the irrefutable evidence that favors patterning. Because a neuron responds to multiple taste qualities, its activity is only interpretable in the context provided by the responses of other neurons. A salt neuron may give the same response to a weak salt and to a strong acid. Only by comparing the response to that being given simultaneously by acid cells can it be interpreted. There may be taste neuron types and even coding channels, but they cannot operate in isolation. Taste in the central nervous system must be an integrated sense rather than a federation of four independent systems.

6. *The Reward of Taste*

Eating is fundamentally a process of turning 'other' into 'self.' The raw materials for doing so—carbohydrates, proteins, fats, sodium—must come from the diet. The taste system is charged with identifying them and with providing the reward that motivates their consumption. Cloaked though it may be in table manners, the primitive, taste-inspired reward of eating nutritious foods is irresistible to many.

In modern developed societies, however, taste is viewed paradoxically as an enemy to good health. This is not because the taste system has changed, but rather the definition of health. Where once it was sufficient strength through the childbearing years, it is now clear arteries at age 70. Technical advances in recent centuries have provided nutrients in unprecedented quantity. The over consumption that followed revealed a set of pathologies that had played little role in evolutionary selection: cardiovascular disease, adult-onset diabetes, hypertension, and joint problems. Taste, tuned so exquisitely to the chemical environment in which it evolved, now clashes with the very society that has learned to pander to, and profit from it. The biological reward of eating is dulled by the social disgrace of gluttony, and by the deleterious effects on health that appear only at ages our ancestors never achieved.

Teacher Behavior and Student Outcomes

1. *Teacher Behavior and Student Achievement*

One empirical approach to developing information about effective teaching involves documenting relationships between classroom processes (especially

teacher behaviors) and student outcomes (especially adjusted gains on standardized achievement tests). Such process–outcome research has identified some of the classroom management and instructional behaviors associated with achievement gains.

2. Process–Outcome Research

Classroom teaching is difficult to study because it is a multifaceted professional practice that takes place in a complex and evolving interpersonal context. Nevertheless, research on teaching has begun to establish a knowledge base capable of informing teachers' planning and decision making. Especially relevant findings come from studies designed to identify relationships between classroom processes (what the teacher and students do in the classroom) and student outcomes (changes in students' knowledge, skills and dispositions that represent progress towards instructional goals). Two forms of process–outcome research that became prominent during the 1970s were school-effects research and teacher-effects research (see *School Effectiveness Research*).

Teacher effects research (reviewed in Brophy and Good 1986) identified teacher behaviors and patterns of teacher–student interaction associated with student achievement gains. Such research initially was limited to correlational studies and focused mostly on basic skills instruction in the early grades. However, eventually it encompassed a wider range of grade levels and subject areas and included experimental verification of some of the causal hypotheses suggested by its correlational findings. Some conclusions established through this research are:

(a) *Teachers make a difference*. Some teachers reliably elicit greater gains than others, because of differences in how they teach.

(b) *Teacher expectations/role definitions/sense of efficacy*. Teachers who elicit strong achievement gains accept responsibility for doing so. They believe that their students are capable of learning and that they (the teachers) are capable of teaching them successfully. If students do not learn something the first time, they teach it again, and if the regular curriculum materials do not do the job, they find or develop others that will.

(c) *Exposure to academic content and opportunity to learn*. Teachers who elicit greater achievement gains allocate most of the available time for activities designed to accomplish instructional goals. They do not schedule many activities that serve little or no curricular purpose.

(d) *Classroom management and organization*. These teachers establish their classrooms as effective learning environments and gain the cooperation of their students. They minimize the time spent getting organized, making transitions, or dealing with behavior problems, and maximize the degree to which students are engaged in ongoing academic activities.

(e) *Active teaching*. Rather than depend solely on curriculum materials as content sources, these teachers interpret and elaborate the content for students and stimulate them to react to it during interactive discourse. They do not merely maximize 'time on task;' most of their time is spent actively instructing their students during interactive lessons featuring teacher–student discourse, so their students do not spend much time working silently on assignments.

(f) *A supportive learning environment*. Despite their strong academic focus, these teachers maintain pleasant, friendly classrooms and are perceived by their students as enthusiastic, supportive instructors.

In addition to these more generic findings, teacher effects research has contributed knowledge about qualitative aspects of instructional methods and classroom processes. Research on teachers' lectures and demonstrations has verified the importance of delivering these presentations with enthusiasm and organizing their content so as to maximize their clarity and 'learner friendliness.' Various studies have shown the value of pacing, gestures, and other oral communication skills; avoiding vagueness, ambiguity, and discontinuity; beginning with advance organizers or previews that include general principles, outlines, or questions that establish a learning orientation; briefly describing the objectives and alerting students to new or key concepts; presenting new information with reference to what students already know about the topic; proceeding in small steps, sequenced in ways that are easy to follow; eliciting student responses regularly to stimulate active learning and ensuring that each step is mastered before moving to the next; finishing with a review of main points, stressing general integrative concepts; and following up with questions or assignments that require students to encode the material in their own words and apply or extend it to new contexts.

Research on teacher–student interaction processes has identified important dimensions of interactive discourse that need to be adjusted to the instructional goals, the students, and various context factors. The difficulty levels of questions need to be suited to the students' levels of ability and prior knowledge. The forms and cognitive levels of the questions need to be suited to the instructional goals. Primarily closed-ended and factual questions might be appropriate when teachers are assessing prior knowledge or reviewing new learning, but most instructional goals require more emphasis on open-ended questions that call for students to apply, analyze, synthesize, or evaluate what they are learning. Questions should be addressed to the class as a whole rather than to an individual designated in advance. This encourages all of the students, not just the one who eventually is called on, to listen carefully and respond thoughtfully to each question. Another important dimension is wait

time. After posing a question, teachers need to pause to allow students time to process the question and at least begin to formulate responses, especially if the question is complicated or high in cognitive level of response demand.

When teachers have posed a question and elicited an answer, follow-up options include providing immediate feedback about correctness, praising or criticizing the answer, asking other students to comment on it or suggest alternatives, accepting it and moving on, or probing to elicit more information When the student answers incorrectly or is unable to respond, follow up options include repeating the question, providing clues or rephrasing the question, shifting to a lower level question, giving the answer, or redirecting the question to the class. Teacher effects research has not produced findings indicating consistent relationships between these follow-up alternatives and student achievement gain, probably because optimal teacher response varies with the nature and goals of the instruction. These response options are worth considering in planning recitation and discussion activities, however, particularly in determining when and why it makes sense to terminate an interaction with the original respondent by giving the answer or calling on someone else versus sustaining the interaction by repeating or rephrasing the question or giving clues. Sustaining is often desirable as a way to scaffold thinking and develop confidence, especially in reticent or self-doubting students. However, teachers often feel the need to terminate and move on owing to time pressures or growing restlessness among onlooker students.

Teacher effects researchers have not had much to say about desirable activities and assignments, except for studies relating homework practices to student achievement gains. Findings have been equivocal for the elementary grades, but tend to show positive relationships between assignment of homework and achievement gain in the secondary grades. However, Cooper (1989) cautioned that attention is needed to qualitative aspects of homework such as the goal relevance and pedagogical value of the assignments, the degree to which they are suited to students' prior knowledge, how homework performance figures into overall grading, and the degree to which the teacher does not merely assign homework but reviews it promptly, gives feedback and requires correction of omissions or mistakes.

Research on learning tasks suggests that assignments should be varied and interesting enough to motivate student engagement, new or challenging enough to constitute meaningful learning rather than pointless busy work, and yet easy enough to allow students to achieve high rates of success if they invest reasonable effort. The effectiveness of assignments is enhanced when teachers explain the work and go over practice examples with students before releasing them to work independently, then circulate to monitor progress and provide help when needed.

Research on strategy teaching indicates that general learning and study skills as well as domain-specific skills (such as constructing meaning from text, solving mathematical problems, or reasoning scientifically) are learned best if taught as strategies to be brought to bear purposefully and implemented with metacognitive awareness and self-regulation. Many students do not develop effective learning and problem-solving strategies on their own but can acquire them through explicit instruction that includes not only demonstrations of and opportunities to apply the strategy but also explanations of when and why it is used.

Research on cooperative learning indicates that collaborative work in pairs or small groups is associated with a variety of positive affective outcomes. If the cooperative learning combines group goals with individual accountability, it may enhance student achievement gains as well (see *Cooperative Learning in Schools*).

3. *Research on Teaching for Understanding and Use of Knowledge*

Early process–outcome research focused on important but very basic aspects of teaching that did not include the more subtle fine points that distinguish the most outstanding teachers. Also, most of this research relied on standardized tests as the outcome measure, which meant that it assessed mastery of relatively isolated knowledge items and skill components without assessing students' understanding of networks of subject-matter content or ability to use this information in authentic application situations. During the 1980s a newer kind of research emerged that emphasizes teaching for understanding and use of knowledge. It focuses on particular curriculum units or even individual lessons, taking into account the teacher's instructional goals and assessing student learning accordingly. This research indicates that clear explanations and modeling from the teacher are important, but so are opportunities to answer questions about the content, discuss its meanings and implications, or apply it in authentic problem-solving or decision-making contexts. Increasingly, research is pointing to thoughtful discussion, and not just teacher lecturing or student recitation, as characteristic of the classroom discourse involved in teaching for understanding.

Researchers have also begun to stress the complementary changes in teacher and student roles that should occur as learning progresses. Early in the process, the teacher assumes most of the responsibility for structuring and managing learning activities and provides students with a great deal of information, explanation, modeling and cueing. As students develop expertise, however, they can begin regulating their own learning by asking questions and by working on increasingly complex applications with increasing

degrees of autonomy. The teacher still provides task simplification, coaching, and other scaffolding needed to assist students with challenges that they are not yet ready to handle on their own, but this assistance is gradually reduced in response to gradual increases in student readiness to engage in independent and self-regulated learning.

Research on teaching school subjects for understanding and use of knowledge supports the following principles, which might be considered components in a model or theory describing good subject-matter teaching:

(a) The curriculum is designed to equip students with knowledge, skills, values, and dispositions that they will find useful both inside and outside of school.

(b) Instructional goals emphasize developing student expertise within an application context and with emphasis on conceptual understanding of knowledge and self-regulated use of skills.

(c) The curriculum balances breadth with depth by addressing limited content but developing this content sufficiently to foster conceptual understanding.

(d) The content is organized around a limited set of powerful ideas.

(e) The teacher's role is not just to present information but also to scaffold and respond to students' learning efforts.

(f) The students' role is not just to absorb or copy input but also to actively make sense and construct meaning.

(g) Students' prior knowledge about the topic is elicited and used as a starting place for instruction, which both builds on accurate knowledge and stimulates conceptual change if necessary.

(h) Activities and assignments feature authentic tasks that call for problem solving or critical thinking, not just memory or reproduction.

(i) Higher order thinking skills are not taught as a separate skills curriculum but instead are developed in the process of teaching subject-matter knowledge within application contexts that call for students to relate what they are learning to their lives outside of school.

(j) The teacher creates a social environment in the classroom that could be described as a learning community featuring discourse or dialogue designed to promote understanding.

Embedded in this approach to teaching is the notion of 'complete' lessons that are carried through to include higher-order applications of content. This implies the need to limit the breadth of content addressed in order to allow for more in-depth teaching of the content that is included. It also implies the need to structure a great deal of thoughtful discourse. Instead of rapid-fire questioning and short answers, there is sustained examination of a small number of related topics, in which students are invited to develop explanations, make predictions, debate alternative approaches to problems, or otherwise consider the content's implications or applications. Some of the questions admit to a range of defensible answers, and some invite discussion or debate (e.g., concerning the relative merits of alternative suggestions for solving problems).

Enthusiasm for recent findings needs to be tempered by some important qualifications and cautions. First, the research base on teaching for understanding is still quite thin, and few studies have included both comparison groups and systematic measurement of student outcomes. Also, some of the best known and most widely respected innovations, such as Reciprocal Teaching, have produced mixed rather than uniformly positive results. Finally, like the process–outcome research that preceded it, this more recent research has finessed basic curricular issues (i.e., identifying the most important content to teach) rather than addressed them. Process–outcome research did it by using standardized tests as the criteria for learning. More recent research has equated the teaching of school subjects with enculturation into the academic disciplines. This leads to problematic curricular decisions, because the school curriculum should reflect deliberations about what constitutes basic knowledge that all citizens need to know. This knowledge should be consistent with disciplinary knowledge, but it should be selected, organized, and taught as general citizen education. Content does not necessarily belong in the school curriculum just because it is currently of interest to one of the disciplines.

4. *Conclusion*

The best teaching is adapted to the context, including instructional purposes and goals, the students, and the subject matter. Techniques associated with active teaching or strategy instruction are most relevant when the context calls for presenting new information, modeling skills or coaching students as they attempt to implement new learning Techniques associated with teaching for understanding are most relevant when one wishes to develop understanding and appreciation of networks of knowledge through shared construction and negotiation of meanings and implications. The principle of transferring responsibility for managing learning from the teacher to the students applies to all teaching contexts, but determining exactly how to apply it (how much modeling, explanation, coaching, and other scaffolding to provide, and how quickly to fade this support) takes experience with the content and the students. As research on teaching progresses, more is being learned about the complexities involved in adapting instruction to students and contexts.

Teacher Education

This entry describes the current status of teacher education across several Western countries. It begins with a brief historic note before reviewing policy initiatives, programs and programmatic orientations, teacher educators, and prospective teachers. The entry concludes on a pervasive theme, namely, that while contemporary teacher education has high potential, it remains fraught with problems.

While teacher education varies a great deal across and within most Western countries, common patterns do emerge. The historic evolution of teacher education shows similarities across Europe and North America. Formal teacher education began in the USA in the 1820s and 1830s with the establishment of 'normal' schools that derived their general design from European models. State and large city normal schools spread rapidly in the latter half of the nineteenth century and the first part of the twentieth century. By 1914 every city in the US with a population of at least 300,000 maintained normal schools, usually in conjunction with the public schools and typically integrated with the curriculum of those schools. However by 1940, normal schools had become largely obsolete, evolving into 2-year teachers colleges. In the latter half of the century they became 4-year state or city colleges and in several instances became multi-purpose colleges and even universities.

This pattern of teacher preparation evolving from normal schools to colleges and university campuses occurred in Canada and several European countries shortly after World War Two. The reasons for this move provide a useful context and perspective for understanding the state of contemporary teacher education in Western society. The policy arguments offered for making the move did not vary much from one country to the other. Feiman-Nemser (1990) described the trend in the USA as a means to professionalize teaching. Europeans and Canadians believed that by moving teacher preparation from colleges to universities candidates with higher academic standing would enter the profession, an improved context for research would be created, and new and more innovative programs for teacher preparation would develop (Gwyne 1976, Myers and Saul 1974). The contemporary picture of teacher education presented in this entry can be judged in part at least by how well these expectations have been met. Clearly, achieving those goals has been mixed. For example Sheehan and Fullan (1995) argue, '…teacher education has failed to achieve the place it deserves in the improvement of education' (89). In 1990, Goodlad and his colleagues concluded their study of teacher education with concerns that remain common today:

> To be sure, the crisis that we speak of (in teacher education) is one of degree, affecting education faculty and their organizations variously. This was certainly the case for the 29 institutions in our study. Yet, we did not sense that there was a strong bond of shared identity in purpose and self-confidence sufficient to ward off intrusion and to develop political strategies for long-term survival and organizational renewal. Perhaps other professional schools in multiversities are similarly affected. But it seems to us that schools of education are particularly vulnerable to being pushed around by arts and sciences, by central administration, and by state lawmakers and certification boards. (1990, p. 398)

On the other hand, progress made by many groups and institutions at the ground level frequently goes unnoticed by the critics and policymakers.

1. *The Policy Arena*

Policy in teacher education differs from one country to another both in terms of who determines it and the nature of that policy. The USA and Canada differ from other countries that have Ministries of Education, which develop and implement national education policies, which affect all levels of education from higher or post-secondary to elementary and secondary education. In the USA and Canada teacher education is a state or province responsibility and elementary and secondary education is viewed as

primarily a local responsibility with an overlay of accountability in each of the 50 state agencies and 10 provinces. Unsurprisingly, then, little curriculum articulation exists between the two sectors and standards for pupil achievement in elementary and secondary schools do not interface with emerging standards for prospective teacher performance. Perhaps most disturbing is the broad scale lack of intersection between reforms in the organization and culture of elementary and secondary schools and those initiated in higher education teacher education. In contrast, the Ministry of Education in Britain has total authority over all levels of education including teacher education. In Australia, both national and state Ministries have jurisdiction. But as Tisher (1995) points out, the federal government in Australia has been increasing its authority in recent years.

The situation in the USA, where policy is now focused squarely on the testing of teacher performance, illustrates this trend for more external control of the enterprise. Driven by recent research which underscores dramatic differences in teacher performance as revealed in student test scores (Sanders and Rivers 1998), the testing and accountability movement has moved from the kindergarden to grade 12 (K–12) sector to teacher education. Measuring teacher performance has become the current focal point in teacher education 'reform' with program approval moving from processes to products. While performance assessments have some ways to go in terms of sound psychometric principles, the majority of States have enacted recent legislation with respect to teacher testing and the National Council for the Accreditation of Teaching (NCATE) has also adopted a teacher performance assessment posture. It should be noted that national voluntary accreditation of teacher education has been available since 1927. What is particularly telling is that less than 600 education schools of over 1300 are accredited, although those accredited do prepare more than two-thirds of the United States' licensed teachers. Thus from a policy perspective major limitations exist here.

Beyond performance assessment, the 50 states vary greatly in terms of policies impacting teacher education. Some of these policies appear enabling, but others do not. The teaching professions, research community and learned societies have typically, but not always, provided the input for these policies. However state legislative bodies have become increasingly intrusive and in some instances have curtailed the number of professional courses and mandated what should be taught. Several States have also initiated alternative routes to certification.

The centralized governance systems in Australia and Britain have produced substantial policy changes in teacher education. Pimm and Selinger (1995) described the situation in Great Britain in terms of the 'commodification of teaching.' Under the Thatcher government initial teacher preparation has been nationalized with proposals to give elementary and secondary schools a stronger role in initial teacher preparation, provide more time in these schools for prospective teachers, and require courses to equip them with specific competencies. Apparently, the government hoped to give schools the full role of training teachers with or without the accreditation of higher educational institutions.

Policy developments in Australia followed a period of public criticism of teacher education (Tisher 1995). The critics saw teacher education as having a weak knowledge base, a shallow curriculum, and an inability to attract top students. Hence policy moves included, among others, encouraging stronger partnerships with the schools such that more of the pedagogical studies would occur there, a stronger base in academic subjects for beginning teachers, and a better integration of pedagogy and research. The policy decisions since have led to numerous closures and amalgamations of institutions that provide teacher education.

Policy in Canadian teacher education has been left largely to the faculties of education themselves. Provincial Ministries of Education who have responsibility for teacher preparation typically limit their efforts to insuring that potential candidates have the necessary courses to graduate. Consequently, intrusive policies of teacher testing and radical restructuring do not exist in Canada. Ministries do occasionally undertake reviews of teacher education in Canada. In Nova Scotia, for example, following such a province wide review, four of eight teacher preparation programs were shut down. In two provinces, Ontario and British Columbia, Colleges of Teachers have recently been established to set standards for certification, but their long terms impact on policy has yet to be determined. (Sheehan and Fullan 1995.)

A common historic policy approach across these countries becomes evident. In the 1960s and 1970s, after teacher education had moved to Universities, schools and faculties of education appeared to enjoy considerable freedom in how they undertook the preparation of teachers. But the 1990s have seen numerous initiatives on the part of governments, particularly in the USA, Australia and Great Britain to exercise greater and greater control over teacher preparation in the form of mandating standards, introducing programs of teacher testing, and placing limits on curriculum within schools and faculties of education. The reaction of academics appears to vary from one country to the next. Tisher (1995) notes that the policy changes in Australia went unchallenged by a docile group of teacher educators. Taylor (1994), who finds teacher education in England under attack, proposes alliances to improve the image of teachers and to assist educators to defend teacher education from its enemies.

The motivation of policymakers to undertake such moves appears to rest with economic concerns. Sanders (1995), for example, who examined the

political influences in Germany, perceives that the need for high levels of productivity in the economy drove policy changes in that country.

In sum, themes emerge across these policy initiatives. First, in every country steps have been taken by policy makers to reform teacher education from outside the institution itself. The reform initiatives within institutions, which we describe elsewhere, have either not matched the expectations of policy makers or have been ignored by them.

Second, most policies mandate or support greater involvement of the schools in teacher education either in the form of school/university partnerships or in other cases control by schools over teacher education. However, such policy proposals for restructuring and innovative activity have not typically been followed by a major reconceptualization of what should actually occur as a result of such collaboration.

Third, across these western countries is a move toward greater accountability which too often translates into a narrower, more technical view of teaching. For example, the British experience is built around a national curriculum with the development of competencies for teachers to teach for that curriculum. The apparent simplicity of many of these policies has the potential of 'dumbing down' the curriculum for teacher education. The notion of teaching as a complex endeavor and the beginning teacher as an educated person appears to have been lost in these policies.

2. *Teacher Education Programs*

The program landscape of teacher education takes the form of a common organizational model within which alternative orientations appear. Traditionally, learning to teach has been a process of providing beginning teachers with knowledge and skills about teaching through coursework followed by a school experience where beginning teachers are expected to apply and integrate such knowledge. Britzman (1986) terms this an implicit theory of simple and immediate integration of knowledge about teaching. The university provides the knowledge, the school the field experience and the students integrate the experience. Because it has more in common with the culture of the university than it does to the culture of the school, links to the field are often ignored. As Guthrie and Clifford (1988) note, as Schools of Education have drifted toward the shores of academe they have drifted away from schools. During that period of drift, schools and faculties of education have lost the clear sense of mission that typified the normal schools. What has changed over the years however is the type of knowledge, skills, and expectations that are acquired by beginning teachers during the coursework phase.

These changes have come about with the move of teacher education to the university which has achieved the intended goal of creating a setting for research and scholarly activity to address issues in teacher education. This has produced a rich and varied knowledge base ranging from research on teaching and reflective practice to the philosophical and psychological studies leading to the notions of constructivism. This diverse corpus of knowledge, which Zeichner (1999) calls the 'new scholarship in teacher education,' can potentially equip beginning teachers with the tools and understanding to better approach their teaching than was possible in the days of the Normal schools.

Also, numerous studies of program attributes have contributed to successful teacher learning (Howey and Zimpher 1989, Goodlad et al. 1990, Darling-Hammond 1996). Howey and Zimpher identified in their case studies the following attributes of coherent programs:

> Programs have one or more frameworks grounded in theory and research as well as practice, frameworks that explicate, justify, and build consensus around such fundamental conceptions as the role of the teacher, the nature of teaching and learning, and the mission of schools in this democracy. These frameworks guide not only the nature of curriculum as manifested in individual courses but, as well, questions of scope; developmental sequence; integration of discrete disciplines, and the relationships of pedagogical knowledge to learning how to teach in various laboratory, clinical, and school settings. Programs embedded in such frameworks clearly establish priorities in terms of key dispositional attitudes and behaviors enabled and monitored in repeated structured experiences. Programs reflect consideration of ethos and culture building and the critical socialization of the prospective teacher. (1989, p. 242)

3. *Varying Orientations to Teacher Education*

While a common organizational tradition has remained prevalent over the years, alternative approaches in all countries have developed. These reforms push against this predominant tradition of teacher education. These tend to occur at the ground level, where individual and small groups of faculty members develop and carry out innovations. These alternatives are driven by competing conceptions of teaching and learning including progressive/critical, personalistic, competency, traditional, and academic orientations. For example, the RATE (Research About Teacher Education) study in the United States in 1990 polled teachers and students and found that about two-thirds of both groups identified a discernible orientation guiding the program they were engaged with at that time. Context greatly affected responses, as liberal arts institutions were disposed toward content knowledge, early childhood and elementary preparation programs were driven by views of child development, and programs placing students in schools populated by the underclass tended toward a critical posture. No prevalent orientation appeared, but hybrids were common and inquiry into and

reflection on practice represented a common programmatic theme.

Initiatives from different countries illustrate this plurality of orientations. At the University of Melbourne, Australia, an innovative program based on constructivist principles has been ongoing for a number of years. Building on the needs of the students, the program emphasizes group collaboration and a unique organizational structure that combines campus coursework and school experience (Gunstone et al. 1993). Similar constructivist programs incorporating a personalistic approach can be found in several Western countries.

Nigel (1995) examine efforts in European countries to increase the professionalization of teacher training. He reports that France had recently elevated the status of teachers to civil servants hence increasing their prestige and that Germany had strengthened efforts to retain a high degree of academic excellence in its professional training.

In Canada, alternative approaches to the traditional organization of teacher preparation have been occurring for several years. At the University of Simon Fraser, the Faculty of Education has had over 30 years of experience with an alternative model of teacher preparation where initial coursework has been replaced by combined seminar and school activity and where much of the teaching has been undertaken by seconded teachers (Ellis 1968). The orientation in these programs integrates a clinical/practical and personalistic stance.

Brower and colleagues (1987) report an integrated curriculum of alternating college based seminars and school experience at the University of Utrecht. What began and was studied over time in one institution later became adopted in most Universities in the Netherlands and became endorsed as official government policy. Their work illustrates how ground level reform can be supported by research and influence national policy.

Increasingly, in the USA formalized interinstitutional relationships between schools of education and surrounding school districts appear in the form of professional development schools or partner schools. Seventy-five major institutions working in partnership with local schools and school districts form part of a national reform network known as the Holmes Partnership. Within this confederation, 31 partnerships address the challenges of preparing and retaining teachers in urban settings in a reform effort known as the Urban Network to Improve Teacher Education (UNITE).

The United States, Great Britain and Australia have also been characterized by 'blue ribbon' commissions convened regularly to share their collective wisdom about what they perceive as needed future directions for teacher education. Two examples from the USA illustrate these types of reports. A recent report was prepared by a group with the auspicious designation of the National Commission on Teaching and America's Future (NCTAF) titled *What Matters Most*: *Investing In Quality Teaching* (1996). Rennert-Ariev and Valli (1999) examined nine other reform documents disseminated since 1985 against the NCTAF recommendations and found considerable variability across these reports. What these groups, comprised of leaders in education, government, business and industry, have consistently recommended is more rigorous content preparation and increased and improved clinical experiences. A high level of agreement also existed for improving the awareness of multiculturalism and increasing the competence of beginning teachers to deal with students of diversity.

4. *Teacher Educators*

While the role of teacher educators has attracted little research they do shape programs and their delivery. Just who is involved in preparing teachers, what do they tend to do and why? In addition to the school of education professoriate, clinical faculty and professors in the arts, sciences and humanities also play significant roles in shaping the beliefs and practices of beginning teachers.

Ducharme and Ducharme's (1996) research, corroborated by other studies, revealed the following general portrayal of the teacher education professor:

> He is a white male in his late forties or early fifties, tenured at either the full or associate professor level. He acquired his doctorate while studying part-time, and has been at his current place of employment for more than 15 years, during which time he has published six or seven articles in refereed publications. Nearly 80 percent of elementary and secondary (teacher education) faculty had several years of prior work in elementary and secondary schools. (Ducharme and Ducharme 1996, p. 698.)

The scholarly productivity of teacher educators varies widely depending upon the type of institution in which they are located and when they entered the professoriate. For example, those faculty in research institutions tend to publish as frequently as other faculty across the academy and teacher education research has in fact mushroomed in recent years. Division K, Teaching and Teacher Education, of the American Educational Research Association now has the largest membership in this organization and reflects the greatest number of scholarly presentations. Contrary to the claims of critics, the RATE studies revealed that prospective teachers report that teacher educators on the whole are both competent and accessible. Further, work in Canada (Weber 1990) reveals a professoriate committed to high ideals and to a reformist agenda in teacher education, but a context in which they are frustrated by the institution.

Teacher educators reported 55 hours a week on the average devoted to their various tasks and the demands on faculty in recent years have increased as many struggle to straddle the diverse cultures of higher education and elementary and secondary schooling. Teacher educators report spending more time in schools and especially in the growing movement of Partner or Professional Development Schools. However while these teacher educators generally spend increasing time in schools, they tend to do so largely engaged in traditional functions; that is supervising prospective teachers and providing some school-based professional development for veteran teachers. They rarely, if ever, teach youngsters themselves and since it has often been a considerable number of years since they did so, they are often unaware of many of the problems teachers face.

Increasingly, clinical faculty, teachers seconded from the schools to work in Schools and Faculties of Education, play a significant role in teacher education. They typically bring to the university a strong connection with the field, but often represent the unheralded, forgotten workers in teacher education. Teachers in elementary and secondary schools have always played a significant role in educating beginning teachers by acting as cooperating teachers. However, they typically receive little compensation for assisting novices in the complexities of learning to teach while apprenticing at their schools. Current changes in Great Britain propose that the locus for teacher education shift to the school. If this signals the future, then the role of teachers as teacher educators will become even more significant. It should also be recalled that the attitudes and perceptions of future generations of teachers are being shaped through what is termed an 'apprenticeship of observation' as they go through school themselves.

Obviously, the professors of Arts, Science, and Humanities also have considerable influence on those learning to teach. Seldom mentioned in the literature, their influence remains relatively unstudied and understood.

5. *Prospective Teachers*

An understanding of the large and diverse enterprise of teacher preparation in Western countries must also include an examination of the prospective teachers seeking a teaching license. The context in which they teach adds to that understanding.

Criticism of teacher education derives not only from perceptions of the quality of faculty and programs but that of the education students as well. The prevailing perception is that schooling in general is severely constrained by the pedestrian nature of those who choose to teach or, as has been opined by many, those who have no other choice. The RATE data counter these common assertions. Almost 4 in 10 prospective teachers maintained an A average in high school, the great majority had at least a B average and six of seven teacher candidates reported that they were in the top third of their class. In several Canadian provinces entry standards for prospective teachers have risen steadily to the point that an 'A' standing is typically required to enter teaching.

Prospective teachers are somewhat evenly divided in the structure of programs in which they are enrolled. Some begin in their freshman year continually interfacing with their liberal studies and finish with a baccalaureate. Others begin in their junior or even senior year. In many instances the program of preparation is extended to a fifth and in a few instances even a sixth year. Most teachers take at least 5 years to finish their program of teacher preparation. Other teacher preparation programs are strictly at the post-baccalaureate level and some result in a master's degree which is a requirement in some American States, including California.

The research on the 'beginning teacher' reveals a great deal about teacher education programs and confirms many of the points we identified earlier. Where beginning teachers have been asked to assess their programs of teacher preparation, they typically take a critical stance reporting that their real understanding of teaching began when they entered the school. Wideen et al. (1998) cite several reports showing that the first year of teaching for most beginning teachers became a 'sink or swim' proposition for which they felt poorly prepared. Nonetheless upon graduation the vast majority of teachers report they have acquired entry-level skills and are confident they will succeed at least in traditional teaching settings (RATE 1992).

6. *The Future*

Thus, what can we say about the future of teacher education? Depending on the data one decides to emphasize, the future could be the best of times or it could be the worst of times. Those who see the best of times emphasize and believe in the potential of the ground level efforts occurring in all western countries; the university based research efforts, producing new ways of thinking about teaching and teacher education; and the widespread effort that is being made to reform the schools and prepare teachers differently to teach in these new schools. Those on the optimistic side typically ask, what could be more important then the preparation of those who will teach our young?

On the other hand, if the simplistic solutions of many policymakers win the day, if the weak and diffuse institutional base for teacher education remains, if many in the professoriate remain interested in everything other than teacher preparation, and if the public continues to believe that teaching is a relatively simple activity, which can be done by anyone, then it could be the worst of times.

Achieving the best of future times requires that the collective teacher education community work to move beyond the mandates of policymakers, reduce isolationism, and avoid simple solutions to complex problems. Moving beyond mandates requires a reconceptualization process that sets out improved designs for teacher preparation.

Isolationism, whether it involves research, program initiatives, or policy making, will have little impact if it ignores the holistic nature of teacher education. The tendency has been to offer simple solutions to complex problems. Teacher education is a complex phenomenon; future solutions to problems and policy initiatives must reflect this.

Teacher Expertise

Research on teacher expertise is concerned with the knowledge and skills that characterize the successful teacher. The term 'teacher expertise' covers both the teacher's professional know-how and an approach to

research that compares experienced and successful teachers (*experts*) with beginning teachers (*novices*) and so-called *intermediates* (teachers who have already gained some experience). This research approach ties in with basic research on experts in experimental psychology. This field has shown that peak performance in experts is due particularly to knowledge gained through training, as well as through many years of practical experience. In teachers, this professional knowledge covers a wide range of different domains: professional knowledge on the curriculum is joined by pedagogical knowledge on how to teach the subject. Moreover, ideas on the philosophy of the particular school subject are also important. Professional knowledge is not only significant as the content of teaching, but also influences the actions of experts by shaping their categorical perception of classroom events and of students. Teacher expertise also includes action routines that permit quick responses in complex situations.

Whereas it may be taken for granted that members of many qualified professions (such as physicians or engineers) can be called experts, this is not the case for teachers. Less than one-half of the respondents in a survey of teacher-training students considered the expert concept to be appropriate for their future profession (Bromme 1997a). One reason behind this is the idea that teaching and training students is—particularly in elementary school—such an eminently personal process of intersubjective communication that it is impossible to describe the critical requirements in terms of the expertise concept. Expertise, according to this argument, is an idea that has more to do with a technological rationality. In contrast, the teacher-as-expert approach emphasizes that the art of teaching is based on knowledge and skills that can be acquired through training and refined through practice, and that is accessible to empirical analysis.

1. Three Paradigms of Teaching Research

An inspection of the recent history of research on teaching and learning will make it easier to understand the origins of the teacher expertise approach. Over the last 50 years, three paradigms of teacher research can be distinguished (Bromme 1997b).

1.1 The Teacher Traits Paradigm

Empirical teaching research in the 1950s and 1960s focused on the search for positive teacher traits. The interest was in finding personal characteristics that would explain differences in the type of educational impact (not necessarily in learning gains) and could be measured with psychometric instruments. However, this paradigm had two main weaknesses: first, the personality traits proved to be either trivial (cruel teachers have an unfavorable impact) or very complex; second, it was unable to explain how these characteristics impact on different classroom situations, different subjects, and different school grades.

1.2 The Process–Product Paradigm of Searching for Effective Teacher Skills

The methodological influence of behaviorism led to the emergence of the process–product paradigm which measured the effect of narrowly defined teacher skills on student achievements in the classroom. It studied individual teacher behaviors, such as the number of questions, praise following student statements, the clarity of the teacher's language, or requests for students to answer questions. These skills were defined as closely as possible to behavior (i.e., with a low level of inference).

When the process–product paradigm first emerged, it was assumed that the teacher exerted a direct influence on the students' learning process. However, it became clear—roughly at the beginning of the 1970s—that the impact of a specific teacher action on student achievement depended just as much on the students' own activities, interpretations, and interactions as on the subject, the timing of the action, and the sequence (not just the aggregated frequency) of prior events. This reveals one of the weaknesses of a research paradigm that searches for isolated teacher skills. One outcome of this weakness was a brusque rejection of the process–product paradigm; another, its programmatic remodeling. The expert paradigm is a product of this remodeling (Weinert et al. 1992).

1.3 The Expert Approach in Teacher Research

Because the art of teaching consists, above all, in selecting appropriate actions for each situation and modifying one's activities according to the type of student, teaching content, the stage reached in the academic year, and the goal of teaching, it also becomes apparent that the teacher's decisions and deliberations take on a particularly important role. Their direct, action-related cognitions are, in turn, embedded in more long-term considerations regarding the syllabus and in lasting goals and values. Furthermore, they call for the perception of student characteristics and classroom events and, naturally, lasting knowledge on the contents of teaching and the teaching process. These cognitions are the focus of research on teacher expertise.

The process–product paradigm broke down the person of the teacher into a bundle of subskills and was not concerned with whether these could all be realized in one person. The expert approach, in contrast, searches for the competence of the teacher in the sense of a coherent ensemble of knowledge and

skills that coalesces in the individual. In line with the personality paradigm, the expert approach brings the person of the teacher back into the focus of research—no longer in terms of generally defined personality traits, but as the necessary knowledge and skills for designing teaching processes, however.

This remodeling was accompanied by a change in the metaphor guiding research and, simultaneously, in the underlying general psychological theories in studies on the teaching-learning process: The (successful) teacher is now viewed as an expert, and this expresses a programmatic reference to the questions, research methods, and perspectives of research on experts in cognitive psychology (Ericsson and Smith 1991). This field investigates the cognitive conditions underlying peak performance on complex mental tasks. One example is the empirical confirmation that the ability of good chess players to memorize rapidly complex constellations of figures and reproduce them exactly is not based on a general (topic-unspecific) higher memory capacity, but on the knowledge about chess positions acquired through many thousands of hours of practice. Further findings on experts concern their problem-solving strategies, metaknowledge, and self-monitoring strategies, as well as their categorical perception of problems.

The expert approach not only focuses on experts as peak performers like chess grand masters. When addressing other domains of expertise (e.g., medicine, physics), it is also concerned with professionals (possessing practical experience and good performance) by comparing them with novices and intermediates. A consistent pattern of findings indicates that it is particularly domain-specific declarative and procedural knowledge that permits expert performance. This does not just involve a quantitative difference (experts simply know more). It is the *qualitative differences in the contents and organization of knowledge* that are more decisive.

2. *Who Is to Say Who Is an Expert?*

Naturally, specifying how experts should be defined for research implies a normative decision. A favorite measure is student-learning gains—although, of course, any computation of this measure has to control statistically for the variety of preconditions present among students. The vast number of other factors in addition to teacher behavior influencing student achievements makes it necessary to use large samples, along with major standardizations of teaching contents, before this criterion can be applied for the selection of experts. Such conditions are not always available—often just for practical reasons. Furthermore, studies on expert knowledge are difficult to carry out with large samples, because tapping the professional knowledge of teachers often also requires intensive individual interviews and observations. Therefore, experts are also identified with further external criteria, such as: ratings by colleagues, superiors, and students; classroom observations; completion of certain training; extent of training; and, finally, length of professional experience. The latter naturally takes it for granted that one can talk about experts only in the sense of professionals. The term no longer implies any particular quality of instructional outcome.

3. *Examples of Studies on Teacher Expertise*

3.1 *Differences in the Categorical Perception of Classroom Events*

Berliner (1992) and his colleagues compared the cognitive processing of photographed classroom situations, videotapes, and written information on students in experts, novices, and intermediates. They found clear differences in the categorical perception of classroom events: whereas the experts' perspective was characterized by concepts about typical classroom events and consideration of the class as a whole, novices tended to perceive the separate individual students in the class. Experts tended to interpret what they saw, whereas novices only described the scenarios (Carter et al. 1987).

It seems that teachers perceive the lesson and structure it for themselves more holistically in the form of typical *classroom episodes*. This perspective also shapes their recall of past classroom events. Bromme (1987), for example, asked experienced mathematics teachers immediately after the lesson whether they could remember problems encountered by individual students and the progress they had made. At first glance, results seemed disappointing: teachers could recall hardly any problems or the learning progress in single students. Instead, their answers revealed that the categorical units of recall (and probably also of situation-specific perceptions) were not so much individual students but more the classroom episodes that provided the communal staging of the teaching content. Putnam (1987) has suggested that these proposed screenplays in teachers' minds should be called *curriculum scripts*. They are part of the teacher's professional knowledge and form a focus of empirical research within the expert paradigm.

3.2 *Stable but Flexible Pursuit of Action Goals*

A further empirical finding on expert teachers addresses the flexibility of their actions. Leinhardt and Greeno (1986) have reported, for example, that their experts were characterized particularly through a situationally appropriate (stable but flexible) pursuit of an elaborated repertoire of goals. Concrete goals in

the classroom were, for example, checking homework in all students, presenting a mathematical algorithm, or carrying out practice exercises. However, expert teachers pursued these concrete action goals in completely different ways depending on which difficulties arose. Moreover, compared with novices, they also pursued a larger number of different subgoals simultaneously.

The idea that the intraindividual breadth of the action repertoire is one of the conditions underlying successful work is also confirmed indirectly through similar findings on the interindividual variance in the classroom activities of expert teachers. The students' learning processes can be supported and encouraged by teachers in a broad variety of ways. Weinert et al. (1989) have shown, for example, that expert mathematics teachers who achieve not only above-average learning gains in their students but also a reduction in the divergence in achievement in their class differ greatly in the teaching behavior they use to attain these goals.

3.3 Routines and Flexible Action

Such flexibility nonetheless also presupposes routines; in other words, many of the behaviors needed to teach the lesson are enacted without any particular conscious decisions. As in any complex activity, practiced routines facilitate action and provide the necessary preconditions for setting targets, carrying out fine-tuning, and simultaneously bearing other aspects in mind. Research on teacher expertise also discusses routines in another sense that has to be distinguished theoretically from the psychological process of automating complex activities. *The concept of routine* is also used to describe the socially established activity patterns that teachers and students pursue during the lesson. It has been confirmed empirically that it is favorable for teachers to establish a set of behavioral rules as quickly as they can after taking over a class. These then provide, so to speak, the framework for spontaneous behavior. Agreement on set behavior patterns also reduces cognitive strains and encourages the formation of routines in the former sense. Furthermore, routine expert activity is strongly domain-specific and is determined by the extent of prior experience: when experienced teachers have to face new demands (e.g., a new teaching method), they tend to behave in similar ways to novices (Rich 1993).

4. Important Variables Related to Expertise

4.1 Expertise and Experience

Basic cognitive research on expertise in narrowly defined domains (e.g., chess) has confirmed empirically that years of practice is an important predictor for the establishment and development of expert knowledge. Can a (linear) relation between job experience and teaching success also be found in teachers? Although empirical findings are inconsistent, indications are that the relationship is curvilinear (Barnes 1985). At the beginning of their professional career, teachers have to accumulate practical experience. However, as the years of teaching go by, stress factors also emerge that, in turn, impact on teacher behavior in a way that generally does not lead to further improvement but to more of a deterioration in instructional outcomes. Emotional exhaustion and its effects due to occupational stress have been summarized under the label 'burnout.' Because *enthusiasm* about the contents of teaching impacts positively on the learning gains of students, it is plausible to assume that any strains impairing such enthusiasm may increasingly mask the positive effect of cumulating experience. Moreover, burnout is a contributing factor in the relatively high proportion of teachers who quit their jobs before reaching retirement age. The resulting selection effects could also be one reason for the inability tofind any statistically significant relations between occupational success and the length of job experience.

4.2 Expertise and the Extent of Subject-matter Knowledge

As well as confirming the role of length of practice—as mentioned above—basic research in cognitive psychology has also revealed that the extent and quality of domain-specific knowledge are important predictors of experts' achievements. In the case of teacher expertise, it has to be noted that, as with years of teaching, moderating factors have to be taken into account when assessing the relation between subject-matter knowledge and the expert's instructional outcomes.

In the 1970s, some surprising empirical studies were published that revealed no measurable connection between the extent of teachers' subject-matter knowledge and instructional outcomes. Druva and Anderson (1983) have summarized the empirically established relationships between the extent of education in the natural sciences and both teacher and student behavior, as well as performance in class. The number of courses the teachers had taken in sciences (as a measure of their subject-matter knowledge) explained about 10 percent of the variance in student performance. Although this may seem rather small, it is actually a good predictor of student performance, because individual teacher-related variables are never able to explain more than a relatively small part of students' learning outcomes. It seems to be self-evident that teachers must possess the subject-matter knowledge they are supposed to teach.

This, however, does not permit the conclusion of a direct linkage between the extent of subject-matter knowledge and students' outcomes as measured by standardized tests. The relation between subject-matter knowledge and student outcomes can be ascertained only by making qualitative differentiations in subject-matter knowledge; in other words, by analyzing more precisely what professional knowledge experienced teachers possess. On the side of teaching activity, there is a need for both a theoretical and empirical clarification of which mediating processes are to be found between the quantity and, above all, the quality of the teacher's professional knowledge and instructional outcomes. Up to now, such mediating processes have been described mostly only in case studies (e.g., Stein et al. 1990).

5. *A Cartography of Teacher Knowledge*

A comprehensive description of the professional knowledge of teachers requires some kind of cartography of teacher knowledge that could define the most important areas more precisely and allow a systematic study of the impact of the proposed variables on the instructional process. It is not enough to take the catalogue of subjects that teachers have to study during their training, because this overlooks areas that develop only implicitly and through practical experience. Extending a proposal from Shulman (1986), the following categories can be proposed.

(a) *Content knowledge*. This covers all elements of knowledge that refer to the field to be taught or the school subject (e.g., knowledge from the domain of mathematics in mathematics teachers).

(b) *Curricular knowledge*. The contents of learning in, for example, mathematics instruction are not just a simplified form of mathematics but make up an autonomous canon of knowledge. The relevant instruction concepts cannot simply be derived from the state of knowledge in the scientific discipline. Instead, ideas about the goal of teaching (e.g., concepts on general education) intermingle with subject-specific meanings. A psychological analysis of professional knowledge requires discrimination between content knowledge and curricular knowledge, because the aspects and focuses essential for implementing the curriculum may well conflict with the self-images of teachers who perceive themselves primarily as competent representatives of a discipline.

(c) *The philosophy of the school subject*. These are the ideas regarding the usefulness of subject-matter contents and how they relate to other areas of human life and knowledge. The philosophy of the school subject is also an implicit content of teaching. During, for example, the mathematics class, students learn whether their teacher considers that the essence of mathematics is operations with a clear, previously defined language, or rather the referential relations of the symbols applied, or that mathematics is primarily a tool for describing reality. Numerous studies on sciences and mathematics have provided empirical confirmation that these general ideas impact on teaching practice (e.g., the type of teacher explanations or the integration of student utterances into the development of the subject matter (Brickhouse 1990)).

(d) *General knowledge on pedagogics and didactics*. This covers that area of knowledge that is important for optimizing teaching-learning situations but is relatively independent from the individual subject. It includes, for example, knowledge on how to generate and maintain the necessary patterns of interaction and working styles for the planned course of instruction, or knowledge about how to deal with difficult situations and problem cases. This field can be differentiated along the same lines as the domains of subject-matter-related knowledge to produce two subdomains. The first domain encompasses knowledge in a narrower sense, such as empirically tested facts, rules, or tricks of the trade. A second domain refers to the aspects of pedagogic philosophy. This includes, for example, normative ideas and issues such as educational goals and attitudes.

(e) *Subject-specific pedagogic and psychological knowledge*. The logical structure of the subject-matter content does not permit any inherent decision on the optimal design of teaching. Empirical analyses of teaching have revealed broad variations in the didactic approach of different but equally successful teachers, even when they are teaching exactly the same curriculum (Leinhardt and Smith 1985). This shows how highly individualized the knowledge of professional teachers can be. It is something that emerges during the course of their careers through an increasing integration of general pedagogic, didactic, and psychological knowledge and specific subjective teaching experiences.

Systematic (empirical) research on the internal structure of teacher knowledge is only just beginning. Any study of the professional knowledge and actions of teachers also has to consider the possibility that research participants accumulate their own experiential knowledge that may well differ from the available theoretical concepts learned during their professional training. If this possibility is not taken into account, the real *wisdom gained through practice* may be underestimated.

6. *The Psychological Structure of Professional Knowledge*

Whereas the cartography described above deals with the semantic content—in other words, the different domains of teacher knowledge—it is also necessary to distinguish the psychological structure of knowledge, i.e., the quality of mental representation. This requires further conceptual differentiations. One widespread but very imprecise differentiation is that between

declarative knowledge (e.g., on facts and relationships) and procedural knowledge (i.e., the know-how for putting actions into effect). However, empirical analyses of teacher expertise require more precise theoretical differentiations of knowledge types like those proposed by, for example, de Jong and Ferguson-Hessler (1996). The authors discriminate between, for example, *situational knowledge* (referring to typical episodes and contexts), *conceptual knowledge* (about facts and principles within one domain), *procedural knowledge* (about actions), and *strategic knowledge* (a metacognitive component). However, the knowledge domains described above do not appear within one knowledge type alone. For example, curricular knowledge includes not only conceptual knowledge, as is immediately apparent, but also episodes containing typical task structures for the lesson. Likewise, the philosophy of the school subject should not be classified to strategic knowledge alone, but also contains elements of conceptual knowledge.

A differentiated discrimination of content domains and knowledge types is important, because it can explain why the formation and development of expertise requires a variety of different types of learning.

7. Teacher Training: The Development of Expertise

The structural ways in which teachers are trained vary greatly from country to country as well as according to the type of school within each individual country. Nonetheless, an inspection of the dimensions of this variation reveals that the organization of teacher training is always based on a—frequently only implicit—different weighting of knowledge domains and knowledge types. In other words, each specific organizational structure of teacher training also reflects different ideas about what makes up the expertise of teachers and how it comes about.

The first organizational dimension deals with the relation between *curriculum-related* and *educational-psychological* training. In many countries, training for teachers in secondary education tends to focus on subject-matter and curricular aspects, whereas elementary school teachers receive more instruction in educational psychology and didactics.

A further dimension is the *proportion of practical elements* in training. There are major differences regarding how far teacher students participate in actual lessons during their training. Likewise, variations are to be found in the relation between teacher-training institutions and the universities. Teachers do not all receive university training for all types of school in all countries. In some cases, the entire course is completed outside the university system in independent academies. In other cases, some phases of training take place at universities; others, in special teacher-training institutions. These practices are associated with different ideas about the best way to impart situation- and context-related expert knowledge.

A further dimension involves the *specialization of courses available for teachers*. In some systems, the decision to aim for a teaching qualification is made before entering tertiary education. In other countries, teacher students are recruited among persons who have already completed part of their university education, bringing different degrees of polyvalence into training. This, once again, harbors the issue of the domain specificity of the knowledge that teachers need to acquire in order to fulfill their professional tasks.

All these differences reflect critical conditions in the development of expertise, and they also weight different components of expertise in specific ways. For example, an intensive, academically oriented training broken down into subject-matter fields and oriented toward the corresponding scientific disciplines may well facilitate the development of subject-matter-related knowledge. However, the above-mentioned cartography of knowledge also shows the need to distinguish between subject-matter domains (e.g., mathematics, history) and the canon of knowledge on the subjects taught in schools. This reveals that there is also a need for special training elements that address cognitive processing of this difference.

However, at the present time, there is no general, empirically and psychologically founded model of the development of individual expertise from which a normative model of teacher training could be derived. Indeed, the wide breadth of potentially effective teacher behaviors would indicate that such an unequivocal model is probably impossible. Nonetheless, a few general findings provide at least indirect orientations regarding questions on the design of ways to train teachers. Some examples are: (a) It is clear that the development of expertise takes a domain-specific path. Therefore, training should be oriented toward the particular field of work at the earliest possible stage. (b) Expertise covers different types of knowledge, and its development requires time: time for an active analysis of the theoretical foundations of the profession (e.g., the subject-matter-related knowledge) and enough time to gather practical experience. (c) Because the mere length of a career does not lead to the development of expertise, metacognitive foundations for processing personal events are also required, so that merely passing thorough one's career actually turns into an experience leading to improved performance. (d) The research on teacher expertise reported above has shown that situation-related, experience-based knowledge (e.g., on appropriate teaching-learning arrangements structured as academic tasks for students) is an important part of expert knowledge. It can also be confirmed that the development of these components of expertise needs to be supported by the teacher students' personal confrontation with real-life situations. Nevertheless, the hidden *curriculum of field experiments* is not enough by

itself to provide an adequate preparation for high performance as a teacher (Putnam and Borko 2000). Immersion in practical experience can also lead, for example, to a reactivation of personal experiences as a student that may tend to trigger rather negative instructional behaviors. Hence, the development of teacher expertise also requires components of teacher education that make it possible for teacher students to distance themselves from and reflect on the prior experience they bring with them from their own school days. This concerns categorical and metacognitive knowledge that has to be conveyed in an academic way and in a form that also promotes a thoughtful detachment from the primary experience.

Teacher Stress and Burnout: Methodological Perspectives

1. Teacher Stress

Stress researchers regularly lament the lack of agreement in the field about what stress is and how it should be measured. The absence of a shared conceptual framework is especially evident in the study of teacher stress and has led to tremendous heterogeneity with respect to the measurement strategies used to operationalize the construct. Some investigators have focused on organizational pressures (e.g., unavailability of needed resources, workload, lack of control), others have examined the effects of interpersonal conflicts, and still others have studied teacher stress in terms of occupational dissatisfaction. In many cases, investigators have used idiosyncratic measures of teacher stress constructed specifically for their study, rather than established instruments. This practice needs to be abandoned as it introduces an undesirable source of variance that further obfuscates an already murky picture.

2. Teacher Burnout

The term 'burnout' was first introduced by Freudenberger (1974), who described it as a frequent and serious occupational hazard among professionals working under difficult conditions in alternative insti-

tutions (e.g., free clinics, halfway houses). Despite important methodological difficulties, to be discussed later, the study of teacher burnout has not been plagued by the conceptual and measurement problems that are endemic to the teacher stress literature. To a large extent, this can be attributed to the fact that investigations of teacher burnout have generally adopted the tripartite conceptualization of burnout offered by Maslach and Jackson (1981). According to this model, emotional exhaustion, depersonalization, and reduced personal achievement are the three key components of the burnout syndrome. Widespread acceptance of this formulation has resulted in the virtually uncontrasted choice of the Maslach Burnout Inventory (MBI), an instrument developed to assess the three constituents of burnout.

It is important to note that proper evaluation of the teacher stress and burnout literature is impeded by a pervasive tendency to use those terms interchangeably rather than as separate constructs. This confusion becomes especially evident when one considers the sizeable literature on the relationship between stress–burnout and health in teachers. In some studies stress and/or burnout are investigated as predictors of ill health, in other studies they are used as outcome measures, and in yet other studies they are treated as both. Although stress can be profitably studied as a possible antecedent of poor health, the same cannot be said for burnout. Burnout is generally conceptualized as a coping failure, an outcome that results from one's inability to deal with prolonged occupational stress. The MBI, in fact, is replete with items describing physical and emotional symptoms. Viewed in this way, what sense does it make to ask, for example, whether feeling fatigued and used up accurately predict physical exhaustion?

3. *Teacher Stress, Burnout, and Health*

Much of the current interest in the study of teacher stress and burnout was sparked by the idea that pathogenic occupational factors might compromise the health of teachers. The question of whether job stress is causally linked to poor health outcomes in teachers is obviously timely. Should the empirical evidence point to such a link, our educational system would benefit from worksite intervention and prevention programs. A recent review (Guglielmi and Tatrow 1998) identified 40 empirical investigations of the health effects of teacher stress and burnout. Approximately half of those studies were conducted outside the USA in such countries as the UK, Finland, Canada, Australia, Israel, Sweden, and Northern Ireland. What does this abundant cross-cultural literature indicate? At first glance, the findings would appear to support the presence of an association between stress–burnout and ill health in teachers. Guglielmi and Tatrow's critical analysis of this literature, however, makes it abundantly clear that a definitive answer is not yet possible. With respect to conceptual rigor and methodological sophistication, the study of teacher stress, burnout, and health is still in its infancy. It is useful to outline the numerous serious problems that characterize this area of research because the same inadequacies are ubiquitously present in the teacher stress and burnout literature as a whole. In the following sections, these difficulties are identified and recommendations for future research are offered.

3.1 *Inadequate Measures and the Problem of Self-report*

As indicated earlier, a lamentable measurement anarchy pervades the teacher stress literature. In the specific area of teacher stress and health, well over half of the published studies have used 'homegrown' stress measures whose psychometric properties are unknown. Such practice raises grave concerns about the validity and reliability of measurement, makes it difficult to compare findings across studies, and will ultimately thwart the comparative assessment of occupational stress associated with teaching in relation to other professions. Another important problem centers around the virtually exclusive reliance on self-report as a way to gather information about stress, burnout, and health. Self-report measures are notoriously vulnerable to selective distortion by self-presentational biases which seriously threaten the validity of measurement. Moreover, when the predictor measure (stress or burnout) and the criterion measure (health status) are both assessed by the same method (self-report), a problem known as shared method variance might spuriously produce statistically high but conceptually trivial correlations that, then, can be erroneously interpreted as meaningful and as indicating a causal association between predictor and criterion (Kasl 1978). Independent objective indicators of stress (e.g., teaching load, class size, availability of resources) need to be added to the subjective measures. The same applies to the assessment of the criterion; physiological indicators, behavioral measures, and objectively established clinical endpoints need to be considered in addition to self-reported health status.

3.2 *Unwarranted Causal Inference*

Drawing unwarranted causal inferences from correlational investigations obviously leads to erroneous conclusions about the relationship between teacher stress or burnout and health. Several possible obstacles that make causal inferences unwarranted need to be considered.

3.2.1 Reverse causation. The stress and burnout reported by teachers could be the consequence,

rather than the cause, of ill health. It has been noted repeatedly that people's self-reports of past events or experiences (e.g., stress) are distorted by a type of recall bias known as retrospective contamination. Being ill, in other words, may cause teachers to over report the amount of stress experienced as they try to find logical antecedents for their poor health (Leventhal and Tomarken 1987).

3.2.2 Construct overlap. If the presence of somatic symptoms is considered a defining component of the stress and burnout constructs, a high (but again meaningless) correlation between ill health and stress–burnout is guaranteed. As indicated earlier, for example, the most commonly used measures of burnout, the MBI and the Burnout Measure, contain many physical exhaustion items. If a burned out person is, by definition, also ill, there is obviously little value in demonstrating that this individual suffers from some physical symptoms.

3.2.3 Can the cause follow the effect? If stress or burnout are causes of ill health, they must precede the health problems. In the vast majority of cases, the published literature makes it impossible to establish whether the required temporal sequence of events is satisfied because no attempt is made to determine whether the physical symptoms occurred before or after the research participants started teaching.

3.2.4 Third variables. Although statistically significant correlations between stress–burnout and ill health are often interpreted in causal terms, it is certainly possible that no causal link actually exists and that a third unidentified variable is the cause of both. Psychological disturbance or personal difficulties unrelated to the job, for instance, could produce both a reduced tolerance to occupational demands and a heightened vulnerability to illness (or perhaps a tendency to exaggerate one's physical problems).

Fundamentally, whether or not causal links can be established and whether or not the direction of causal relationships can be clarified are research design issues. The methodological shift advocated in the next section will hopefully go a long way toward dealing effectively with these causal inference problems.

3.3 Inappropriate Research Design and Lack of Attention to Individual Difference Variables

The importance of individual characteristics in mediating or moderating the impact of stressors has long been acknowledged in the occupational stress literature and, more generally, in the stress research field. The teacher stress and burnout literature stands out as a glaring exception in its insensitivity to this issue. Variables that have been repeatedly found to influence the impact of occupational stressors include personality characteristics (e.g., hardiness, Type A behavior pattern in its old and new formulations), gender and other demographic characteristics (e.g., age, race), the availability of supportive networks, as well as other individual factors (e.g., cognitive appraisal). Against this backdrop of complex relationships and interactions, the teacher stress literature has typically failed to adopt appropriate multivariate strategies and has preferred instead to focus on simplistic bivariate relationships between, for example, teacher stress on one side and job satisfaction, or psychological dysfunction, or physical symptoms, or stress reduction approaches on the other side. Cross-sectional investigations of bivariate relationships are unlikely to enhance our understanding of the individual and interactive contribution of multiple variables. More sophisticated research designs, better equipped to test multifactorial models of teacher stress, are urgently needed (Kasl 1987).

The investigation of teacher stress and burnout would benefit from a shift to carefully designed longitudinal studies, in which the predictor is assessed before the criterion. When appropriate multivariate data–analytic strategies are applied (e.g., hierarchical regression, crosslagged panel correlation, structural equation modeling), these research designs can be used to test the fit of causal models of teacher stress. They hold the potential to answer questions about both the direction of causality and about the interactive contribution of multiple factors (Frese and Zapf 1988).

3.4 Empiricism in Need of a Theory

From a conceptual and methodological perspective, the overall quality of the teacher stress and burnout literature trails considerably behind its parent occupational stress literature. Over the last 20 years, several heuristically fruitful theoretical formulations (e.g., the Person–Environment Fit Model, the Demand–Control Model, the Effort–Reward Model) have guided empirical contributions to the general area of occupational stress. Despite the demonstrated value of those theoretical perspectives, the teacher stress–burnout research has remained unfortunately impervious to their influence. The typical teacher stress–burnout study is essentially atheoretical. Dozens of measures are intercorrelated and *post hoc* explanations of statistically significant associations are offered without an effort to interpret those findings within a theoretically meaningful framework. The adoption of a theoretical framework would help organize research findings across investigations, would introduce consistency in the way constructs are operationalized and assessed and, most importantly,

would point to focused research hypotheses to be tested empirically.

In the occupational health literature, for example, the Demand–Control Model has emerged as a particularly influential theoretical perspective which has stimulated a tremendous amount of work, especially in Europe. According to this model, job demands (e.g., workload, deadlines) and decision latitude (e.g., freedom and control) are the key factors that increase and decrease, respectively, job strain (Karasek and Theorell 1990). On the basis of this model, focused hypotheses can be formulated concerning the conditions that are likely to exacerbate or to alleviate occupational stress. The predictive value of the Demand–Control Model has been empirically established in a variety of work settings (Kristensen 1996, Theorell and Karasek 1996); yet, the study of teacher stress has not been inspired by it. The futility and sterility that characterize much of the current research efforts in the field of teacher stress and burnout are especially disconcerting when one considers the ultimate importance of this work. The field is ready for a shift from atheoretical, descriptive, and cross-sectional studies to theory-based prospective evaluations of causal models of teacher stress and burnout. Until this happens, stress-reduction interventions targeted at teachers are obviously premature.

Teaching and Learning in the Classroom

The typical image of a classroom is misleading. Classrooms are not neat, orderly places with a teacher standing in front of about 25 students listening to what the teacher is saying or working on a well-defined task. Even in quiet, well-behaved classrooms, this image fails to capture the complex, multifaceted nature of classroom teaching and learning.

Classroom life is an active, dynamic, and social experience. Cognitive, cultural, social, affective, emotional, motivational, and curricular issues occur simultaneously. Teachers and students work together in a rich psychological soup, the ingredients of which often are not apparent to a casual observer. Friends, strangers, adversaries, and dating partners (current, future, and imagined) find themselves together for long periods of time. Many agendas are operating in addition to learning the desired curriculum.

Teaching and learning in a classroom occur on many levels at the same time. Although cognitive and curricular factors typically receive the most attention, learning and understanding do not occur in isolation. Nor is cognition the only process influencing what students learn. It is impossible for students to acquire subject-matter knowledge without simultaneously acquiring or reaffirming a variety of non-cognitive outcomes associated with his or her prior knowledge, affective predispositions, and the instructional experience within which the learning occurs.

A student does not merely learn facts about World War II, for example. He or she also learns whether the study of history is enjoyable or boring. Attitudes about Europeans, Russians, Italians, Japanese, and Americans are acquired or reaffirmed, as are the extent to which certain individuals can be trusted and the horrors (or glory) of war. Students also discover whether he or she is a good student with good ideas and the ability to learn history (or school subjects in general). These outcomes are all part of what students learn, *whether or not these issues are an explicit part of the lesson*. Contrary to popular belief, it is impossible to present a lesson in such a way that only cognitive information is acquired.

In their attempt to understand and explain teaching and learning, researchers commonly distinguish among cognitive, affective, social, communicative, and

curricular factors. Distinctions also are made between the external world of the classroom (the environment) and the internal world of the student (their mental processes, prior experiences, and present interpretations). Students, however, do not engage in this type of analysis as they encounter all of these things simultaneously. The above distinctions mean little if anything to them, as they seek to make sense of what they are experiencing and learning (Nuthall 1999). Thus, it is helpful to consider teaching and learning from the perspectives of both external analysis and the internal experience of students.

1. Classroom Characteristics

A variety of classroom characteristics have been suggested in the research literature (Shuell 1996). Several of these were identified in the preceding paragraphs, including the reality that many things occur simultaneously on different levels. Other characteristics include the following.

(a) *Immediacy*. Things happen at a rapid, come-and-go pace with little time for reflection.

(b) *Unpredictability*. Given the many factors that operate during social interactions in a classroom, it is difficult if not impossible to predict how a particular activity will play out, and unexpected turns of events are common.

(c) *Publicness*. Classrooms are public places with most events witnessed by a large portion of the class. Most students are aware of how the teacher treats or reacts to a particular student and how other students react to one another and the teacher.

(d) *History*. Any group that remains together for a period of time develops a history of common experiences, norms, and routines that influence the way they perceive and relate to one another. History is a characteristic of all interpersonal relationships, and it is an important determiner of how people relate to one another as relationships mature. The group history of a class is an important aspect of classroom teaching and learning.

(e) *Academic goals*. Every classroom strives to achieve certain academic goals. Some of these goals are explicit while others are implicit. Although these goals differ considerably among classrooms, every classroom has academic goals that students are expected to achieve. The way in which these goals play out, however, is influenced by differing perceptions among students and between teachers on the nature of academic tasks and the respective role of teacher and students.

(f) *Social norms*. Social norms exist in every classroom. These norms dictate appropriate behaviors for teacher–student and student–student interactions *in that classroom*. 'Appropriate' does not necessarily refer to any particular set of outside guidelines. For instance, the social norms of a particular classroom may permit students to talk back to the teacher or to use profanity.

(g) *Student characteristics*. Students differ in many ways. The unique combination of student characteristics in a particular classroom helps define how the teaching–learning process plays out in that classroom. Students' prior knowledge, prior experiences, affective predispositions (attitudes), and values, as well as the range of characteristics that exist in a particular classroom, are important factors influencing classroom life.

(h) *Philosophy of education*. Some philosophy of education and/or theory of student learning is inherent in every classroom (this reality is discussed at greater length in the next section). Classroom participants (including the teacher and principal) often are not aware of the particular theory on which their activities are based. In a few cases, however, a group of people will work to establish a school or classroom based on a particular theoretical or philosophical perspective, e.g., student centered, back to basics, and case-based learning, to name only a few.

2. Inherent Philosophy/Theory of Education

No two classrooms are the same. There is considerable variation in the social organization, group norms, and specific activities that occur in a particular classroom. There are many reasons for these differences, but one important reason is that the factors identified in the preceding section are held together and orchestrated by different philosophies, beliefs, and theories of education.

Every classroom is based on some theory of teaching and learning. The types of learning activities, instructional practices, and assessment procedures differ, depending on the particular theory being followed (see *Learning Theories and Educational Paradigms* for examples of different theoretical approaches to learning). This theoretical foundation usually is implicit, however, and the participants are not aware that their activities and interactions reflect a particular philosophy of education. Some of these philosophical differences have endured for centuries, and the debate will undoubtedly continue, for they represent fundamental differences in how people view humankind. For example, the 'factory model' of schooling that dominated education in the United States and parts of Europe for many years is based on production and management procedures proven successful during the industrial revolution. This perspective on teaching and learning stands in sharp contrast to the voices of Thoreau, Dewey, and others who advocate discovery, social reform, and freedom as the appropriate means of education (Shuell 1993).

Thus, depending on the theory operating in the classroom, students may engage in memorizing factual information or engage in activities designed to produce

meaningful learning. These different philosophies are evident in the many metaphors used to characterize teaching and learning, e.g., 'ship captain,' 'midwife,' and 'learning community.' Different models of teaching serve as organizational structures for classroom activities and procedures (Joyce et al. 1992).

These different conceptions of teaching and learning influence both the research that is conducted and the practices, procedures, and activities that are implemented in the classroom (Shuell 1996, Nuthall 1997). One conception may need a relatively simple theory to explain what occurs in a classroom and to establish appropriate practices and activities, e.g., having students rehearse factual information so they are able to reproduce it on demand. Another conception may require a fairly complex theory to accomplish the same purpose, e.g., having students explain to one another the implications of the material they are studying.

Several different perspectives on classroom teaching and learning are clearly evident in the current literature. Each perspective typically employs different theoretical models of learning and assesses students using different criteria and different types of assessment instruments. Four common ones are discussed below (more detailed discussions are available in Shuell (1996), Nuthall (1997), and see *Learning Theories and Educational Paradigms*).

2.1 Behavioral Perspectives

Although behavioral conceptions of teaching and learning are not popular in the current education literature, many classrooms are still based on these traditional theories. In these classrooms, the curriculum generally consists of factual information and methods for solving well-defined problems. Learning occurs, according to this perspective, as a result of reinforced practice of predefined material for the purpose of reproducing this information or skill when needed. These classrooms can be recognized from activities that stress factual information (often isolated from other information), repetition (in one form or another), and correct answers.

2.2 Cognitive Constructivist Perspectives

Cognitive constructivist conceptions of teaching and learning focus on students understanding the material being studied rather than on the acquisition of factual information and skills; that is, on mental processes rather than behavior. Knowledge is not seen as a commodity passed from teacher or textbook to students' minds. Rather, this perspective believes that students construct their own understandings as they seek to make sense of the material and the classroom experiences in which it is embedded. Learning is seen as the creation and reorganization of students' conceptual structures (knowledge) as a result of cognitive processing. These classrooms can be recognized by students engaged in sense-making activities and authentic (real-life) learning tasks.

2.3 Sociocultural and Community-focused Perspectives

Sociocultural perspectives see teaching and learning as a social rather than cognitive activity. Based on the work of Russian psychologist Lev Vygotsky (1978) and anthropologists such as Jean Lave (Lave 1988, Lave and Wenger 1991) and Barbara Rogoff (Rogoff 1990, Rogoff et al. 1996), this perspective believes that focusing on individual learners is a mistake, in sharp contrast with behavioral and cognitive views. Acquiring culturally relevant knowledge is a process in which the learner becomes a member of a community of practice or community of learners (Brown and Campione 1996, Rogoff et al. 1996). An apprenticeship model of teaching and learning is often employed (Shuell 1996). Classrooms representing this perspective are recognizable by students working on group projects with individual students working on interrelated subtasks. The ability of individuals to work together in negotiating solutions to problems and conceptual understandings is stressed, with the teacher supporting and helping students, as appropriate, to accomplish these goals.

2.4 Linguistic Perspective

The linguistic perspective is similar to the sociocultural perspective in that language is seen as a cultural artifact. It differs from sociocultural views, however, in that language is seen as playing a far more central role in shaping the social interactions that occur in the classroom. As language communities, classrooms develop their own forms of communication. The negotiations that occur as part of this process create opportunities to learn and give birth to the knowledge and meanings that comprise the curriculum. Narratives and stories, rather than cognitive schemata or social participation, are seen as the primary way in which students 'process, come to understand, and remember experiences' (Nuthall 1997, p. 713). Classrooms based on this perspective can be recognized by the instructional use of student–student and teacher–student discussions in which students explain and negotiate the meaning of the topics being studied.

3. Instructional Experiences in the Classroom

Within the complex social environment of the classroom, teachers and students engage in a variety of activities as they work together to accomplish tasks

with academic, social, and personal consequences. Schools and their classrooms, of course, are organized in many different ways. The classroom community may be one that focuses on intellectual activities and in which the members generally enjoy one another's company. Or the community, not necessarily by design, may focus primarily on social relationships (positive or negative) and personal agendas. Whatever the environment, it sets the stage for the teaching and learning that occur in the classroom.

Classroom teaching and learning, however, are not the unidirectional process they often are thought to be. The teacher's philosophical and theoretical beliefs clearly affect what happens in the classroom, but the teacher is not the only one in the classroom determining what occurs. Students, as well as teachers, hold personal theories of learning and teaching that influence the instructional tone of the classroom. A teacher may believe, for example, that learning results from problem solving and critical thinking and provides activities consistent with this belief. The students, however, may believe (perhaps encouraged by parents and previous classroom experiences) that learning is a process in which information is remembered (memorized) well enough to be reproduced in a test. (The opposite scenario, of course, is just as plausible.) Thus, the instructional process that actually transpires in the classroom must either be negotiated among the participants or dictated by the teacher. In either case, social as well as intellectual consequences are involved.

Given the complexities that exist in classrooms, not all students in the same classroom learn the same thing. Even when students engage in the same activities, they learn different things in different ways, and they learn more than they are taught (Nuthall 1999).

4. *The Ideal Classroom?*

Some people hold a myth that there is a single best way to organize and run a classroom. There are many ways in which classrooms can be compared, but in order to judge one classroom as being better than another, agreement must exist on the criteria used to determine 'best,' i.e., best for what? Given the diversity of perspectives and philosophies discussed above, it is not surprising that different people insist on different criteria.

An effective classroom is one that achieves its goals. When schools or classrooms have different goals, comparisons regarding which set of outcomes is 'best' becomes a philosophical discussion. Differences in desired outcomes can occur even when the curriculum appears to be the same, e.g., a particular school or teacher may implement the same formal curriculum (either intentionally or unintentionally) by having students learn factual knowledge or by engaging them in critical thinking. Different assessment practices and procedures can also result in different interpretations of the formal curriculum.

Different instructional methods are appropriate for accomplishing different goals. Educational research and theory can be of assistance in identifying appropriate classroom activities, once desired outcomes are identified. The latter, however, is largely a philosophical issue. Regardless of the goals and curricula pursued, there is greater likelihood those goals will be attained if the teacher and students consider them to be important and adopt them as their own personal goals. Goals and tasks imposed on someone by others usually are pursued with little enthusiasm.

5. *Summary*

Classroom teaching and learning is a complex, multilayered, and social experience. Many things happen at the same time, and the students and teacher must interpret and process these events with considerable rapidity. Teaching is not a one-way transmission of information, for students influence the process as much as the teacher. The teacher plays an extremely important role in establishing a meaningful classroom environment for students, but in the final analysis, it is the social and psychological activities and responses of each student that determines what he or she learns.

The way in which each student perceives, interprets, processes, and understands classroom activities—not what the teacher does—is the single most important factor in determining the educational outcomes acquired by that student. Teachers and outside observers must be careful when making inferences from observations of student performance (either formal or informal). The students' perceptions, interpretations, and understandings may be very different from what they appear to an external observer. A student's performance on an assessment instrument, for example, may reflect something rather different from the teacher's interpretation, for there are many ways for a student to answer questions and solve problems.

Given the complexity that exists in classrooms, different theoretical perspectives and philosophies of education are common. These different perspectives add richness to our understanding of classroom teaching and learning, but they belie a belief in an ideal classroom experience appropriate for all students. Fundamentally different philosophical beliefs about education and human existence lead to fundamentally different criteria for both the curriculum and classroom practices. Some of these differences have existed for centuries, and the debate is likely to continue. Nevertheless, our understanding of the dynamics and complexity of classroom teaching and learning has grown considerably in recent years.

Teaching as a Profession

This entry initially outlines the contested nature of the concept profession. There then follows an examination of how professionalization has been a key project of teaching as an organized occupation and the implications of this project for status and power. From the mid-1970s, teaching as a profession began to undergo fundamental changes and these are viewed from the perspectives of proletarianization and deprofessionalization. Finally, the worldwide 'educational reform movement' is shown as predicated on conceptualizations of the new professionalism.

1. Profession

Profession is a much-disputed sociological concept, and the existence of criteria which allegedly distinguish professions from other occupations has been strongly contested. Yet the concept has not fallen into desuetude and continues to constitute the focus of lively debate (see Freidson 1986, for a discussion of the concept profession). The critique of the idea of profession was initially a reaction to a functionalist perspective which dominated much of the earlier theorizing. This depicted professionals as exercising knowledge-based skills as autonomous practitioners in nonroutine contexts according to a client-focused ethic guaranteed by a self-regulative professional body. From this theory were derived sets of distinguishing criteria which Millerson (1964) showed to be highly diverse. However, despite this diversity, some criteria were common to most lists. These core criteria were exemplified in the list proposed by Lieberman (1956) in his early study of teaching as a profession: the provision of an essential social service, intellectual techniques, lengthy specialized training, practitioner and group autonomy, personal responsibility for judgments, an emphasis on service, and a self-governing body.

Critics of the functionalist perspective argue that the idea of a profession, and the alleged distinguishing characteristics, is less an analysis of practice than the theorization of a self-interested ideology developed historically by a small group of elite occupations characterized by independent practitioners (e.g. lawyers, doctors) offering a service for fee. An alternative power perspective presents these occupations as having succeeded over time in gaining control over a market for a service, achieving responsibility for bestowing the license to practice through a self-regulating body, strengthening the occupational boundary through credentialism and social closure and using increments of power to enhance levels of status and remuneration.

Despite the power critique that demonstrates the ideological nature of the idea of a profession and of the alleged criteria, profession retains a heuristic potential in the exploration of issues of autonomy, control, knowledge, practice, etc. This heuristic deployment entails treating profession as a particularistic phenomenon the social construction of which varies over time and space (see Ginsburg 1997 for a wide-ranging review). In this connection it can be noted that many of the key issues addressed in the sociology of the professions are different in the Anglophone countries than in continental Europe where the state is more involved in training and employment, and where status is derived more from the institutions of higher edu-

cation which practitioners attended than from market position. The heuristic deployment of profession also entails an emphasis on professionals—their work relations and practices, their lives and careers (see the study of school teaching as a profession by Lortie 1975). In this entry professionalization provides the major organizing theme.

2. Meanings of Professionalization

Professionalization is a process whereby occupations have become, or seek to become, publicly recognized as professions according to the degree to which they meet the alleged criteria. Professionalization can be seen as having two strands. One strand is concerned with the improvement of status. The other strand is concerned with the improvement of the capacity of members to enhance the quality of service which is provided. It is generally assumed that these two elements proceed *pari passu* but this need not be the case. The terminology in relation to this distinction is confusing, however, recent usage distinguishes between professionalization as the pursuit of status and professionalism as the improvement of skills and hence service. The latter terminology will therefore be used here.

One can perhaps refer to 'early' professionalization as the process whereby the elite professions established their position and 'late' professionalization as the period beginning in the late nineteenth century when with 'the rise of professional society' (Perkin 1989) a large number of occupations, including teaching, began their quest for professional status by taking measures to meet the alleged criteria. In these terms, it can be said that teaching was in the process of professionalization from the mid-1870s to the mid-1970s, increasingly so after World War II. The length of the period of teacher education was extended. An increasingly higher proportion of teachers were graduates. Teacher training institutions became integrated into the universities. The knowledge base of teaching became more extensive. Teachers enjoyed a high degree of pedagogical autonomy within a loosely-coupled school structure. Teachers' organizations increased their influence with government. And in some systems, e.g. Malta, teaching achieved the legal status of a profession. However within this general process of professionalization are acute gender differences (Gitlin and Labaree 1996).

3. Professionalization and the Occupational Status of Teachers

Status is multidimensional, and the success of the professionalization project varies across these dimensions. If occupational status denotes the degree to which an occupation meets the alleged criteria of a profession, then the status of teaching in most countries has been increasing. However, this has not been reflected in any obvious improvement in the occupational prestige of teaching, defined here as the relative position of an occupation in a hierarchy of occupations as ranked by samples of members of the public. Teaching is in most countries ranked in the upper quartile of such hierarchies, but below the major professions of medicine, law, etc., the status group of aspiration for teachers who thereby experience a degree of relative deprivation.

International comparisons of occupational prestige (Treiman 1977) show some differences in the relative ranking of the single occupational title of schoolteacher across societies but the data are too sparse to allow generalization and no obvious patterns suggest themselves. Perhaps of greater significance are the quite marked intra-occupational differences in rank, according to age of the students taught and the social and academic character of types of school. Comparative data show that hierarchies of occupational prestige have a high degree of stability—rank correlations over time and space almost invariably exceeding 0.9, which suggests that there is relatively little scope for an established occupation to enhance its prestige to any substantial degree.

It has been suggested that some inherent characteristics of teaching as an occupation are likely to have an inhibiting effect on enhanced prestige. Leggatt (1970) grouped these into three categories, i.e. characteristics of the practitioner group (e.g. size, social class, background of entrants), characteristics of clients and client relations (e.g. children as clients, compulsory and protracted relationships), and characteristics of work performance (e.g. unclear expertise, performance hard to evaluate).

Perhaps of more significance, because potentially more achievable, is the esteem in which teachers are held, defined here as the noncomparative evaluation of an occupation on the basis of such factors as quality of service, client-orientated values and practitioner commitment. Esteem is relatively independent of both status and prestige. In many countries, especially in Asia and Africa, the teacher—as 'guru'—enjoys high esteem but this is not reflected in the hierarchy of occupational prestige. However, esteem is an amorphous phenomenon shaped by various factors, for example, personal experience, image as conveyed by media representation, etc., and is currently under-researched.

4. Professionalization and Power

The professionalization project of teachers in Anglophone countries emerged in the late nineteenth century, coinciding with the growth of mass public education and the formal training of teachers. It was shaped by teachers in the public sector whose salaries

were ultimately paid from public funds. Teachers were thus *de facto* public employees, though the condition of their employment varied between countries. Their collective power was therefore shaped by their relationship with their employer. Two main strategies of professionalization were open to teachers: a professional body strategy, which focused on improving status on the assumption that this would extend to an enhancement in salaries and conditions, and a trade union strategy which put a priority on improving salaries and conditions and thence status. In most systems the trade unionism emerged as the major strategy though this was also accompanied by a 'professional' rhetoric. In the USA this tension is revealed in the contrasting strategies of the National Education Association and the American Federation of Teachers.

A full discussion of teacher unionism is beyond the scope of this entry. However, attention can be drawn to a group of studies which have explored the state–profession relationship in the UK in socio–historical detail (Ozga and Lawn 1981). These studies show that teacher professionalization was the function of a fluid exchange relationship between teacher unions and the state whereby the state conceded a 'legitimated teacher professionalism' in exchange for teachers' acceptance that their legitimate sphere of professional activity was the classroom and not the political arena.

5. *Critics of Professionalization*

The central criticism of professionalization is that it is a project for self-aggrandisement at the expense of client interests. Critics are to be found across the political spectrum, though their analyses are differently nuanced and they propose competing prescriptions. The targets of all critics tend to be the same, namely the 'criteria' which constitute the quest of professionalization. Just two of these will be considered: practitioner autonomy and theoretical knowledge.

One line of criticism is that teachers' protection of their autonomy is a barrier to collaboration between teachers and their immediate clients: students, their families and the community. Ginsburg (1997) has contrasted a 'professionalization' project, which leads to teachers remaining aloof from their immediate clients, with a 'political' project, whereby teachers collaborate with their communities in order to pursue an equitable educational system. Hargreaves (1999) has envisioned a future whereby the teaching profession in partnership with the public becomes 'a vigorous social movement of acting subjects rather than frogmarched individuals' (p. 71). Another form of critique sees teachers' autonomy as a mechanism for avoiding legitimate accountability to a variety of stakeholders, not least the state. The policies which follow from this view entail teachers accepting a managerially led collective accountability for their professional activities. A third form of the critique is that autonomy is a barrier to the increased professionalism of teachers as defined above. Lortie (1975) drew attention to the strong strain of individualism in the culture of teaching and a strong norm of noninterference which he saw as inhibiting teachers from building a strong technical culture.

The knowledge base of teaching has two components: knowledge of subject matter and knowledge of pedagogical, curricular and educational theory. It is the second of these which has been the focus of much criticism, not least from within the profession, as generations of teachers have questioned the relevance of theory. But there is an ambivalence here as teachers' organizations see a strong knowledge base as facilitating a link with the academy which is seen as a source of prestige. However, the likelihood of the full academic acceptance of educational theory has been doubted. The thrust for building a body of educational theory came largely from teacher educators. These criticisms of autonomy and knowledge—and criticisms directed at codes of ethics, self-government, etc.—have, over the past 20 years, fuelled a political reconceptualization of teaching.

6. *Deprofessionalization or 'The New Professionalism?'*

The decline in professional society began in the mid-1970s as politicians in many countries began to question the perceived monopolistic position, producerism and the weak accountability of the professions, together with rising costs of professional services. In education this contributed to a worldwide 'reform movement.' The patterning of this movement varied across countries but some of the main characteristics are as follows: the decentralization of school management and the creation of local markets; the centralization of policies relating to the curriculum, its delivery, its objectives and its measured outcomes; the introduction of a range of accountability procedures nationally and locally; and an increased expectation of the services which the school would deliver.

Three major perspectives on these changes can be identified and discussed: proletarianization, deprofessionalization and 'the new professionalism.'

Proletarianization focuses particularly on the intensification of teachers' work as they are increasingly required to fulfill a wider range of functions, as much managerial as pedagogical. This process is seen as entailing the deskilling of teachers as their range of knowledge and skill is reduced and routinized and a loss of control over their work. The proletarianization position is a component of a social class perspective which is an alternative to the status perspective which dominates much of the literature on the professions (see Robertson 2000, for a post-Fordist analysis of

teachers' work, and Smyth et al. 2000, for a theoretical account and illustrative case study of the labor process approach to teachers' work). The proletarianization perspective is also critical of professionalization as an attempt to enhance teacher autonomy as this is seen as inimical to the interests of students and their families.

The deprofessionalization perspective focuses on the degree to which teaching has regressed from the levels achieved in meeting the traditional criteria. The knowledge base of teaching is seen as being eroded with a move towards competency-based training and school-based professional development. Teacher autonomy is seen as undermined as curricular content and learning objectives become more highly specified. And the impact of teachers' organizations on policy is seen as having been greatly reduced.

'The new professionalism' is an emerging concept and is not readily defined. Essentially it marks a move away from the idea of a profession and the 'status' dimension of professionalization. It implicitly shifts the emphasis to professionalism with its emphasis on skills and service. In political and administrative discourse it marks a growing emphasis on professional rather than profession and can be over-simply summarized as follows: to be 'professional' is to have acquired a set of skills through competency-based training which enables one to deliver efficiently, according to contract, a consumer-led service in compliance with accountability procedures collaboratively implemented and managerially assured.

In educational discourse 'the new professionalism' embraces a number of perspectives which accept, to a greater or lesser degree, the emphasis on professionalism defined as 'commitment to the improvement of service.' Writers who have delineated 'the new professionalism' include Caldwell and Spinks (1998) from the perspective of school management and Hargreaves (1994) from the perspective of teachers' professional development.

7. *Conclusion*

The increasing worldwide political salience of education has led over the past 25 years to changes in the conceptualization of teaching as a profession. In the terminology adopted in this entry, the shift has been from a focus on professionalization to a focus on deprofessionalization and, latterly, to professionalism, i.e. from a concern with status to a concern with the quality of service—without accepting uncritically political and managerial conceptions of quality. In fact, professionalism may entail a resistance to official policies in giving priority to the perceived needs of immediate clients.

The focus of enquiry has also changed. Of growing significance are studies of the teacher's work (e.g. Little and McLaughlin 1993, Helsby 1999) and of teachers' lives and careers (e.g. Day et al. 2000), which are open to the complexities of the situations. An example of this is an openness to the different meanings and practices conceptualized as collaboration or collegiality. These recent studies explore how collegiality can be professionally constraining or liberating, depending on the forms which it takes. It is the exploration of this complexity in local as well as national contexts, and of the relationship between 'the new professionalism' and 'the new managerialism,' that is beginning to characterize the study of teaching as a profession.

Teaching for Thinking

Is it possible to teach thinking skills that improve a person's cognitive functioning? Can a person learn to become a more effective problem solver? In short, can thinking be taught? These are the kinds of questions examined in this article. After an introduction which contains definitions, a rationale, and an example four issues are examined concerning teaching for thinking—what to teach, how to teach, where to teach, and when to teach.

1. Introduction

1.1 Definitions

Teaching for thinking refers to instruction that is intended to improve the effectiveness of a people's thinking. This definition consists of two parts: (a) *teaching*—teaching for thinking involves instruction, and (b) *thinking*—the goal of the instruction is to improve someone's ability to solve problems. *Teaching* refers to manipulations to a learner's environment which are intended to foster a change in the knowledge of the learner, whereas *thinking* refers to cognitive activity aimed at solving a problem. In sum, teaching for thinking involves instructional manipulations that are intended to foster the learner's knowledge of how to solve problems.

Teaching for thinking is a type of cognitive strategy instruction (Halpern 1992, Mayer and Wittrock 1996, Pressley and Woloshyn 1995). In cognitive strategy instruction learners are taught how to control their cognitive processing such as how to think, how to learn, how to remember, or how to motivate oneself. Thus, cognitive strategy instruction involves fostering metacognitive knowledge—knowledge of how one's mind works—and strategic knowledge—knowledge of how to develop plans for accomplishing goals—rather than procedural knowledge—knowledge of how to carry out a routine—and declarative knowledge—factual knowledge about some topic.

1.2 Rationale

Students are expected to be effective thinkers but rarely are taught how to think. Students are expected to be able to solve problems but rarely are given productive experience that would foster the development of problem-solving skills. Although the formal curriculum in any subject area may emphasize the learner's acquisition of content knowledge, an often neglected part of the curriculum concerns the learner's being able to use what was learned to solve problems. Instruction in how to think is sometimes not part of the formal curriculum but rather is part of the hidden curriculum; although unstated it is expected that learners will be able to use what they have learned in problem solving. For these reasons, there has been a growing call for explicit instruction in how to be a more effective problem solver (Halpern 1992, Mayer and Wittrock 1996, Pressley and Woloshyn 1995).

1.3 Example

The Gestalt psychologist, Wertheimer (1959) offers a classic example of the challenges of teaching for thinking. He describes a classroom in which a teacher presents a lesson on how to find the area of a parallelogram. The teacher draws a parallelogram on the chalk board, drops a perpendicular line from the top base to the bottom base (which is called the height), measures the height, measures the base, multiplies height times base and gives the result as the area (using the formula area = height × base). After the demonstration, the teacher calls on a student to solve a similar problem at the board and the student is successful in carrying out each of the steps. Later the students do very well on a quiz in which they must compute the area of parallelograms.

In spite of the apparent success of the lesson, Wertheimer (1959, p. 15) criticized the teaching for its lack of emphasis on thinking: 'Most people would say, "This is an excellent class; the teaching goal has been reached." But observing the class, I feel uneasy, I am troubled. "What have they learned," I ask myself. "Have they done any thinking at all? Have they grasped the issue? Maybe all they have done is little more than blind repetition."' As a test, Wertheimer presents an unusually shaped parallelogram, and the students respond by saying 'We haven't had this yet.'

In contrast to teaching for rote learning, Wertheimer suggests that students should be encouraged to discover that the triangle on one of the parallelograms could be cut off and placed on the other end to form a rectangle. In this way, students could see that a parallelogram is simply a rectangle in disguise. Since they already know how to find the area of a rectangle, the solution to parallelogram problems now becomes much easier. Wertheimer referred to this method of teaching as learning by understanding, and claimed that it resulted in superior problem-solving transfer, that is, in being able to use what was learned in new situations. According to Wertheimer, rote teaching methods lead to reproductive thinking—being able to repeat what was taught—whereas meaningful teaching

methods can lead to productive thinking—being able to use what was taught in new situations.

When the goal is teaching for thinking—that is the promotion of productive thinking—instructors need to consider four issues: what to teach, how to teach, where to teach, and when to teach. In addressing these four issues, Mayer (1997) has compared four common-sense principles of teaching for thinking with corresponding alternative principles based on research in cognitive science.

2. *What to Teach*

The first issue concerns what to teach. Should instruction focus on thinking as a single monolithic ability or as a collection of smaller component skills? The common-sense view casts thinking as a single ability: the ability to solve problems is a unitary skill so teaching for thinking involves improving one's mind in general through learning certain school subjects that require mental discipline and orderly thinking. An implication of the single ability view of what to teach is that the mind is a sort of mental muscle that needs to be exercised to increase its overall functioning. When the mind is improved through learning a school subject that exercises the mental muscle, then the learner will also show improvements in a wide variety of academic tasks.

In the early 1900s the dominant view among educational scholars was the doctrine of formal discipline, namely, the idea that learning certain school subjects, such as Latin, geometry, and logic, promoted proper habits of mind including mental discipline and orderly thinking. One of the first tasks of the newly established field of educational psychology was to test the doctrine of formal discipline in a scientifically rigorous way. For example, in a convincing series of studies, Thorndike and co-workers found that students who had learned Latin performed no better than students who had not learned Latin in learning a new school subject such as bookkeeping (Thorndike 1924). Similarly, more recent claims that learning programming languages such as Logo would improve children's minds were also put to the test; researchers found that students who learned Logo did not outperform non-Logo learners on problem-solving tasks unrelated to Logo (Mayer 1988). Overall, the research evidence failed to support the common-sense view of thinking as a single ability.

In contrast, a common theme in modern research in cognitive science is that a person's performance on any cognitive task—such as solving a word problem or writing an essay—depends on the degree to which the person possesses relevant component skills (Sternberg 1990). To write an essay, for example, students need to engage in three main cognitive processes—planning, translating, and reviewing (Flower and Hayes 1980); to solve an arithmetic story problem students need to engage in four cognitive processes—translating each sentence into a mental representation, integrating the sentences into a coherent mental model of the situation, planning a set of steps to solve the problem, and executing the solution plan (Mayer 1992).

According to the multiple skills view, teaching for thinking should focus on helping students learn the collection of component skills that are relevant for each important cognitive task rather than on improving the mind overall. For example, Pressley and Woloshyn (1995) have shown how focused instruction in component skills can improve students' performance in reading, writing, maths, and other cognitive tasks. In answer to the question of what to teach, their answer is to teach a collection of smaller component skills.

3. *How to Teach*

The second issue concerns how to teach. Should instruction focus on encouraging students to generate correct answers (i.e., the product of problem solving) or on the methods used to solve problems (i.e., the process of problem solving)? The common-sense view favors the product-of-problem-solving approach: as in learning any skill, the best approach to learning of thinking skills is to get plenty of practice in answering questions along with feedback on whether or not the answers are correct. Although drill-and-practice instructional methods can be effective in improving performance on problems like those presented during instruction, they sometimes fail to help students solve transfer problems that go beyond those presented during instruction.

For example, in a classic study, Brownell and Moser (1949) taught students to solve two-column subtraction problems (such as $76-48=$ ____) by drilling them in the steps of the procedure or by showing how the steps correspond to using sticks that bundled into groups of 10 (i.e., by using concrete manipulatives). Although students who learned with concrete manipulatives did not outperform the traditionally taught students on retention problems—two column subtraction problems like those given during instruction—they did excel on transfer problems, such as solving three-column subtraction problems. Brownell and Moser concluded that students understand the material better when the emphasis changes from product to process.

Apprenticeship approaches offer a straightforward way to focus on problem-solving processes because learners attempt to model the cognitive processes of more skilled performers. For example, in an early study, Bloom and Broder (1950) taught unsuccessful students how to answer exam questions by modeling the problem-solving processes of successful students. First, a successful student described his or her thought process while answering an exam question. Second,

the unsuccessful student described his or her thought process while answering the same question, and then the unsuccessful student compared his or her process with that of the successful student. After 10 to 12 sessions with different questions, the unsuccessful students were much better able to answer new exam questions than were a group of matched students who received no training. Bloom and Broder concluded that teaching for thinking is most effective when instruction focuses on the process of problem solving rather than solely on the product of problem solving.

According to the process-of-problem-solving view, teaching for thinking should focus on helping students learn the methods for how to solve problems rather than solely on practice in getting the right answer. Modern research in cognitive science has demonstrated the value of apprenticeship approaches that emphasize the process of problem solving (Collins et al. 1989). Successful techniques include reciprocal teaching of reading comprehension skills (Brown and Palinscar 1989). In answer to the question of how to teach, their answer is to model the process of problem solving.

4. *Where to Teach*

A third issue concerns where to teach. Should instruction be given as a general, independent, stand-alone course or should instruction in thinking be incorporated into specific subject matter areas? The common sense view favors the independent approach: all students should be required to take a course in problem solving, in addition to their regular content courses. An implication is that problem-solving skills are best learned as an isolated subject, separated from the context in which they will be applied.

The Productive Thinking Program was intended as a stand-alone course in problem solving, aimed at helping elementary school students learn to generate and test hypotheses (Covington et al. 1966). It consisted of a series of 15 cartoon-like booklets, each describing a mystery or detective story. The reader was asked to participate in solving the case by generating and testing hypotheses, along with help from various characters in the booklet who modeled appropriate processes for generating and testing hypotheses. Students who took the course tended to outperform matched students who had not taken the course on solving problems like those in the booklets, but not on problems that were from a different context (Mayer 1992). Thus, in spite of attempts to teach context-free problem-solving skills, students tended to perform best in using the skills within the context they were presented. These results tend to refute the common-sense view that teaching for thinking should occur as a separate course.

In contrast, cognitive science research points to the domain-specificity of learning. For example, people were asked to determine which of two products was the best buy, such as a 10-ounce can of peanuts at 90 cents or a 4-ounce can at 45 cents. In school, the most common approach is to compute unit cost, yielding 9 cents per ounce versus 11.25 cents per ounce. However, in a supermarket, people tended to use a ratio approach in which they reasoned that the larger one costs twice as much but contains more than twice as many ounces. Similarly, Nunes et al. (1993) found that students who could solve arithmetic problems without error in the context of their job as street vendors made many errors when confronted with the same problems in a school setting. In addition, research on expertise demonstrates that people who are expert problem-solvers in one domain (such as physics or chess) are generally not superior in problem solving in other domains (Mayer 1992). These results support the idea that the usability of problem-solving strategies depend on the context in which they are learned.

According to the specific-domain view, teaching for thinking should take place within a specific context rather than in a context-independent environment. Research on the lack of transfer of school-learned mathematics (Nunes et al. 1993) is consistent with the specific-domain view. In answer to the question of where to teach, their answer is to teach cognitive skills within the specific context they will be applied.

5. *When to Teach*

The final issue concerns when to teach. Should instruction focus on teaching higher-order thinking skills only after the learner has mastered lower-level basic skills or should instruction on thinking begin when the learner is still a novice? The common-sense view favors the prior-mastery approach: students cannot understand higher-order skills until they have mastered lower-level ones.

However, cognitive science research on teaching reading, writing, and mathematics shows that students can benefit from learning higher-order thinking skills before they have completely mastered the basics. In reading, for example, elementary school students can benefit from learning how to summarize a passage, how to predict what will come next, and how to recognize portions that need clarification even if they are still not fluent in basic decoding skills (Brown and Palinscar 1989). In writing, students can benefit from writing creative essays even before they have mastered spelling, grammar, and punctuation (Kellogg 1994). In mathematics, students can benefit from direct instruction in how to represent word problems even before they have completely automatized their computational fluency (Sternberg and Ben-Zeev 1996). In contrast to the prior-mastery view, this research provides support for an approach that can be called constraint removal—providing scaffolding support that enables students to work on tasks they have not

yet mastered (such as allowing a student to dictate an essay).

According to the constraint-removal approach, teaching for thinking can begin while the learner is still a novice. In answer to the question of when to teach, supporters of this approach argue that it makes no sense to wait until the student has automated all lower level skills.

6. Summary

In summary, teaching for thinking involves helping students to be able to use what they learn to solve new problems. In contrast to common-sense views, teaching for thinking is likely to be most successful when the focus is on (a) teaching thinking as a collection of smaller component skills rather than as a single monolithic ability, (b) teaching the process of how to solve problems rather than solely the product of problem solving, (c) teaching thinking within a specific subject domain rather than as an isolated domain-free course, and (d) teaching while students are novices rather than waiting until they have mastered all basic skills.

Teaching Social Sciences: Cultural Concerns

The concept of a *social* science is at once more elastic and ambiguous than that of *natural* science, for the content of the latter is essentially fixed by the properties of matter and energy in various degrees and combinations. Accordingly, the first task facing teachers of the social sciences is to make clear the grounds on which events and processes are taken to be *social*, and then identify the subject matter that defines a given discipline within the social sciences. Both of these objectives can be met only approximately and in ways influenced by seasonal shifts in perspective, as well as by developments in other and not always kindred specialties within the social sciences. These provisional solutions to problems of definition and classification serve as an introduction to comparably vexing and interrelated problems of explanation, measurement, modes of inquiry and standards of theoretical adequacy. The following sections consider these and related issues.

1. Defining the Social Sciences

The so-called unity of science was a primary objective of that positivism that was heralded in the Enlightenment and developed systematically during the first half of the twentieth century. Taking the subject matter of any and every science to be that which is in principle

observable, positivists found no principled argument against the possibility of subsuming even the most complex social phenomena under general laws. Illustrative of this perspective is Hempel's *Aspects of Scientific Explanation* (1965) in which such diverse fields of inquiry as psychology, history, and economics are judged to be amenable to scientific study and (ultimately) reducible to scientific laws.

Formidable arguments have been arrayed against this perspective based on what is taken to be unique to genuinely *social* phenomena. Dray (1957) rejected positivistic attempts to equate explanations in history with those in science. Unlike the phenomena of science, historical events are singular, are shaped and defined by specific participants, derive their essential features from the plans and purposes of these participants, and are subject to various but equally compelling and coherent explanatory accounts. Indeed, what makes an event 'social' in the first instance is just this constellation of personalities and purposes interacting in ways that are neither mechanical nor replicable.

The 'Battle of Waterloo' may be used illustratively. Consider first the nature of an event that qualifies it as a 'battle' rather than, say, a gang-war or a riot. An event takes on the character and proportions of a battle only insofar as it is a *military* action with clear political or economic or religious ends; only insofar as it is organized for these ends by persons in authority. Authority itself is grounded in complex social, legal, and cultural foundations, to be exercised in recognized ways, and to be retained or lost according to certain standards of conduct. Such a battle then becomes *decisive*, in just the way that Waterloo was decisive, to the extent that it yields consequences beyond the time and space within which the battle itself is waged. It becomes *historical* to the extent that these consequences then shape later and even larger political destinies, including those of nations that may not even have existed at the time of the decisive battle. There is no 'Battle of Waterloo' in the historical sense unless there is Napoleon, the delicate state of Anglo–European affairs in the wake of the French Revolution, the prospect of England's sea power, in the event of victory over Napoleon, supporting a great expansion of imperial influence, etc.

On a very small scale, the same considerations would apply to star-crossed lovers such as Romeo and Juliet. Their story is not indifferent to complex familial rivalries, to cultural values and ideals, to the unique bond that formed between them. Understanding Juliet's suicide is not achieved by studying suicides and reaching some general conclusion, e.g., unhappy persons see no cause for better days sometimes take their own lives. Rather, Juliet's actions become intelligible only under a set of descriptions unique to her life and her time.

In light of such considerations, it has been argued that the understandings to be sought within the social sciences must be drawn from a domain distinctly different from that in which merely physical interactions take place. The domain in which social phenomena occur is *social* owing to features not revealed by any of the prevailing physical or merely natural conditions. Thus, the very *idea* of a social science is constructed on grounds removed from those staked out by physics or biology (Winch 1958).

To these very counters, however, there are positivistic rejoinders and these, too, must be dealt with if students are to be informed as to the ongoing and keen disputes surrounding research and theory in the social sciences. After all, suicides are not random events, and battles tend to be won and lost for reasons historians are able to discern. This much alone suggests the operation of forces or principles that (ultimately) should give rise to scientific explanations of such events. What is important as regards the teaching of the social sciences is the recognition that these meta-scientific issues are central, not peripheral, to the agenda of the social sciences. The position one takes on them effectively dictates the sorts of events chosen for study, the method of inquiry, the nature of the explanations that will be taken to be successful, and the character of the more general theory that grounds such explanations.

Even as debates such as these unfold, specialists work with undaunted energy on problems that retain their interest no matter how the social sciences are defined. A more or less common sense standard is adopted with which to identify a problem as 'sociological,' 'historical,' 'economic,' 'psychological,' 'political', 'cultural.' One can instruct students on, e.g., 'Issues in Post-Soviet Society,' without taking a firm stand on whether (ultimately) the issues in question will be settled by subsumption under a general law. The issues are understood to be social in virtue of their grounding in a *society* recently liberated from an oppressive regime and now attempting to establish new and effective practices and institutions. Similarly, a course serving as an 'Introduction to Medieval Studies: The Age of Dante' is able to record and respect the artistic genius of Dante even as the themes of the *Divine Comedy* are shown to be influenced by medieval philosophy and wider currents of medieval thought. For all practical purposes, then, a field of inquiry is defined as 'social' when the dominant influences are interpersonal, when the salient occurrences reflect social aims and purposes, and when the causal factors are not readily or even plausibly rendered in physical–natural terms.

2. *Classifying the Social Sciences*

If social psychology is defined as the study of *interpersonal influence*, how does it differ from sociology? Also, if one of the major sources of influence is culture

itself, how are sociology, anthropology, economics, social psychology, and (cultural) history to be distinguished? Following the model of the great German research universities of the nineteenth century, doctoral programs have been developed to provide training in ever narrowing fields of specialization. As a result, the questions raised above tend to be answered by referring to just such specialized training. What makes a field of study anthropology rather than, say, social psychology is that it is populated by anthropologists and, as such, is examined and developed by methods of inquiry and standards of explanation of a distinctly 'anthropological' nature. In general, the anthropologist would seek to explain the nature and purpose of enduring customs within the given community; the social psychologist, the manner in which such prevailing customs influenced relationships between and among those living within the community; the economist, the manner in which such customs worked to the material advantage of the participants, perhaps especially in their relationships with trading partners, etc.

If this were all there was to the matter, there would be no substantive difference between teaching and training. Specialists devoted to a set of issues would simply undertake to train the next generation of workers who would then dutifully add to the data-base and seek evidence to 'verify' current speculations. The venture would be faithful to the received methods but, in the sense intended by Francis Bacon, would yield some fruit, but rather little light.

Surely one who examines the effect of trade on personal wealth must understand that 'wealth' may be construed in significantly different ways from one cultural enclave to another. A society made up of those who share the values of Henry James would regard as wealthy all who could 'satisfy the needs of the imagination.' It is a truism that the *value* of wealth depends on how its deployment or use operates at the level of lives individually lived and mutually influential. This, in turn, is related to core values and beliefs, often of a religious or transcendent or aesthetic nature, not reducible to coins of the realm. The point, of course, is the obvious one: specialized fields of inquiry tend to explain little beyond the artificially contracted domain within which the accepted methodology is (allegedly) applicable. Robust and plausible explanations then, require movement beyond such narrowly worked fields to a distance allowing a wider perspective and a deeper understanding. Those likely to find such a vantage point have been educated and not just *trained*.

3. *Methodologies*

Anthropological and cultural studies are dominated by field research that does not permit systematic control and manipulation of factors judged to be related causally to the events of interest. This does not mean that such studies are devoid of measurement *per se*; only that the mode of inquiry is not *experimental*. Sociological and social psychological research includes both experimental and field studies. The prevailing ethos within the social sciences favors the experimental mode of inquiry, a preference seemingly indifferent to the fact that experimental findings bear little relationship to the actual social phenomena they seek to explain or 'model.' The preference itself records a lingering attachment to scientific positivism.

Statistics is a methodological feature of experimental social science. A separate chapter in intellectual history is called for if students are to recognize the adoption of statistical standards of proof and the quite limited sense in which these standards are 'objective' (Daston 1994; Polanyi 1985). The commitment to general laws is *per force* at the expense of the individuated events giving rise to the collective. Inescapably the possibility is ever present that resulting general laws describe *none* of the participant-events and therefore explain none of them. To the extent that the general law thus derived is a model of anything, it may be a model of the data rather than of the social reality that was the instigating source of the inquiry.

More recently the mounting criticism of mainstream statistical methods has led to a liberalization of methods and to modes of inquiry more realistically connected to social beings in their actual complex and various interactions. So-called 'discourse analysis' avails itself of the relatively unconstrained reports of persons engaged in social practices. It is assumed that language itself, the bearer of meaning, reveals the essential nature of those joint ventures that define the social. So, too, with *narratological* methods of inquiry where participants themselves explain the dynamics of their social participations. If such nonmainstream methods can now claim only a little by way of discovery, they can claim much more by way of revealing the limitations and narrowness of the conventional alternatives.

4. *Explanation*

However defined, a 'science' (social or natural) offers itself as a set of practices and principles capable of explaining events in the real world; events in the world of social interactions, e.g., which would include bartering, voting, warring, cooperating, deceiving, assisting. But what does it mean to say that such occurrences and undertakings have been *explained*? Any adequate preparation of those who would advance or just comprehend the social sciences must reserve a central place for the issue of explanation itself. It is, after all, explanation that is the goal or end for which specialty fields are created, defninitions are crafted, methods are adopted.

Within the natural sciences, an event is judged to be explained when its occurrence can be predicted by or subsumed under a general law. Thus, the tendency of massive objects to move toward the center of the earth is explained by the universal law of gravitation. An object's 'falling' is but an instance of the law such that, if the law is true, the 'falling' is but a logical deduction.

The question thus arises as to whether this is the right model of explanation for the social sciences. Is the best explanation of Jack and Jill marrying, one (ultimately) grounded in a causal law of which this particular marriage is but an instance? Or, instead, are significant social undertakings tied not to causal laws, but to idiosyncratic purposes? Are social phenemona accounted for best by *reasons* explanations rather than *causal* explanations?

Students, to be prepared to understand the nature and the implications of such questions, are best served by studying special topics within philosophy devoted to just these matters. The fields of philosophy of social science, philosophy of psychology (Robinson 1985) and metaphysics include close examinations of what it means to explain events and, indeed, what it is that qualifies an occurrence as an 'event' of the relevant sort (Davidson 1980; Mele 1992).

5. *Theoretical Adequacy*

The social sciences now, owing to the relentless specialization within each of them, can claim a number of well-developed microtheories. This same specialization has, it would seem, retarded progress at the level of macrophenomena and, even more obviously, at the level of reality itself. As used here, 'level of reality' refers to the indisputable fact that actual persons seldom are moved by unitary motives toward stable and singular goals, attentive to but one set of environmental cues, and in a fashion rigidly determined by prevailing cultural standards and local meanings. Indeed, such a person would be a candidate for therapy. In teaching the novice or even the advanced student the methods and prevailing theories in any of the social sciences, it becomes important to distinguish between theories (more or less) supported by findings, and those (more or less) supported by the warp and weave of lives actually lived. Too often the 'findings' arise from methods of inquiry so inextricably bound to theoretical presuppositions as to achieve no more than a rediscovery of the presuppositions themselves. What William James dubbed 'the psychologist's fallacy' might be applied generously across the social sciences. James's version refers to the adoption of an experimental method—say the use of a memory-drum in a paired-associate study of memory—that virtually guarantees the form the targeted process will take, e.g., subjects remember terms that have been associated with other terms! Where a general theory assumes that the prime motive to action is economic, and where the modes of inquiry leave little room for any influence other than economic influences, there will result nothing but jejune 'verifications.'

Before the age of specialization, what would be understood as social science was the speculative field occupied by humanistic scholars and philosophers, by writers in law and politics, by designers of buildings and even entire cities. A 'social' science stood as a systematic inquiry into the social conditions that thwart or realize human potentialities; social conditions including but not limited to parental guidance, systems of law, literature and the arts, material means, modes of employment, religious teachings, and institutions. For Plato and Aristotle, the social and the political were inseparable, and the person was understood to be powerfully shaped by both. A developed 'social' science then, presupposed a civic or political science, itself based on a defensible if imprecise theory of human nature. What the ancient accounts lacked in precision they make up for in breadth, integration, and realism.

At present, and in light of prevailing standards and habits, the social sciences offer no comparably realistic and integrative theory of social life. This is one, but not the only, or even the principal, reason why major figures in the history of philosophy continue to attract the attention of those seeking such integrations. These same major figures are usefully consulted in the teaching of social scientists, if only to alert them to the nature of systematic and integrative thinking on matters of social consequence.

Teaching: Trends in Research

Research on teaching came into its own as a field of study beginning in the early 1970s when large-scale research on teaching studies attempted to tie teacher behaviors to student achievement. In these studies, teachers who were identified as more or less effective on the basis of their students' scores in achievement tests were observed and their behaviors recorded. Correlational data analysis identified differences in behaviors between the more and less effective teachers. This information, much of it leading to the concept of *time on task*, was used for purposes of teacher evaluation, teacher education, and staff development.

Concerns about the nature of the product measures (reading and mathematics multiple choice achievement tests), research methodology, and potential context effects eventually led to the development of different approaches to studying classrooms. Disciplinary frameworks other than educational psychology were applied in the research. These disciplines included anthropology, socio-linguistics, and sociology. Research employing qualitative methodology and case-study approaches began to be published in the major journals. Also, the cognitive revolution turned the attention of researchers away from teacher behaviors toward teachers' thought processes as they plan, implement their lessons, and reflect on their practices. During the late 1980s and early 1990s, this movement to teacher cognition affected all aspects of research on teaching, including the conception of the effective teacher and the research methodologies used to explore teaching.

During this period of time, an even more significant social theory trend was strongly influencing the nature of research on teaching: the movement from modern to postmodern thinking. Between the previous edition of the *Handbook of Research on Teaching* (3rd edn.) (Wittrock 1986) and the present one, the field has experienced a time of turbulence similar to that in other fields. Postmodernism raises questions that jar the very foundations of our understanding of research. These questions concern the nature of knowledge, who owns it, who produces it, and how it should be used. The dissonance between modern and postmodern ways of thinking are evident in the trends described below, and visible in the current edition of the *Handbook of Research on Teaching* (4th edn.) (Richardson in press). The conflicts go beyond the old qualitative–quantitative methodology controversy as described in the 1986 *Handbook*. They now focus on the very nature of research and knowledge and the uses of research in the improvement of practice.

1. *A Vision of Teaching*

During the 1980s, the vision of teaching changed from that of a teacher standing in front of the class and transmitting information and skills to students to one of the teacher as facilitator of learning. The newer conception of teaching originates from constructivist learning or meaning-making theory that suggests that individuals create their own new understandings based upon the interaction of what they already know and believe, and the ideas with which they come into contact. The teacher facilitates student learning by creating environments, tasks and dialogues in which students access their prior knowledge, consider alternative premises, and alter and add to their existing understandings with information and ways of thinking that are introduced to them by the teacher and other experts, readings, other students, and their own research. Current classrooms have students with diverse backgrounds. Since each student has unique background knowledge and experiences, the teacher is compelled to keep track of individual differences, and to adjust lessons on the basis of this knowledge.

Within this conception, teaching requires complex thought and decision making in situations of uncertainty with diverse student bodies and variable contexts. Notions of the complexity of teaching and the variability of the context work together to help promote the view of the teacher as a thinking, decision-making, reflective, and autonomous professional. Since teaching is complex and contexts vary, teachers themselves need to make decisions and reflect on their situations and teaching in order to act in appropriate ways.

Current research on teaching reflects this change in the conception of the teacher, as will be highlighted in the sections below that reflect the current trends in the field.

2. *Teacher Change*

As the conception of teaching changed from transmission to facilitation, the question of how teachers themselves could be encouraged to change their ways of thinking and approaches to teaching became paramount in the research, policy, and practice literatures. Since the various subject-matter standards, such as the national mathematics standards for students, called for a very different approach to teaching, research and practice began to focus on processes of teacher change. The anticipated changes in teachers and teaching were thought to entail more than the acquisition of a new teaching method, but involved changes in beliefs and practices around the nature of teaching. This form of change, itself, required the development of conceptions of teacher change, and

research on processes that would be effective in helping teachers develop these newer teaching roles.

The newer research on teacher change contests the view that teachers are recalcitrant and do not change. The recalcitrant label stems from a view of change in which individuals or groups outside the classroom mandate or suggest the changes that teachers should make. In fact, research suggests that teachers voluntarily change all the time. They reorganize their classrooms, try different activities and texts, change the order of topics in the curriculum, attempt different interpersonal skills, and so on. When teachers experiment with new activities in the classroom, the new practices are assessed on the basis of whether they 'work.' When these activities work, it means that they engage the students, do not violate the teacher's particular need for control, and help the teachers respond to system-determined demands such as high test scores. If they do work, they are internalized and absorbed into the teacher's repertoire of activities.

This new understanding of naturalistic teacher change has led to a considerable number of studies of processes that would help teachers change their beliefs about learning, the nature of teaching, and the role of the learning environment in student development. These studies often focus on particular subject-matter areas such as mathematics, science, English, and social studies since the learning and teaching standards are usually developed around these subjects. The most productive research-based approach to staff development suggests a long-term effort in which teachers are engaged in inquiry into their own often tacit beliefs and practices. This process is enhanced through dialogue, particularly with those who understand practice and the particular context in which the teacher is working. A certain trust level is important within the community since it is important for the participants to accept and talk about practices that do not seem to work, and to accept responsibility for them. Thus, the development of a discourse community is productive in beginning this process of change.

Research on teacher learning that examines changes in knowledge and beliefs as well as practices has led to the development of a number of different conceptions and forms of teacher knowledge and belief.

3. *The Nature of Knowledge in Teaching*

As the focus of attention in research on teaching shifted from teacher behaviors to teacher cognition, beliefs and knowledge have become the two most important factors in the explanations of teacher practices and in considerations of teacher change. In the traditional philosophical literature, knowledge requires a 'truth condition' that suggests that a proposition is agreed upon as being true by a group of people. Propositional knowledge has epistemic standing, that is, there is some evidence to back up the claim. By contrast, beliefs do not require a truth condition. They have also been found to be powerful in their effects on teaching practices.

However, within research on teaching, the differentiation between beliefs and knowledge is not strongly evident. Many in the field define knowledge as that which is held in the teachers' heads, with or without a truth condition. This psychological view of knowledge has led to the identification of and research on a number of different forms of knowledge. Two forms of knowledge that have been studied extensively are *practical knowledge* and *pedagogical content knowledge*. Practical knowledge differs from *formal knowledge* in that formal or warranted knowledge is much more closely related to the philosophical conception of knowledge. Formal knowledge may be found in textbooks and research articles; whereas practical knowledge may be found in teachers' heads and in their actions and focus on their own classroom contexts. Pedagogical content knowledge, on the other hand, combines formal and practical knowledge.

Beliefs, defined as propositions that are accepted as true by the individual holding the beliefs, are of interest in research on teaching in the investigation of the ways in which beliefs may affect teaching practices. Most current studies of teacher beliefs are conducted within the hermeneutic tradition (that is, they focus on how the individual teacher makes sense of the environment in which s/he is operating). These studies suggest a complex relationship between teachers' beliefs and actions. In most current research-based conceptions, the perceived relationship between beliefs and actions is interactive. Beliefs are thought to drive actions; however, experiences and reflection on action may lead to changes in and/or additions to beliefs.

Beliefs are seen as important in teaching and teacher education in several ways. The first suggests that students of teaching bring powerful beliefs into their teacher education classes. These beliefs must be attended to by both the student teacher and the teacher educator if the student teacher is to move beyond the images of teaching acquired as a student. An additional and related way is instruction that focuses directly on beliefs. As Tom Green (1971) suggested, one goal of teaching is to help students form belief systems that consist of a large proportion of beliefs based on evidence and reason. Thus, the investigation of beliefs in the teacher education classroom should involve their rejection, alteration, or transformation into knowledge with warrant and evidence attached. Without attention to beliefs, transformational changes in teaching practices have a low probability of success.

Practical knowledge is an account of how a teacher knows or understands a classroom situation. Practical knowledge is gained through experience, is often tacit, and is contextual or local. This form of knowledge is not, however, synonymous with beliefs because it is thought of as embodied within the whole person, not just in the mind. Embodied knowledge is more than

cognitive and relates to the ways in which people physically interact with the environment. It is this knowledge that may be used in an improvisational manner in the classroom. This conception of knowledge as practical does not separate the knower from the known, is personalized, idiosyncratic, contextual, and emerges during action.

Pedagogical content knowledge refers to a way of knowing the subject matter that allows it to be taught. It is grounded in the disciplines but adds an understanding of how to transform formal knowledge of the disciplines into the enacted curriculum within a teaching context. This knowledge combines that of the subject matter itself with knowing how students learn the content, students' preconceptions that may get in the way of learning, and representations of the knowledge in the form of metaphors, examples, demonstrations, etc., that allow it to be transformed into material that the students may learn. Inquiry into teachers' pedagogical content knowledge has been active since 1985. This research suggests that teacher education students' formal knowledge of the disciplines is fairly weak, and that formal teacher education programs are a weak contributor to the formation of pedagogical content knowledge. However, there is strong evidence that those becoming teachers benefit from the courses that emphasize pedagogical knowledge as compared with those who enter teaching with subject matter background, but no pedagogical education.

4. *Areas of Interest in Research on Teaching*

The shift from teacher behavior to cognition and from the transmitter to facilitator models of teaching has brought forward a number of areas that are of particular interest in research on teaching.

4.1 *Constructivist Teaching*

Constructivism is a descriptive theory of learning, and most constructivists would agree that the traditional approach to teaching—the transmission model—promotes neither the interaction between prior and new knowledge nor the conversations that are necessary for internalization and deep understanding. The information acquired from traditional teaching, if acquired at all, is usually not well integrated with other knowledge and beliefs held by the students.

While these are common understandings, there are also considerable disagreements. Further, and more importantly in this context, there is not a direct relationship between the theory of learning and the practice of teaching. Constructivism is a theory of individual learning. While constructivist learning theory may speak closely to a tutoring situation, it does not direct teaching practice within a 'normal' classroom. Thus, considerable research attention focuses on the constructivist classroom. Some of the questions that are being addressed are as follows: (a) what is the place of formal knowledge in a constructivist classroom, and how it should be introduced, and (b) at what point during instruction does it make sense to 'tell' students formal knowledge and/or answers to questions? These issues are being worked out within the different subject matters, and evidence indicates that constructivist classrooms vary depending upon the subject matter.

4.2 *Teaching to Individual Differences*

Constructivist learning theory suggests that the background knowledge, beliefs, and understandings that students bring to the classroom strongly affect what they learn within the classroom. Given this frame, and the current attempts to integrate students with differing cultural and language backgrounds as well as learning styles and abilities, suggests that attention to the backgrounds of students is critical in the teaching process.

Research on differences in the ways teachers approach girls and boys in the classroom has a longstanding tradition in research on teaching. There is no doubt that teachers, by and large, treat girls differently to boys and that teachers are not aware of doing so. Examples are the questions asked of boy versus girl students. They are often qualitatively different, and the intellectual follow-up on answers is often different and usually more thorough for boys than girls. However, it is also the case that girls act differently than boys in classrooms, and the effort continues to be made to understand teachers' different behaviors as a reaction both to the differences in classroom behavior of boys and girls and the social forces that may drive these different behaviors.

Multicultural education has received considerable attention in research on teaching as schools and classrooms continue to be more integrated. Further, it is also the case in many countries that the teaching population itself is dominated disproportionately by teachers of the majority culture. Knowledge and understanding of different cultures and ways of approaching the tasks of teaching and learning thus becomes imperative for teachers. Of particular importance in this area is the development of the concepts of *culturally relevant learning* and *teaching*. Based on research of successful teachers of African-American students, this concept suggests that knowledge of the culture and community of the students is brought into these classrooms and guides elements of classroom action such as the discipline system.

4.3 *Moral Development*

For years, research has focused on student achievement in the basic skills of reading and mathematics. More recently, other subject-matter areas such as science, writing, and geography have been included in

this research. It is also the case, however, that teachers may have a strong influence on the moral development of students. Current research in this area is investigating the moral dimensions of classroom life, and indicates that the moral life of the classroom is robust and powerful. Teachers, however, are often unaware of the nature and/or consequence of their actions in relation to the moral development of their students. Further research is needed to examine the effects of these the moral dimensions on students, and will undoubtedly affect the ways in which teachers approach this important aspect of classroom life.

5. *Methodology*

The methodology for research on teaching has shifted dramatically from quantitative to qualitative. Case studies are proliferating, particularly in studies of teacher change that focus not just on documenting the fact that the teachers changed, but also on building a theory of the change process. While quantitative methodology is still being used in large-scale studies of educational reform, most studies that examine the teacher learning and change processes are qualitative in nature. Qualitative methodology, however, is not monolithic. There are many different approaches, and Robert Donmoyer (in press) in a chapter in the *Handbook of Research on Teaching* (4th edn.) has differentiated among them in relation to five different purposes for conducting the research. These purposes range from 'truth' seeking to the praxis/social change purpose. Other trends that are found in research on teaching are outlined below.

5.1 *Teacher Research and Self-study*

Teacher research refers to a form in which the teacher conducts research on or inquires into his/her own practices. Self-study is the same process used by teacher educators. This trend is a part of the action research movement that suggests that practitioners are in the best position to inquire into their own practices for purposes of solving problems in the contexts in which they reside and understand. The purpose of teacher research and self-study is primarily the improvement of the teacher/teacher educator's teaching practice. However, there is some debate about this, as a number of scholars suggest that research conducted by teachers is not only useful for the teacher-researcher but of interest to others. There are also questions about the nature of the research that is conducted, e.g., do teacher research and self-study warrant different methods and procedures to research that leads to formal knowledge?

5.2 *Narrative Research*

Narrative research stems from the sense that narrative is a mode of thinking—an expression of cultures' storehouse of knowledge (Bruner 1986). It is argued that teachers' knowledge and understanding of school and classroom practice is stored in narrative and discourse about practice is often in narrative form. The aim of narrative research is to capture school and classroom practice and tell others about it in such a way as to conform to this natural mode of thinking. As described by Gudsmundsdottir (in press): 'narrative approach moves research on school practice as a field out of the constraints that educational psychology has placed upon our community and enables us to move where we belong—into the realm of human sciences as conceptualized by Dilthey.' The inquiry focuses on mediated action, and it is qualitative and interpretive in nature. As a relatively new approach in research on teaching, it has its strong advocates and detractors. It also means different things to different people. However, the attempt to develop a research methodology of practice will keep it in the limelight for some time.

5.3 *Studies of Teacher Change*

A classical experimental design relies heavily on a linear process that involves the prespecification of the treatment and the desired outcomes. Many current change processes—particularly inquiry-oriented staff-development programs—are not of this nature. They are collaborative with the practitioners, and the process moves along a path marked by constant inquiry and reflection. It is questionable whether the use of a control group adds to our understanding of teacher change. Since so many current change processes are fairly individualized without stipulated goals for changes in practice, the question that remains is whether the teachers in the control and treatment group changed. Since we are operating in a model of change that suggests that teachers change all the time, we would assume that even the control teachers would be changing as well.

Thus, in examining teacher change in depth, the questions of significance, validity, and worth must be addressed. The set of questions are as follows: was there change in teaching practice? can this change be attributed to the change process being examined? is the effected change desirable? This calls for a rethinking of research designs that, for example, leads to the ability to tie observed changes in practices to the substance of the conversations that took place in the staff-development process.

Teamwork and Team Training

During recent years, teams have emerged as the cornerstone of many organizations. Team efforts are required in many businesses and industries (e.g., government agencies, aviation operations, military organizations, and hospitals) to meet their missions and goals (Ilgen 1999). When applied correctly, teams may offer several advantages over individuals or groups. For example, teams can perform difficult and complex tasks, motivate their members effectively, and in some cases outperform individuals (Foushee 1984). Specifically, teams can be more productive, make better decisions (Orasanu and Fischer, 1997), perform better under stress, and make fewer errors (Wiener et al. 1993). When organized, designed, and managed correctly, teams can be a powerful organizational tool (Guzzo and Dickson 1996).

The purpose of this article is to provide a brief overview of what we have begun to learn about the nature of teamwork and what can we do to enhance it. Five questions will be discussed: (Sect.1) what is a team? (Sect.2) what are team competencies? (Sect.3) what is teamwork? (Sect.4) what is team training? and (Sect.5) what is team measurement? Several key concepts will be defined.

1. *What is a Team?*

According to Salas and Cannon-Bowers (2000) a team can be defined as 'a set of two or more individuals who must interact and adapt to achieve specified, shared, and valued objectives' (p. 313). Teams must also have meaningful task interdependencies—the job cannot be done by a single individual—and usually task-relevant knowledge is distributed among the team members. Other characteristics of teams are that members: (a) have roles that are very defined and functional; (b) are hierarchically organized; (c) share two or more information sources; and (d) have a limited time span (Salas and Cannon-Bowers 2000).

This definition is important because it highlights the fact that not all teams are created equal. Teams differ from groups (e.g., task forces, committees) with respect to the degree of task interdependency, structure, and requirements (Salas and Cannon-Bowers 2000). In addition, teams differ from groups regarding essential knowledge and skills; necessity of critical team feedback for success; and development of shared goals, expectations, and vision. Since teamwork is characterized by synchronizing goal-directed behaviors, interdependent activities, and functions that are separate from the task itself, teams hold unique features, which most other small groups do not. Therefore, one needs to understand the competencies needed for team members to succeed in a team; they will be discussed next.

2. *What are Team Competencies?*

In recent years, research has uncovered the knowledge, skills, and attitudes (i.e., competencies) necessary for effective team performance. These team competencies allow organizations to establish the appropriate requirements for their teams and strategies to enhance teamwork and performance. Teamwork competencies can be characterized as resources that team members draw from in order to function. As noted, they include knowledge, skills, and attitude-based factors.

Knowledge-based competencies (i.e., what team members 'think') refers to the necessity of understanding facts, concepts, relations, and underlying foundations of information that a team member must have to perform a task. For teams to perform required tasks, they must possess a certain set of knowledge. (see Table 1 for some examples.) It has been noted that team members must have synchronized mental models (i.e., knowledge structures) about the roles of their

Table 1
Knowledge-based competencies examples

Type of knowledge	Definition
Cue-strategy associations	Knowing how and when to use environmental cues to change coordination strategies
Team-mate characteristics	General tendencies, abilities, preferences, strengths, weaknesses of team mates
Accurate and shared task models	Team members must share a common interpretation and understanding of task strategies and demands
Task sequencing	Knowing how to organize tasks inputs according to team and task demands

Source: adapted from Salas and Cannon-Bowers 2000

Table 2
Skill-based competencies examples

Type of skill	Definition
Adaptability	Process by a team to use information from a task environment to alter strategies through compensatory behavior, dynamic reallocations of functions, and flexibility
Situational awareness	Process by a team to develop compatible models (or shared understanding) of internal and external environment of team
Communication	Process by which information is exchanged between two or more team members with clarity and accuracy
Decision making	Process by a team to gather and integrate information, use sound judgment, recognize alternatives, select the best solution, and evaluate the consequences

Source: adapted from Salas and Cannon-Bowers 2000

teammates, the tasks, and the situations that the team encounters (see Cannon-Bowers and Salas 1998). Expectations created by these knowledge structures allow team members individually to generate predictions concerning how to perform during routine and novel situations that the team encounters. It has also been shown that it is necessary for team members to possess knowledge about the purpose and objectives of their mission, the available and needed rewards, and the expected norms to be followed.

An important knowledge-based team competency, cue/strategy associations, has been suggested as important for the functioning of teams in complex, knowledge-rich environments (Salas and Cannon-Bowers 2000). Through cue/strategy associations, team members are triggered to perform in a certain way by a pattern of cues in the environment. Essentially, team members make associations between this pattern of cues and what they should do. Teams are able to adapt, reallocate functions, and occasionally perform without the need for overt communication because of this knowledge. While the cue/strategy associations competency is key, there are other knowledge-based competencies that are useful to teams such as: knowledge of teammate characteristics, accurate and shared task models, and team sequencing (Salas and Cannon-Bowers 2000).

Skill-based competencies (i.e., what team members 'do') are the necessary behavioral sequences and procedures needed for task performance. It is clear that team members must behave in certain ways and do certain things in order to achieve their goals. Specifically, teams perform various actions—coordination, communication, strategization, adaptation, and synchronization of task-relevant information. The information can be verbal, nonverbal, or visual. Team members require skills to perform in a fashion that is accurate and timely. As with knowledge-based competencies, there are also many skill-based competencies required for effective team performance (see Table 2 for more examples).

Attitude-based competencies (i.e., what team members 'feel') refer to the affective components needed to perform the task. Teamwork is greatly affected by how team members feel about each other and the task. Due to considerable research, several attitude-based competencies have emerged (i.e., motivation, trust, shared vision, importance of teamwork) which affect teamwork and team outcomes (see Table 3 for a more in-depth description). For example, collective self-efficacy (i.e., the belief that the team can perform the task) and collective orientation are important in team functioning.

The team competencies described here are the necessary elements for effective teamwork and become the desired target when developing team training. The final goal of team training is to improve and foster effective teamwork. To do this, researchers must

Table 3
Attitude-based competencies examples

Type of attitude	Definition
Motivation	Process by a team in which objectives are defined and members are energized to achieve them
Mutual trust	Team members' attitude regarding mood or climate of team's internal environment
Shared vision	Team members' common attitude regarding the team's direction, goals, and mission
Importance of teamwork	Team members' attitude regarding working as a team
Efficacy	Belief that a team can perform effectively (or be successful) as whole when given specific task demands
Collective orientation	Belief that team approach is better than an individual approach

Source: adapted from Salas and Cannon-Bowers 2000

uncover, analyze, and address the necessary knowledge-, skill-, and attitude-based competencies, while also considering the nature of the team task (Salas and Cannon-Bowers 2000). A discussion of what comprises teamwork follows.

3. *What is Teamwork?*

Teamwork can be defined as the ability of team members to work together, communicate effectively, anticipate and meet each other's demands, and inspire confidence, resulting in a coordinated collective action. However, a clear and direct answer to the question 'What is teamwork?' has not been provided. According to McIntyre and Salas (1995), teamwork is a critical component of team performance and requires an explanation of how a team behaves. There are four key behavioral characteristics that compose teamwork: (a) performance monitoring, (b) feedback, (c) closed-loop communication, and (d) back-up behaviors.

The first requirement of teamwork is that team members monitor the performance of others while carrying out their own task. Monitoring ensures that members are following procedures correctly and in a timely manner, while also ensuring that operations are working as expected. Performance monitoring is accepted as a norm in order to improve the performance of the team in addition to establishing a trusting relationship between members.

Next as a follow-up activity to monitoring, feedback on the effectiveness or ineffectiveness of performance is passed along to members being monitored. Team members must feel at ease when providing feedback for teamwork to be effective. No obstacles (i.e., rank, tenure) should stand between members who are giving and receiving this vital information. Free-flowing feedback exists in the highest level of teamwork.

Teamwork involves the effective communication between a sender and receiver. Closed-loop communication describes the information exchange that occurs in successful communication. There is a sequence of behaviors that is involved in closed-loop communication: (i) the message is initiated by the sender; (ii) the message is accepted by the receiver and feedback is provided to indicate that it has been received; (iii) the sender double-checks with the receiver to ensure that the intended message was received. This type of communication is especially apparent in emergency situations.

Finally, back-up behaviors (i.e., the willingness, preparedness, and liking to back team members during operations) are required for effective teamwork. Team members must be willing to help when they are needed and must accept help when needed without feeling they are being perceived as weak. This requires that members know the expectations of their jobs while also knowing the expectations of others with whom they are interacting.

These four complex behavioral characteristics—performance monitoring, feedback, closed-loop communication, and backing-up behaviors—are necessary for effective teamwork. A failure of one of these aspects could result in ineffective team performance. Next, team training and four training strategies will be defined.

4. *What is Team Training?*

Team training can be defined as a set of tools and methods that form an instructional strategy in combination with requisite competencies and training objectives (Salas and Cannon-Bowers 1997). It is concerned with the design and development of theoretically based instructional strategies for influencing the processes and outcomes of teams. Team training consists of strategies derived from synthesizing a set of outputs from tools (e.g., team task analysis); delivery methods (e.g., information-based); and content (e.g., knowledge, skills, and attitudes (Salas and Cannon-Bowers 1997, Cannon-Bowers and Salas 1998).

Team training has one basic objective—to impact crucial team competencies. More specifically, team training seeks to foster in the team members, sufficient

and accurate mental representations of the team task and role structure, and the process by which members interact.

There are four team training strategies that have emerged in the literature and will be discussed—team coordination training, cross-training, team self-correction training, and team leadership training.

Team coordination training, also known as team adaptation and coordination training, is the most common team training strategy (Salas and Cannon-Bowers 1997, Entin and Serfaty 1999). This training strategy is widely used in the aviation industry and is known in commercial aviation as crew resource management, and in military aviation as aircrew coordination training (Wiener et al. 1993).

First, team coordination training is based on the shared mental model (SMM) theory. SMM theory posits that shared knowledge enables team members to predict the needs of the task and anticipate the actions of other team members, allowing them to adjust their behavior accordingly (Cannon-Bowers and Salas 1998). Expectations of what is likely to happen, are formed by team members, as a means to guide action. Especially in a novel situation (when they cannot strategize overtly) teams must exercise shared models of the task and team in order to maintain performance. Thus, the role of shared mental models in explaining team behavior stems from the team's ability to allow its members to generate predictions about team and task demands in the absence of communication. The idea of SMMs and their relation to team effectiveness provide several implications for the understanding of team performance and training (see Cannon-Bowers and Salas 1998).

Team coordination training was designed in order to reduce communication and coordination overhead within the team. Its development was a result of testing and observing successful teams who adapted to increased levels of stress by changing their coordination strategies. Research has shown that these teams performed significantly better on posttraining scenarios than did teams assigned to control conditions. Changes in communication dynamics of team members under stress were used to enhance team performance. Practice on effective teamwork strategies is important in order to change behaviors so they adapt to increasing task demands, which has been demonstrated through team coordination training (Cannon-Bowers and Salas 1998).

Next, the cross-training strategy, also based on the SMM theory, is necessary to lessen the decline in team performance due to turnover. It should be designed so that commonly shared expectations, called interpositional knowledge, regarding specific team-member functioning can be developed. To accomplish this, all parties can be provided with 'hands-on' experience regarding the tasks, roles, and responsibilities of other members within the team. Cross-training research has shown that it is an important determinant of effective communication, task coordination, and performance (see Cannon-Bowers and Salas 1998).

Third, team self-correction training emphasizes the need for team members to provide each other with feedback regarding their performance on a task and the underlying expectations for effective performance. This helps to clarify correct expectations and intentions between members, while facilitating modifications of expectations and intentions that are incorrect. This approach trains teams to observe both their own and each other's performance in order to provide feedback following task completion. Teams are then able to modify their knowledge, skills, and attitudes without intervention from an outside source. Along with team coordination training and cross-training, team self-correction training is based on the SMM theory (see Cannon-Bowers and Salas 1998).

Finally, team leadership training is another team training strategy. When training team competencies, or KSAs, the training begins with the team leader. However, effective team leadership requires: (a) competence that is both technical and operational, (b) knowledge of how to lead a team, and (c) willingness to listen and use team members' expertise. A critical factor in the success of a team is the team leader. A team leader, through specific instruction, can guide the team members to develop those KSAs needed to perform effectively. The influence of a team leader can impact, either advantageously or otherwise, the learning skills of a team and the instructional value of an experience. However, the team leader may not possess the skills needed to accomplish the task. To give him the necessary skills, team leadership training should be implemented. The team leader should be taught to recognize and target crucial teamwork skills needed for training such as communication, coordination, decision-making, and adaptability/flexibility. In the following section, what needs to be measured to diagnose effective or ineffective teamwork is discussed.

5. *What is Team Measurement?*

Measurement of team performance is a component that is critical in team training. Salas and Cannon-Bowers (2000) state that 'measurement is the basis upon which we assess, diagnose, and remediate performance' (p. 322). They continue by noting that learning is promoted and facilitated through measurement. Measurement also produces and provides information about skill acquisition and a metric upon which capabilities and limitations of human performance can be judged. For team training, the dynamic, multi-level nature of teamwork must be able to be captured by the measurement approach. Measurement not only serves to describe teamwork, but it can also be used in the development and guidance of instruc-

tional events. The multiple pieces of information needed for feedback must be integrated by a complete team performance measurement system. In addition, the measurement system must have the following features to foster team training: be theoretically based; assess and diagnose team performance; address team outcomes as well as processes; capture moment-to-moment behaviors, cognitions, attitudes, and strategies; consider multiple levels of analysis; consider multiple methods of measurement; provide a basis for remediation, and rely on observation by experts (Salas and Cannon-Bowers 2000).

According to Salas and co-workers, team performance measurement should be able to: (a) identify the processes linked to team outcomes, (b) distinguish between deficiencies in individual and team levels, (c) describe interactions between team members to capture occurring moment-to-moment changes, (d) produce assessments that may be used to deliver performance feedback, (e) produce reliable and defensible evaluations, and (f) support operational use (Salas and Cannon-Bowers 2000).

Performance measurement is done for the purpose of inferring something about the knowledge, skills, and attitudes of the team member. Observations of critical team behaviors is also required of team performance measurement in order for inferences to be made about categories of behavior or dimensions such as communication, coordination, and adaptability. Techniques have been established for measuring teamwork skills and for studying the relationship between teamwork and team task performance (Ilgen 1999).

A team task analysis, which is needed to uncover the coordination demands of complex tasks, is generally the first step for measuring team performance and designing team training. These analyses provide information about the necessary team learning objectives and team competencies. Key information necessary for designing and delivering team training is also generated by the team task analysis. In addition, team task analysis provides information about the KSAs, cues, events, actions, coordination demands, and communication flows needed for teamwork to be effective. Typically, subject matter experts (SMEs) are asked to provide information on these aspects of the task. This information is then utilized to specify objectives of team training, to create a task inventory that focuses on those objectives, and to guide training scenario development (Salas and Cannon-Bowers 2000).

There are two methodologies that need to be considered for measuring team skills: (a) team vs. individual measures, and (b) outcome vs. process measures. Individual measures assess the skills required to perform and meet individual tasks and responsibilities. On the other hand, teamwork measures focus on the coordination requirements (e.g., performance monitoring, feedback, communication, and back-up behaviors) that are necessary between team members. Process measures (i.e., how the task was accomplished) are important for determining problems in performance that may prevent successful outcomes. However, successful outcomes can be achieved when processes are flawed. Outcome measures usually rely on opinions from experts or automated recording of performance. Because outcome measures do not provide information that is useful in determining the cause of poor performance or performance improvement, it is necessary to measure both process and outcomes to ensure that team performance is effective.

It is important when measuring team performance and training to follow the theory and methodologies outlined above. The team task analysis, or theory level, will allow the researcher to define the critical dimensions, behaviors, objectives, and competencies required of the team training. Team performance and training should be measured next. Measurement of team skills is usually accomplished using the team vs. individual measures approach and/or the outcome vs. process measures approach. It is important to measure all aspects of a team's performance to ensure its effectiveness.

6. *Conclusion*

The purpose of this article has been to provide information regarding teamwork and team training. The authors have attempted to present an overview of these areas by providing definitions of a team, teamwork, and team training. In addition, the necessary team competencies—knowledge, skills, and attitudes—were briefly described. It should be noted that the KSAs mentioned are neither exclusive nor exhaustive. In addition, several team training strategies necessary for effective team performance were discussed. Finally, team measurement through a team task analysis (i.e., development of team training objectives and competencies) and methodologies were shown to be an important part of effective team performance.

Technological Change in a Multicultural Context, Applied Psychology of

This article addresses a combined set of issues, namely technological change and multicultural contexts. Each issue has received extensive attention in its own right, but in combination there is comparatively little directly relevant literature. After a brief introduction to the two sets of issues, the article highlights three issues that will become increasingly important as areas of investigation in future years.

1. *Technological Change*

Technological change has a long history, and each new wave of technological development has resulted in changes to the nature of work (Wilpert 2000). Examples include the Industrial Revolution, developments in transport (air, land, and water), and most recently the information technology and communications revolution. The uptake of new technologies has not been uniform across the globe, and it is therefore difficult to speak of this without acknowledging the diversity of stages of technological change in different countries and cultures.

Industrialization has resulted in a particular form of work that emphasizes the division of labor, centralization of functions, and new forms of labor relations. The information technology revolution has added another layer of change with major implications for the location of work in time and space, and for the immediacy of communication irrespective of distance. Machine tooling provides an instructive example of the impact of technology. Early blacksmiths required carefully honed craft skills that involved the use of a range of tools. Lathe and mill technologies used by fitters and turners evolved into computerized numerical control (CNC) machines that have radically altered the skills required. Perceptual motor and hand–eye coordination skills were replaced with a need for the conceptual and cognitive skills required for writing numerical control code in order to program the machines. Retraining was not always possible because of the very different skill set that often required a high level of mathematics.

More recent developments of a similar nature include electronic data exchange (EDE), computer aided design (CAD), and computer supported cooperative work tools. Information technology is now pervasive with e-learning, e-commerce, and e-communication via the Internet rapidly replacing existing approaches. These developments have major implications for the nature of work. In general, many new jobs have been created, existing jobs have changed radically, and some jobs have disappeared. New jobs are usually more complex and require a broader set of skills.

Technological change of the sort described above is best understood within a broader work context. A useful framework has been provided by Emery (1969) who presents a model of organizations as consisting of interacting technological, social, and managerial components. The technological system includes all the equipment, infrastructure, and technology in the workplace. The social system includes individuals and groups and the social processes and informal channels used by these groups in communicating and negotiating in the workplace. The managerial system is concerned with the power and authority within the organization, and formal lines of communication. Cultural issues have been widely discussed within the social and managerial system, but to date there has been comparatively little attention to cultural issues within the technical system. Technological change has an obvious and direct impact on the technical system but also on the social and managerial systems, and hence on any cultural system.

2. *Multicultural Contexts*

Organizations and workplaces are increasingly multicultural. This has arisen because of globalization of industry, education, and many other activities, and increased migration and portability of populations. Developments in transport and communication technologies have provided an enabling basis for these trends. The workforce of large corporations is increasingly multicultural even within single organizations (Bochner and Hesketh 1994). Many large international firms have branches throughout the world, with a consequential requirement placed on their employees to deal with a variety of different cultures. These trends have led to the recognition of a need to understand different cultures as consumers and employees.

Triandis defines culture in terms of the group's characteristic way of perceiving its social environment (Triandis 1972, p. 3). This should be extended to the group's way of perceiving the technological and managerial environment. Values are fundamental to these perceptions, and Schwartz (1994) and Smith and Schwartz (1997) have made a major contribution to thinking in the area through their empirically based typology for evaluating environments cross culturally. Cultures differ in terms of: (a) Conservatism (collectivism), where the emphasis is on group goals, interdependence, and closely knit groups; (b) Hierarchy, where resources and roles are allocated by the hierarchy; (c) Mastery, where the emphasis is on self-enhancement and achievement; (d) Autonomy (individualism), with independence emphasized in the pursuit of individual goals; (e) Egalitarian commitment, where the welfare of others transcends self-interest; and (f) Harmony, for the world as it is and for the preservation of the environment. Nations can be characterized in terms of distinct cultural value pat terns or profiles that map on to a circumplex. Bochner and Hesketh (1994) present data that show how these types of value differences, particularly collectivism and individualism, can be found within one multicultural organization.

3. *Technological Change in a Multicultural Context*

Several themes will be used to illustrate the reason for examining technological change within a multicultural context. First, the ways in which technology and culture might contribute individually and interactively to performance and other outcomes will be examined. Second, the impact of information technologies on work organization will be reviewed with a particular emphasis on the implications of the new communication technologies for trust in a multicultural context. Finally, the importance of training for changing technologies and for working in multicultural contexts will be highlighted.

3.1 *The Technology–Culture Interaction*

Hesketh and Neal (1999), in a chapter on technology and performance, highlighted the confounded relationship between individual differences and technology in understanding the contribution of each to performance. Using a sporting analogy, they illustrated how racquet technology has interacted with individual differences in skill level to greatly enhance the performance capability of tennis players. Unfortunately it is difficult to determine how much of the improvement is due to the technology or to individual skill in interaction with the technology because of the confounded nature of the relationship.

The same type of analysis can be used to examine the contribution to performance of factors such as individual differences, technology and culture, and the various combinations of these. Gelfand and Dyer (2000) draw attention to the concept of the tightness or looseness of a culture. Tight cultures provide strong norms, with little opportunity for individual differences. Loose cultures are more likely to provide opportunities for a wider range of behavior and influences. Similarly, some technologies are extremely constraining, with resultant re-engineering that forces systems and cultures to fit their design criteria. Other technologies are more adaptable, providing the opportunity for individuals or cultures to tailor the technologies to fit their values. Using these analytical tools it should be possible to make predictions about the types of changes likely to emerge from technological developments in different multicultural contexts. Although this research is yet to be undertaken, current trends suggest an overwhelmingly strong main effect for technology that appears to be swamping cultural differences. For example, Jarvanpas and Leidner (1999) found no effect for culture in their research on trust in virtual work teams. In some respects technology is providing the common platform for communication within diverse multicultural groups. Even language translations are likely to be more instant and pervasive with future developments in the use of technologies.

3.2 *Technological Change and Work Organization*

The growth in communication technologies has made it possible to provide flexible work arrangements that are no longer restricted in time and space. These changes have major implications for the nature of supervision, monitoring of performance, and labor relations generally. Employees will need greater self-reliance and remote work self-efficacy (Staples et al. 1999).

Research into the newer forms of work organization is essentially descriptive. Current research has com-

pared various forms (telecommuting, teleworking, satellite work stations, neighborhood work centers, and traditional work arrangements) in terms of hours worked, satisfaction, perceived flexibility, and the impact on work and family balance. Telecommuting is a term that is used to describe a work arrangement where an employee is provided with a computer for use in an office at home. The extent to which this is used varies from arrangements that systematically substitute the home office for a work office for anything between one and five days per week, to simply extending work into 'non-work' hours at home. Teleworking covers a broader range of work arrangements including the use of a car as a mobile office, call centers, and home work. In a large US study, Cree and Sorenson (2000) found that teleworkers worked more hours than traditional workers (56.4 hours versus 47.1 hours). Because of the longer hours, teleworkers perceived that the arrangement had a negative impact on work and family balance. However, when hours worked was controlled, teleworking provided the hypothesized benefit for work–family balance.

Most new forms of work require greater self-direction, and potentially alter the modes of communication and informal hierarchies at work. Given the centrality of trust and absence of distrust for effective performance (Baba 1999), it is important to understand how technology affects relationships. Trust and distrust are aspects of social relations that are found in all societies, although their bases may differ vastly. The ingredients and behavioral manifestations of trust are culturally bound. Technology can either improve or interfere with trust depending upon previous experiences with the technology and the manner in which it is introduced. Jarvanpas and Leidner (1999) report on a preliminary study examining issues of communication and trust in global virtual teams. Virtual teams are permeable, form rapidly, and dissolve quickly when no longer needed. They are often located across time, space, and culture, and make extensive use of e-communication. Jarvanpas and Leidner (1999) grouped their cases according to the levels of trust at the start and later in the team lifespan. Those teams that started with high trust and maintained it were able to function most effectively. Establishing trust early was important. Many employees have developed strong distrust of new technology in part because it has changed the ways in which they work. In examples where the technological change includes the development of multicultural virtual work teams, considerable effort is needed to overcome cultural barriers and to develop trust as this has traditionally depended on personal relationships. Jarvanpas and Leidner (1999) found that groups able to maintain trust without social contact were better able to manage uncertainty and complexity. It appears very difficult to overcome early events that disrupt trust or produce distrust.

Technologies differ in terms of the extent to which they provide employees and groups with opportunities to obtain informational control, something that most groups seek. If trust is lacking, the efforts of the workgroup to gain some form of control over their work tasks may yield counterproductive outcomes. Excellent case examples are provided by Baba (1999).

3.3 Training for Technological Change in a Multicultural Environment

Developing methods of training for adaptable and transferable skills has become essential in the face of ongoing technological change. This need has resulted in a remarkable increase of research on training, much of it drawing on recent developments in cognitive psychology (Quinones and Ehrenstein 1996). A multicultural context also presents a major need for culture training. One needs to both skill and multiskill the workforce. Hesketh and Bochner (1994) reviewed issues associated with culture and training. The chapter addresses issues linked to the impact of social change, the changing ethnic composition of work, work-related contacts between societies, a decrease in work-related discrimination, an aging workforce, and attitudes toward change. Training now needs to develop multiple flexibility, including flexibility in response to continuing technological change and flexibility in working with colleagues from a variety of cultural and religious backgrounds. A key issue relates to the development of trust sufficient to endure the many new forms of work. In achieving this, one aim of training is to develop a shared mental model about whatever task or negotiation is being undertaken, including an understanding of the cultural differences in the group. The early development of a shared mental model helps reduce uncertainty, and allows each individual to predict how others in the group might react. Trust is a component of such mental models in that trust allows one to have expectations regarding the behavior of another. Violation of expectations about behavior can often be the start of the development of distrust which is difficult to overcome. A deep understanding of cultural differences facilitates the development of accurate mental models that underlie trust, particularly where the tasks and communications include a multicultural group. Where ongoing interactions are required, then shared mental models are needed to increase trust and communication.

4. Summary and Comment

Technological change has resulted in major and ongoing change to work organization in a multicultural context. To date there is comparatively little empirical data that is useful in making effective use of

technology in this context, although several of the papers listed in the bibliography provide good analyses of the difficulties and issues. The very nature of the technology makes it possible to do research of a different form with the availability of possibilities for electronic capture of communication and output, and on-line surveys of attitudes and reactions. Such research and any forms of electronic monitoring will need to be handled in ways that maintain trust and provide employees with a sense of control.

Technological Determinism

'Technological determinism' refers to a pervasive, yet controversial, theory about the relationship between technology and society. Although the term has had a variety of meanings, two related claims have been central to discussions of this topic: (a) the development of technology proceeds in an autonomous manner, determined by an internal logic independent of social influence; and (b) technological change determines social change in a prescribed manner (Staudenmaier 1985, Misa 1988, Bimber 1994). The claims address two major questions about technology: how and why is technology developed and what is the relationship between technological change and social change? Arguments against the first claim have been a staple of research in the history and sociology of technology since the 1960s. The second claim has been at the center of debates about Karl Marx's theory of history since the early twentieth century. Weaker versions of technological determinism, sometimes called 'soft determinism,' maintain that technology is a major cause, but not the sole determinant, of social change.

1. History of the Concept

It is important to distinguish between widely held beliefs that an autonomous technology is the primary cause of social change and the use of the term 'technological determinism.' In the United States, the Enlightenment doctrine that improvements in the mechanic and industrial arts fostered social progress was replaced over the course of the nineteenth and early twentieth centuries by a more technocratic concept of progress, in which improvements in technical and economic efficiency became ends in themselves, instead of the means for creating desired social ends. Through the writings of the economist and social theorist Thorstein Veblen and others, the word 'technology' gradually displaced phrases like 'mechanic arts' in scholarly and then popular discourse in the twentieth century. In this period, the older meaning of 'technology' as systematic knowledge of crafts and industry was joined to the anthropological one of the artifacts and related practices of a culture. The term's connotations of abstractness and scientific objectivity served to reinforce the idea that technology was an autonomous social force.

These meanings entered popular culture through such media as utopian novels, exhibits at World's

fairs, the Technocracy movement in the 1930s, and company advertisements that endlessly touted new products as the cure for social ills and the source of all happiness. The organizers of the 1933 Chicago World's Fair encapsulated the gender biased, applied science aspect of technological determinism with the motto, 'Science Finds, Industry Applies, Man Conforms.' Ironically, twentieth-century critics of technology's harmful effects, such as technological unemployment and environmental degradation, have tended to reify the notion that technology is an autonomous agent of change in their attempts to control it (Smith 1994, Marx 1994).

The term 'technological determinism' is more recent, with roots in the turn-of-the century debates about Marx's theory of history. While Europeans used the phrases 'historical materialism' and 'economic determinism' to describe Marx's theory, many American social scientists employed the broader phrase, the 'economic interpretation of history,' popularized in a non-Marxist manner at the turn of the century by Edwin R. A. Seligman, editor-in-chief of the first edition of the *Encyclopaedia of the Social Sciences*. Historian Werner Sombart in Germany and economist Alvin Hansen in the United States argued that Marx's theory should more properly be called a 'technological interpretation of history' (a phrase which Hansen seems to have coined). Although many scholars questioned this view, prominent Soviet theorists established a 'technicist' version of historical materialism as the dominant interpretation in orthodox Marxism during the first half of the century (Bober 1927, MacKenzie 1984, Miller 1984).

During the early Cold War, social scientists and historians, who were increasingly concerned about how to control the effects technology apparently was having on daily life, began using the starker term, 'technological determinism' to criticize Marxist theories of technology and society. They also used the term to criticize the controversial views of such authors as Veblen, historian Lynn White, Jr, and the philosopher Jacques Ellul. White and Ellul said their views were not a strict determinism. Only a few authors, such as economist Robert Heilbroner (1967), have labeled their position a form of 'technological determinism' (soft determinism in Heilbroner's case). Philosopher Langdon Winner criticized scholars for dismissing the issue of technology's social effects because of the flaws in the concept of technological determinism. Saying that the 'idea of determinism is not one that ought to be rejected out of hand,' Winner argued that technology does constrain human activities (Winner 1977, p. 77).

By the mid-1970s, the issue of technological determinism had become a central topic in both Marxist scholarship and in the interdisciplinary study of science, technology, and society (Cohen 1978, Staudenmaier 1985). In the recent turn toward social constructivism in the latter field, the issue of technological determinism remains a focal point around which to criticize a theory of technology and society that is still prevalent in other disciplines and in popular culture.

2. *Was Marx a Technological Determinist?*

Recent scholarship is sharply divided about whether or not Karl Marx's theory of history, the *locus classicus* of technological determinism, is, indeed, technological determinism. Much of the debate centers on the meaning of an often-quoted excerpt from the preface to Marx's *A Contribution to the Critique of Political Economy* (1859): humans enter into 'relations of production [*Produktionsverhältnisse*] which correspond to a definite stage of development of their material productive forces [*Produktivkräfte*]. The sum total of these relations of production constitutes the economic structure [of society], the real basis on which arises a legal and political superstructure' (quoted in Cohen 1978, p. 28).

Those who argue for a technological interpretation of Marx usually equate 'forces of production' with 'technology' and interpret the verb 'correspond' to mean that the relations of production evolve to maximize the productivity of the forces of production. William Shaw, who includes instruments, raw materials, and labor power (including knowledge) in the category of productive forces, calls Marx's 'technological determinism' more properly a 'productive-force determinism.' Shaw acknowledges that Marx allowed for interplay between forces and relations of production, but maintains that productive forces are the 'long-run determinant of historical change' (Shaw 1979, p. 160). Gerald Cohen defines productive forces in a similar, broad manner, but rejects the label of 'technological determinism' in favor of a '"technological" interpretation of historical materialism.' In this functionalist view, social structures adapt to technological change to increase productivity (Cohen 1978, p. 29).

Those who argue that Marx was not a technological determinist typically have concentrated on the manner in which he wrote history. Harry Braverman, Nathan Rosenberg, and Donald MacKenzie point to the dialectical aspects of Marx's writings, especially where he attributed the development of productive forces to social relations. Indeed, MacKenzie characterizes Marx's treatment of the history of machinery in the Industrial Revolution as an 'attempt to develop a theory of the social causes of organizational and technical changes in the labor process' (MacKenzie 1984, p. 492). Richard Miller argues that Marx was not a technological determinist because in his historical work, 'economic structures do not endure because they provide maximum productivity. Productive forces do not develop autonomously. Change in productive forces, in the narrowly technological sense

that excludes work relations, is not the basic source of change in society at large' (Miller 1984, p. 188). Bruce Bimber, who defines technology narrowly as artifacts, argues that, for Marx, human characteristics of accumulation and self-expression drive the forces of production. Thus Marx was an economic, not a technological, determinist (Bimber 1994).

3. *Varieties of Technological Determinism*

Bimber and Thomas Misa effectively analyze varieties of technological determinism. Bimber distinguishes between normative, nomological, and unintended-consequences accounts (Bimber 1994). Normative accounts, evident in the writings of such critics of technology as Lewis Mumford, Jacques Ellul, and Jurgen Habermas, claim that society is relinquishing control over technology, or replacing political and ethical norms with those of the technologist's goals of efficiency and productivity. Nomological accounts, such as that by Heilbroner (1967), evoke the two-part definition of technological determinism given above: technology develops autonomously according to an internal logic and forces a prescribed social change. In unintended consequences accounts (e.g., Winner 1977) technology produces unpredictable social change, a view that challenges determinism, but reinforces the idea that technology is out of control. Bimber argues that the term 'technological determinism' should be reserved for nomological accounts, which are the only ones that satisfy his strict definition of the term.

In his survey of scholarship about the relationship between technology and social change, Misa (1988) found that sweeping, macro-level accounts were more likely to be technologically determinist (using the two-part definition of the term) than micro-level accounts, which focused on specific practices. Philosophers, business historians, urban historians, and historians of physical sciences were generally more deterministic than technological historians and labor historians.

Another form of technological determinism is what Claude Fischer (1992) criticizes as the 'impact-imprint' model of technology. Rather than investigating how consumers use a technology, scholars assume that a technology's capability (e.g., the ability of the telephone to enable people to talk at a distance) leads to a predictable 'impact' (e.g., new, long-distance communication patterns).

4. *Political Artifacts and Systems*

Winner and Thomas Hughes have proposed influential theories of technology and society that address the question of technological determinism. Winner (1986) argues that artifacts have politics (i.e., are associated with specific social changes) in two ways. Technologists can design a (plastic) artifact to promote a certain type of politics, as when Robert Moses built low bridges over the Long Island Expressway in order to prevent inner-city buses (carrying poor minorities) from traveling to Jones Beach. Secondly, the design and building of some systems seems to require a certain type of politics. Nuclear power plants, for example, require a centralized form of government to run the reactor and prevent the proliferation of nuclear weapons. Hughes (1994) states that his concept of technological systems allows for the social construction of a system when it is young, but technological determinism comes into play once it is established and shapes society more than being shaped by society.

5. *Social Construction of Technology*

The advent of the approach known as the social construction of technology (SCOT) in the mid-1980s (Pinch and Bijker 1987), along with a contextualist history of technology (Staudenmaier 1985), has challenged the technical aspect of technological determinism (the first part of the definition given above). Sociologists and historians of technology have published numerous case studies of the development of technologies that argue that their design was the outcome of negotiations between several social groups (such as inventors, engineers, managers, salespersons, and users), rather than the product of an internal, technical logic (see *Technology, Social Construction of*). When Winner (1993) and others criticized this approach for leaving out power relations among social groups, constructivists responded by investigating the social aspect of technological determinism (the second part of the definition). Bijker (1995) employed a semiotic version of Michel Foucault's 'micropolitics of power' to show the mutual construction of artifacts and social groups. Ronald Kline and Trevor Pinch (1996) utilized theories of gender in the original SCOT approach to show how gender relations and the automobile were mutually constructed when farm men in the United States before World War II adapted the car, as a stationary and mobile source of power, to a variety of novel uses, such as grinding grain, washing clothes, and plowing fields. Fischer (1992) employed a similar user-heuristic to argue that callers in the United States used the telephone before 1940 to widen and deepen existing communication patterns, rather than to create new ones.

6. *Conclusion*

Although historians and sociologists of technology have discredited the tenet of technological determinism, so much so that it has become a critic's term and a term of abuse in their academic circles, the idea that an autonomous technology drives social change per-

vades other fields of scholarship and popular culture. This is especially evident in discourses claiming that new information technologies have created an information society in the United States and Europe. It remains to be seen if this scholarship will overturn the widely held belief in forms of technological determinism.

Technological Innovation

Technological innovation is the successful implementation (in commerce or management) of a technical idea new to the institution creating it. Innovations are distinguished from inventions, technology and research, but may arise from any of the three. A variety of models of the innovation process are described, for they are useful in developing public policies for encouraging innovations as well as for managing their creation. The more advanced of these models include consideration of complementary assets and social capital, which helps explain the differences in innovative capacity in different societies. The American society is particularly given to the use of banners under which to rally public opinion to the advance of economic well being. In the middle 1970s, when 'high tech' industries emerged as the key to growth, and American firms were immediately challenged by the technically adroit Japanese, the banner was 'critical technologies' derived from defense and space research. When the economic challenge became serious in the 1980s and early 1990s the banner was 'competitiveness'; even conservative President Reagan launched a White House taskforce to suggest how government could enhance American competitiveness in the face of serious price and quality competition in technology intensive industries, especially in Asia. As we prepare to enter the next millenium, the new banner, in nations rich and poor, is 'innovation.'

1. Definitions

While a firm can become more competitive by cornering a market or slashing worker's wages, innovation implies a transformation in the market—the invocation of imagination and daring in the adoption of new ways of doing things. The word innovation has an old history. The Oxford English Dictionary uses a broad definition: 'A change in the nature or fashion of anything; something newly introduced, a novel practice, method, etc.' and traces its first use back to 1553. In its contemporary usage, Burke is quoted as writing in 1796 'It is a revolt of innovation; and thereby the

very elements of society have been unfounded and dissipated.' In modern usage we must distinguish innovation from invention, technology, and scientific or engineering research. Invention is the conception of a new artifact or process that is useful, original, and non-obvious. Technology is the capability to perform a technical task or process. Research leads to understanding of how things work. Innovation, as defined by Richard Nelson (1993), is 'the processes by which firms master and get into practice product designs and manufacturing processes that are new to them…' Thus, an invention does not become an innovation (and many never do) until the invention is successfully embodied in a product and introduced to the market.

Even then, an innovation does not necessarily make a successful contribution to the economy. As David Teece (1987) observed, many products that embody little novelty are successful in the market place, while innovations that are not supported by a variety of 'complementary assets' may fail. The complementary assets of an innovation are all the requisite ingredients of success that are not provided by the innovator and may not be readily available in society because of the novelty inherent in the innovation. Thus, the first personal computers became wildly successful only after a cottage industry provided a wide variety of software applications. A new drug cannot make money for its innovator until the manufacturer receives approval from government regulators.

Nelson's definition requires that an innovation be new, at least to the innovator, and that it must be in production and use, but it does not have to embody an invention or be the result of any research. Thus, many of the innovations with the greatest impact on society were marketing, institutional, or managerial innovations. The Sears Roebuck catalog revolutionized marketing to families in a predominantly agricultural society. The corporate research laboratory that flowered at GE, DuPont, and ATT early in the twentieth century provided a more productive way to create useful technology. Just-in-time manufacturing is a Japanese managerial innovation that reduces cost and accelerates product cycles and quality control. This article focuses on technical innovation—that class of innovations based on technical novelty.

2. *Technical Innovation Models*

The popular imagination is excited by the creation of new firms by the marriage of daring investors with the dreams of inventors and other would-be innovators. The US economy is noteworthy for the dynamism of its venture capital industry, and new research breakthroughs often capture the imagination with their economic potential. Thus, when materials that could conduct electricity without any resistance and do so at or near room temperature were discovered (and the inventors were rewarded with Nobel Prizes) the potential to destabilize the entire electrical machinery industry was in everyone's mind. After over a decade of dashed hopes, finally a company has mastered a technology to make superconducting motors that operate at temperature far above liquid helium temperature. They have a contract to sell such motors to the US navy.

The innovation process that follows such a discovery is described by the time honored, but oversimplified 'linear model' of innovation, in which technical innovations begin with a scientific discovery or an invention. The idea is then explored through a period of applied research. When the technology is sufficiently understood, the work is transferred to product and process development, followed by production, quality control, distribution and marketing. This is a reasonable description of one way a new invention arising from scientific research may be exploited. Scott Shane (2000) has shown that the most radical or fundamental inventions patented and licensed by MIT are most likely to be successfully exploited in a new firm, created by investors for the purpose. Such radical innovations often must create their own markets. However, technical innovations do not always arise from a scientific breakthrough; they are quite frequently the response of technically clever people to an identified market need. This is reflected in the saying 'necessity is the mother of invention.' The transistor was a discovery in search of a more economical switch for telephone exchanges, and the integrated circuit was the answer to the excessive power consumption, size, and manufacturing cost of computers made of discrete electrical elements. In these examples, as in many other cases of science-based innovations, the new capability not only solves the identified need, but does much more, creating new markets or even entirely new industries. Innovations are compounded both of answers looking for questions and questions looking for answers. In the real world both are intimately linked. This fact gives rise to the 'chain link' or 'spiral' models of innovation in which new ideas are stimulated by new market needs, which in turn are extended when the capabilities of the innovation are better understood (Kline and Rosenberg, 1996). Thus, it is rare that a technically radical innovation is introduced into a totally new market. The more typical trajectory is interative. First a new market is found for an existing technology (a market innovation); then new technology is brought to this new market (a technical innovation), and so forth.

At the level of product development, an analogous interaction takes place, between research to understand the new technology and product development to define product performance and cost. Thus when an invention is being reduced to commercial practice, one must know what the product specifications (function and cost) will be in order to know what tests to apply. But function and cost cannot be known until the

technology is developed. This iterative process describes almost all incremental or evolutionary innovation in existing companies.

3. *Innovation as a Socioeconomic Process*

Futurists have often called attention to the remarkable fact that progress in meeting many of the needs of society does not improve linearly with time, but rather exponentially. Thus, if one plots on semi-log graph paper the speed of commercial transportation against the year of introduction, from the horse-drawn trolley, to the train, the airplane, and the rocket, one gets a surprisingly straight line. The same observation is inherent in Moore's Law, which observes that the density (and hence speed divided by cost) of integrated circuits has doubled every 18 months for many years and continues to do so (Lester 1998). What accounts for this remarkable attribute of technical innovations? It is not inherent in the nature of technical progress, but rather is the result of the socioeconomic dynamics of an economy that rewards innovation. Consider the typical time history of a radical innovation arising, let us say, from new university research. After a promising discovery there is typically a period of intense excitement. The most daring investors leap into the business, hoping to acquire that 'first mover' advantage and intellectual property protection that the economist Schumpeter recognized as necessary if a firm hoped to gain enough profit to repay the risks and costs of innovation. Then after perhaps 5 to 7 years the recalcitrance of nature becomes widely evident; the low hanging fruit has been plucked, and the number of firms decreases sharply—through failure, merger, or switch to a more conventional product opportunity. Those who persevere in pursuit of commercial advantage from the discovery and have the requisite financial staying power and the technical skill and knowledge may then master and reduce to practice the technology required for the innovation. The business may then take off with exponential growth as the technology matures, costs fall, and new applications for the technology are found. Investors and inventors alike observe the exponential growth of the business and invest their money and their imaginations in the expectation that exponential growth will continue.

Sooner or later the chosen technical approach becomes increasingly difficult to improve, given the limitations imposed by real materials and the laws of natural science. Continued rate of performance growth and cost reduction slows; the technology is reaching its natural limits. The curve of progress vs. time starts to become S shaped. The gap between expectation and reality begins to widen, and a huge incentive to find another technology that can satisfy the future expectation for improvements in product function and cost is created. Because science has made such extraordinary advances in the last half century, the potential for invention is enormous. It is the reward of filling the expectation gap that converts that potential to another innovation. Thus, another S-shaped curve becomes tangent to the first one, and the exponential growth in capability and in economic activity continues unabated. In this way performance advances seamlessly from horse to auto, to airplane, to rockets. Similarly Moore's Law continues to be valid despite evolution from vacuum tubes to single transistors, to integrated circuits of every increasing complexity.

4. *National Systems of Innovation: Social Capital*

Because innovation is a socioeconomic as well as a technical process, one might expect different societies to exhibit different strengths and weaknesses in their capacity for innovation. Indeed this is true, as observed by many students of comparative innovation policy. As Patel and Pavitt (1994) pointed out, the economic theory prevailing in the 1960s predicted that buoyant demand and an open trading system would allow the international (and domestic) diffusion of technology and this would lead to equalization of technological performance of the industrial nations at the national level. This prediction, they argued, was based on a flawed model of science-based development, indeed of technological change. It presupposed that technical change would be fully determined by investments in better machinery, the diffusion of public technical information, and the acquisition of 'tacit' knowledge resulting from relatively costless 'learning by doing.' If this model were equally applicable to all countries in a similar state of development, it would follow that the gaps between the US economy, and that of Japan, the United Kingdom, Germany, France should have closed rather rapidly. It has not happened. Japan and Germany have moved ahead; the UK and France have fallen behind. Taiwan, Korea, and Singapore have leapt ahead from a very backward state 30 years ago. Brazil, Mexico, and India, all in better economic health than the Asian Tigers at the end of World War II, have failed to do so to the same extent. These three assumptions in the 1960s economic model have persisted, in more recent years, in the form of a Cold War paradigm of the innovation process. It was widely believed in the US government (as well as in the UK and France) that one could gain commercial advantage by force-feeding industrial technical development in pursuit of government missions. This is the 'spinoff' theory of defense industrial research. Defense research investments, under this theory, would bring into existence new machinery, abundant and accessible new technical knowledge, and the private sector could quickly assimilate the embedded knowledge by 'learning by doing.' The problem with the three post-war economic assumptions is that the efficiency of each of these processes varies strongly from one national

socioeconomic setting to another. Patel and Pavitt conclude that technology diffusion, productivity learning, and transfer of embodied technology have large transaction costs when they encounter cultural, managerial, and institutional barriers. It is the absence of these barriers and the presence of efficiently functioning networks connecting innovators, investors, producers, supporting service providers and consumers that largely govern the benefits that flow from technical innovations. These attributes of the economy are referred to as 'social capital.' Richard Nelson's ambitious study entitled *National Systems of Innovation* (Nelson 1993) examined the policies and institutional settings for innovation in 14 countries. It is clear that the structure of economies, socioeconomic policies, cultural factors, and natural endowments all influence the environment for innovation. In addition, Nelson recognizes that innovation systems may not be national, but rather sectoral or regional. For example, the world oil industry shows little variation in its innovation practices from country to country, while it differs significantly from other industries in all countries. The levels of trust that exist among entrepreneurs, the financial sector, government and industry leaders are as influential in the capacity of a society to innovate as is the role of education and the participation of higher educational institutions in the nation's research and invention activities. As firms turn away from vertical integration and increasingly look to global sources of innovation to keep them competitive, issues of social capital will become more important. The methods of microeconomics are still essential but are no longer sufficient to understand why some societies are more innovative than others. Thus the importance of social capital forces the study of innovation beyond the boundaries of the firm into an understanding of the complex relationships among interdependent players in a high-tech economy.

Henry Ergas addressed this problem by defining a model of the innovation process at the level of the economy, rather than of the firm (Ergas 1989). His model is also a dynamic one, in that it incorporates the response of the economy to the introduction of an innovation, which in turn will affect the next generation of the innovation. Ergas sees four parts to the innovation process:

(a) *Generation*—all the activities from technical and market concepts to introduction into manufacturing, in other words virtually all of the activity calling for research and development skills.

(b) *Application*—commercialization: manufacturing learning, introduction of a complete product line and system of distribution, up to initial customer acceptance.

(c) *Verticalization*—the responses of suppliers, distributors, providers of complementary assets, and of competitors to the introduction of the innovation, responses that will, in turn, change the innovation and the way it is received.

(d) *Diffusion*—the responses of the rest of the socioeconomic environment, especially the way the innovation changes the end user's behavior. One can then expect user organizations, and perhaps society as a whole, to be transformed to the degree the innovation has that power (as for example the personal computer accomplished). Society then may change regulations and laws, introduce new curriculae in schools, and eventually modify the culture. Thus the next round of innovation takes place in a new environment calling for still more creativity.

5. *Role of Governments*

Fostering innovation and entrepreneurship is not a natural role for governments. As Nathan Rosenberg and L. E. Birdzell, Jr. (1985) recognized in their classic book, *How the West Grew Rich*,

> In all well-ordered societies, political authority is dedicated to stability, security, and the status quo. It is thus singularly ill-qualified to direct or channel activity intended to produce instability, insecurity and change.

Nevertheless, promoting innovation and entrepreneurship is increasingly seen as a pro-active responsibility of government. Nations that once relied on science and technology policy, by which they usually meant public investments in scientific research, came to realize that this supply-side policy would probably be ineffective without demand-side policies to put those ideas to work. Thus, there is now widespread acceptance of the idea that Science and Technology Policy should be replaced by a Research and Innovation Policy (Branscomb and Keller 1998).

The goals of an innovation policy are clear enough, even if the means for their attainment are not: full employment, decreased income disparities, rising real incomes, safe, healthy working conditions, and satisfying work. What policy tools, other than investing in research, can one use to encourage innovation? The list is long: economic policy, trade policy, tax policy and accounting rules, competition policy, regulation of equity markets and industry structure, intellectual property law, industrial relations, education and training, and the full range of environmental, health, and safety regulations.

This list of policy tools would seem to offer states a lot of options. In fact these policies must also be seen as a set of potential barriers to innovation, set up one behind the other. Any one of them, if sufficiently mismanaged, can seriously discourage would-be innovators. It might seem obvious that all these economic issues should be dealt with by economic policy makers who should appreciate the fragility of an economy increasingly based on science-based innovation. But science policy experts have for so long insisted (erroneously) that innovations happen auto-

matically as a result of research, that economists have mostly left these issues to 'science policy.' And science policy does not enjoy a priority on political agendas any where near economic, trade, tax, or regulatory policy. Furthermore, only a few of these policy tools (intellectual property law is an example) can be used to create a positive, specific incentive to innovation; most exist for other reasons and must be examined to ensure that suppression of innovation is not an unwanted side effect. To ensure that every government agency is alert to this responsibility, it may be most effective to entrust a policy body at or near the top of government with monitoring agency diligence. The challenge to governments is formidable, not only for the reasons given by Rosenberg and Birdzell but because, as discussed earlier, building an innovative society requires developing the social capital of society, a task that most governments perform poorly or are reluctant to even attempt. Thus, whatever the quality of the social capital, innovations must still come from the creativity, imagination, and determination of individuals who want to change the way things are.

Technology and Organization

The term 'technology' is in common everyday use. It may be popularly visualized in purely physical terms as 'equipment,' 'apparatus,' 'pieces of hardware and software,' and it may be defined by different commentators in different ways. Whatever the case may be, what are much more serious than definitional problems are the practical implications of the development, implementation, and control of technology by *a few* for the use of *the many* in an organization and in wider society. This article addresses the issue of technology and the relationship between technology and 'organization.'

1. Organizing and Organization: An Overview

To initiate a discussion on the relationship between organization and technology it is important first to define what is meant by each of the two terms. First, what is meant by the term 'organization'? Well, to organize something is to 'systemize' it for a certain desired end. 'Organizing' a group of people is a process that aims to give an orderly structure to that group with a view to achieving a goal or fulfilling an objective in mind. In such a process the group in question acquires, or is brought into, a state of being 'organized.' This definition is quite a broad one; it is meant to be so since an encompassing conceptualization of the term is required to grasp the range of possible positions and influences of technology in and on organizations.

From an organizational studies perspective, organizations are defined as social arrangements for the controled performance of collective goals (see Huczynski and Buchanan 1991). In a broad sense, therefore,

examples of an organization may include an African tribe, Juventus Football Club, a consumer electronic goods manufacturer, the European Union, or the University of Harvard.

2. *Defining Technology*

Technology has received increased attention since the late twentieth century, because of the pace of technological advancement and the magnitude of its diffusion in society. Indeed, it is likely to impose itself as a pivotal organizational issue more forcefully than ever before, because of the pervasiveness of 'new' technology and its effects on organizing and on the structure and functioning of organizations as well as the behaviour of individuals and groups within them. Examples of new technologies include information technology, biotechnology, materials technology, space technology, and nuclear technology.

But what is technology? Well, again there is no single answer to this question, although to a layperson it is merely 'equipment,' 'apparatus,' or 'pieces of hardware and software.' Even amongst commentators in the field of organizational studies differences can be found as to how technology is defined. Regardless of the way it is defined, however, technology is an important factor in organizing and organizational life. A suitable working definition for the purpose of this article is that, in essence, technology is a man-made creation of a *system* that is supposed to work logically and consistently and is made operational to produce a desired accomplishment that is valued by its inventor or user. Such an accomplishment is often reproducible, through the system, to a given set of performance criteria or precision.

The creation of such a system involves translating some pure science knowledge into an *input–conversion–output* system format based on engineering principles and composed of elements which are functionally arranged or configured so as to yield a certain output as specified by the designer or user (see Clark et al. 1988). According to this definition, technology is defined not only in terms of its physical objects but also in terms of its methods of operation, use, or production and the technical know-how needed to apply them successfully. Human intervention in the operation of a system usually takes the form of monitoring the system's conversion process and controling its output through a specific feedback mechanism.

3. *Conceptualization and Meaning: From Neutral Rationality to Political Sensitivity*

Conceptualization of technology merely in terms of 'equipment,' 'apparatus,' 'pieces of hardware and software' carries with it shades of pure rationality in mind. This conceptualization depicts technology as nothing more than a physical construction of a proven scientific idea or inference. The emphasis here is on technology as a manifestation of a purely logical effort which produces a neutral 'object' or 'pattern of operation' that helps mankind *per se* rationalize a given work task or improve the quality of a certain aspect of social or work life. This is often achieved by substituting human effort with machine effort, a phenomenon which began historically with physical effort (mechanization) and continues today with human coordination and intellectual efforts being replaced with inputs from 'smart machines' (computerization and automation). This takes place in an information age where information technology has become part of a global culture and knowledge-based artificial intelligence is likely to progress further. Thus far the notion of technology could be described as an objective description of an outer form of a disinterested, 'inanimate' object or mechanistic pattern of operation.

The above chosen *system* definition of technology, however, goes beyond this rather simplistic conceptualization as it takes on board the role of the designer or user in *configuring* a system which gives an output in accordance with the designer's prespecified performance criteria. Therefore, the proposition that technology could be explained merely in terms of presumed neutral rationality grounded in a specific scientific logic appears suddenly to be in question as a credible explanation because of the interference of the subjectivities of those associated with its instrumentalization and operation in the real world.

Just how politically sensitive technology is can be illustrated by explaining how significant it is to organizing and organizations. This is a turning point in conceptualizing technology as a serious organizational development involving actual and perceived impacts of a system's output upon organizing and within organizations. In this sense, technology is capable of being socially divisive. That is, a system's output can and does affect the status quo of any organization which accommodates it or comes to live under its influence. This will have implications for any long-established equilibrium in relationships, balances of power, and any sense of continuity within the organization. It may also have implications for the wider industrial sector or economy in which the organization operates and with which it interacts. Additionally, it may indeed have implications for the environment (e.g., pollution and health hazards in the case of a nuclear technology). Since differences of interpretation among individuals and groups will inevitably occur in the world of meaning, a system's output will signify and symbolize different things to different people; it will be highly valued by some but not by others; seem useful to some as something that improves the quality of working life, for example, and harmful to others who see in it a threat or deterio-

ration. In short, it is liable to being controversial and bringing about a sense of dispute as to why it has been acquired in the first place and, now that is has, how it should be managed and controlled to minimize its potential damage.

Furthermore, what makes technology a politically sensitive issue in organizational life is the fact that invariably technology is decided upon, adopted, designed, implemented, and changed by a minority of people in an organization (e.g., managers) on behalf of the majority of the organization's members (e.g., employees) who have to live with the consequences of operating it as an integral part of their jobs. Nonusers are also likely be affected, in that their jobs will now require different coordination skills to keep them in harmony with a changed rhythm and workflow throughout the workplace, for example, where new production methods are introduced by management. A common concern for users and nonusers alike may be that the introduction of a new *input–conversion–output* system format into the workplace is going to disrupt stability and that they have to change their working methods in order to suit the operational requirements of a new and somehow threatening technology-dictated work system.

By the same token, technology, at a societal level, is often invented by a single individual (e.g., a scientist) or an elitist minority in society (e.g., a technology research centre or a team of top biochemists); it is commercialized, marketed, and diffused by another minority (e.g., entrepreneurs or manufacturing companies) who are driven by a different set of motives (e.g., profit-making); it is regulated and controlled centrally by yet another minority (e.g., a sovereign state's legislature or a federal government). Yet, this technology is highly likely to be consumed by the vast majority in society. Even nonconsumers are likely to be affected by it in either a positive or negative way, or both. Because of this minority–majority situation, technology acquires necessarily social, economic, and political implications as well as rational, logical, and technical significances.

It is no wonder, therefore, that the politics of organizational change are increasingly accomplished through technologies in a digital age. Many of the most radical redesign projects for organizations have been in and through the use of digital technologies: from computer integrated manufacturing (CIM) to process re-engineering in manufacturing industry; from projects for 'virtuality' to extensive teleworking, organizations are being sold on projects of technical rationality as visions for the future. Yet so many of these projects appear to be stillborn: the technologies work but the organizational designs do not. Sometimes people sabotage the technologies; othertimes the technologies sabotage them. In a way, organizations are reduced to criteria of design from which most considerations of the politics of organizational change are absent. This is often the case even where the projects are explicitly political or require explicit politics to manage their changes. It is the politics of organizational change technologies that make the critical difference: how, and whether, they work.

4. *The Relevance of Technology to Managing and Management*

It would be misleading to suggest that management should constitute an homogeneous team making rational decisions. Different levels and functions of management within an organization tend not to be a single social or political decision-making group sharing a single rationality; these will therefore tend to hold different perceptions of technological change and are likely to differ between themselves as to how it should be managed (see Pettigrew 1985). Yet it is clear from the discussion so far that an organization includes people who, because of their membership of a collective social group, interact with one another in certain ways to achieve goals which if they act alone they cannot accomplish. Since it is management's responsibility to have work tasks carried out by employees, in the context of a business organization for example, it follows that the impact of technology is of central concern to managers *per se*, particularly those who are in charge of implementing projects involving the introduction of a new technology. Planning, control, implementation, and evaluation activities relating to such projects require decisions to be made, ranging from individual motivation through job design to the management of change and coordination of a newly designed work organization. Such decisions are made by managers occupying different positions within an organization's management structure. Regardless of how successful or unsuccessful those decisions will come to be judged by others, it is *management* as an institution that is going to be judged in terms of its rationality and political sensitivity as well in terms of its dominant attitudes, values, and ideological persuasions.

Whatever the type of organization or management an external observer chooses to study, technology is relevant to organization because the latter is necessarily a source of the following:

(a) money and physical resources, including technology itself;

(b) meaning and purpose, including how different individuals and groups within an organization perceive technology in relation to these variables;

(c) order and stability, including how stabilizing or destabilizing it is in the context of a change project involving the introduction of a new technology;

(d) security and protection, including the consequences of change for security of employment and health and safety concerns;

(e) prestige and self-confidence, including possible improvement or degradation of job design and sat-

isfaction following the utilization of a certain technology; and

(f) power and control, including technology-related assignment of authority and shifts in the *de facto* balance of power due to empowerment caused by, for example, expert knowledge of a key technology.

Therefore, management's role in, and responsibilities for, technological change should be emphasized as a legitimate concern for an organization's stakeholders who are not members of the *governing* institution of management, because of, among other things, the strategic, operational, and control choices available to managers in planning, design and implementation (see Buchanan 1983, Sorge et al. 1983, Child 1987).

5. *The Technology–Organization Link: Empirical Studies and Theorization*

The relationship between technology and organization could be perceived, explained, and theorized upon differently by different people and groups, depending on many factors as explained above. This is in harmony with a central assumption of this article, which recognizes the legitimacy of a multiplicity of views as to what constitutes this relationship.

Such multiplicity is reflected in the management literature, including major empirical studies theorizing upon the organization–technology relationship. Examples of these studies include Joan Woodward's (1965) investigation of 100 firms in south east England, which used different unit and small batch, large batch and mass, and process production technologies. The main conclusion of this study was that *technical complexity* caused increases in the length of chain of command, in executives' span of control, in the proportion of indirect to direct labor, and in the proportion of managers to the total employed workforce. The technology used to manufacture a product placed certain requirements on those who operated it, which, in turn, were reflected in the organizational structure. Woodward's variable was further studied by Charles Perrow (1976) whose name is also associated with 'technological determinism' since he argued that specific aspects of job discretion, coordination, and group interdependence were determined by the type of technology used, much more so than by other variables such as leadership style or small group dynamics.

The Aston research program in Birmingham, England (e.g., Pugh and Hickson 1976, Pugh and Hinings 1976) contributed to organization theory by blending some of the research methods and assumptions of psychology with conceptions of organizations and their workings from sociology and economics. The empirical work undertaken by the Aston group aimed to link organizational structure and functioning, group composition, and interaction, as well as individual personality and behavior. It did so by researching organizational structures in terms of their degrees of 'specialization,' 'standardization,' 'formalization,' 'centralization,' and 'configuration.' According to the Aston studies, an organization's size and its dependence upon other organizations were found to be much more significant variables than technology and ownership.

Other relevant empirical contributions to theory include that of Eric Trist and his colleagues, of London's Tavistock Institute, who studied the effects of mechanization in coal mining (e.g., Trist and Bamforth 1951, Emery and Trist 1960). Their 'sociotechnical perspective' contributed considerably to the Quality of Working Life movement, particularly in the USA and Canada, where Fredrick Taylor's (1947) 'scientific management' style dominated the industrial scene as many large organizations followed Henry Ford's mass production model, which caused degradation in working conditions in the context of a capitalist economy.

Classical theorizing about organizational technology has produced a set of typologies for categorizing technology, which are often used to develop and empirically test contingency theories, including Woodward's (1965) above mentioned work, giving rise to the notion of 'technological imperative.' Other important issues concerning social structure are associated with the position of technology in modernist organization theory, including task interdependence, uncertainty, complexity, and change in the environment of an organization. Linear models of technological innovation are increasingly being challenged, however, by posmodernist theorists and social constructionists (e.g., Clegg 1990, Gergen 1992, Pettigrew 1985) who emphasize the need for researching the contexts in which technologies are introduced.

6. *Conclusion*

In summary, this article has addressed questions pertaining to the management of technology adoption and organizational adaptation in organizations. It defined the terms organization and technology and discussed the relationship between them. One single point remains at issue: the desire for an 'optimum fit' between the two is a noble concern, but in practical situations involving many users and a few decision makers and, equally, in theoretical situations involving numerous typologies and competing interpretations, on whose terms?

Technology and Social Control

The last half of the twentieth century has seen a significant increase in the use of science and technology for purposes of social control. Examples include video and audio surveillance, heat, light, motion, sound and olfactory sensors, electronic tagging of consumer items, animals and humans, biometric access codes, drug testing, DNA analysis, and the use of computer techniques such as expert systems, matching and profiling, data mining, mapping, network analysis, and simulation. Control technologies have become available that previously existed only in the dystopic imaginations of science fiction writers. Many technologies developed for the military such as spy and global positioning satellites and night vision scopes have become commercially available. Six technology-based strategies of control and some social and ethical issues they raise are discussed.

As used here social control refers to efforts to enforce norms by preventing violations or discovering and apprehending violators, rather than to other aspects of social control such as the creation of norms, processes of adjudication and sanctioning, or the broad societal guidance and integration which was of concern to early theorists of industrialization and urbanization. The engineering of social control can be differentiated from related control forms such as the creation and manipulation of culture and socialization, the redistributive rewards of the welfare state and interpersonal influences.

The increased prominence of social control via engineering is related to concerns over issues such as crime, terrorism, drug abuse, border controls, AIDS, and economic competitiveness; and to technical developments in electronics, computerization, artificial intelligence, biochemistry, architecture, and materials science. The scale, mobility, and anonymity of mass society and ironically, increased expectations of and protections for privacy, have furthered reliance on external, impersonal, distance-mediated, secondary technical means, and database memories that locate, identify, register, record, classify, and validate or generate grounds for suspicion. The perception of catastrophic risks in an interdependent world relying on complex technologies and the entrepreneurial efforts of the security industry and governments such as the United States with its war on drugs, have helped spread the technologies internationally.

There is a magisterial, legitimacy-granting aura around both law and science (Ericson and Shearing 1986). Too often they serve as their own justification divorced from broader critical questions. Technological controls, presumably being science-based, are justified as valid, objective, neutral, universal, consensual, and fair. This view tends to overlook the fact that results are socially interpreted (and thus potentially disputable) and it overlooks the personal interests of control agents and the sectarian, socially constructed interests agents may represent. This legitimacy is strengthened in free-market societies where the tactics can often be used by citizens (e.g., video cameras to record police behavior or DNA analysis offered by a criminal defendant) and internally by police managers for guarding the guards.

Of course the inventors and builders of the first locks, safes, moats, and castles and the developers of early biometric identification systems (e.g., the Italian criminologist Cesare Lombroso, 1835–1909) were engaged in the engineering of social control. What are new are the scale and relatively greater scientific precision, continual invention and experimentation, and rapid global diffusion. Technical means of control

saturate modern society, colonizing and documenting ever more areas of life.

The roots of contemporary social control lie in the development of large organizations and standardized control technologies (Beniger 1986). They are one strand of broad processes of rationalization, professionalization, and specialization occuring with modernization (Weber 1958, Rule 1973, Foucault 1977, Cohen 1985, Laudon 1986, Gandy 1993, Zuboff 1988, Lyon 1994, Shenhav 1999).

The ratio of machines as protectors, monitors, and controllers relative to humans continues to increase. Control has become softer and less visible partly because it is built-in (e.g., software that sends an Internet message or shuts down if it is misused or that monitors work—such as the number of keystrokes entered or the driving behavior of truckers), and partly because of more sophisticated uses of deception (complex undercover operations and disguised video cameras). Much contemporary control is better symbolized by manipulation than coercion, by computer chips than prison bars, and by remote and invisible tethers and filters than by handcuffs, straitjackets, and physical walls. Being more covert, embedded, and remote, it is often involuntary, occurring without the awareness or consent of its subject. Controllers are increasingly able to know things about subjects that the latter do not know about themselves, and to make decisions affecting their life chances of which they are unaware.

Contemporary social control has become more *extensive* and casts a much wider net than at mid-twentieth century, continuing an expansionary trend that began with industrialization and the rise of the nation-state. Control involves ever more integrated information-sharing networks, blurring many traditional institutional and organizational borders (e.g., within and between agencies and levels of government, banks, insurance, healthcare, education, work, telecommunications, and sales and marketing organizations). This data sharing is taken further in the United States than in Canada or Europe.

Technical controls are capital- rather than labor-intensive and hence the cost of control per unit of information has decreased. More objects and areas are subjected to inspection and control and there is a broadening from the traditional targeting of a *specific suspect* to *categorical suspicion* (e.g., the computer search, video camera, or metal detector capture information on all those within their province) and from *individuals* to *networks* and *organizations*.

Control has also become more *intensive*, probing deeply beneath protective surfaces. Many contemporary controls transcend boundaries of distance, darkness, physical barriers, and time—factors that traditionally protected liberty, as well as malfeasance. Data can be easily stored, retrieved, combined (from different places and in different forms such as visual, auditory, print, and numerical), analyzed, and communicated. Control may be remote and deterritorialized, with buffers between controllers and those controlled. Control and knowledge of others' behavior are no longer restricted to what the senses directly reveal through interaction or to a bounded physical place.

Contemporary social control themes are seen in their most extreme form in the maximum security prison (e.g., continuous surveillance, extensive use of computer dossiers, decisions about individuals based on actuarial data, the engineering of control). However, with the spread of such controls throughout the society, we may ask if we are not moving toward becoming a *maximum security society* (Marx 1988).

The *surveillance society's* more omniscient and omnipresent technical social control is seen in a broad variety of rule enforcement contexts beyond public policing or prisons. The original eighteenth-century French notion of an all-knowing, absorbent political police (Brodeur 1983) to protect the state has become generalized across institutions and applied by new users and for new goals.

A reliance on technology for social control is a hallmark of private police who, in the United States (although not in Europe), far outnumber public police. It is also seen in the workplace, the marketplace, schools, and even among friends and family members. In the case of children, for example, there are at home video and audio room monitors, geographic location devices for tracking teenagers in cars, drug tests, beepers, records of phone and computer use, and internet content filters that censor what can be accessed. Consider also 'intelligent highway systems' or the 'smart homes' that are appearing on the market in which all data flows into, and out of, the home are part of an integrated, continuously monitored system.

In an *engineered society*, the goal is to eliminate or limit violations by control of the physical and social environment. As in other areas of social intervention such as public health, there is a strong emphasis on prevention. Ideally problems are anticipated and simply designed away (Sects. 1 and 4), or where that is not possible, the goal is to create deterrence by reducing the gain or increasing the likelihood of identification and apprehension (Sects. 2, 3, 5, and 6) (Marx 1995).

1. Six Social Engineering Strategies

1.1 Target Removal

The logic of prevention is clearest and most effective here. Something that is not there can not be taken. The move toward a cashless society is one example. Merchants who only accept credit or debit cards, or whose registers never have more than a modest

amount of cash are unlikely to be conventionally robbed. Furniture built into the wall cannot be stolen. Subway and bus exteriors built with graffiti-resistant metals are hard to draw upon. Through software programming, computers and telephones can be blocked from sending or receiving messages to, or from, selected locations.

1.2 Target Devaluation

Here the goal is to reduce or eliminate the value of a potential target to anyone but authorized users. The target remains, but its uselessness makes it unattractive to predators. Examples include products which self-destruct, as with some car radios when stolen, or which leave clear proof of theft, as with exploding red dye packs that stain money taken in bank robberies. Encrypted messages can often be easily intercepted, however, without the decryption code, the data are useless. Telephones, computers, automobiles, and even guns are increasingly available which can only be used with access devices such as a unique biometric identifier (e.g., retinal, voice, or geometric hand pattern), card, or access code.

1.3 Target Insulation

With this ancient technique the object of desire remains, but it is protected. Perimeter-maintaining strategies such as fences, walls, moats, guards, and guard dogs can be separated from more specific protections surrounding an object such as safes, chastity belts, goods that are in locked cases or chained to an immovable object, and the hiding or disguising of valuables. High-security, gated communities in which access and egress is controlled carefully and the use of networked sensors, alarms, and in some cases even Internet video of public areas, are becoming more common. The architectural development of 'skywalks' linking downtown private buildings creates 'sanitary zones' more subject to control than the potentially disorderly public streets below.

1.4 Offender Incapacitation

This classic strategy seeks to render potential offenders harmless with respect to the will or ability to violate the norm in question. The means may act directly on the body by permanently altering it and making certain offenses impossible—literal or chemical castration for sex offenders, cutting off the hands of thieves. Passivity may be created by tranquilizers and other medications such as Depo-Provera or psychosurgery for the violent. A variety of nonlethal restraining or blocking devices, from pepper spray to straitjackets to a net fired over a disruptive person, are available. Related efforts deal not with the body of the offender but with the instrumentalities involved in the offense. The goal is to render useless or unavailable something that is essential for the violation. For example, antidrunk driving interlock systems which require passing a breath analyzer test attached to the automobile ignition system before a car will start, or limiting gun purchases to those who have undergone computer checks for purchase eligibility (e.g., no felony conviction), or not permitting adolescents to purchase magic markers that can be used for graffiti, or mixing a bad-smelling chemical into a product to prevent it from being inhaled for its hallucinatory effects.

1.5 Exclusion

Potential offenders have been kept away traditionally from targets or tempting environments by exile, prison, curfew, and place or activity exclusions (e.g., bars for juveniles or for the home of an ex-spouse of an abusing husband). The ultimate form is capital punishment. A related form is the visible warning offered by a stigma such as the brand or clipped ear of offenders in medieval Europe, which encouraged others to stay away.

Electronic monitoring or location devices based on Global Positioning Satellites are contemporary examples. In one form alarms go off and messages are sent to authorities if an adjudicated person wearing a transmitter gets too close to a prohibited person or area or leaves an areas they are restricted to. With the human genome project completed, eugenics will become a contentious issue. For example, the belief (which ignores interactions with the environment and the socially crafted character of most rules) that DNA is linked to violence and other antisocial behavior could generate another ultimate form of exclusion—requiring a license indicating an 'acceptable' genetic pattern before a child could be born.

1.6 Offense/Offender/Target Identification

Where it is not actually possible to prevent the violation physically, or where that is too expensive, it may be possible to at least know that it took place and perhaps who is responsible and where they are. The goal is to document its occurrence, and identify the violator. A major goal of nineteenth-century forensic science was to develop reliable biometric measures of identity based on the analysis of fingerprints, facial measurements, and chemical properties (Thorwald 1965). One technique used by the former East Germany involved identifying individuals by their unique olifactors. Architectural design emphasizing visibility as a deterrent fits here (Newman 1972), as do video, audio, motion, and heat detection means and access codes that are presumed to document who enters an area, or is using a resource such as a computer. Hand-activated personal alarm systems or a luggage alarm that goes off if a purse or suitcase is illegitimately moved or opened, and the electronic tagging of

consumer items or expensive tools at work which give off an alarm if wrongly removed, are other examples.

New information technologies have made it possible not only to watch everyone, but for everyone to be a watcher. This greater ease of mobilizing the law by involving citizens in social control is one characteristic of the Anglo-American police tradition, although not in the rest of Europe. Citizens are encouraged to use hot lines to report infractions (e.g., erratic highway drivers, drug dealing, poaching, or 'whistle-blowing' regarding organizational malfeasance) via cell and traditional telephones and e-mail. The police use mass communications media to help identify and locate wanted persons via posting warrant information on web sites and crime re-enactments on television.

2. *Some Other Social Control Dimensions*

The six 'ideal type' concepts above are based on combining several aspects such as whether the focus is on the potential offender, a resource used in the violation, the offense, or the target of an offense, and whether the action involves removal/exclusion, devaluation, insulation, incapacitation, or identification. Such ideal types can be useful as a shorthand for classification and comparison. Yet they also distort by combining sources of variation that can be analyzed separately.

Another approach starts with single dimensions which may cut across the different forms. Some other relevant dimensions include classifying based on: visibility or invisibility; openness or secrecy regarding use of the tactic both generally and specifically; control access into or out of a system; the individual, an organization, or a network; a focus on the body, consciousness or the environment; the degree of reliability and validity and relative cost of errors and mistakes; the relative availability and ease or difficulty in neutralizing or using a tactic; and the presence or absence of democratic decision-making and review processes regarding the adoption and application of a tactic.

There has historically been much more research on those who violate rules than on those who enforce them. We know little about the prior social correlates and consequences of the above dimensions. While anyone who travels will see a certain international standardization of technical control (e.g., at airports, national borders, banks, nuclear power plants, or with telecommuncations) there is still much local variation. Distinctive histories, social organization, and cultures mean that sweeping generalizations across all technologies and countries are unwarranted (Marx 1995). Singapore, for example, appears to have taken electronic surveillance the furthest, while Japan and China are far behind (if for different reasons). In the United States drug testing, undercover operations, citizen informers, and consumer and work monitoring are widespread, while in Europe these are seen much less often. Great Britain is the world leader in video surveillance and Germany has been among the most innovative in computer matching and profiling. The Scandinavian countries make the most extensive use of social census data as part of their welfare states. France, Italy, and Spain have been generally slower than Anglo-American countries to adopt the new technologies. While the polygraph is rarely used in Europe because of doubts about its validity, handwriting analysis has credibility in France that is lacking in most other countries.

3. *Some Social and Ethical Implications*

However ideal a technical control system may appear in the abstract from the viewpoint of those advocating it, the world of application is often much messier and more complicated. The search for the perfect technical fix is like the donkey forever chasing the carrot suspended in front of it. To the person with a hammer everything may look like a nail. The technology's narrowing of focus may come at a cost of failing to see larger systemic contexts, alternatives, and longer-range consequences.

The complexity and fluidity of human situations makes this a rich area for the study of trade-offs, irony, and paradox. There are some parallels to iatrogenetic medical practices in which one problem is cured, but at a cost of creating another. Technical efforts to insure conformity may be hindered by conflicting goals, unintended consequences, displacement, lessened equity, complacency, neutralization, invalidity, escalation, system overload, a negative image of personal dignity, and the danger of the means determining or becoming ends.

Bars over windows to keep out thieves may prevent occupants from escaping through the window in the event of a fire. In commercial settings where access to merchandise is important, attaching expensive clothes (e.g., leather jackets) to a rack with a locked cable reduces the likelihood that an item will be stolen, but also complicates trying clothes on and impulse buying.

The discovery that a target has been rendered useless to an offender may increase violence, whether as a resource to gain the needed access, or out of frustration. For example, the appearance of 'car-jacking' is related to more sophisticated antitheft devices on cars. The use of access codes to activate autos and appliances may mean that the crime of burglary is converted to robbery or kidnapping, as thieves confront property owners and demand not only the property, but the code to make it work. A frustrated thief may respond to a self-destruct automobile radio by firebombing the car.

While the rule breaking in question may be blocked, the problem may be displaced rather than disappear or new problems may be created. In efforts to keep the homeless away from heating vents or entrances to

subway systems, a variety of grates and barriers have been developed. These do nothing to solve the issue of homelessness, but move it elsewhere. Some persons manage to get off of heroin but only by becoming addicted to methadone.

Equity issues are raised when displacement involves a shift to new victims. If relatively effective technical solutions are commercialized (as with embedding hidden transmitters in cars which permits locating them by remotely activating the transmitter) or gated communities to keep out would-be thieves, predators may focus greater attention on those unable to afford enhanced levels of security.

A related equity issue involves who has access to the technology and its results. Video cameras and desktop computers are potentially egalitarian in their low cost, ease of use, and widespread availability. But other technologies such as satellites and highly sophisticated computer programs are disproportionately available to the most powerful. There is the possibility of societies becoming even more stratified, based on unequal access to information in which individuals live in glass houses, while the external wall of large organizations, whether government or private, are one-way mirrors.

Whether out of self-interested rule breaking or human contrariness, individuals can be very creative in neutralizing systems of control. Faith in the technology and its routinization may create complacency in control agents and a predictability that undermines effectiveness. That locks open with keys and borders require access points means they are eternally vulnerable.

The initial antidrunk driving car interlock systems could be beaten by saving air in a balloon or by having someone else blow into it to start the car. A variety of means are available for beating drug tests—from contaminating the urine with bleach on one's hand to using a catheter to insert drug-free urine into the body. Dogs in heat have been used as antidotes to male guard dogs and debugging devices help discover hidden surveillance.

In a free-market economy new controls create incentives to develop means of neutralization, whether legally or available through the black market. Police use of radar detectors against speeders was soon followed by antiradar detection devices. Police in turn developed a tool for detecting when a driver was using the latter. The guilty may now face charges for the secondary or derivative offense of possession, even if they were not speeding. Not long after antitheft ignition protection systems appeared on automobiles, a device that permitted bypassing the lock appeared.

When systems cannot be technically defeated, as with very sophisticated encryption, then their human context may be compromised, whether through coercion or deception. For example, a thief who could not break a manufacturer's sophisticated encryption code, nevertheless managed to embezzle millions of dollars through generating fake invoices. He did this by having an affair with the individual who had the decryption codes.

There are also important questions around validity and reliability. Even if a measure is empirically valid, that does not guarantee a socially meaningful result. Thus, a DNA match between material from a crime scene and a suspect cannot reveal if a death resulted from a homicide or self-defense. The sample might also have been planted, or a secure chain of evidence custody not maintained. A computer match between persons on welfare and those with bank accounts may reveal a person over the savings limits, but that is not proof of cheating since funds may be held in trust for a funeral—something legally permitted, but not built into the computer program. Audio and video recordings may reflect what was done and said, but will not necessarily reveal why, or what a suspect intended. Seeing should not automatically mean believing. Thus, a suspect in an undercover scheme may have been threatened or entrapped off camera. A threat or seeming admission of a crime may have been said in jest or as boasting. Nor is a drug test, even if 'valid' indicating the presence of drugs within a person's system, a necessary indication of a violation. Depending on the assessment used, if the standard is set low enough it is possible to have a positive reading as a result of just being in a room where marijuana is being smoked (false positive). Conversely justice issues involving false negatives may also be raised if the threshold is set too high. Drug tests may also be distorted by what an individual has eaten (e.g., poppy seeds) or by some over-the-counter medications. Tests may be of doubtful validity to begin with. Concern over the validity of the polygraph led the United States Congress to greatly restrict its use (although that led to an increase in paper-and-pencil honesty tests whose validity has also been questioned).

New control techniques may be turned against control agents. While authorities may have an initial advantage, this is often short-lived. Thus, more powerful armor, bulletproof vests, and sophisticated communication systems are no longer the sole property of police. There may be something of an escalating domestic arms race in which the interaction becomes more sophisticated, but the fundamental dynamic does not change.

Documentation of *all* infractions may overload the control system. This may lower morale among enforcers who feel overwhelmed, or offer corrupt officials a resource (*nonenforcement*) to market. Since resources for acting on all the information may not be available, authorities may be accused of discriminatory enforcement.

Even if adequate resources for full enforcement action were available, organizational effectiveness could be harmed. Automatic technical solutions developed without adequate appreciation of complexity and contingency run the risk of eliminating the

discretion, negotiation, compromise, and informal understandings that are often central to morale and the effective working of organizations (Dalton 1959, Goffman 1961).

If technical solutions could somehow be effective at eliminating all rule breaking (holding apart the conflict between, and ambiguity in, and lack of consensus on, many rules), there could be some unexpected costs. Systems might become too rigid and unable to change. Much innovation is initially seen as deviance. Experimentation and risk taking can be aided by anonymity and secrecy. A socially transparent, engineered society would be more orderly, but likely less creative, dynamic, and free.

If order depended primarily on technical means of blocking infractions, rather than on legitimacy, how would people behave when the means failed, as at some points they invariably would? A social order based primarily on technical fixes is likely to be as fragile over time as one based primarily on overt repression.

Even if systems could somehow be made fool- and fail-proof with ever more, and more advanced, technology, there is a danger of viewing humans as robots, rather than as creative beings with a conscience capable of making choices about how they behave. The former image is inconsistent with belief in the dignity of the autonomous individual in a democratic society. Whatever a technology is *capable* of, the view of humans as volitional (and hence responsible for their behavior) and beliefs about the inviolability (absent clear justification) of the borders that protect private personal zones around one's body, mind, relationships, communications, physical space, and past history are central to ideas of respect for personhood.

The search for stand-alone mechanical solutions also avoids the need to ask why some individuals break the rules and points away from examining the social conditions which may contribute to violations and the possibility of changing those conditions. Technical solutions seek to bypass the need to create consensus and a community in which individuals act responsibly as a result of voluntary commitment to the rules, not because they have no choice, or only out of fear of reprisals.

A well-known, if often naïve expression given social inequality, holds that *where there is a will there is a way*. This speaks to the role of human effort in obtaining goals. With the control possibilities made available by science and technology this may be reversed to *where there is a way there is a will*. As the myth of Frankenstein implies, we must be ever vigilant to be sure that we control the technology rather than the reverse. As Ellul (1964) argues, there is a danger of self-amplifying technical means silently coming to determine the ends or even becoming ends in themselves, divorced from a vision of, and the continual search for, the good society.

G. T. Marx

Technology Assessment

The term 'technology assessment,' often abbreviated as TA, covers a variety of usages. The main meaning is the early identification and assessment of eventual impacts of technological change and applications, as a service to policy making and decision making more generally. The term TA is also used when firms, consultancies and technological institutes, agencies in health care and other social sectors, want to assess the promise, and the profit, of new technological options, and/or carry out a broad version of cost–benefit analysis, sometimes also including risks. In both cases, there is an element of anticipation of future developments (of technology, and its relation to markets and society) and an element of feedback of such anticipations into relevant decision arenas. This combination is the defining characteristic of technology assessment exercises.

1. Context

Practical and political concerns about uncertainties involved in developing and applying new technologies were the breeding ground for TA in the 1960s. One response was to try to manage the uncertainties through a combination of technological forecasting and the development of techniques to address and evaluate impacts. US organizations such as the Rand Corporation pioneered such TA techniques. This managerial response could be broadened to include wider societal impacts; the impacts of the US space program, for example, were explored by making comparisons with the impact of the railroad on American society.

The other response was policy-oriented and political, taking the emerging concern about the negative impacts of technology, for example, on the environment or in relation to defense and security issues, as a starting point to try to evaluate such impacts at an early stage. Ways to do so could include the techniques developed in the managerial approach, but would also build on policy analysis and on action-oriented research.

Special agencies could be made responsible for such a task, as when in 1970 in the USA a federal law established a Congressional Office of Technology Assessment (OTA), as 'an aid in the identification of existing and possible impacts of technological application.' Congress was interested also because such analytic support would increase its power vis-à-vis the Executive. The example of OTA was noticed in European countries, and followed, with some delay, the specific format depending on the political tradition of each country.

By the mid 1980s, TA was a recognized activity, both professionally (cf. Porter et al. 1980) and politically. Gradually, the earlier and almost exclusive emphasis on analytic approaches and the production of reports, was complemented with an interest in linking up more closely with decision making, or at least contributing to setting an agenda. Public debates about energy and environmental issues helped to make this aspect of TA more prominent.

By the 1980s, a philosophy of TA, already recognizable in the 1960s, had become widely accepted: the anticipation of impacts and feedback in order to reduce the human and social costs of learning how to handle technology in society compared to when this happens by trial and error. The experience of a number of chemical and nuclear accidents, as well as uncertainties about the new biotechnology (and life sciences more generally) since the mid-1970s, contributed to the legitimacy of TA exercises. This philosophy is shared by what would otherwise seem to be

a wide variety of approaches, ranging from technology forecasting to the consensus conferences, popular as we enter the twenty-first century. This philosophy is also visible in debates about technology policy (implicit in the USA, explicit in most other countries), with the suggestion that technology policy should include a strong TA component. Some economists have argued that TA is the only justifiable component of government technology policy in a market economy (Freeman and Soete 1997).

2. *Main Strands in the Variety of TA Approaches and Activities*

By the late 1990s, four established, plus one emerging, strands of TA could be distinguished, each with its own style and addressing different audiences:

(a) TA in firms and in technological institutes, oriented toward mapping future technological developments and their value to the firm or institute, and used as an input in strategy development (Hastbacka and Greenwald 1994). 'Picking the winners' (or 'avoiding the losers') used to be the overriding orientation. This strand of TA has developed relatively independently of 'public domain' TA, but links are emerging because of the need of firms to take possible societal impacts and public acceptance into account. The biotechnology sector became a clear example by the late 1990s. The 'insiders' are interacting with the 'outsiders,' and the effect is that prudent firms are receptive to public-interest assessments.

(b) TA in specific sectors, such as environment or health care and regulation, as an instrument to determine acceptability of a project, or a new product or technological option, in relation to the public interest in, and policies about, that sector. Environmental Impact Statements are now required in many countries before projects can be implemented (Vanclay and Bronstein 1995). Medical and health care TA is a recognized specialty with its own international society and meetings, focusing on evidence-based evaluations of concrete medical and health-care activities and options (cost–benefit analysis, risk analysis), not on wider societal impacts.

(c) TA for policy development and political decision making about projects or broad programmes with a strong technological component (for example, the electronic superhighway or modern agriculture) or important technologies (for example, genetic modification). One can call this 'public service' TA, and consider the now-defunct US OTA as the embodiment of this type of TA. OTA, during its lifetime, developed a robust approach to TA studies (see Wood 1997, Bimber 1996). Other TA bodies serving national parliaments and/or national governments tend to include participatory TA methods in addition to expert-based approaches.

(d) TA exercises can be oriented to the public arena more generally, and focus on articulation and building an agenda for handling new technology in society. This most recent strand takes up the increasing calls for participation (at least by so-called new stakeholders such as environmental groups). While it is particularly visible and more or less institutionalized in some European countries (Denmark, the Netherlands), participatory methods such as consensus conferences have been taken up all over the world (Guston and Bimber 1997). Agenda-building TA has a longer history, however, given that controversies over new projects or new technologies (and the studies and documents produced in the course of the controversy) induce learning about potential impacts and articulation of the value of the technology. Agenda-building TA merges into informed consultation processes to reach agreement on the value of new technology. Thus, there is overlap between TA and more general political and policy approaches for articulation and learning (e.g., hermeneutic policy making).

The contrast between private domain TA and public domain TA seems strong, because of the difference in goals and in the actors involved. The scope of private domain TA is less broad than public domain TA, but the assessments try to be more precise, and their outcomes are fed back into strategy development and decision making. Building on the broadening of private domain TA (strand 1) and attempts of agenda-building TA to include various private actors (strand 4), a fifth strand in TA has emerged, even if it is still somewhat programmatic.

Constructive TA emphasizes that impacts of new technology are a joint product of the technology, the actors involved, and wider interactions. The experience with introducing new information and communication technologies within and between organizations was important in this respect (Orlikowski 1992), as well as the attempts of private actors to broaden the scope of their assessment processes, already at an early stage of new product or process development (cf. strand 1). Societal experiments with the introduction of new technologies, such as electric cars, mix private and public actors, and are occasions for societal learning about new technologies and for feedback into further development and uptake. While still programmatic in parts, Constructive TA has also developed generic strategies such as Strategic Niche Management (Schot and Rip 1997).

3. *Methodological Issues*

The combination of anticipation and feedback, characteristic of all varieties of TA, entails a methodology which combines, so to speak, writing a history of the future, supported by judgments of experts and by social-science insights and data, and informing action or preparation for action. Relevant social-science insights derive from sociology and economics of technology (Schot and Rip 1997) and from organiz-

ational sociology (Orlikowski 1992), and emphasize the co-evolution of technology and society. Estimating impacts is speculative, of course, but the speculation is controlled, and there are bodies of relevant experience (Vanclay and Bronstein 1995). Uptake into action remains precarious, exactly because of the fallibility of such estimates: Who could have predicted the further development and impact of the Internet in the early 1990s? On the other hand, efforts at foresight can be productive even when they turn out not to be correct, when they stimulate joint learning.

Methods of TA can emphasize data collection and analysis about present impacts and trends, and some counterfactual speculation, or consultations of experts and refinement of the results, and/or sociotechnical scenarios. The toolkit of TA contains a wide variety of tools, from forecasting broadened with social and sociotechnical mapping, multi-criteria analysis, and integrated assessment, up to mediation and communication techniques. The selection of appropriate tools is related to the sponsor of the exercise (private/promoter, sectorial/regulator, public policy, the public domain more generally), and is often eclectic. While there are recognized TA professionals, TA exercises are carried out by a wide range of consultants, academics, dedicated agencies and their committees, and volunteers.

There is a fundamental dilemma, which has been called the anticipation and control dilemma (Collingridge 1980). At an early stage of technology development, the nature of the technology and the articulation of interests are still malleable—but it is unclear what the effects and impacts will be. By the time these become clear, the technology is entrenched and vested interests make it difficult to change the technology. As with the pesticide DDT, the only possible response is to forbid further deployment of the technology. More is possible, however, than in this stark version of the control dilemma.

Recent economics and sociology of technology have shown how path dependency increases over time in technological development, and how co-production of impacts occurs along those paths. The QWERTY keyboard of typewriters, and now also of computers, is a well-known example of path dependency. From the point of view of TA philosophy, increasing path dependencies are an opportunity: they allow better anticipation of future developments. Furthermore, understanding the dynamics which generate path dependency allows one to modulate them to some extent.

A generic strategy to avoid decision regret is to remain flexible as long as possible, at the risk that none of the various options will be pursued sufficiently far so as to see what they are worth. A concrete example is the 1991 French Law on nuclear waste handling which requires three options to be maintained for a period of perhaps 15 years, and with annual public evaluation of progress and prospects. The Parliamentary *Office d'Evaluation des Choix Scientifiques et Techniques* is involved, and over time, modifications can be made to the trajectories.

When there is an addressee or identifiable audience, feedback of TA exercises on policy and on implementation of technology will occur. The direct impact of public service TA on science and technology policy and decision making has not been large, except when there are controversial issues, and the TA exercise provides ammunition for the contending parties.

Government technology policy most often focuses on promotion of (selected) technologies, as when stimulating the electronic superhighway. The main question for such technology policy is to 'pick the winners,' now for society as a whole. On the other hand, other agencies of the same government may be occupied with reducing the human and social costs of the introduction of new technology, for example, through safety and environmental regulation. This dichotomy between promotion and control of new technology is part of the *de facto* constitution of modern societies, and is reflected not only in the division of labor between government agencies, but also in cultural and political views, as in the assumption that there will be proponents and opponents a new technology (Rip et al. 1995). TA becomes a victim of these views when technology promoters see, and condemn, technology assessment as technology harassment or arrestment. While contestation will continue, there is now more interest in constructive approaches (cf. strand 5).

4. *Situating TA, and Future Directions*

One key point, related to divisions of labor in modern society, is the asymmetry between 'impactors' (those at the source of impacts) and 'impactees.' The asymmetry can be due to a difference in power, but it also always involves a difference in timing. Initiators of technological development know more, and have invested more, at an early stage, and impactees and TA agents have to wait and, in a sense, follow their lead.

The asymmetry has another component: technology developers are insiders and do not necessarily know very much about the outside. Adoption and diffusion, however, are up to 'outsiders' who have other knowledge, interests, and expectations. The story of nuclear energy since the 1960s is in part one of a struggle between insiders and outsiders. On a much smaller scale, the same storyline is visible in the development of cochlear implants for deaf people, where it turned out—unexpectedly for the insiders—that the deaf community was very negative about taking deaf people out of their own culture by providing them with implants (Garud and Ahlstrom 1997).

A second key point is that there are cumulative effects of living in a technological society. Risk

repertoires emerge in which the impacts of a new technological development are treated similarly to those of earlier ones. In the 1970s and early 1980s, the risks of recombinant DNA research were seen as those of a runaway organism and addressed with probabilistic risk analysis, exactly as had become accepted for runaway accidents in nuclear power plants. Other more appropriate framings, such as loss of biodiversity, were slower to emerge .

A third key point is that anticipation and feedback can occur without dedicated TA efforts. Early warnings and controversies over new technologies are examples, and may be starting points for TA exercises. We live in a risk society and modernity has become reflexive (Adam et al. 2000). The rise of TA is then an indicator of reflexive modernity, and a conduit to enhance reflexivity—while also channeling it in certain ways. There were criticisms of the instrumentalization of reflexivity and possible technocratic tendencies of TA in the 1970s and 1980s, and of the symbolic nature of participatory TA exercises in the 1990s. Both the critiques and the concrete TA exercises actually build on the TA philosophy, but emphasize different parts of it.

Uncertainties about new technology and society are associated with risks of the unknown and the need to do something, anything, about them, and with the variety of views and values and interests involved—which make decision making and *de facto* acceptance of new technologies difficult, and difficult to anticipate.

A striking new development is the increasing acceptance of the so-called precautionary principle (since the Rio Declaration of 1992): action is justified even if there is not yet any conclusive evidence about risks, or negative impacts more generally. Precaution is predicated on speculative scenarios about what might happen. Quality control of such scenarios is what TA can offer.

Clearly, TA is not just a new professional and managerially oriented activity since the late 1960s, and an approach to interactive agenda-building since the late 1980s. It is part and parcel of larger developments. The co-evolution of technology with organizations and with society is being taken more seriously than in the earlier 'cannon-ball' approaches to impact assessment. This is particularly visible in assessments of information and communication technologies, and their embedding in society, but also in assessments and debates about energy, transport, and infrastructure, even if vested interests and established sociotechnical regimes can be obstacles to a balanced debate. The rapid developments in the life sciences and their applications, with genetics as the most striking example, are promising and a cause for concern at the same time. There, the 'cannon-ball' storyline is still prominent, and concerns about traditional ethical values reinforce a proponent–opponent dichotomy. It is a major challenge for TA to overcome such limited definitions of the *problematique*, and to do so in productive interaction with key actors in the relevant areas.

Technology, Anthropology of

Taking as its point of departure the fundamental sociality of technological activities, the anthropology of technology develops anthropological perspectives on 'techniques' and 'technology.'

A human universal, 'technique' includes any skilled activity (Ingold 2000), including—but not limited

to—the use of a tool, an object that skilled people can use to extend their capacity (Sigaut 1993). What interests the anthropology of technology concerning techniques is the interpenetration of material and social factors in the creation, use, maintenance, and disposal of 'artifacts' (technically modified objects). In contrast, a closely related field, material culture studies, is interested primarily in the artifacts themselves—and the ways people employ them in systems of social signification—rather than the material and social factors of their production.

Of debatable universality and anthropological utility is the second of the two notions, 'technology.' The term is a seventeenth-century neologism. Contemporary definitions of 'technology' that stress 'the application of science to conquer nature' reveal the modernist ideology underlying this term. As will be seen, anthropologists of technology are sharply divided on the wisdom of using the term 'technology' to understand technical activities in nonmodern societies.

1. Objectives of the Anthropology of Technology

Anthropologists who study technology share many goals and concerns with scholars in kindred research areas, such as science and technology studies (STS), material culture studies, ethnoarchaeology, and behavioral archaeology. All these research areas share an interest in revealing the deep interpenetration of technological and social phenomena. What makes the anthropology of technology distinctive is an interest in the way people employ the material/social intersection to create 'technoscapes.' A 'technoscape' is a socially constructed world of meaning and sociality that is the consequence of technological activity (Pfaffenberger 1999). A considerable body of anthropological scholarship, some of it concerned with technology, focuses on specific modes of production.

2. Origin and Development of the Anthropology of Technology

In French anthropology, technology has been accepted as a valid topic for anthropological inquiry since the 1930s, and a considerable body of advanced scholarship has arisen that is, regrettably, almost unknown outside France. In striking contrast, British and American anthropologists have developed perspectives inimical to the anthropological study of technology, and are only now beginning to study the subject.

2.1 The Anthropology of Technology in France

French interest in the anthropology of technology is attributed to Marcel Mauss's pioneering work on the technology of the body (1973 [1935]) and, especially, to the intellectual leadership and charisma of a social anthropologist, André Leroi-Gourhan (1911–86). Leroi-Gourhan launched an interdisciplinary project in the 1950s to comprehend the human technological adventure. This work has been far more influential than most Anglophone scholars realize. In his work on the role of gesture and speech in human evolution, Leroi-Gourhan argued (1993 [1964]) that prehistoric tool use stems not from the 'noble fruit of our thought,' but rather from the development of the hand. With the mouth freed for new uses, humans developed the capacity to externalize and remember what they learned in the form of various modes of representation—including not just speech, which generates an externalized mythology, but also 'gesture,' a parallel development that Leroi-Gourhan believed to be just as expressive as speech. Speech generates mythology, while gesture, united with tools for create techniques, generates 'mythography,' externalized graphic representations with markedly different properties than the representations enabled by speech. By refusing to privilege speech, Leroi-Gourhan provided Derrida with the ammunition needed to launch the poststructuralist attack on 'phonocentrism,' the doctrine that speech is the source and inspiration for all forms of human communication.

Another of Leroi-Gourhan's influential notions is the *chaîne opératoire* (Leroi-Gourhan 1943), a series of habitually learned steps or a 'recipe' for transforming a raw material into a finished artifact. Sketched out only nascently in Leroi-Gourhan's work, this concept has been elaborated by French prehistorians and social anthropologists; they developed a series of powerful theoretical concepts that point to the interpenetration of the material and the social. For example, Pierre Lemonnier (1980) distinguishes between the invariant components of a *chaîne opératoire*, those that cannot be omitted without 'upsetting' the technical process, and the variant components; the latter represent adaptations to the underlying social system. In a wide-ranging study of *chaînes opératoires* in pottery, van der Leeuw (1993) asserts that the social inserts itself into material processes at the cognitive level—specifically, whether the vessel is fundamentally understood (for example) as a transformation of a sphere, cone, or cylinder. What has sometimes been lost in this literature, however, is a point of major significance that follows from Leroi-Gourhan's work on gesture and speech: if gesture is no less meaningful than speech, it follows that techniques themselves, and not just the material culture produced by techniques, are a major locus of meaning-formation in human society.

A recent feminist critique of the *chaîne opératoire* concept points the way toward fulfilling the promise implicit in Leroi-Gourhan's work. Dobres (1999) points out that androcentric biases—such as the belief that technology is about production, not reproduction—often lead observers to exclude activities

involving women. Studies of the technical sequence involved in Iñupiat whale-hunting, for example, depict a male-only picture, because men and men alone hunted whales on the open sea. Yet the Iñupiat captain will say, 'I am not the great hunter; my wife is.' When the *chaîne opératoire* is broadened sufficiently to include the pre-hunt and post-hunt activities in which women figure prominently, one learns that the hunt's success is thought to depend on the wife's comportment before the hunt and her skill with her knife afterwards. Through these means the captain's wife calls forth the whale and makes it possible for the whalers to kill it.

Dobres' work shows that the anthropology of technology should adopt a version of the 'principle of symmetry' in science studies. This principle holds that a *sociological* understanding of science becomes possible only when explanations are no longer phrased in terms of the truth or falsity of scientific theories; 'true theories' and 'false theories' should be treated equally. In the anthropology of technology, the boundaries of a *chaîne opératoire* should not be determined by 'technicist' principles—that is, by the identifying sequences that 'really are technology because they work' as opposed to those that are 'merely symbolic.' At stake is the very possibility of an *anthropological* understanding of technical activity—that is, an understanding that is equally concerned with what techniques mean as with what they do.

Few studies of *chaînes opératoires* employ the principle of symmetry, but they strongly suggest that technical activities are among the most potent of the means by which people make culture. What is more, they help to shed light on key anthropological debates concerning how people make culture. For example, Munn's (1986) work on Gawan canoe-making depicts the *chaîne opératoire* as a kind of moral theater in which 'good selves' and 'bad selves' are represented in such a way that people come to understand the 'type of moral conflict in which they are engaged.' Ridington (1999) shows how Athapaskans employ a flexible repertoire of techniques, not to conquer or control nature, but to reveal and establish bonds with a 'nature' that is understood to be filled with sentient beings. The picture of culture-making that emerges from these studies is consistent with the theory of practice (habitus), which was originally formulated by Mauss (1973 [1935]), advanced by Leroi-Gourhan's *chaînes opératoires* concept, and brought to fruition by Bourdieu (1977): by engaging in the various habitual and nonconceptual skilled behaviors that are sequenced in a *chaîne opératoire*, people discover meanings, but only by 'enacting them' and 'unfolding them in time' (Bourdieu 1977). Yet they do not do so in a field of unbounded subjectivity.

What Munn found to be true of Gawa, namely, that canoe-making takes place within a kind of moral theater in which it matters very much what type of people the participants become, seems to be generally true of nonmodern and modern techniques alike (Pfaffenberger 1999). Charlie Yahey puts the nonmodern Athapaskan perspective this way: 'Animals come closer … to people who sing and dance together' (Ridington 1999). In modern technology, most of the significant technical innovations of personal computing—the graphical user interface, the mouse, the laser printer, and more—were inspired by Douglas Englebart's fervent insistence that people need to deal more effectively with an increasingly complex world, and they could not do so without graphical computer systems capable of simulating complexity on-screen. One could multiply examples *ad infinitum*, but it seems clear that personhood and technology are much more closely associated than most scholars suspect.

2.2 The Anthropology of Technology in Britain and the USA

In contrast to the anthropology of technology in France, the British and American schools of anthropology rejected technology studies as irrelevant to the discipline, and relegated the subject to museums, which were subsequently deprived of the resources needed to advance the field. Twentieth-century Anglophone anthropologists did so, in part, to distance themselves from the unscientific speculations of Victorian anthropology, with its armchair scholars, amateur collectors, and 'wild-guess' theories based on artifacts shorn of their social context. The rejection was accompanied by theoretical developments that served to brand technological activity as theoretically uninteresting. In the UK, Leach portrayed technical and ritual activities as if they were at opposed poles of a continuum ranging from the instrumental (technical) to the expressive (ritual). In the USA, Kroeber asserted that what is cultural about an artifact, and therefore of interest to anthropology, was the idea behind it, not its material incarnation or the methods of its manufacture. Both theories place technical activities into a residual category of nonsocial, mundane activities that appear to anthropologists as uninteresting subjects.

The first inklings of anthropological interest in technology did not appear until anthropologists encountered the Internet and asked whether cyberspace could become a legitimate and productive object of anthropological inquiry (Escobar 1994). This question, in turn, led them to discover the work of scholars in science and technology studies (STS), including feminist scholars who were developing a broad-ranging critique of Western science. Although the anthropologies of cyberculture (e.g., Haraway 1997) and the biosciences (e.g., Rabinow 1992) continue to attract anthropological interest, few British or American anthropologists have broadened this interest to include technological activities in the social settings that anthropologists traditionally study. Fewer still are aware of the achievements of the anthropology of

technology in France, or indeed of the fact that Leroi-Gourhan provided part of the inspiration for the poststructuralist views that are professed by so many Anglophone anthropologists, particularly in the USA.

3. 'Formalist' and 'Substantivist' Views in the Anthropology of Technology

A division has emerged in the anthropology of technology that resembles the 'substantivist' vs. 'formalist' split in economic anthropology. In brief, 'substantivists' believe that the 'laws' of economics are historical constructions of market capitalism and do not apply to noncapitalist economies, while 'formalists' believe that economic concepts can illuminate aspects of human behavior in all human societies. In the anthropology of technology, the 'substantivist' position—as expressly stated in an important work by Ingold (2000)—asserts that the 'technology' concept is a construction of modernism and can only mislead when applied to nonmodern societies. The 'strong formalist' position in the anthropology of technology is characterized by certain American archaeologists who argue, in various ways, that nonmodern techniques are subject to selection processes and therefore embody a tacit rationality (see, for example, Durham 1990). However, there is a moderate 'formalist' position that takes postmodern and anti-essentialist critiques of Western ideology seriously. Although there is no single, formal statement of this moderate 'formalist' position, it can be adduced from the work of behavioral archaeologists (e.g., Schiffer and Skibo 1997) and social anthropologists who have worked with historians of technology (e.g., Pfaffenberger 1999). The moderate 'formalist' position argues that the 'technology' concept is indeed relevant to nonmodern as well as modern societies, but only after the term is redefined in a way that eliminates its normative and ideological components.

3.1 'Technology,' Science, and 'Disembeddedness'

The 'substantivist' position is in accord with the central objective of the anthropology of technology: to reveal the interpenetration of the social and material and show how people use technical activities to construct worlds of meaning. It is for precisely this reason that Ingold refuses to use the term 'technology'—and indeed declares, 'there is no such thing as technology in premodern societies' (2000, p. 314). The 'technology' concept, in this view, is historically specific and utterly misleading when applied to nonmodern societies: it arose in the seventeenth century and is associated with the emergence of a new, science-based 'mechanistic ontology' that became increasingly hegemonic over time. The rise of a new science-based technological order went hand-in-hand with multiple forms of disembeddedness: machines 'exteriorized' production by replacing human skills with automatic mechanical movements, engineers staked out a higher status than technicians by establishing rationalist and scientific canons of technical design, and production became separate from consumption. To apply the term 'technology' to premodern societies, therefore, is to apply to these societies the very idea that destroyed them; 'technology' is the result of a historical process of disembedding and hegemony formation that destroyed the former integration of the material and the cultural.

The moderate 'formalist' response faults the 'substantivist' position for taking the definition of 'technology' at face value. Underlying the 'science discovers, technology applies' notion evident in dictionary definitions of 'technology' is a normative component, which holds, essentially, that science should discover and technology should apply; the normative dimension of the term can be fully grasped only by understanding the historical and social processes by which the 'pure sciences' were elevated to an exalted status in British and American universities and, conversely, the 'applied sciences' were denigrated and marginalized (Weiner 1992). In addition, the 'science discovers, technology applies' mythos inverts history. Historians of technology have demonstrated repeatedly that modern disciplines taken as the very essence of science (such as thermodynamics) resulted from new, widely adopted technologies (such as the steam engine) that were poorly understood theoretically.

Moreover, science and technology have differing goals. Science asks, 'Is it true?' while technology asks, 'Will it work?' Technological practitioners can answer that question only by assembling a heterogeneous ensemble of human and nonhuman actors into a network that, as Law (1987) puts it, is capable of resisting dissociation. Such a network can succeed only to the extent that it integrates the material and the social. For example, Napster, Inc., attempted (unsuccessfully) to dominate the distribution of recorded music on the Internet by uniting the MP3 file format, youths' disdain for copyright law, certain elements of US copyright law that the company believed erroneously would exonerate them from liability, and an initial public stock offering that occurred during a period of inordinate enthusiasm for Internet stocks. Although it is certainly true that modern technologies are 'disembedded' through such means as the emergence of an engineering profession, scholars in science and technology studies have demonstrated that the 'disembedding' of engineering practice is more normative than descriptive. It is only very recently, in areas such as biomedicine and genetic engineering in agriculture, that anything like the union of science and technology envisioned in dictionary definitions of 'technology' has occurred; historians of technology

use the term 'technoscience' to distinguish such fields from the largely unscientific technologies of the nineteenth century and much of the twentieth.

3.2 Technological Knowledge

The 'substantivist' position in the anthropology of technology argue that, under the sway of 'technology' definitions laden with modernist ideology, scholars in many disciplines have fundamentally erred in characterizing the type of knowledge associated with 'techniques.' Viewing the world through the lens of 'technology' leads scholars to see 'technology' anywhere there is 'technique.' In this view, as the historian of technology Edward Layton (1974) argues, all technological activity, ranging from the simplest techniques of premodern societies to twenty-first-century space-age technology, begins with the human conceptual ability to conceive of a way to adapt available means to preconceived ends—in other words, to design. If technique necessarily involves conceptual knowledge, then even the most 'primitive' technology involves not only a set of procedures and skills, but also a body of knowledge that differs only in complexity, extent, and sophistication from that possessed by modern practitioners.

Countering Layton's view, Ingold (2000) argues that skilled technical practice cannot be grasped as the mechanical execution of a preconfigured design, as if techniques represented the unfolding of an interior and conceptual algorithm. As evidence for this, Ingold offers a description of various techniques that employ iterative or recursive procedures, thereby eliminating the need for a preconceived design. To equate the knowledge employed in technical practice with that of industrial design is to overstate the role of verbal knowledge in the acquisition of skills; to be sure, verbal imperatives help novices to get started—beginning bicyclists, for example, are told to refrain from leaning until they wish to turn—but this knowledge is insufficient to fully describe technical mastery, which necessarily involves direct experience and imitative learning. At some point, a skilled practitioner abandons the novice's verbal formulations. To retain or elaborate these verbal formulations, Ingold suggests, would be tantamount to learning the map instead of the country. In short, the 'knowledge-for' that is associated with technical skills is far less systematic and verbalizable than the 'knowledge of' propositions that Ingold (wrongly) assumes to characterize the knowledge systems of modern technology.

In response, a moderate 'formalist' position concurs with Ingold's assessment of the destructive impact of an unexamined definition of 'technology,' through the lens of which indigenous knowledge systems are mistakenly seen to be prototypical sciences (Sillitoe 1998). But modern (nineteenth and early-to-mid twentieth century) technologies are equally misunderstood by likening their knowledge systems to science. Modern technological systems are known to proceed, and are even capable of generating significant advances, despite the lack of a complete theoretical understanding; for example, a century of highly successful aeronautical design has proceeded without a sound theoretical understanding of turbulent flow. What is more, these systems can operate quite successfully on the basis of false understandings; for example, aeronautical engineers assumed for nearly a century—wrongly, as is now realized—that stability in flight should overrule all other design considerations. Technological belief systems—which Bijker (1995) terms 'technological frames'—serve important roles in constituting and uniting communities of practitioners, guiding the formation of the meanings attributed to technical activities and artifacts, and providing ready-to-use recipes for technical design. Technological knowledge in modern technological systems also differs from scientific knowledge in that much technological knowledge is embodied in tacit visual representations or experientially learned skills that are exceptionally difficult to verbalize. For example, NASA has conceded that it cannot rebuild the powerful Saturn V booster rockets used in the Apollo program, and not simply because there is no surviving set of blueprints; more damaging is the loss of the tacit, nonverbalized skills possessed by the thousands of men and women, now retired or deceased, who built and flew the rocket with such stunning success.

Arguably, it is only the moderate 'formalist' position, which acknowledges the similarities between nonmodern and modern technologies, that can fully reveal the interpenetration of the material and the social. Unaware that modern technologies function quite well even though they may be founded on 'unscientific' or 'false' belief systems, anthropologists have never known quite what to do about the 'false' beliefs associated with nonmodern technology. One approach, 'technicism,' simply ignores them. Malinowski (1935) explains away the 'false' beliefs Trobriand Islanders maintain about their gardens by viewing these beliefs as a sign of 'anxiety' over the outcome of production. Ingold's approach is to see such beliefs as the subjective outcome of an individual's skilled, nonverbal interaction with an environment or lifeworld. A moderate 'formalist' perspective is in agreement with Ingold's view, except that—in line with the theory of practice developed earlier—it would point out that the meanings drawn from subjective experience are not formulated in a vacuum. The beliefs associated with technological activities in nonmodern societies, such as the Iñupiat whaler's assertion that his wife is the great hunter, are recounted and shared socially by means of the stories communities tell about their experiences (Ridington 1999). Such stories are analogous to the 'technological frame' of modern technologies (Bijker 1995), from which modern and nonmodern technologists alike are able to locate their history and identity.

4. Technological Change

The anthropology of technology is also concerned with long-term technological change, working with a canvas that includes all of prehistory and history combined. It is difficult to resist the tendency, apparent in modernist views of the technological past, to see all previous technologies as forming a unilinear path of development, characterized by ever-swelling cranial capacities and increasingly sophisticated tools, that culminates in today's technological achievements. Whether approached from the 'substantivist' or moderate 'formalist' perspective, the anthropology of technology suggests that to do so would be a very serious mistake.

4.1 Tool Sophistication, Skill, and Intelligence in Prehistory

By stressing the importance of skilled technique (Ingold 2000) and the habitual sequences by which gestures and tools are integrated in the nonmodern *chaîne opératoire* (Leroi-Gourhan 1943), the anthropology of technology sounds a note of profound warning to prehistorians who would interpret every sign of increasing sophistication in the manufacture of tools as evidence of a corresponding increase in human intelligence or the complexity of language. Very smart people may well prefer simple tools, and compensate by developing spectacularly complex skills that, although inordinately difficult to acquire, enable them to work just as efficiently as people who opt for more complex and specialized tools. Simple tools do not signify simple minds.

4.2 'Evolution' of Technology

The anthropology of technology also calls into question 'evolutionary' conceptions of technological change in archaeology, in which the forces of natural selection are seen to punish 'inefficient' technologies (and the groups that cling to them). For one thing, what might seem like an 'inefficient' technology may have been quite efficient in skilled hands; for example, Bantu ironsmiths are known to have been able to produce consistently good iron blooms from their 'primitive' furnaces, but the skill they once possessed has unfortunately been lost; modern attempts to reconstruct and operate these furnaces produce uniformly disappointing results. Furthermore, microanalyses of technological change in both modern and nonmodern societies demonstrate conclusively that it is not the quest for greater 'efficiency,' but rather demands imposed by changes in underlying social and ideological systems, that leads innovators to modify techniques or invent new ones (cf. Schiffer and Skibo 1997). It is only by stepping back from such microanalyses, ignoring discrepant evidence, and abstracting technological change from its social and ideological context that one sees a 'unilinear evolution' of technology (Basalla 1988). The appearance of cumulative technological advance, in sum, is generated by concealed social strategies and belies the fact that the knowledge underlying abandoned technological systems can be unrecoverably lost.

Technology Districts

Technology districts are areas where activities to create and enhance knowledge for practical (especially commercial) uses cluster and constitute a major source or stimulus of value added to the local economy. They include what geographers refer to as 'high-tech region,' 'science/tech city,' 'technopole,' and 'technopolis' (Castells and Hall 1994, Malecki 1997, Scott 1993), which all contrast with traditional industrial districts based on manufacturing.

1. *Common Features*

Silicon Valley, Route 128, and the Research Triangle in the US, Cambridge in the UK, Sophia-Antipolis in France, Tsukuba and Kansai in Japan, Hsin-chu in Taiwan, and Bangalore in India are examples of technology districts. While their activities do not demonstrate a uniform pattern, there exist some similarities, such as interplay between public and private initiatives, active involvement of local educational and research institutions in innovation, a large proportion of highly educated and skilled personnel in the local labor force, and access to a wide range of urban infrastructural facilities.

2. *Driving Forces*

Technology districts are post-World War II (WWII) phenomena. Their genesis and development have been shaped by diverse factors (Sternberg 1996).

2.1 *State Action*

In some countries (e.g., the US and the UK) extensive defense spending since WWII has provided a powerful boost for corporate R & D in selected regions. It has also led to a significant growth of locally anchored university-industry ties through shared research facilities, joint or commissioned projects, and training. A further result is the increase of local technological diffusion and linkages through subcontracting and spin-offs. On the other hand, domestic politics has driven some local and national governments to make territorial high-tech development a major policy agenda. Efforts to carry it through often involve planning, funding, regulatory support, tax incentives, intermediary services, and improvement of physical, social, and research infrastructure in targeted locales.

2.2 *Changing Milieu of Innovation*

Technological change in the postwar era has been accompanied by concurrent weakening of regulatory barriers to entry, lowering of knowledge threshold for tapping the potentials of new technologies, and rise of venture capital. These developments have intensified competition and shortened the cycle for technology-intensive products. This makes it increasingly difficult to reply on organizationally integrated division of labor as the primary mode of innovation. Synergy from interactions across organizational boundaries, thus, assumes greater importance for technological development. Such synergy may derive from territorial clustering of innovation activities, as spatial proximity is conducive to mutual learning, exchange of information, sharing of infrastructure, pooling of skilled human resources, development of trust, containment of risk and transaction cost, coordination of R & D efforts between interdependent parties, and formation of industry and service linkages.

2.3 *Economic Globalization*

In the last quarter of the twentieth century, the gradual lowering of barriers to cross-national movement of resources, information, products, services, and organizational practices has redefined the spatial character of international division of labor. National and regional competitiveness hinges increasingly upon innovation rather than resource endowment and factor cost. The challenges and opportunities posed by such reality have prompted convergent responses from growing numbers of governmental, corporate, and university decision-makers. A focal strategy is to identify and develop viable niches of locational advantage in which to form critical masses of innovation activities that are globally competitive. This leads to the creation or reformation of regulatory and infrastructural enclaves within or outside old manufacturing belts and metropolitan areas. They are intended to channel and attract resources from domestic and international sources for territorially concentrated technological development. A related goal is to strengthen the ties between the local economy and global conditions of demand and supply.

3. *Variations*

The formation and trajectory of technology districts vary in different historical and local contexts. Some districts evolve mainly out of university–industry interactions, whereas others are created and developed under government auspices. To certain extent, the

level, scope, and scale of innovation activities in different technology districts are conditioned by the level and form of regional and national economic development (Castells and Hall 1994).

Moreover, not all efforts to build technology districts are successful, and some established districts have experienced difficulties, stagnation, and decline. Some studies (e.g., Saxenian 1994) attribute this to the rigidities in path-dependent local corporate structure and business culture that hinder the development of innovation networks. Other factors that may stifle local synergy include poor planning, weak entrepreneurialism in face of tight bureaucratic control, predominance of divergent agendas and interests (e.g., property development), and intradistrict negative externalities (e.g., infrastructural overloading and environmental deterioration).

4. *Consequences*

The full socioeconomic ramifications of technology districts remain to be explored. What are their effects on interregional disparities? How do they stimulate economic growth and institutional change beyond the region? How and to what extent do they foster elitism and increase cleavages in society? These are some of the important issues that have been raised but need to be examined more closely.

Furthermore, technology districts are evolving with the forces that they help unleash. In particular, their spatial organization faces growing impact from the explosive expansion of the Internet and rapid development of information technology, which could significantly reduce the constraints posed by distance and locality-specific institutions on social interaction. How this redefines the role of location in fostering innovation will be a major focus of attention among both practitioners and observers.

I. Eng

Technology, Social Construction of

SCOT is one approach among several constructivist ways of studying science and technology that emerged in the 1980s. Here, 'constructivist' means that the truth of scientific facts and the working of technical artifacts are studied as accomplishments—as being constructed—rather than as intrinsic properties of those facts and machines. The term 'social construction of technology' can be used to denote two different things. First it is a research approach to study technical change in society, both in historical and in contemporaneous studies. Second, it is a theory about the development of technology. Historically the development of SCOT is closely linked to the sociology of scientific knowledge (SSK) and to the science, technology, and society (STS) movement in the 1970s. In the 1980s and 1990s, it developed primarily as an academic enterprise, but then also found application in the policy domain, in innovation management, and in discussions about new forms of democracy.

1. *Constructivist Studies of Science and Technology*

The phrase 'social construction' was first used by Berger and Luckmann (1966) in their *Treatise in the sociology of knowledge*. Building on the phenomenological tradition and particularly on the work of Alfred Schutz, they argue that reality is socially constructed and that these processes of social construction should be the object of the sociology of knowledge. Berger and Luckmann focus on the social construction of ordinary knowledge of the sort that we use to make our way about society. They are concerned with the reality of social institutions and their focus is on society at large, rather than on subcultures such as science and technology. Nevertheless, scholarship developed around such themes as the social construction of mental illness, deviance, gender, law, and class. Similarly, in the 1970s the social construction of scientific facts developed (Latour and Woolgar (1986)), followed in the 1980s by the social construction of artifacts (Bijker et al. 1987) (see *Laboratory Studies: Historical Perspectives*; *Scientific Controversies*; *Scientific Knowledge, Sociology of*).

Constructivist studies of science and technology

come in a wide variety of forms, both mild and radical (Sismondo 1993). The mild versions merely stress the importance of including the social context when describing the development of science and technology. Examples of such work are Constant's (1980) account of the turbojet revolution, Douglas' (1987) history of radio broadcasting, Nye's (1998) studies of the electrification of America, and Kranakis' (1997) history of French bridge engineering. The radical versions argue that the content of science and technology is socially constructed. In other words, the truth of scientific statements and the technical working of machines are not derived from nature but are constituted in social processes. Radical constructivist studies of science and technology share the same background, have similar aims, and are even being partly carried out by the same authors. The remainder of this article will focus on technology studies (see *Scientific Knowledge, Sociology of*) and more precisely on the radical versions of SCOT.

2. *The Origin and Development of the Social Construction of Technology*

SCOT grew out of the combination of three distinct bodies of work: the STS movement, SSK, and the history of technology. The first started in the 1970s, mainly in the Netherlands, Scandinavia, the United Kingdom, and the US. Its goal was to enrich the curricula of both universities and secondary schools by studying issues such as scientists' social responsibilities, the risks of nuclear energy, the proliferation of nuclear arms, and environmental pollution. The movement was quite successful, especially in science and engineering faculties, and some of the STS courses were incorporated into degree requirements.

SSK emerged in the late 1970s in the United Kingdom on the basis of work in the sociology of knowledge, the philosophy of science, and the sociology of science (see *Scientific Knowledge, Sociology of*; *Strong Program, in Sociology of Scientific Knowledge*). The central methodological tenets of the 'strong program' (especially its symmetry principle) seemed equally applicable to technology. The symmetry principle called for a symmetrical analysis of true and false scientific statements, explaining their development with the same conceptual framework. In studying technology, this should mean that working and non-working machines should be analyzed symmetrically and in the same terms.

In the history of technology, especially in the US, an increasing number of scholars began to raise more theoretical and sociologically inspired questions (influential were Constant 1980, Hughes 1983, Cowan 1983). Path-breaking advocacy for this body of work in the history of technology was provided by the reader edited by MacKenzie and Wajcman (1985). Citing the title of this volume, the phrase 'social shaping of technology' is used to denote a broader area of research, including work in industrial sociology, technology policy, and the economics of technical change (Williams 1996).

Researchers from these three traditions convened an international workshop in 1984 in the Netherlands. The subsequent volume from that workshop, edited by an STSer, a historian of technology, and a sociologist of scientific knowledge (Bijker et al. 1987), has been heralded as the starting point of SCOT. To understand the role of this workshop and volume, it is helpful to distinguish between a broad and narrow usage of the phrase 'social construction of technology' (but to note that both notions fall within the radical meaning of social constructivism).

When broadly used, the 'social construction of technology' encompasses all the work represented in the 1987 volume, including the actor-network approach by Callon, Latour, and Law (see *Actor Network Theory*), and the technological systems approach advocated by Hughes (see *History of Technology*). Used more narrowly, it refers primarily to the program set out by Pinch and Bijker (1984). For this latter program of the social construction of technology, the acronym 'SCOT' was introduced; but this acronym is now increasingly used in the broad sense too, without reference to one specific approach in constructivist studies of technology. The remainder of this article is primarily about SCOT in the narrow sense, although SCOT also broadened its agenda (for reviews of SCOT in the broad sense, see Bijker 1995b).

SCOT developed like any normal scientific program: its agenda, central concepts, and even unit of analysis shifted in response to research findings and discussions among contributing scholars. In that sense, one can distinguish early and late (or recent) versions of SCOT.

An important, though negative, starting point for SCOT was to criticize technological determinism (see *Technological Determinism*). Technological determinism was taken to comprise two elements: (a) technology develops autonomously, and (b) technology determines societal development to an important degree. This view was seen as intellectually poor and politically debilitating. Technological determinism implies a poor research strategy, it was argued, because it entails a teleological, linear, and one-dimensional view of technological development. In addition, it was considered politically debilitating because technological determinism suggests that social and political interventions in the course of technology are impossible, thus making politicization of technology a futile endeavor. To bolster this critique, it was necessary to show that the working of technology was socially constructed, with the emphasis on 'social.' Key concepts in this program, as will be discussed in the next section, were 'relevant social group,' 'interpretive flexibility,' 'closure,' and 'stabilization.' The

unit of analysis was the single artifact. The choice of the artifact as unit of analysis was a choice of the 'hardest possible case.' To show that even the working of a bicycle or a lamp was socially constructed seemed a harder task, and thus—when successful—more convincing, than to argue that technology at a higher level of aggregation was socially shaped.

The agenda of demonstrating the social construction of artifacts by detailed analysis at the micro level resulted in a wealth of case studies. A few years later, the program was broadened in two ways (Bijker and Law 1992). First, questions were raised at a meso and macro level of aggregation as well: for example about the political construction of radioactive waste, clinical budgeting in the British National Health Service, or technically mediated social order. Second, the agenda was broadened to include again the issue of technology's impact on society, which had been bracketed for the sake of fighting technological determinism. Concepts developed for this agenda were 'technological frame,' and various conceptualizations of the obduracy of technology. The unit of analysis was broadened from the singular technical artifact to the more comprehensive and heterogeneous socio-technical ensemble. The emphasis now was on 'construction' rather than on 'social.' (A similar shift occurred in the social construction of science. Thus, for example, Latour and Woolgar (1986) dropped the word 'social' from the subtitle of their book *Laboratory Life* when it was reprinted in 1986.) The aim became to study the mutual shaping of society and technology, rather than the one being shaped by the other.

Present research in SCOT combines ongoing empirical case studies with more general questions about the modernization of society, the politicization of technological culture, and the management of innovation. It has become increasingly difficult (and unfruitful) to observe the boundaries between the various approaches within the broader social construction of technology. Research collaboration and conceptual combinations have emerged between, for example, the actor-network approach, SCOT in the narrow sense, and gender and technology studies. Connections are developing with studies in the social sciences more generally, including politics, economics, and law.

3. *The Social Construction of Technology as a Heuristic for Research*

As a heuristic for studying technology in society, SCOT can be laid out in three consecutive research steps (Bijker 1995a).

Key concepts in the first step are 'relevant social group' and 'interpretive flexibility.' An artifact is described through the eyes of relevant social groups. Social groups are relevant for describing an artifact when they explicitly attribute a meaning to that artifact. Thus, relevant social groups can be identified by looking for actors who refer to the artifact in the same way. For describing the high-wheeled ordinary bicycle in the 1870s, such groups were, for example, bicycle producers, young athletic ordinary users, women cyclists, and anti-cyclists. Because the description of an artifact through the eyes of different relevant social groups produces different descriptions—and thus different artifacts—the researcher is able to demonstrate the 'interpretive flexibility' of the artifact. There is not one artifact, but there are many. In the case of the ordinary bicycle, for example, there was the unsafe machine (through the eyes of women) and there was the macho machine (through the eyes of the young male ordinary users). For women the bicycle was a machine in which your skirt got entangled and from which you frequently made a steep fall; for the 'young men of means and nerve' riding the bicycle was a means to impress people (including young ladies!).

In the second step, the researcher follows how interpretive flexibility diminishes, because some artifacts gain dominance over others and meanings converge, and in the end one artifact results from this process of social construction. Here, key concepts are 'closure' and 'stabilization.' Both concepts are meant to describe the result of the process of social construction. 'Stabilization' stresses process: a process of social construction can take several years in which the degree of stabilization slowly increases up to the moment of closure. 'Closure,' a concept stemming from SSK, highlights the irreversible end point of a discordant process in which several artifacts existed next to one another.

In the third step, the processes of stabilization described in the second step are analyzed and explained by interpreting them in a broader theoretical framework: why does a social construction process follow this course, rather than that? The central concept here is 'technological frame.' A technological frame structures the interactions among the members of a relevant social group, and shapes their thinking and acting. It is similar to Kuhn's concept of 'paradigm' with one important difference: 'technological frame' is a concept to be applied to all kinds of relevant social groups, while 'paradigm' was exclusively intended for scientific communities. A technological frame is built up when interaction 'around' an artifact begins. In this way, existing practice guides future practice, though without logical determination. The cyclical movement thus becomes artifact, technological frame, relevant social group, new artifact, new technological frame, new relevant social group, etc.

Typically, a person will be included in more than one social group, and thus also in more than one technological frame. For example, the members of the Women's Advisory Committees on Housing in the Netherlands are included in the technological frame of male builders, architects, and municipality civil

servants. This allows them to interact with these men in shaping public housing designs. But at the same time, many of these women are included in the feminist technological frame, which enables them to formulate radical alternatives to the standard Dutch family house that dominates the male builders' technological frame (Bijker and Bijsterveld 2000).

This three-step research process thus amounts to: (a) sociological analysis of an artifact to demonstrate its interpretive flexibility, (b) description of the artifact's social construction, and (c) explanation of this construction process in terms of the technological frames of relevant social groups. The remainder of this section discusses some methodological and critical issues.

It is important to appreciate that SCOT provides a research heuristic for interpretive sociology, not a research machine to churn out case studies as Russell (1986) and Winner (1993) seem to suggest. For example, the adage 'identify all relevant social groups by searching citations of the artifact by a variety of actors' does not diminish the researcher's obligation to decide which groups are important to include in the account, and which groups only obfuscate the picture by adding useless details.

As a research heuristic, SCOT shows its debt to the history of technology by an emphasis on case studies and narrative, and to SSK by a preference for qualitative methods such as ethnography. Besides providing a theory of technology and society (as discussed in the next section), SCOT aims at helping researchers to give a detailed and insightful account of the development of technology in society. Concepts such 'relevant social group' and 'interpretive flexibility' primarily help to open up a case and to ask original and thought-provoking questions; they are less important for telling the story (for a debate on this issue, see Buchanan 1991, Law 1991, Scranton 1991). These case studies may be historical or contemporaneous. In the latter, the researcher will often find herself or himself drawn into the case and become one of the actors (see, for example, Bucciarelli 1994)

It is also a mistake to think that studies of SCOT only focus on the early stages of an artifact's development, the design and prototype phases. If the key idea of SCOT—that all kinds of relevant social groups contribute to the social construction process—is taken seriously, then one should also accept that this construction process takes place in all contexts and all phases. Thus, for example, the rural car in the US acquired its specific functionality (including its use as stationary power supply to washing machines, butter churns, corn shellers, water pumps, and wood saws) only after it had come off the production line as a car (Kline and Pinch 1996).

Two concepts may be fruitfully used to highlight one specific methodological cornerstone of research on SCOT: seamless web and symmetry. The phrase 'seamless web of technology and society' is often used as a reminder that non-technical factors are important for understanding the development of technology, and that these factors are closely related. A second, more sophisticated meaning is that it is never clear *a priori* and independent of context whether an issue should be treated as technical or social. Was the Challenger accident a technical failure, an organizational mistake, or primarily a lack of adequate funding (Vaughan 1996)? The activities of engineers and designers are best described as heterogeneous engineering, network building, or system building, rather than as straightforward technical invention. The recognition that all kinds of social groups are relevant for the construction of technology supports this second usage of the seamless web metaphor. The third interpretation of seamless web extends the symmetry principle into the principle of general symmetry. Not only should we treat working and non-working machines symmetrically; the very distinction between the social and the technical world can be treated in that way. The 'stuff' of the fluorescent lamp's invention is economics and politics as much as electricity and fluorescence. Let us call this 'stuff' sociotechnology. The relations that play a role in the development of the fluorescent lamp are thus neither purely social nor purely technical: they are sociotechnical. The principle of general symmetry casts this into a methodological principle: human and non-human actors should be treated similarly, and the construction of society and the construction of technology should be explained in symmetrical terms. In other words, technical reductionism and social reductionism are both outlawed as explanatory strategies. Instead, new forms of explanation need to be developed. The next section ends with an example. (For the lamp case, see Bijker 1995a; for the general symmetry principle, see Callon 1986.)

4. *The Social Construction of Technology as a Theory of Technology in Society*

SCOT also provides a theoretical perspective on the relation between technology and society, and on their joint developments or co-evolution.

As was discussed, the development of technology can be explained as a social process in which a variety of relevant social groups participate. This social process does not stop when an artifact leaves the factory, but continues when users give the technology its specific usage and meaning. Laws of physics and economics are relevant but insufficient to characterize technology's development. Artifacts can be shown to have interpretive flexibility, due to the different constructions that various social groups make. When these relevant social groups interact, typically one meaning of the artifact will gain dominance and stabilize. At the end of that social process, closure occurs, and interpretive flexibility vanishes.

Analogously, the development of social institutions in modern society cannot be fully understood without taking into account the role of technology. Such institutions as the church, capital, the government, labor, communications, and education may keep the social fabric of society together; but where would all of these be without technology? Social order in modern society can only be explained by reference to technology (Latour 1992). This requires a view of technology's impact on society. In SCOT, conceptualizing the hardness or obduracy of technology does this.

An artifact can be hard in two distinctly different ways. The first form, 'closed-in hardness,' occurs when the humans involved have a high inclusion in the associated technological frame. For example, upon meeting problems with printing a letter, a student with a high inclusion in the PC users' technological frame will check cabling, control panels, and printer definitions. Only after some time will it occur to her that she could also write the letter by hand: she was 'closed-in' by the PC technology. Another student having the same problem, but with a low inclusion in the PC users' technological frame, has no clue about cables or control panels; he can barely locate the power switch. He experiences the second kind of impact by technology: 'closing-out obduracy.' He sees no alternative but to leave the technology aside and pick up his fountain pen. In both cases, the technology has an impact on these students, but in completely different ways.

These two forms of hardness of technology can also be seen on the societal level. Automobile technology, for example, exerts a 'closed-in hardness' on the inhabitants of Los Angeles: much differentiation within auto culture, but no alternatives outside it. The standardization of main power voltage and wall plugs means a 'closing-out obduracy' to most people: accept it by buying the right plug and apparatus, or not use electricity.

This constructivist analysis provides a theoretical perspective on both SCOT and the technological impact on society. It offers a reconciliation of the previously opposed social constructivist and technological determinist views. This reconciliation asks for a theoretical elaboration, extending the conclusion of the previous section: that the distinction between technology and society can be transcended and that the proper subject matter for analysis is sociotechnology. The concept 'technological frame' provides the theoretical linking pin between the two views.

A technological frame describes the actions and interactions of actors, explaining how they socially construct a technology. But since a technological frame is built up around an artifact and thus incorporates the characteristics of that technology, it also explains the influence of the technical on the social. Part of the societal impact of the standard Dutch family house was that it dominated architectural thinking in the 1950s through 1970s, and thus made it very difficult to conceive alternatives: architects and even members of the critical Women's Advisory Committees were 'closed-in' by the builders' technological frame, only seeing the two-parents-two-children-house.

5. *The Politicization of Technological Culture*

We live in a technological culture: our modern, highly developed society cannot be fully understood without taking into account the role of science and technology. SCOT offers a conceptual framework for politicizing this technological culture. 'Politicizing' here means showing hidden political dimensions, putting issues on the political agenda, opening issues up for political debate. SCOT approach not only gives an affirmative answer to Winner's (1986) question 'Do artifacts have politics?' but it also offers a handle to analyze these politics. Technology is socially (and politically) constructed; society (including politics) is technically built, and technological culture consists of sociotechnical ensembles. (See Sclove's manifesto 1995 for designing a democratic technological society.)

Studies that elaborate this agenda do not exclusively extend the SCOT framework, but typically draw on social constructivist technology studies in the broad sense. One of the most fruitful bodies of work is the analysis of gender and technology (Cockburn and Ormrod 1993 and Lerman et al. 1997) (see *Gender and Technology*). Another now quickly expanding domain of research focuses on the politicization of information society and information and communication technologies (see Schmidt and Werle 1998 for a fruitful approach via standardization issues). Studies like MacKenzie's (1990 history of guided missiles, Hecht's (1998) history of nuclear power in France, and Vaughan's (1996) account of the Challenger disaster demonstrate that the new framework can be productive for the analysis of classical political themes too (Jasanoff 1994, Wynne 1988) (see also *Risk, Sociology and Politics of*).

The issue of political decision-making about technological projects acquires a special guise in the light of SCOT (see also *Technology Assessment*). If it is accepted that a variety of relevant social groups are involved in the social construction of technologies and that the construction process continues through all phases of an artifact's life cycle, it makes sense to extend the set of groups involved in political deliberation about technological choices. Thus, several countries experiment with consensus conferences, public debates, and citizens' juries. One of the key issues here is the role of expertise in public debates (see *Science and Technology Studies: Experts and Expertise*). The SCOT approach suggests that all relevant social groups have some form of expertise, but that no one form—for example that of scientists or engi-

neers—has a special and *a priori* superiority over the others.

Technology-supported Learning Environments

The idea of learning environments refers to settings that are purposively designed and implemented to facilitate learning in students. The term 'learning

environments' has only recently become current in the educational literature, and reflects an important shift in the basic conception of education, namely from a predominantly information transmission and absorption model toward a more constructivist view, and, consequently, a shift in perspective from teaching to learning (Collins et al. 1996). Technology-supported learning environments are, then, contexts for learning that involve technological devices that are assumed to foster students' acquisition of the intended educational objectives. In this respect, the expression 'technology-*supported*' is also a relative newcomer in the educational vocabulary; in comparison to the frequently used term 'technology-*based*,' it attributes a less central role to the technology in the learning environment.

Using technological devices as teaching aids to facilitate learning has a relatively long history in education and educational research. A constant runs through this history as a continuous thread: initially there is great optimism and high expectations about the potential of the new technology for the improvement of the quality and the outcomes of learning and teaching, but this is afterwards followed by disappointment because the expectations are not met and the expected positive effects fail to appear. For instance, in an excellent historical overview of the classroom use of technology since 1920, Cuban (1986) quotes the following claims: 'The central and dominant aim of education by radio is to bring the world to the classroom, to make universally available the services of the finest teachers, the inspiration of the greatest leaders' (Darrow 1932, p. 79, quoted in Cuban 1986, p. 19); 'The time may come when a portable radio receiver will be as common in the classroom as is the blackboard. Radio instruction will be integrated into school life as an acceptable educational medium' (Levenson 1945, p. 457, quoted in Cuban 1986, p. 19). Obviously these predictions have remained unfulfilled. On the other hand, these statements echo many similar ones heard afterwards with respect to educational television, and more recently about the educational use of the computer. However, there is now robust evidence that in these cases too the euphoric, but naive expectations were not fulfilled (Hawkins 1996, Salomon and Gardner 1986); they were probably more based on wishful thinking than on well-grounded arguments. In sum, the history of educational technology has more or less repeated itself throughout the twentieth century, and apparently not much has been learned from it.

But paralleling the shift from an information transmission to a constructivist view of education, there has recently also been a trend toward a more productive application of educational technology that moves away from the romantic and naive technological optimism of the past, and is in accordance with the new perspective on education. Mainly focusing on the educational use of the new information and communication technology, this article will briefly document this trend, after first identifying major causes of the past failures.

1. *From Adding-on Toward Embedding Computers in Learning Environments*

A major cause of the relative failure of educational computing—as well as of previous 'novelties' in the instructional technology toolbox—is that since the early 1980s the computer has been mainly introduced in educational settings as an add-on to an existing and unchanged instructional setting (Salomon 1992). In other words, the typical application of computers could better be described as 'computer-added instruction' than as 'computer-supported learning.' In mathematics, for instance, the large majority of the available software fitted into the category of drill-and-practice programs, aiming mainly at exercising computational skills and replacing in this respect traditional worksheets (Kaput 1992). This means that the new information technology was implemented to reproduce and preserve the status quo.

The situation in other subject-matter domains of the school curriculum, but also in nonschool settings was largely similar. In language teaching, for example, programs focusing on practicing rules of spelling and grammar also prevailed, and much less software was available that supported the more essential aspects of reading and writing, namely comprehension and communication. It has now become obvious that this mere add-on strategy of educational computer use cannot produce the improvements in the quality and the outcomes of learning that were originally anticipated. A partial explanation of the inefficacy of this strategy is that the predominant drill-and-practice applications elicit only lower-level mental activity in learners, and do not at all exploit the specific potential of the computer such as its interactive possibilities and its tremendous capacity for data presentation and handling.

A more fundamental reason, however, for the failure of the add-on strategy is that it is based on the erroneous assumption that computers will evoke productive learning by themselves (Hawkins 1996). A representative illustration in this respect relates to the way Logo was often used referring to Papert (1980): it was expected that 'mindstorms' resulting in improved thinking and problem-solving skills, would arise of themselves in children's heads due to the unique characteristics of the Logo environment. Contradicted convincingly by well-designed studies, as well as by practical experience, this viewpoint has been abandoned. The point of view has rapidly gained ground that effective computer support for learning requires that it is embedded in powerful teaching–learning environments, i.e., instructional settings that elicit in students and trainees the acquisition processes neces-

sary to attain worthwhile and desirable educational objectives. Embedding means here that the computer is not just an add-on, but is judiciously integrated in the environment capitalizing on its specific strengths and potential to present, represent, and transform information (e.g., visualization and simulation of phenomena and processes), and to induce effective forms of communication, interaction, and cooperation (e.g., through exchanging data, information, and problems via a network). But, there is also a physical aspect to the embedding; indeed, as argued by Collins (1996), the spatial design of the classroom and the design of the computer are currently incompatible with the appropriate and widespread use of computers in schools.

2. *From Computer-controlled Tutoring to Student-controlled Collaborative Learning*

Paralleling the large-scale introduction of computers in education and training, the cognitive science community interested in learning and teaching has invested a lot of work and effort in the design of intelligent tutoring systems (ITS), which can be characterized as computer-supported learning environments based on artificial intelligence (AI) (for an overview see Seidel and Park 1994, Wenger 1987). It is interesting to ask whether this interdisciplinary research endeavor has contributed to overcome the flaws of educational computing discussed above. The question arises because a major incentive for designing ITS derived from dissatisfaction with traditional computer-assisted instruction (CAI). In fact, educational software involving AI was originally called 'intelligent' computer-assisted instruction (ICAI). The critical distinction between CAI and ITS is that CAI involves static systems that embody the decisions of expert teachers, whereas ITS contain the expertise itself and can use it as a basis for taking decisions about instructional interventions.

The domain of AI and education is an interdisciplinary crossroad and, consequently, the development of intelligent tutors is guided by a substantial and varied body of inquiry-based knowledge. Nevertheless the field is strewn with pitfalls. For instance, one very robust result of research on learning and instruction is that learners' prior knowledge is a very strong determinant of their future learning. Therefore, instruction should explicitly be linked up to prior knowledge, and the ITS community has taken this principle seriously. Indeed, a major component of an intelligent tutor is the student model which, as Wenger (1987, p.16) states : '… should include all the aspects of the student's behavior and knowledge that have repercussions for his performance and learning.' But the same author adds immediately that building such a student model is a very difficult task for computer-based systems. Moreover, it is not clear how far one should go in the construction of student models, and how flexible and diagnostic a system should be in view of providing the most appropriate guidance.

An even more fundamental issue concerns the nature of the guidance that an ITS should provide, taking into account the now well-documented conception that learning is an active and constructive process: Learners are not passive receptacles of information, but they actively construct their knowledge and skills through interaction with the environment and through reorganization of their prior mental structures. Consequently, as argued by Scardamalia et al. (1989), computer-based learning environments should support the constructive acquisition processes in students. The question arises whether the existing ITS are in accordance with this constructivist view of learning. Indeed, intelligent tutors that base their instructional decisions on a detailed diagnosis of student's knowledge can easily lead to a preponderance of highly structured and directive learning situations lacking sufficient opportunities for active learner involvement and participation (Kaput 1992). More recent new approaches in ITS have taken such criticisms into account, and imply a more active participation of the learner in the learning process, especially by involving (learner-controlled) interaction and cooperation between the learner and the system using a kind of built in colearner or learning companion (Frasson and Aimeur 1996).

3. *Toward a New Generation of Computer-supported Learning Environments*

Identification of the deficits of the past approaches to educational computing, together with a better theoretical understanding of the characteristics of effective learning processes, have fostered the emergence of the view that technology-supported learning environments should not so much involve knowledge and intelligence to guide and structure learning processes, but that they should rather create situations and offer tools that stimulate learners to make maximum use of their own cognitive potential (Scardamalia et al. 1989). In this connection Kintsch (1991, p. 245) has launched the idea of 'unintelligent tutoring':

> A tutor should not provide the intelligence to guide learning, it should not do the planning and monitoring of the student's progress, because those are the very activities the students must perform themselves in order to learn. What a tutor should do is to provide a temporary support for learners that allows them to perform at a level just beyond their current ability level.

The major characteristics of productive learning processes that have resulted from research on learning and instruction during the past decades can be summarized in the following definition: Learning is an

active, constructive, cumulative, self-regulated, goal-directed, situated, collaborative, and individually different process of knowledge building and meaning construction (for a more elaborated discussion see *Instructional Psychology*). In line with this conception of learning a new generation of technology-supported learning environments has emerged, characterized by a clear shift toward supportive systems that are less structured and less directive, that are more focused on coaching and scaffolding than on tutoring, that involve student-controlled tools for the acquisition of knowledge, and that attempt to integrate both tools and coaching strategies in interactive and collaborative learning environments (Cognition and Technology Group at Vanderbilt 1996). In those environments the technological tools and scaffolds are embedded in the sense as defined above. Different groups of researchers have designed and implemented computer and/or multimedia programs around which novel, powerful learning environments were built that are in accordance with the characteristics of effective learning processes and thus embody the new conception of technology-supported learning (see e.g., Lehtinen et al. 1999, Vosniadou et al. 1996). By way of illustration a few representative cases are briefly described.

A major example is the 'Jasper project' of the Cognition and Technology Group at Vanderbilt (CTGV 1997), focusing on learning and teaching mathematical problem solving in the upper primary school. The CTGV introduced the notion of anchored instruction representing one approach to implementing technology-supported learning: Instruction is anchored in videodisk-based complex problem-solving spaces that provide a richer, more realistic, and more dynamic presentation of information than textual material; the videodisk (such as 'Adventures of Jasper Woodbury' relating to trip planning) creates an environment for active, cooperative learning and discussion in small groups, as well as for individual and whole-class problem solving.

CSILE (Computer-Supported Intentional Learning Environment) is a domain-independent hypermedia environment that can be used as an educational medium throughout the curriculum (Scardamalia et al. 1994). The system allows students to build and elaborate their own common database consisting of text and graphical material relating to problems and topics under study. All students have access to the database and they can comment on each others' notes. This latter feature of the environment aims at inducing collaborative problem solving and knowledge construction in the classroom. A software tool derived from CSILE called 'Knowledge Forum' (Scardamalia and Bereiter 1998) is available on the World Wide Web.

Since 1993 the two previous projects ('Adventures of Jasper Woodbury' and CSILE) have collaborated closely with Brown and Campione's (1996) 'Fostering Communities of Learners' (FCL) program in the framework of the overarching 'Schools for Thought' (SFT) project (Lamon et al. 1996). Important in this respect is that—in line with the view of technology-supported learning put forward above—the SFT project aims at restructuring and transforming the entire learning environment in schools founded on present-day theory of learning from instruction, and integrating the new technologies (Cognition and Technology Group at Vanderbilt 1996).

A last example, Cabri Géomètre, developed in Grenoble, France (Baulac et al. 1988), consists of a series of computer programs that create a powerful learning environment in which students become active learners and explorers of Euclidean geometry guided by their teacher. The underlying ideas are that students can make their own mathematics, and that formulating and testing conjectures constitute the main activities of doing mathematics. The program elicits and facilitates such activities by offering a tool for constructing, manipulating, and exploring geometric shapes.

These technology applications are excellent examples of what Kaput (1992, p. 548) has called 'implementing technology toward reformed objectives.' Indeed, these programs embody major principles for the design of good technology-supported learning environments discussed above: They stimulate active learning oriented toward higher-order cognitive skills in a collaborative and teacher-guided context, and they exploit optimally the computer's interactive potential as well as its capacity to present and manipulate graphic and symbolic information. While a number of educational software projects, of which the three mentioned cases are representative examples, show promising results in small-scale studies, they do not get widely disseminated. A major obstacle in this respect is that most of the available products are expensive, incompatible, and inflexible. Solving this problem is a main challenge for software research and development in the near future. A promising avenue is the 'component' approach to educational software, the gist of which consists in the construction of a digital library of reusable (i.e., adaptable to new needs without the help of the original developers) software modules that can be easily mixed and matched. The further elaboration of this strategy should make it possible to reduce the cost, to increase the reuse, to decrease incompatibilities, and to enhance the flexibility of educational software (Roschelle and Kaput 1996).

4. *The Potential of the World Wide Web for Designing Powerful Learning Environments*

The end of the twentieth century saw schools rapidly acquiring access to the Internet. For instance, according to a recent survey in the USA over 90 percent of

the public schools have some kind of access to the Internet, and 39 percent of the teachers (grades 4–12) have some sort of connection in their classroom (Becker 1999). This new technological *tour de force* again fuels great enthusiasm and high expectations about the potential of the World Wide Web for enhancing learning and teaching. There is no doubt that the WWW has such a potential; however, a critical approach is indicated in order to avoid once again replicating the naivety and errors from the past with respect to other media.

Obviously the Web is a tremendously rich information source, but this is accompanied by the danger of information overload; also the Web can be used as a channel for communication, but its value as a tool for collaboration should not be overestimated (Roschelle and Pea 1999). Furthermore, making information available and facilitating communication does not yet imply that the Web will foster the quality and the outcomes of student learning; in this respect it is useful to remember that the Web was developed at first as a tool for sharing research information in the community of high energy physics scholars, and not as an educational medium. The following important issues have recently been raised from an educational perspective: the lack of integration of today's Web with the structure and content of K-12 education; the difficulty of using the Web as a medium for constructive learning (because receiving information on the Web is much easier than creating information); the inability of the Web by itself to foster higher-order skills such as problem solving, creative and critical thinking, and teamwork (Roschelle and Pea 1999). All this implies that in view of exploiting the educational potential of the WWW there is a need for thorough research on the impact of its application in classrooms on the quality and the results of students' learning and teachers' instruction, as well as for innovative development aiming at overcoming the educational weaknesses of today's Web.

Technology Transfer

The concept of technology transfer (hereafter, transfer of technology or TOT) has diverse roots: in myth, in the nineteenth century preoccupation with the diffusion of technological artifacts, and in the economics of knowledge. The Promethean act of stealing fire from the gods could be considered a creation myth of technology transfer. Lynn White's classic essay on the origin and diffusion of the stirrup is paradigmatic of the studies on the diffusion of technological artifacts (1962). But TOT as an everyday concept could only come into being with the idea of what Whitehead dubbed the 'invention of invention.' In *Science and the Modern World*, he observed, 'to understand the modern epoch, we can neglect railways, telegraph, radios, spinning machines and synthetic dyes. We must concentrate on the method itself' (1938, p. 118). Whitehead insisted that 'scientific knowledge is not an abundant storehouse from which one readily helped oneself. An intense period of imaginative design lies between them. One element in the new method is how to go about bridging the gap between a scientific idea and its ultimate product' (1938, p. 18).

The idea of the transfer of technology reflects at once a model of governance, a civics we may say, and a paradigm for the interaction between science and technology (S&T). Also present in this concept is a recognition that science and technology operated as parallel streams throughout most of history. If anything connected them, it was the use of scientific instruments. Till the nineteenth century, science was not a systematic part of the productive process. Economic historians now agree that science played little role in the industrial revolution, which was more the work of craftsman inventors who had little systematic education in science or technology. The concept of technology transfer recognizes the problematic relation between S&T and seeks to increase the reciprocity and frequency of the interaction.

In its most rudimentary form, the TOT concept is founded on the idea of the innovation chain as a sequence of the three stages of invention, innovation, and diffusion, which are non-monotonic. Invention represents the conceptualization of a scientific idea conventionally in a laboratory and its concretization in a sample or prototype. Innovation represents the scaling up of the product or process for commercialization, and diffusion is the wider extension of the product in society. Innovation chains represent the lifecycle of a scientific idea within the technological and commercial domain. The nature of the schema disguises certain ideological and cultural biases. First, it assumes that science and technology axiomatically have separate spheres of operation, which the creativity and purity of science requires. Institutionally, science was seen as operative in laboratories and universities; technology in factories and engineering studios. The innovation chain was a linear sequence proceeding from pure science to applied science to development and production. TOT was conceived as following the same linear pathway.

Second, the schema is associated with a set of conceptual separations that tended to reinforce a ritual and institutional separation among the three stages. The relation between pure science, applied science, and development provided the stuff of science policy in the USA for years. If one seminal book embodied this model, it was Vannevar Bush's *Science, The Last Frontier*, which provided the paradigmatic formulation for the science policy of the Cold War years (1945). Bush's work was representative of the time and reflected the era's static understanding of the categories of research. Bush argued that basic research is the engine of technological progress and that it must be separated from applied research because applied research invariably drives out the pure.

Third, present in Bush's writings was not only an understanding of the dynamics of science but of nation building. Bush argued that nations which depend on others for their pure science would lose their competitive edge in world trade. The TOT model thus embodied the ideological assumptions of a particular subculture of science which equated invention with basic science and superiority in basic science with

supremacy in world politics (see Stokes 1997). This subculture was challenged both by the Japanese successes in competing with America in the 1980s and by a newly revisionist history which saw S&T as a more interactive field, in which scientists like Maxwell, Pasteur, and others derived their pure science questions from industrial and agricultural problems. The linearity was also challenged by the development of the new materials sciences which posited and institutionalized a reciprocal relation between science and technology (see Roy 1970). But there were also ideological reasons for the collapse of the conventional paradigm. If the quarrel of the categories constituted the stuff of the science policy discourse in the Anglo-Saxon postwar world, the challenges to technology transfer models came from a different array of positions in the Third World.

1. *Critical Discourses*

The debates on technology transfer resonated with the wider debates on development. As development produced discursive epicycles of equal development, community development, participative development and sustainable development, technology transfer too produced a spate of critical discourses centering on intermediate technology, alternative technology, and alternative science. These responses were not merely driven by academic critiques but evolved as philosophies of grassroots movements.

Present in all these approaches was a geography of power. The innocent horizontality of TOT was now read across the center-periphery axis. The political economy of technology transfer saw the basic choices of S&T as emerging from the metropolis. The periphery was regarded not as a source of independent innovation but only as a recipient of it. The idea of TOT was embedded in the policy of import substitution; industrialization was seen as a passive civics that pulled its subjects into forms of governance over which they did not have active control.

The recognition of intellectual and economic inequality underlying TOT produced spectrum of responses. From Latin America came the work of the centre-periphery theorists who argued through LAFTA and UNCTAD for better terms of trade. Here technology was absorbed in the wider discourse of political economy. Inspired by his work in Burma, E. F. Schumacher articulated the idea of intermediate technology (1973). The Vietnam War, the energy crisis and the peace movement produced a search for soft-energy paths captured in the idea of appropriate or alternative technology (see Lovins and Price 1975). All these critiques continued to see science as universal knowledge but felt that technology was local and adaptable. They believed that local knowledges, ethnosciences, could be brought into play to produce a more local and creative technology less discordant with culture. A fourth approach, however, sought to challenge the epistemological hegemony of science, seeking an alternative basis for science through critiques of Judeo–Christian cosmology and the ethnocentrism of modern science. The Indian chemist C. V. Seshadri argued that if the notions of efficiency implicit in the laws of thermodynamics were applied to Third World societies operating at ambient temperatures, such decisions would work against tribals in the Third World, or peasants opting for indigenous or traditional agricultural practices (Seshadri 1993). The idea of intermediate technology and the emphasis on local knowledges was gradually adopted in World Bank models of technology transfer. The epistemic critique however faced a more ambiguous fate and was subjected to benign neglect.

All the above critiques tried to modify TOT as an antiseptic managerially limited discourse and to relocate it within the wider politics of knowledge and production. They reworked technology within an ethical worldview, arguing that the transfer of technology was also a transfer of values (see George 1984, pp. 75–6). Ivan Illich's work on education, medicine, and energy was a critique of the basic professionalism implicit in the TOT model (1992). He saw it as a disabling, iatrogenic programme, a cultural code for disempowerment.

The effervescence of these critical movements dimmed by the 1990s, though they continue to inspire the struggle against large dams, the critique of forestry, and the logic of urban planning in Third World countries. Intermediate technology in its heyday produced a flowering of locally sensitive technologies such as biogas and modified kitchen stoves, and also revived traditional technologies for housing (see Warren et. al. 1995). As dissenting imaginations, they were powerful, but their critical edge was blunted or absorbed by the UN sponsored idea of sustainable development. Sustainable development gave the TOT model a new lease on life by offering the possibility of a balance between ecology and development, renewability and productivity, the long run and the short run.

By the 1970s and 1980s, Science and Technology Studies (STS) had advanced beyond marginality to produce a more variegated set of discourses. The resurgence of the economics of scientific knowledge revitalized studies of the R&D system. Till the 1960s, economists thought that knowledge, like waste, was something external to the production system. Knowledge was not treated as a factor of production like land, labor, or capital. The work of Jewkes et al. (1958), Rosenberg (1976), Freeman (1974), and Machlup (1962) had a far-reaching impact in visualizing technology transfer as a policy discipline. They provided systematic studies exploring the relation between R&D expenditure and rates of productivity. They emphasized the systematic role of patents in evaluating the productivity of such systems and

introduced methodologies of cost-benefit analysis to audit TOT processes. In all, they provided a fine-grained set of analytical constructs and empirical studies that helped professionalize science policy as a discipline. They also emphasized that the rationality of the firm was altered by the military-industrial complex.

2. *Transfer of Military Technology*

The conceptual world of technology transfer still operated at a split-level with a tendency to dichotomize civilian and military transfers of knowledge. One link between the two was the concept of 'spin-off,' the idea that investments in military research eventually had civilian potential and therefore legitimized the former. The other was the idea of conversion which suggested the transformation of swords into ploughshares, a notion which became popular after the Cold War. One of the finest critiques of military innovation chains was Mary Kaldor's *Baroque Arsenal* (1982). Kaldor argued that while military technology was once innovative, it had become decadent or baroque after World War II. She traced the baroquization of military technology to the interaction between 'the capitalist dynamic of arms manufacturers and the conservatism that characterizes armed forces and defence departments in peace time' (Kaldor 1982, p. 4). Baroquization is a consequence of the paradoxical dynamic between, on the one hand, armies which cling to designs from the previous war and, on the other, the competition to stay in business and win contracts that demands incessant technological effort.

The consequence is an involuted technology of perpetual improvements within a conservative framework. What we face is a narrowing of options, greater uniformity, and diminishing returns. More and more money is expended on small improvements ultimately to obtain military hardware which is difficult to maintain. Cost factors increase to such an extent that by 2020, Kaldor suggests, the defence department might be able to afford one plane. Built into such technology as well is planned obsolescence. What was created by Alfred Sloan of General Motors for the car becomes a part of weapons systems. The useful life of a weapon is much shorter than its physical life because of the inexorable power of obsolescence. The emphasis is more on luxuries, accessories, and minor improvements.

Kaldor warned that such military technology when transferred is dangerous both for industrialized and industrializing countries. She argued that the idea of 'Atlanticism' is not just a set of treaties, but a shared technological paradigm posited on a bipolar confrontation between Western and the (then) Eastern totalitarian systems (see Kaldor 1987, p. 143). She showed how the security concerns of the UK, France, and Germany make them replicate the baroque technologies of the USA, resulting in similar cost overruns and duplication. Worse, alternative forms of defence, including Precision Guided Munitions (PGM) which implied decentralized and dispersed military organizations, could not be developed.

The impact of arms transfers is predictable in developing countries, as illustrated for instance in the regime of the Shah of Iran. The high incidence of arms transfers impairs the capacity to import what is needed for development and industrialization. Once a weapon system has been imported, a chain of supplementary imports is induced. Modern fighter aircraft, tanks, and naval units require an extensive network of support facilities including spare parts and presence of foreign experts. 'The installation of sophisticated military infrastructure is also suboptimal for the development process and often negative for existing traditional infrastructures. Simply put the stability of triage or a road for a tank has to be much higher than for a bullock cart' (Locke and Wulf 1984, p. 114). The chain of demands appears endless. This pervasive logic of military technology independently suggests that Third World nations can arrive at a self-reliant position in military technology only if they abstain from imitating the military paradigms—both doctrines and weapons systems—developed in the context of the confrontation between industrialized nations. In this context, the Vietnam War was a model confrontation between two modes of technology transfer. Unfortunately the debate did not sustain itself into the new millennium.

Technology transfer as a discourse made incremental responses to new problems. It responded gradually to issues of obsolescence, pollution, proliferation, risk, spin-off on separate grids, while also keeping civilian and military processes on separate registers. There was a need to link concepts such as obsolescence and proliferation. If obsolescence raised problems of value and time in TOT models, proliferation emphasized the question of excess. Military technology represents the classic case, but all too often military technology transfer is restricted to a limited scenario with the legitimate nation-state as actor, without realizing that the smuggler, the mercenary, and eventually even 'rogue states' may be the agents of proliferation or illegitimate transfer.

Proliferation is officially impermissible diffusion. It is a cancerous threat to the ordered chaos of diffusion. As good civics, diffusion reinforces the system of innovation. Nuclear proliferation, however, threatens it, demanding a network of laws, treaties, alliances to restrict its flow. One is simultaneously caught in the debate between atoms for peace and atoms for war, unless one agreed with Robert Jungk (1976) that the distinction was a spurious one, difficult to maintain empirically. The question of proliferation was handled at two levels—technologically as well as legally and politically. Technological measures attempted to control latent proliferation through interventions in the nuclear fuel cycle. Scientists have proposed that

proliferation resistance become a design criterion for nuclear energy systems through such techniques as isotopic denaturing. There was, however, a realization that such technical measures needed to be complemented with the political. Within the political domain, proliferation was met by two general strategies. First was the universalist argument in which, through the Nuclear Non-Proliferation Treaty and other legal measures, a full framework of integrated treaties worked for the elimination of nuclear regimes. The other, more restricted effort seeks to argue that a *controlled* spread of nuclear energy alters the behaviour of adopting states, adding a dose of restraint and confidence to their behaviour.

3. *TOT and the Risks of Development*

Throughout the 1960s to the 1980s, the TOT discourse operated between the axes of disarmament and development. It took four decades of development for experts to realize that development, the chief objective of TOT, might produce more refugees than war. India by some counts has over 40 million refugees from development projects; in fact it arguably has more refugees from development than from the wars it has fought after independence. Not unnaturally, some grassroots groups considered TOT as a continuation of war by other means (see for instance, Visvanathan 1997, p. 41).

The accidents at Windscale, Chernobyl and Bhopal introduced into the public sphere of TOT discourse the concept of risk and the more comprehensive idea of the risk society (Beck 1992). The 1984 gas leak at Bhopal, India, the world's biggest industrial disaster, proved that international transfers of technology needed to be located within a wider ethics of responsibility than mere compensation. One needed not only a more systematic right to information and disclosure but also ideas of justice and rehabilitation beyond monetary compensation. The issues of pollution and the proliferation of hazardous waste facilities introduced into the TOT domain new and enlightened legal ideas, including the polluter pays principle. Actors within the legal system realized that as technology moves from certainty to uncertainty, and even to risk, one has to redefine both the rationality of technology and the notion of responsibility. With the rise of environmentalism, risk assessment became a significant element of the TOT discourse. It also brought to the forefront the latent public aversion to science, as enacted in citizens protests. One had to ask whether citizens' worries about environmental hazards from carcinogenic pesticides, nuclear wastes, loss of global ozone was grounded, and then to develop methodologies for resolving such controversy. The work of Douglas and Wildavsky (1982), Brian Wynne (1987), Kristin Shrader-Frechette (1991) were all attempts in that direction, but with different sensitivities to the requirements of science and the demands of democracy.

The question of risk also prompted inquiry into the rationality behind technology. Ulrich Beck (1992) went so far as to institutionalize the problem. Beck argued that in advanced industrial society the social production of wealth is accompanied by the social production of risks. He claimed one needed a new concept of a risk society with which one not only acknowledged that modernization produces risks, but one also systematically and openly sought to answer how risks could be 'prevented, minimized, dramatized and extended' (Beck 1992, p. 21). The notion of the risk society led to a range of debates in the social sciences, raising interesting questions about the role of experts in technology transfer, the question of trust in science, and the construction of scientific knowledge itself.

Meanwhile a revisionist history of the Green Revolution was altering the perception of one of the paradigmatic successes of the technology transfer discourse. The Green Revolution, a project which involved the transfer of hybrid, fertilizer-sensitive seeds to India, Pakistan, and other developing countries, was originally seen as a benign example of successful TOT which saved these countries from starvation and made India self-sufficient in food. Norman Borlaug, one of pioneers of the Green Revolution, received the Nobel Prize for peace. Robert Anderson challenged the received wisdom of the Green Revolution by arguing that it involved not merely high yielding packages of seed, pesticides and fertilizer but also incorporated social ideas of changing agricultural society. 'The broad economic links between modernized agricultural production and US economic interests were crucial elements in the strategy from the beginning' (Anderson et. al. 1991, p. 361). Francesca Bray, arguing from a different perspective, showed that Green Revolution concentrated on only a few crops, 'wheat, and rice for human consumption, corn and soybean for animal feed and cotton for industry' (Bray 1994, p. 30). The capital-intensive, highly mechanized model hastened soil erosion and environmental degradation. Bray and later Vandana Shiva (1992) particularly attacked the monocultural mindset behind such transfer of technology, which ignored the productivity and sustainability of polycultural systems, which not only used several varieties of crop but had several uses for various parts of the crop. Such crops were also resistant to pests. It was the impoverishment of gestalts that constitutes the most devastating aspect of the critique of the Green Revolution as TOT.

4. *TOT and Biotechnology*

But narratives change and so do battle sites. By 1990, even its pioneers recognized the Green Revolution as a dated narrative. The productivity levels of wheat and

rice had levelled off and the scene shifted to biotechnology as the site for the second Green Revolution. While critiques of the Green Revolution came after the event, the movements against biotechnology were spawned almost simultaneously.

The question of the transfer of biotechnology raises fundamental questions for the innovation process in the Third World countries. Pat Mooney (1983, 1998) documents how many crops developed by farmers over centuries became the property of a multinational at the stroke of a pen. Patenting, which was seen as a legal frame for recognizing original innovation, became a technique for appropriating the legacy of innovation in agricultural societies. Important controversies in the 1990s centred around *neem* and *basmati* rice. The growing opposition to chemical products led to a search for natural pesticides and to the *neem*. By 1985, US and Japanese firms had taken out a dozen patents on *neem* pesticides and *neem* toothpaste. The question one has to ask is whether *neem* patents constitute novel forms of knowledge or are such forms of novelty only based on the ignorance of a 2000-year-old tradition of biopesticides in India?

The controversy over *basmati* rice raised similar issues. In 1997, a patent was granted to Ricetech, Inc., a US company, on *basmati* lines and grains. The *basmat*i variety was derived from the Indian *basmati* and crossed with semi-dwarf varieties. The question is whether Ricetech *basmati* is the Indian *basmati* and novel at the same time. If *basmati* patents were recognized in India, Indian farmers would ironically be forced to pay royalties to Ricetech.

A patent does not recognize the prior custody of farmers over their seeds. There is no recognition of prior art. Culturally, the patent defines agriculture as an activity performed in a laboratory rather than on a farm. It is a derecognition of an entire intellectual commons. The juridical framework of GATT and TRIPS has possibilities of becoming a new enclosure movement—comparable in spirit to the actions of fifteenth century British landowners—which turns a farmer who saves and replants the seed of patented or protected plant into a violator of the law.

There was a second, equally fundamental problem. Hybridization disables the seed from reproducing itself and forces the farmer to return to the breeder for further stock. Farmers who were custodians of the seed now were systematically deskilled both by technology and law. Finally, there is the ethical question of whether life forms can be patented at all as many of these communities locate the seed within the domain of the commons and the gift.

4.1 TOT and Information Technology

If biotechnology appears as a dismal science for the TOT process, information technology, as a narrative, was more celebratory. The rise of technologically innovative groups in Silicon Valley, California, created a new paradigm for industrialism outstripping in its impact Boston's legendary Route 128 (Castells 1996). Silicon Valley created a false belief that distance and location did not matter in the transfer of technology. Over the last decade, governments in India, China, Malaysia have pursued the holy grail of reinventing Silicon Valleys in their countries. Information technology and the legend of the innovative successes of Bill Gates and Sabir Bhatia, of Oracle, Sun Microsystems, and Intel created a myth that innovation chains could reproduce themselves anywhere. As Manuel Castells remarked:

> The development of the information technology revolution contributed to the formation of the milieux of innovation where discoveries and applications would interact, and be tested, in a recurrent process of trial and error, of learning by doing; these milieus required (and still do in the 1990s, in spite of on-line networking) spatial concentrations of research centres, higher education institutions, advanced technology companies, a network of ancillary supplies of goods and services, and business networks of venture capital to finance start-ups. (Castells quoted in Mcgray 1999, p. 153)

Information Technology is symptomatic of the cornucopian myths present in TOT. At its most reductive level, technology transfer is a methodology of hope combining the powers of science and technology. It appears as a discourse on management but, as it unravels, its reaches beyond management to the complexities of law, political economy, ethics and anthropology. What begins as a science policy issue transforms itself into a multidisciplinary exercise. Technology transfer is one of the great myths of the twentieth century, a belief that science and technology, if naturally diffused, can fulfil any democratic dream. It is the task of science and technology studies to show the lags, the gaps, the ironies that sustain the myth. What one needs to chronicle is these very lags, gaps, worries and possibilities as the myth of TOT acts itself out in the form of policy.

Teen Sexuality

Since the 1950s, societal views of sexuality have changed dramatically, and with those changes, there has been an increased focus on teenage sexuality. Sexual activity among teenagers has increased while the age that teenagers begin sexually experimenting has decreased. Although the exact nature of the association is unclear, sexual intercourse at an early age has been consistently linked with greater psychological risks (e.g., problem behavior, substance use, poor school performance, and disrupted family and parental relationships). Unsafe sex practices and limited sexual and contraceptive knowledge place adolescents at high risk for sexually transmitted diseases (STDs) and early childbearing (Bingham and Crockett 1996).

1. *Definition*

'Teenage sexuality,' a difficult term to define, includes two complex themes: teenage and sexuality. By teenage, most researchers refer to the adolescent years or adolescence. Adolescence begins at puberty, with physiological and hormonal changes. While entrance is defined largely by biological markers, exit has become less clear. Within contemporary Western society, the legal age of 18 has been the traditional marker for the end of adolescence and the beginning of adulthood. With a changing economy and societal structure, for many, education extends beyond the age of 18 and traditional hallmarks of adulthood (e.g., financial independence, marriage, and childbearing) are postponed. Given that adolescence covers the ages of approximately 12 to 21 years, researchers often talk about early, middle, and late adolescence, each period with its own developmental characteristics.

Sexuality encompasses a wide array of domains including sexual behaviors, attitudes, and knowledge (Miller et al. 1986), sexual identity (see Miller and Simon 1980), sexual orientation (see Savin-Williams and Rodriguez 1993), contraception, and pregnancy (see Piccinino and Mosher 1998). Although the sociali-

zation of sexuality begins in infancy, when gender role expectations and identity are imparted, it is in adolescence—when biological factors interact with social expectations—that sexuality becomes a central issue of development. Within the context of other developmental goals, the adolescent is expected to become a 'self-motivated sexual actor' (Miller and Simon 1980). This article will focus on sexuality among heterosexual adolescents, including current statistics on behavior and attitudes, an overview of theoretical and historical perspectives, measurement issues, and directions for future research.

2. *Current Statistics*

Since the 1950s, we have seen a dramatic increase in the rates of sexual activity among teenagers in the USA. Teenagers of both sexes are having sexual intercourse at younger ages than ever before. By the age of 17, more than 50 percent of teenagers report having had sexual intercourse, and by age 19 that figure jumps to approximately 80 percent (Singh and Darroch 1999). Traditionally, boys begin having sexual intercourse earlier than girls, but that gap has decreased steadily in recent years (AGI 1994). Sexual intercourse before the age of 15 is still relatively rare with approximately 80 percent of teenagers reporting that they are sexually inexperienced at the age of 15. Sexual intercourse prior to the age of 13 is reported by adolescents as mostly nonvoluntary or unwanted (Singh and Darroch 1999).

Encouragingly, pregnancy rates among teenagers have declined 17 percent from 1990 to 1996. Contraceptive use at first intercourse increased during the 1980s from 48–65 percent with the use of condoms doubling. By 1995, 78 percent of sexually active teenagers reported using some form of contraception at first intercourse, with 66 percent of these adolescents using condoms. Overall, 90 percent of sexually active teenagers report using some form of contraception. Unfortunately, a large percentage of this group do not use contraceptive methods consistently or correctly (Piccinno and Mosher 1998). Despite an increase in contraceptive use, 25 percent of sexually active teenagers will still contract an STD during adolescence, and 19 percent of sexually active girls will get pregnant before the age of 19. Seventy-eight percent of teenage pregnancies are reportedly unplanned.

3. *Theoretical and Historical Perspectives*

No single theory has adequately explained adolescent sexuality. In their overview of several theoretical perspectives on adolescent heterosexual behavior, Miller and Fox (1987) focus on two major but conflicting paradigms on sexuality: sexuality as an emergent drive and sexuality as a socially learned behavior. The first paradigm, sexuality as emergent drive, encompasses biologically-based (e.g., Udry et al. 1985), psychologically-based theories (e.g., Jessor and Jessor 1977, Miller et al. 1986), and theories of social control (e.g., Hirschi 1969, Parsons 1951).

Biological influences help explain some of the social changes in adolescent sexual behavior (Dyk 1993). Since the mid-nineteenth century, the onset of puberty has dropped gradually in age for both boys and girls. For example, in the 1850s the average age of menarche was 17 years. By 1990s, the average age was 12 years (Dyk 1993). In support of biological theories, a growing body of research suggests that male hormones play an identifiable role in shaping the sexual behavior of adolescents, both boys and girls. For example, a measure of serum androgenic hormones, known as the 'free testosterone index,' was shown to be predictive of virginity status, sexual behavior, and noncoital sexual behaviors among adolescent virgins (e.g., hand holding, kissing) (see Udry et al. 1985).

The view of sexuality as an inner drive also encompasses psychologically-based theories. Early sexual behavior among adolescents has been portrayed as an attempt to satisfy a strong need for affiliation or intimacy (Miller et al. 1986), or a desire for excitement or novelty (Miller and Fox 1987). Although self-esteem and expectations for achievement have been touted as the best predictors of sexual behavior, results from longitudinal studies have yielded inconsistent and contradictory results (Jessor and Jessor 1977).

Social control theories have sought to explain why many adolescents do not act on their biological impulses and look to processes that serve as restraints. Parsons (1951) and Hirschi (1969) propose models of social constraint centering on the roles of parents. In Parsons' model, parents 'serve as policing agents of the social order' (Miller and Fox 1987, p. 273). Parents deter the sexual behavior of their adolescents through rules, supervision, and surveillance. Hirschi's (1969) model stresses the parent–child bond as the constraint mechanism. Because of the emotional bonds formed with parents, and consequent desire to please, adolescents conform to parental expectations.

In contrast to emergent drive-based theories, socialization paradigms (i.e., the process through which acceptable behaviors in a given society are taught and learned) posits that sexuality is socially shaped more than internally driven. Areas of inquiry include how society shapes the expression of sexual behavior, how certain sexual behaviors come to be viewed as appropriate or inappropriate, and how erotic meanings come to be attached to certain objects, persons, or behaviors. Because parents serve as models through which accepted behaviors and norms of a society are learned, parents are considered crucial socialization agents and their influence has been widely investigated. Communication, particularly discussions about sexual issues between mothers and their young adolescents, has a strong influence on the attitudes adolescents

have about sexuality and sexual behaviors (Jessor and Jessor 1977, Treboux and Busch-Rossnagel 1995) During this age period, peers also serve as strong socialization agents. Adolescents often exert explicit pressure on each other to conform to a standard of behavior and look to their peers as a reference point or standard by which they can measure their own behavior. For example, adolescent girls are less likely to become sexually active if their best friends are virgins as well (Billy and Udry 1985). Research suggests that the relative influence of parents and peers may differ as a function of the age of the adolescent. For younger adolescents, parents appear to have a strong influence on sexual behaviors and attitudes, but this influence declines as teenagers approach later adolescence and peers become more influential (see Treboux and Busch-Rossnagel 1990, 1995).

In addition to proximal influences on behavior, contextual factors (e.g., religion, economy, and culture) shape views of teenage sexuality. Reiss' (1967) sociological theory of premarital sexual permissiveness stresses that changes in individual sexual behavior mirror shifts in social views. Prior to the 1960s, intercourse outside of marriage for adults was widely disapproved, especially for women. In the 1990s there was a greater acceptance of premarital sexual activity among adults (see Downs and Hillje 1993 for an overview of historical perspectives on adolescent sexuality). Although social attitudes regarding adult sexual behavior and preadolescent behaviors are clear across Western subcultures, mixed attitudes regarding adolescent sexual behaviors prevail. Young people are biologically defined as sexually mature while simultaneously defined as socially and psychologically immature. Caught in a transitional stage between childhood and adulthood, the task of integrating differing views from the larger society as well as peer subcultures may be quite confusing for adolescents (Graber et al. 1998).

Some researchers have integrated the two approaches, examining both innate and learned influences. Using a biosocial model, Smith (1989) argues that biological factors (i.e., onset of puberty, the variance in hormonal levels) play a clear role in adolescent sexual behavior, but these biological changes are mediated by social and cultural forces and expectations. Smith further suggests that these two influences may fluctuate, with one force becoming stronger than the other at different times. A late maturing girl may not have a strong biological influence to become sexually active at an early age, but within a social setting that accepts and encourages sexual promiscuity (e.g., a peer group of early maturing sexually active girls), she may be influenced to engage in sexual activity. Within a biosocial framework, both components are consistently interacting to affect sexual behavior and attitudes (Smith 1989). Although useful as a conceptual model, it has yet to be tested empirically.

4. *Methodological Concerns*

The nature of the population (i.e., minors) and the topic lead to inherent methodological problems, namely sample and self-report biases. As required of all minors, parental consent is mandatory and often difficult to obtain. Parents are often concerned that simply being asked questions of a sexual nature will encourage their young adolescents to become sexually active.

Even when parents consent, teenagers may be tempted to overstate behavior if they are embarrassed at their lack of sexual activity. In a longitudinal study, Alexander et al. (1993) examined the issue of consistency in reports along three dimensions: whether or not respondents had ever had sexual intercourse, the number of lifetime intercourse experiences, and the age of first intercourse. One year later, 90 percent of adolescents were consistent in their reports of virginity, and 85 percent were consistent in reporting the number of lifetime experiences. However, only 43 percent were consistent in reporting their age at first intercourse.

Designed to explore the causes of adolescent health behaviors, the National Longitudinal Study of Adolescent Health (Udry and Bearman 1998) uses technology to address such methodological problems. Adolescents, grades 7 through 12, enter their responses directly into a computer. Automatic skip patterns prevent students from viewing questions that they are not meant to answer. For example, if participants respond that they are not sexually active, they will not see questions regarding sexual partners, contraception, and so forth. This is an important feature for several reasons: (a) it helps assuage parental concerns that children will 'get ideas' from sex-related questions; (b) it prevents teenagers from lying to match their peer behavior; and (c) the absence of interviewers in the room and a hard copy at the end of the session promotes assurance of confidentiality of responses.

5. *Directions for Future Research*

To date, most psychological and sociological studies have taken an epidemiological approach toward adolescent sexuality. We know who is having sex, at what age, and with whom. We also know that there is an association between adolescent sexual activity and other psychosocial behaviors. However, we have yet to explore fully the meaning that sexuality holds for teenagers. Until recently, research on adolescent sexuality has not been embedded in a developmental framework. As Graber et al. (1998) stress, the adolescent life phase is a period of dramatic change and developmental challenges. Research that examines sexuality within the context of these other changes would provide more meaningful information.

Although researchers stress the importance of considering the influences of culture and religion, as well as integrating the influence of biology, there is sparse research exploring the roles of these influences and/or examining the contexts of community, school, peer group, family, friends, and romantic partnerships. New models and methods of research designed to take more developmental and holistic approaches to the study of adolescent sexuality are needed (e.g., Cairns et al. 1998).

The Add Health project (Udry and Bearman 1998) is currently attempting a longitudinal study using such an approach. The study is unique in its exploration of the roles various relationships—romantic sexual partners, nonromantic sexual partners, same sex as well as opposite sex relationships—are playing in the lives of teenagers. The longitudinal nature of the sample will allow us to examine the natural progression of these relationships.

Finally, because statistics point us to the middle and late years of adolescence as the age where sexual activity begins (Singh and Darroch 1999), most research naturally focuses on the sexual behavior and attitudes of adolescents over the age of 15. Bingham and Crockett (1996) found that psychological adjustment problems associated with early sexual activity are present prior to first intercourse, not as a result of early sexual intercourse. Thus, a greater understanding of the attitudes and behaviors forming in younger adolescents and middle school age children is of great import.

Teenage Fertility

In traditional societies, the transition from childhood to early adulthood usually occurs rapidly around the time of puberty. For women this almost always means entry into marriage and childbearing. In industrialized

societies, however, preparation for the assumption of adult responsibilities requires extensive further education and job training for both men and women. Thus, the modern way of life has led to a period of adolescence, covering roughly the teenage years, during which young people are capable of reproduction but have not yet achieved the economic and social independence necessary to support families of their own. In any given society, childbearing at this stage may be seen as more or less problematical, depending on both the level of development and the particular culture. The topic is now of special importance, because of the surge in the numbers of teenagers worldwide. The focus in this entry is almost entirely on females; although the issue clearly involves males as well, men are less likely on the whole to become fathers while they are still teenagers, the consequences of parenthood are apt to fall less heavily on them, and, most importantly, very little information is available on male fertility.

1. Patterns

1.1 Birth Rates for Women aged 15–19 Years

The most commonly used measure of teenage fertility is the age-specific birth rate for women 15–19 years old, i.e., the number of births to women in this age group divided by the number of women in the age group. Although some births occur among women below 15 years of age, relatively few of these younger women are exposed to the risk of childbearing, and the usual practice is simply to add these births to the numerator of the rate for women aged 15–19. The implications of childbearing tend to be quite different for women aged 15–17 from those aged 18–19 and, ideally, the rates for the two groups should be separated, but the necessary data are not often available.

Table 1 shows age-specific birth rates per thousand women aged 15–19 in the 1970s and the 1990s for the major regions of the world and their component subregions, as defined by the United Nations. At the regional level, the rates range from a minimum of around 30 for Europe to a maximum that is about four times as high in Africa, where as many as one woman out of eight in this age group gives birth yearly.

There is considerably more variation in the rates for subregions. North America, Australia and New Zealand and the four subregions of Europe comprise the great majority of developed countries. Within this group, the rates for the 1990s are very low in Western and Southern Europe, and are particularly elevated in Northern America (dominated by the USA) and in Eastern Europe (dominated by the former USSR). The underlying national data show that relatively high rates of teenage fertility are common to all of the English-speaking countries. Among less developed areas, the picture in Asia is extremely varied: in the 1990s, Eastern Asia (dominated by China but also including Japan, a highly developed country) exhibits the lowest rate of any subregion, while teenage fertility in South-central Asia (dominated by India, Pakistan and Bangladesh) is higher than anywhere else outside of Africa. Intermediate levels are found in Latin America and the Caribbean and in Other Oceania. The rates are extremely high in sub-Saharan Africa.

In all regions and most subregions, the rates had declined since the 1970s. At the regional level, the steepest drop (24 percent) occurred in Asia. This is due largely to an 86 percent decline in Eastern Asia and took place despite very little downward movement in South-central Asia. The rates rose substantially in two subregions, however: by one-third in Southern Africa (dominated by South Africa) and by one-quarter in Eastern Europe.

1.2 Teenage Fertility Relative to Overall Fertility

In addition to age-specific fertility rates, it is useful to consider teenage reproductive behavior in the context of that of all women, i.e., to examine the proportion of the total fertility rate (TFR) contributed by women aged 15–19. (The TFR is a hypothetical measure representing the number of children a woman would have if she experienced throughout her reproductive career the actual fertility rates of women in each successive age group at the time and place of observation.) These percentages are also shown in Table 1; in the 1990s, they range from less than one in every 30 births (3 percent) in Western Europe to one birth out of six or seven (16 percent) in Eastern Europe.

Comparison of the percentages between the 1990s and the 1970s reveals that in some cases the trends in teenage childbearing noted above parallel those among older women. In Eastern, Middle and Western Africa and Northern America, the rates for women aged 15–19 represent approximately the same proportion of the total fertility rate in the 1990s as in the 1970s. In many subregions, however, teenage rates changed independently of shifts in overall fertility. Adolescents came to account for a much larger fraction of all births than formerly in Eastern Europe and South-central Asia, and their share also grew throughout Latin America and the Caribbean and in Southern Africa. The opposite is true in other parts of Asia and Europe, especially Eastern Asia and Western Europe and, to a lesser extent, in Northern Africa as well as in Australia and New Zealand.

1.3 The Proximate Determinants of Fertility

To understand these patterns, it is necessary to examine the behaviors immediately antecedent to

Table 1
Age-specific fertility rates for women aged 15–19 and percentage contribution to total fertility rate

Region and subregion	1970s Rate per 1,000	1970s Percentage of TFR	1990s Rate per 1,000	1990s Percentage of TFR
Africa	132	9.9	117	10.6
Eastern Africa	147	10.2	137	10.6
Middle Africa	182	14.0	159	14.0
Northern Africa	114	8.7	44	5.8

childbearing. Variation in teenage fertility can be very largely explained in terms of three factors: sexual activity (marriage), contraception and abortion. These are known as proximate determinants of fertility.

A young woman is at risk of pregnancy and childbirth only after she becomes sexually active. Both age at initiation and frequency of intercourse thereafter are important dimensions of sexual activity. There is evidence that age at menarche is now dropping in developing countries as it did earlier in Western countries, creating the possibility of exposure to risk starting sooner than was previously the case. The proportion married among women of reproductive age was considered originally to be an appropriate indicator of exposure to risk and remains so in most of Asia. Elsewhere, however, this measure has become unsatisfactory because nonmarital childbearing is much more common than it was formerly in many parts of the world and because of greater awareness that in some cultures marriage is not an easily identifiable event.

Among sexually active women, the use of contraception can reduce substantially the likelihood that pregnancy will ensue. Contraceptive methods vary, however, in their effectiveness, acceptability and ease of use and thus in their probability of failure. Moreover, young women tend to be less likely than their elders to know about contraception and to have less access to acceptable services, including an adequate choice of methods. In many countries, unmet need for family planning services is concentrated in the early years of reproductive life.

When pregnancy occurs, it does not always lead to a birth. Teenagers are often unready to start childbearing and may seek induced abortion even if the procedure is illegal and unsafe. Because very young women often do not recognize or accept that they are pregnant, however, or because abortion services are not readily accessible, their pregnancies are often relatively advanced before they reach a provider. Reliable data on induced abortion exist for only a few mostly developed countries, making it difficult or impossible to assess its role accurately in many cases.

Differing levels and trends of adolescent fertility are largely a reflection of variation in the balance of these three factors. Very high rates, such as those found in sub-Saharan Africa and South-central Asia, necessarily imply a high level of sexual activity, minimal use

of contraception and infrequent abortion. In the traditional societies of sub-Saharan Africa, early childbearing has typically been widely accepted if not encouraged and often occurs before finalization of a marriage. Recently, growing numbers of young women have attempted to postpone marriage and childbearing, but many are nevertheless sexually active, tending to keep fertility high. In South-central Asia, sexual activity is still confined essentially to marriage, but marriage often occurs shortly after puberty, and childbearing starts soon thereafter. Contraception and abortion do not play a significant role in either of these subregions.

At the other extreme, low rates of teenage fertility may be due to little exposure to risk, extensive use of contraception, widespread abortion, or any combination of these conditions. Late marriage and social pressure to postpone sexual activity until marriage, backed up by easy access to abortion, accounts in large part for the very low rate in Eastern Asia. Although very few women marry below age 20 in most countries of Northern and Western Europe, a substantial majority become sexually active during their teenage years. Effective, modern means of contraception are widely used; abortion is legal, safe and accessible but not often necessary. The elevated birth rate in the USA appears to be due not to greater exposure to risk but rather to less successful pregnancy prevention; there is a high incidence of abortion as well. The situation has been somewhat different in Eastern Europe, where early marriage has been common and abortion the only widely available means of fertility control.

2. *Consequences*

In recent years, increasing attention has been given to the negative consequences of teenage childbearing. There is concern both about health effects and about social and economic effects. Such effects may relate to the individual mother and child, to society at large or, very often, to both. Their impact typically varies with the age and marital status of the mother. Younger adolescents tend to be much more seriously affected than older adolescents. Although issues associated with single parenthood have been most prominent, very young married women may encounter somewhat different but equally grave problems.

2.1 *Health Effects*

Research has shown that teenage mothers and their infants face significantly greater health risks than do older women. Some, particularly those resulting from physical immaturity, are a direct function of age. Declining age at menarche enhances the opportunity for conception among women who are still in their early teens. Social factors also play a prominent role, however. The impact of age itself is often exacerbated by poverty, lack of autonomy and, in some situations, specific cultural customs. Moreover, a high proportion of births to adolescents are first births, which are more likely than subsequent births to incur medical complications.

Pregnant teenagers frequently suffer from hypertension, iron-deficiency anemia and premature labor. Childbirth presents the risk of cephalopelvic disproportion (when the pelvis opening is not wide enough to permit passage of the infant's head, resulting in prolonged labor and/or obstructed delivery), hemorrhage and infections. Female genital mutilation, a practice that is common in parts of Africa, increases the likelihood of obstructed delivery and other complications of childbirth in addition to its negative effects on women's general health and sexual functioning. In addition, the infants of very young mothers exhibit higher rates of morbidity and mortality than those of older women, often associated with low birth weight.

Sexual activity in itself carries potential threats to the health of adolescent women. Sexually active teenagers are at high risk of contracting sexually transmitted diseases (STDs) including HIV/AIDS. In some parts of sub-Saharan Africa, STD infection rates are higher among young women than among either young men or older women. Unsafe abortion is a major factor contributing to high maternal mortality in many countries, and teenagers are over-represented among women treated for complications following such procedures.

2.2 *Social and Economic Effects*

Research in both developed and developing countries indicates that, for most teenagers, childbearing also has lasting unfavorable social and economic consequences. The relationships are nevertheless complex and the causal sequences difficult to disentangle. In addition, the effects are highly variable, and a substantial proportion of women may experience no discernible disadvantage.

Becoming a mother necessarily involves the assumption of certain adult responsibilities. In the traditional societies that still exist in some parts of the world, this is the role expected of females. As long as they are in socially recognized unions, new mothers and their infants take their place in established systems of support that include their partners, other family members, and the community at large. For vulnerable young women, motherhood may offer the only clear path to security and social acceptance. But by the same token, their future options are often limited, while, at the community level, their potential contribution to the growth of human capital and economic output is foregone.

The forces of modernization have nevertheless penetrated even remote corners of the globe. More young women are staying in school beyond the primary years. On the one hand, education delays marriage and childbearing and, on the other, it provides skills, promotes self-reliance and stimulates aspirations for new roles. Unplanned births are likely to arrest this process, however, especially if, as commonly happens, they occur outside of recognized unions and the men involved fail to acknowledge paternity. The mother cannot always count on the support of her family and may be forced to raise the child on her own. In some countries, opportunities for young women to participate in the paid labor force have also opened up with effects that are in some respects similar to those of extended schooling. Moreover, education is an investment that ultimately benefits society at large and employment contributes directly to the economy.

In a few industrialized countries, particularly the USA, the social and economic impact of teenage childbearing has been the subject of considerable investigation. In the USA, the majority of teen pregnancies are unplanned and, relative to other countries, fertility rates are particularly high among women less than 18 years of age. When the issue came to the fore in the 1970s, it soon became clear that early motherhood is linked closely with low education, limited opportunities for employment and poverty later in life. A high proportion of the births occur outside of marriage, and the fathers often provide little or no support. Associations with marital instability, large family size and problems in the children's behavior and cognitive development have also been documented. Although it was initially assumed that having a child at a young age is in itself largely responsible for such detrimental outcomes, it is now widely acknowledged that the mothers tend to be selected from a subgroup of women who were already at a disadvantage beforehand, and that causation typically runs in both directions. Even when prior factors are taken into account insofar as possible, however, a negative impact remains. Ultimately, poor, young single mothers must often depend on public support, placing a burden on community resources and creating a dependence that tends to perpetuate itself from one generation to the next. In most other Western countries, non-marital childbearing has also become more common among women of all ages, but the mothers are nevertheless likely to be in stable sexual partnerships, and this lifestyle has become widely accepted.

Whether in modern or traditional societies and whether or not the birth occurs in an established union, a considerable age difference between the young mother and the father of her child is common. In traditional cultures, men must often wait until they have acquired a certain seniority before they marry. In more modern societies, young women may seek the protection of or be exploited by older men. Such relationships are inherently unequal, hindering free communication, preventing the development of mutually supportive partnerships and depriving women of their essential autonomy.

3. *Policy Responses*

3.1 *International*

The international community has only relatively recently singled out adolescent childbearing as an independent issue and begun to deal explicitly with it. The Programme of Action adopted at the 1994 International Conference on Population and Development in Cairo urges governments for the first time to 'protect and promote the rights of adolescents to reproductive health education, information and care' and to 'greatly reduce the number of adolescent pregnancies.' It recognizes the rights of young women to privacy and confidentiality and their special needs with regard to sexual behavior and reproduction. The recommendations of the preceding conference held in Mexico City in 1984 concerning adolescents were limited to calls for family life and sex education 'within the changing socio-cultural framework of each country' and for an effort to 'reduce maternal mortality and morbidity' due to pregnancy and childbearing at young ages. The World Plan of Action adopted in Bucharest in 1974 did not mention adolescents specifically at all.

3.2 *Developing Countries*

In some countries, especially in Eastern Asia, age at marriage has risen considerably without undermining the traditional function of marriage as the only acceptable context for sexual activity and childbearing, and there is little call for governmental action. In many other parts of the developing world, however, the effect of rising age at marriage has been offset largely by increases in births among unmarried women. Similarly, in the Caribbean and sub-Saharan Africa, where union formation involves complex processes, births outside of socially sanctioned relationships also occur more frequently than formerly. Single parenthood must compete for governmental attention with a host of acute social and economic needs, however, and there is often great reluctance to enter what is seen as a controversial area. Efforts to address the problem have generally been limited to family-life education programs.

Childbearing within recognized unions among women less than 15 years old, which is still common in sub-Saharan Africa and to a lesser extent in South-central Asia, has aroused comparatively little interest. Yet, whether within or outside of marriage, the

medical complications of childbearing soon after puberty constitute a public health issue. Many of the risks could be greatly reduced if not eliminated through modern medicine, including better diet, prenatal care, the attendance of trained personnel at the time of delivery and health services for newborns, but the resources to support such interventions are lacking.

A variety of obstacles prevent sexually active adolescent women, especially those who are unmarried, from receiving the support they need to avoid STDs and childbirth. School curriculae rarely include sex education. Existing contraceptive services are frequently restricted to married women. In many countries, abortion is illegal and consequently dangerous. There is much work to be done to provide adolescents with the skills and services necessary for healthy behavior.

3.3 Developed Countries

The great majority of developed countries have gone a considerable way toward meeting the needs of sexually active adolescents. Almost all of these countries have national health systems that provide basic health care, including reproductive health services, to the entire population at low cost to the consumer. Abortion is typically legal and safe. The extension of publicly sponsored contraceptive and abortion services to unmarried minors has often been taken up as a separate and more controversial issue than their provision to adults, but there is widespread agreement that the consequences of unprotected sex are to be avoided.

Scandinavia and a few other countries of northwestern Europe have moved significantly farther. Public policy there supports a strong social ethic of sexual responsibility, and there are few unintended pregnancies. Adolescent sexuality is accepted as a normal part of the maturation process. Sexual matters are discussed openly, and related information is readily available. In a number of cases, separate arrangements have been made to meet teenagers' special need for sensitive, confidential, readily accessible services.

The situation is quite different in the USA, though the issue receives considerable public attention. The main thrust of publicly funded teenage pregnancy prevention programs is toward delaying the initiation of sexual activity, although the success of such efforts remains open to question. Sexuality education in schools is typically recommended although not required, and the content may be limited. Family planning clinics serve adolescents as well as older, married women, but their location is often inconvenient for young people and most require some payment. Contraceptive and especially abortion services for young people are highly contentious topics and subject to a constant barrage of legislative proposals and judicial decisions that threaten their effectiveness.

Telecommunications and Information Policy

1. Network Regulation

Telecommunications and information policy involves balancing public and private interest through local, national, regional, and international regulation of a growing variety of communications technologies. These include: (a) network facilities and equipment; (b) basic telephony; (c) value-added and information services including data, video, and voice transmission (i.e., the Internet); (d) mobile and radio services; (e) integrated digital networks and integrated broadband networks. Regulation is a dynamic political process that distributes costs and benefits throughout these various sectors. Telecommunications regulation has always had a domestic and international or multilateral component. Traditionally, this was composed of a national government body with the most power in setting the rules of operation, and the International Telecommunications Union (ITU), which served to establish common standards and protocols. Today, telecommunications and information policy is in a period of dramatic transition as a result of what some have called the rise of a global 'network society' (Castells 1996). This transition can be explained by both rapid changes in technology since the 1970s, particularly 'digitalization' which has led to the convergence of new and old media, as well as dramatic political changes, most commonly understood as 'globalization.' This notion of network is based on the interactive switched telecommunications network that was originally developed for basic telephony. In contrast to traditional top-down, one-way mass media, new electronic media function through a 'hub-and-spoke' model.

In terms of regulation, these networks are unique because they are based fundamentally on shared resources. In the case of telephone service, it would make little economic sense for each individual subscriber to connect separate cables to every other subscriber in order to make a telephone call, even though it is technologically feasible. Individual subscribers do not make enough telephone calls to warrant investment in hundreds of cables. Instead, phone calls made by individual subscribers are routed through a local exchange, where using a common connection the calls are connected to a bigger regional exchange that uses high-capacity connections that link major exchanges in order to distribute calls. The value of this network grows as each additional user joins the network, precisely because it spreads the fixed costs around a larger number of users and because it expands the numbers of people each already existing subscriber can contact. Economists argue that because the network can enhance social benefits beyond the members of the network, telecommunications should be seen as a 'public good' because of 'positive externalities' (Garnham 2000). Putting this into practice, public policy experts contend that the telecommunications network should therefore be seen as a 'club' based on members with mutual interests, as opposed to a market. These 'members' generally include different government bodies, domestic and transnational firms, labor unions, consumer organizations, and public interest groups. The problem in regulating both broadcasting and telecommunications networks is what happens when this 'coalition of mutual interest breaks down' (Noam 1987). The conventional wisdom was that telecommunications networks functioned most efficiently as a 'natural monopoly' because of the enormous fixed costs required to build and upgrade the network. The rationale for monopoly in telephone manufacturing and services was based on the understanding that centralization of operations would 'increase reliability' and that monopolies could best tap economies of scale and scope to better 'advance considerations of equity' with the objective of universal service provision (Aronson and Cowhey 1993). Given this economic logic, regulators and policy makers have been historically concerned with how to best achieve universal access at the most reasonable prices. Between the 1920s and the mid-1970s, there was little technological change that directly affected the telecommunications sector. In this period, telecommunications networks were regulated at the national level through a system of cross-subsidy, whereby urban areas subsidized rural areas, long-distance rates subsidized local rates, large (corporate) users subsidized residential users, and telecommunications revenues subsidized the postal system. With the exception of the American system of state-regulated private monopoly of AT&T, most other nations relied on government ownership and/or operation of their Post and Telecommunications Operator (PTO).

In the 1980s, advances in technology coupled with political changes dramatically challenged the logic and scope of national regulation of the telecommunica-

tions network. Technological advances stemming from research in the defense-related electronics sector introduced new satellite, cellular radio, fiber optic, and digital exchange technology that would suddenly transform telecommunications services into the new 'nervous system' of the global economy (Mansell 1995). The telecommunications network could now transmit all types of information through these new technologies, and thus became an increasingly vital component of all sectors of economic activity. Expansion and modernization of the telecommunications network was seen as crucial in facilitating transnational production and distribution of goods and services, including the proliferation of financial markets and new media technologies. Experts in national and multilateral agencies like the International Telecommunications Union (ITU) therefore began to expand their scope by considering questions of regulation for telecommunications *and* information policy. The convergence of different kinds of communications technologies has introduced a new set of problems for regulators both domestically and globally. Whereas regulation of the telecommunications or broadcast network has been seen as legitimate in most societies, regulation of content or the messages passing through the network is often seen as illegitimate, raising concerns about privacy, freedom of expression, and censorship. Equally important as the technological changes, political changes in the era of Reagan and Thatcher led to the 'liberalization' of regulation over national telecommunications policy. Traditionally, national networks were joined together at the borders by international gateways. In the 1980s, however, transnational corporations began to demand 'seamless networks' in order to facilitate the transactions of these firms across national borders (Hills 1998). The deregulation of AT&T in 1984 and the privatization of the state telecommunications network in the UK introduced a distinctly new logic of competition in the global marketplace by policy makers. Most significantly, traditional concerns for establishing 'fair' prices and maximum access to services was replaced by a new turn to neo-classical economics where the concern for the global success of home-based transnational corporations was measured by sales, profits, and a favorable balance of payments (Melody 1994).

With the end of the Cold War and the changing ideological climate, policy makers around the world began to reconsider the legitimacy of the state's role in economic development. Reformers argued that telecommunications policy should be an instrument that encourages market competition within and across national borders, driving down prices for consumers while simultaneously expanding the pace of technological innovation.

In a sense, as telecommunications and information policy became a greater concern for governments and large corporations, expertise in policy was increasingly cultivated in Business and Law Schools, most often in the US (Singh 1999). This created a strategic consensus about the failure of state-operated monopolies, promoting instead global integration and staying clear of nonmarket intervention in setting the terms of network operations. As a result, the rhetoric of the 'information revolution' in the early 1990s relegated policy-making to creating conditions for market reforms of the old public PTO networks.

Today, the dominant approach in terms of the scholarship on telecommunications and information policy is prescriptive, assuming that the market and technology are inherently neutral forces. Robin Mansell contrasts this 'idealist model' of policy analysis to a more critical 'strategic model' that takes into account institutional and economic power. The dominant model espouses an 'evolutionary process of technological innovation in telecommunication and computing technologies … left to the forces of the competitive market' (1993, p. 6). William Melody, one of the most prolific communications scholars writing from this 'strategic' perspective, explains that although the national telecommunications model failed to meet anywhere near universal service objectives in most places, competition cannot be seen as an 'adequate substitute to regulation or public ownership.' Despite the proliferation of new communications technologies, without effective and independent regulation we are replacing a tradition of state-owned monopoly with private monopolies and oligopolies across national borders (Melody 1997).

Although the spread of new communications technology has been astonishing since the 1980s, the expansion has been extremely uneven. Policy makers today are finally talking about the 'digital divide' which includes recognizing the fact that some 75 percent of the world's population has yet to gain access to basic telephone service (ITU 1997). The Internet, hailed by many enthusiasts as the ultimate technological equalizer, is the least accessible communications technology in the world.

It should be clear from the preceding discussion that changes in technology and politics have transformed the telecommunications and information policy process as a result of 'digitalization' and 'globalization.' The second half of this article will examine in greater detail the 'globalization' of telecommunications and information policy, focusing on the growing importance of this issue for nations in Africa, Asia, and Latin America.

2. *Telecommunications and Information Policy Reform in the 'Developing World'*

Telecommunications was not recognized as an economic priority in the so-called developing world until the 1980s. This was reflected in very low rates of

telephone density (between 1 and 10 percent) and very slow absorption of new technologies. In most nations, the state owned and operated the PTO, and the network was regulated based on the cross-subsidy principles discussed above. Although nearly all states advocated universal service (meaning access to a community telephone as opposed to residential telephones), other more pressing economic priorities relegated the telecommunications network to low levels of penetration especially in rural and low-income areas and long waiting lists. As telecommunications and information technologies became an increasingly strategic input for transnational corporations and governments in the 1980s, policy reform became a dominant concern for states throughout the developing world.

In 1985, the International Telecommunications Union (ITU) released its influential Maitland Commission Report entitled *The Missing Link?*, which condemned the extreme inequalities of telephone access between rich and poor nations. Although the report drew global attention to the question of information disparity, its recommendations pressed for the need to reform inefficient national public monopolies and promote the transfer of technologies from advanced to developing nations (ITU 1985). The ITU's report argued that investment in telecommunications should no longer be seen as a luxury service for corporate and national elites, but rather as an essential service that directly leads to economic growth. In fact, teledensity penetration was correlated with tangible growth in gross domestic product. This approach is referred to as the 'telecommunications for development' perspective and posits that investment in the newest telecommunications technologies would allow developing countries to actually 'leapfrog' stages of development. For example, instead of having to replace copper cables with fiber optic technology, developing countries would bypass that stage in development altogether and adopt the most advanced technologies. Similar arguments are made today about wireless and satellite technologies.

In this period, the ITU along with the World Bank began to urgently promote the liberalization of infrastructure and the privatization and commercialization of services through a series of multilateral and bilateral conferences and seminars on telecommunications reform. Both multilateral institutions began promoting the expanded role of the private sector in telecommunications development, with transnational equipment manufacturers like Alcatel, NEC, Ericsson, British Telecom, US West, and others eager to enter new markets offering to provide direct foreign investment on attractive financial terms (Lee 1996). While the first phase of reforms in developing countries consisted of the liberalization of the equipment market, the World Bank in particular began to push for the liberalization of national telecommunications networks.

The argument was that the poor performance of state-operated telecommunications networks throughout Africa, Asia, and Latin America significantly impeded economic growth. The solution was to implement a comprehensive reform process that would enable competition and technological modernization and balance the concerns of equity between those of efficiency. This would include the deregulation of the state-operated network with the ultimate goal of privatization, liberalization of the supply of services, and the separation of the government's policy and regulatory arm from its responsibilities as a network operator (Saunders et al. 1994). In the midst of the African and Latin American Debt crises of the 1980s, the World Bank's policy perspective was particularly influential wherever its sister lending agency, the International Monetary Fund (IMF), financed new loans (Hills 1998).

Between 1980 and 1997, some 40 states engaged in the partial or total privatization of their national telecommunications operators raising $140 billion worldwide. Unlike their Western counterparts, states in the developing world have privatized national telecommunications monopolies primarily as a means to reduce debt burdens and invite foreign capital and expertise. In many nations, the transfer of public resources into private, especially foreign hands, has raised political opposition and public protest (Noam 1998). However, this kind of politicization of what is seen as a technical issue has been brushed aside as imminent concerns about the dangers of missing out on the 'information age' subsumes policy debates.

While 'telecommunications for development' quickly became the dominant perspective among policy makers, communications scholars pointed out that the value of access to telecommunications was contingent on issues of power, between national and global interests, urban and rural interests, and intra-community class interests (Samarajiva and Shields 1990).

These critics concede that the public service monopoly model failed to achieve the objectives of both efficiency and broad universal access, and in most cases they agree that the introduction of fair competition is a pressing concern for most developing states (Melody 1997). States did not adequately fund the public telecommunications operators and these bureaucracies were largely unaccountable to the public they were supposed to serve. Thus, bureaucratic reform is high on the agenda for these critics (Mody 1993). However, unlike the proponents of 'telecommunications for development,' these critics point out that the only way to avoid a tradeoff between efficiency and equity is to create effective political institutional arrangements that lead to sustainable development (Melody 1997, Samarajiva and Shields 1990). Demand for telecommunications policy reform in the developing world came from the biggest users of services, which were mostly business users based

nationally as well as internationally. Critical communications scholars have argued that the pace and institutional structure of telecommunications and information policy reforms tends to privilege the interests of these corporate actors (Dunn1998). To put it most simply, the new market principles shape policy along 'the more you spend the less you pay' principle, generally benefiting the biggest spenders, in most cases corporations. For countries with very low rates of telecommunications penetration—ranging from 1 to 10 percent—who picks up the tab for the low-income majority leads to serious concerns about widening the digital divide. This is a valid concern for most nations in the developing world where 80 percent of the revenue is generated from 20 percent of the customer base and demand for most advanced services that require larger network capacity is confined to transnational corporate users.

The paradox of telecommunications liberalization around the world is that the moral superiority that competition is supposed to ensure is undermined by the alarming rate of consolidation of global firms. The justification for domestic markets opening their doors to private firms is that competition brings down prices for consumers and offers more and better services for less. However, today a handful of global giants dominate the telecommunications industry worldwide and have the resources to buy out and raise barriers to entry to smaller competitors when they choose. Moreover, the merger of traditional telecommunications companies with producers of content (software) further reinforces concentration as opposed to competition in overall services. Finally, the economic centrality of telecommunications services for business in today's global economy puts pressures on national governments to separate the needs of corporate users of high-speed networks and services from the public networks, thereby creating new levels of information disparity (Sussman 1997).

In the developing world, the pressure to privatize and commercialize networks often precedes the creation of effective regulation. Consequently, these analysts point to the absolute necessity of effective independent regulatory regimes to 'protect infant industry, control private monopoly power, offset the tendency to concentration, protect employment, and achieve macro-balance' (Mody 1993). However, these domestic concerns often conflict with global pressures as trade in telecommunications and information services becomes increasingly important in a global network society. Domestic policy is increasingly coordinated by regulatory agreements like the 'Global Telecom Pact' and the 'International Technology Agreement' through the World Trade Organization (WTO). These new global rules clearly prioritize the liberalization of markets and protection of intellectual property as opposed to ensuring effective regulation of competition and establishing accountable regulatory procedures.

Telecommunications: Policy

Telecommunications is a collection of electronic technologies for the movement of data and information. It includes telegraph, telephone, radio, television, satellites, and small wireless devices. Technical standards, extent of deployment, and pricing are all subject to government regulations. Regulatory issues represent major public policy issues for governments, such as how to support or control the use of the Internet. Most research on this topic has been about economic and political issues, normally done within the context of individual nations.

1. *Historic Role of Policy Makers*

Over the past 150 years governments throughout the industrialized world, and today in almost all countries, face two sets of issues concerning telecommunications: what to regulate and why, and how to leverage this technology for national advantages. As new forms of telecommunications appeared, governments have had to make judgments about them. In effect, they have had more forms of technology to regulate, create policies around, and exploit. New technologies will emerge that will create the need for additional policy considerations. While technologies have changed over the years (e.g., adding cell phone where wired telephone systems exist, use of pagers), the issues facing policy makers have remained fairly constant over the past century and a half.

There is a specific set of existing technologies which routinely require the attention of policy makers concerned with communications. They are all electronic, often use computer technology, and are widely deployed in many societies. These include: telegraph, telephone, wireless telephones, radio, television broadcasting, cable television, satellites, wireless information appliances (such as a pager), and most recently, the Internet. This article will not cover paper-based forms of communications, such as newspapers and magazines, because those topics have different issues from those of electronically based communications. The majority of the deployment of electronically based technologies continues to be in the industrialized world, although usage is expanding all over the planet. Some technologies are more ubiquitous than others. For example, radio is virtually everywhere, even where there is no electricity, thanks to batteries and hand cranks, and their relatively low cost. On the other hand, at the beginning of the twenty-first century, the Internet is most widely deployed in North America and in Western Europe. Much of what we know about telecommunications policy issues is drawn from the experience of Europe and North America, seats of the earliest industrial economies.

Historic patterns suggest future ones. Over the past two centuries new technologies emerged, such as the telegraph in the 1840s, the telephone in the 1870s, and satellites in the 1950s. At first, little policy attention was paid to a new technology because its impact was minor. As it deployed within a nation, policy makers then faced several questions. To what extent should the national government make a specific technology available to the majority of its citizens? Should the government support further research and development to improve a device's performance, lower its costs, or to get it further deployed? If the technology is related to an existing one already regulated, what should the regulations cover? Pricing? Access? Monopolistic existence? In the special case of broadcasting (radio, TV, cell phones), governments have to allocate bandwidth for the transmission of signals. That effort requires both technical knowledge on the part of regulators, and also a strategy for allocating frequencies among contending technologies. The process of allocation has increasingly become more complex, particularly in the twentieth century, as additional technologies emerged, especially regarding wireless.

Policy makers have also had to deal with issues of national economic development or defense, thinking through how telecommunications can be leveraged in the interests of the nation. The British government, for example, in the nineteenth century saw underwater telegraphic cable communications as vital to national defense and, therefore, supported the establishment of a global network. The United States did the same thing with satellites in the mid-twentieth century. OECD (Organization for Economic Cooperation and Development) nations in Europe collaborated to create an international standard for cell phone communications as an economic stimulant to the new technology in the last quarter of the twentieth century. At the same time, the United States government made its telecommunications network, originally established for defense purposes, accessible to the public; we know it as the Internet. The reason: primarily to stimulate use of a new technology for economic development. In the last decade of the twentieth century, the American government protected the Internet from practices that would have slowed its deployment, such as the imposition of local sales taxes by state and local governments on transactions conducted over the Internet.

2. *Common Issues Shared by Policy Makers*

Policy makers traditionally face five key issues with each major form of electronic communications. In

addition, new issues are emerging. Some issues are related to national policy considerations, such as defense and economic development, others center on activities of government regulators responsible for implementing legal and policy directives. Each of these five vary in importance, depending on issues of the day (war needs, economic considerations, etc.), but each tends to be constantly evident.

2.1 Economic Development

First, there is the issue of how to use a particular technology for economic development. Can investments in the further development of a technology, such as the use of telecommunications with computers, lead to advances that generate new jobs, sales of additional products internally, and for export? Tax incentives and outright financial subsidies in support of local technology firms and for training of new workers are often the tools of choice of policy makers when they support a new technology for economic reasons.

2.2 Infrastructure Development

Second, there is the issue of how an infrastructure can be built, or should be built, to make the technology either usable or accessible. Telephones are useless unless the majority of a nation has access to the same telephone network. In the 1800s telegraph only became useful when it could reach multiple cities. Postal systems and national highways systems raised the same issues for all nations. A communications technology becomes useful when an infrastructure exists to make it available to the entire nation. Tools of choice are often the same as those used to encourage diffusion of a technology to stimulate economic activities.

2.3 Competition

A third issue concerns the extent to which policy makers wish to encourage competition among service providers or different technologies. In the United States, for example, there is a strong tradition of encouraging competition. That is why there are numerous telephone companies, heavily regulated to ensure competition, but essentially operating in the private sector. European governments have chosen a different path in most cases, namely, to run networks out of national government agencies. In part this was to support a technology that initially would have failed in the marketplace, such as telephone and telegraph services in France in the 1800s. Some governments will thus choose to have a national monopoly, operating in an environment in which competition is not permitted. Either approach still raises the question, however, of what to do when an alternative technology emerges, such as wireless telephones as an alternative to wired phone systems. Are both regulated the same way? Should one be encouraged for other reasons (e.g., national defense or economic development) at the expense of the other?

The economics of implementation prove influential. For example in Africa, wireless telephone systems are seen as less expensive than traditional wired systems because there are lower infrastructure costs involved in deploying such networks. So, African governments frequently support the use of cell phone networks over more traditional telephone systems.

2.4 Access

A fourth issue concerns access to a communications technology by citizens of a nation. To what extent should access to communications technologies be facilitated by the state, and why? These are questions that have long confronted policy makers. In the nineteenth century French policy makers decided to run a national telegraphic network to bring high-speed communications to many parts of France. In the early 1900s the American government implemented policies to encourage use of telephones and, by the end of the twentieth century, was investing tax revenues in providing Internet access to all public schools. In each instance, the nation's interests were considered: Does it help development of the economy? Do we need it for national defense? Is access a fundamental extension of some national basic belief about the open flow of information? Do citizens demand government stimulated access? Is government involvement essential because of the technical infrastructure or complexity involved, as in the case of building satellite networks to transmit information inexpensively even though the initial network is very expensive?

2.5 Affordability and Pricing

A fifth issue concerns affordability and pricing, with primary emphasis on pricing policies. Natural or national monopolies are normally subject to government regulation. One of the central policy issues concerns what prices service providers should charge citizens. If the service provider is a government agency (e.g., a national telephone network), the state can charge whatever it wants, since the concern is not necessarily to turn a profit. The issue in that situation is to what extent does the government want to make access to communications affordable. If communications is provided to a nation through a network of private companies, as increasingly is the case around the world, then the requirement that these companies be allowed to make a profit on their services becomes essential. The issue, then, is how much profit should a firm be allowed to make. Policy makers struggle with understanding the true costs and profits of a firm or

communications industry. They also try to understand the needs of citizens and their ability to pay for such services.

As governments have increasingly evolved into democracies or other forms of representative republics over the past two centuries, the role of information in those societies has become an ever more important issue for policy makers. A fundamental premise of these forms of government is that information about political activities, and hence personal and economic issues, should flow relatively uncontrolled. In more autocratic states, the reverse holds. China is still trying to figure out how to block its citizens from using fax machines and the Internet. Yet, in Central Europe more access to information handling tools and communications is on the rise. In North America, all forms of communications are constantly made available to Americans and Canadians. Communications can also extend to press censorship of books, magazines, and newspapers, or their freedom, as a collateral set of policy considerations implemented at the same time that regulators deal with electronic information handling, such as telephones, television, and radio. The nature of government is, therefore, an integral part of the form of policies implemented toward communications.

3. *Emerging Issues in Telecommunications*

In the last quarter of the twentieth century new issues began to emerge that required the attention of policy makers. Several, in particular, are of growing importance to governments across the world.

3.1 *Governments and Global Economics*

As communications companies became global enterprises, implementing worldwide business strategies and policies, policy makers began asking what role should an individual country play in the affairs of such a firm? For example, in the late 1900s, telephone executives in Spain quietly moved into the Latin American economies, buying up local phone companies, thereby increasing control over telephonic practices from offices in Madrid. American communications companies in the same period implemented global satellite networks used to transmit long-distance telephone calls. In the late 1800s, British cable companies overwhelmingly owned and controlled the underwater cable business. This is not a standards discussion, this is about how a government regulates or influences a multinational company. To what extent can it? National egos, public policies toward access to communications, and issues related to national defense all weigh in as influences. Government agencies maintain that they have a critical right and need to regulate activities within their borders. Many firms argue that economies of scale and scope require that they not be constrained by some local policy or practice. It remains a never-ending debate, but, nonetheless, an increasingly important issue. More frequently, groups of nations establish uniform policies and practices, as is evident in the Common Market nations of Europe. Yet, overwhelmingly, nations still set policies and regulate independently of each other.

3.2 *Control of International Flow of Information*

The international flow of information through a variety of electronically based communications technologies profoundly increased during the second half of the twentieth century. Simultaneously, it has become increasingly difficult for governments to control the inflow and outflow of information. For example, Western European governments began regulating what data could come in and out of a nation via telephone lines linked to computers in the 1960s. That worked for a while but eventually technology breached the walls and today information moves around the globe as if there were no national borders. The Internet is the most recent example of that process at work. While some governments are attempting to control the type of information transmitted over the Internet (e.g., political data in China, pornographic materiel in the United States and in Western Europe), the fact remains that anyone with access to the Internet can send and receive just about any kind of information. Is that a problem for policy makers? It can be if there is a compelling need to control some aspect of the flow of information. But what has happened is that the technology with which to move information around the globe easily, quickly, and inexpensively on a massive basis is now reality. What governments should do about that, and their role in the process, remains unclear.

4. *Special Role of the Internet*

Yet, another emerging reality concerns the specific role of the Internet and computing. Computers and telecommunications are two sets of rapidly converging technologies. They are also becoming ubiquitous, increasingly available to people. At the start of the twenty-first century, nearly half the population of the world had yet to make its first phone call. Half of the others had regular access to Internet-based information appliances, ranging from computers to e-mail machines, to pagers and cell phones, and all relying on the communications backbone of the Internet. Governments now face basic policy questions about the Internet that would have been somewhat familiar to policy makers in the early 1900s puzzling over what to do about radios, telephones, and later television. Local cultural values, issues of national defense, economic development, and historical and legal realities play roles in how policy makers consider the Internet.

What is most different from earlier considerations, however, is the speed with which the Internet became a policy issue. Widespread use of the Internet can be dated to the early 1990s, although access to it in the United States went back to the 1970s, first for the military and their suppliers, and later for the general public. But for all practical purposes, the world began to use the Internet in the mid-1990s and, by the start of the new millenium, approximately a billion users were online across the globe. As of this writing, conservative forecasters called for a doubling of the number of users by about the year 2005. Policy makers tend to react to emerging technologies at a much slower pace than the spread of the Internet. So, uncertainty and tensions exist. In Western Europe, for example, the OECD has run annual conferences and conducted studies and surveys in order to inform policy makers in member nations about what each other is doing concerning the Internet and about its technology. National policies toward the Internet are being created, while public officials are simultaneously coming to realize that this technology is fundamentally changing many economic and societal structures and practices in ways not seen since the arrival of television a half century earlier, or the automobile nearly three-quarters of a century ago.

5. *Common Patterns in Communications Policy*

Are there some fundamental conclusions, therefore, that one can draw about the basics of communications policies? Are the profound changes in communications technologies which have occurred in the past half-century subject to some conclusive approaches? Historical precedence is a guide in these matters because governments have had to deal with various forms of telecommunications for nearly two centuries, relying on prior cases and practices. Often the issues involved are less about the nature of the technology and more about its use and costs. The one major group of exceptions are the myriad of regulations required in response to the physics and scientific realities of a technology, such as how to distribute radio frequencies across different types of transmission, e.g., AM and FM radio broadcasting. Occasionally, national 'champions,' in the form of some locally preferred (or developed) technology, influences these technical decisions, such as the debate which occurred in the last two decades of the twentieth century over analogue vs. digital television transmission standards. That issue is also compounded by the continued evolution of technology which today, for example, makes possible DVD transmissions and also use of the Internet and PCs with which to view programming.

Leaving aside these technical regulatory requirements, which can also be highly politicized, there are some common patterns of behavior by policy makers that can serve to inform contemporary interest in the subject.

5.1 *Policy Makers and Emergence of New Technologies*

First, public policy makers have normally and regularly felt compelled to rule on the development, deployment, and use of every new communications technology that has appeared in the past two centuries. While a new technology might avoid drawing the attention of policy makers for a period of time (e.g., as was the case with the telegraph in the United States for over a decade), eventually the regulators catch up. Related to the inevitable role of policy makers has been an almost universal discussion among public officials about how best to upgrade communications infrastructures within their nations. By the end of World War I, every industrialized nation had wrestled with this issue and by the end of the twentieth century, almost every government in the world had dealt with the topic.

5.2 *Policy Makers and Economic Development*

Second, regulatory practices and public policy normally are linked tightly to economic development, national defense, and the realities of existing political infrastructures. Hitler used television to convey his messages; Roosevelt wanted Americans to listen to him on the radio, while the Belgians worried about American television programming corrupting their local culture in the 1980s. As we move increasingly into a new phase in the economies of the world, one characterized by the extensive use of information and its underlying technologies, the debate increases about what role policy makers should play in fostering use of communications within their national borders. While the debate has a long history, what is new is the intensity and critical nature of the process today because of the increased availability of new communications technologies, which are so rapidly spreading through most nations.

5.3 *Types of Policy Makers and Roles*

Third, policies have been created and influenced by three groups within governments: regulators working inside administrative departments, national and state political leaders, and state and national legislative bodies. Increasingly in industrialized societies with representative forms of government, major initiatives to codify regulations, government policies, and the national will have led to far-reaching legislation on communications. For example, the Telecommunications Act of 1996, passed by the US Congress, fundamentally defined how competition could occur in America for all forms of communications. The OECD is at work on creating overarching guidelines of a similar nature in Europe that all European governments can consistently embrace. Put another way, national legislatures periodically redefine and

codify public policy and practices toward communications, usually about every half century with many, other more narrowly focused, legislation passed in the intervening years. The key pattern, however, is that policy and regulatory matters are always politically charged and invariably involve a nation's politicians.

5.4 Policy Making at National Level

Finally, regulatory actions have normally been most effective when implemented at a national level, although local pricing practices within a state or province exist with reasonable success. However, the pattern evident today is toward national policies, even on pricing issues. The use of international conventions is on the rise because, as with the experience in implementing national practices, the most effective cover large blocks of people. It becomes difficult, even awkward, to implement one policy in a country and a different one in a neighboring state; that tends to constrain effective use of a technology in ways citizens want. So, the impulse, or 'best practice,' has been to expand the implementation of consistent policies and practices to ever-larger portions of the world. The trend toward national and even international policies involve:

(a) Spread of universal technical standards (e.g., as the Europeans have done with wireless telephony).

(b) Policies concerning the type of information that can flow in and out of an economy (e.g., with television programming, use of the Internet, and new forms of copyright and patent protection for software and music).

(c) Trade policies that encourage development and acquisition of new technologies (e.g., computer chips, software, and access to satellites).

(d) Increased interconnections with the communications infrastructures of other nations. No sooner had the Americans invented the telegraph in the 1840s, for instance, people around the world wanted telegraphic infrastructures built so that messages could be sent across a nation and to other countries. We are seeing the same with wireless communications and the Internet.

Perhaps the last word on what policy makers face today in the world of communications should come from William E. Kennard, Chairman of the US Federal Communications Commission (FCC). In communicating his agency's strategy for the future in a written document to the US Congress in August, 1999, he argued that his agency's strategy was designed so that 'it would allow the FCC to enter the next century able to respond fully and quickly to emerging technologies and the inexorable movement from regulation to competition.' While he was addressing the US situation, he could just as easily have been commenting about circumstances in many other countries:

> In five years US communications markets will be characterized predominantly by vigorous competition that will reduce the need for direct regulation. The FCC as we know it today will be very different both in structure and mission.

With the Internet now the major new source of policy concerns, and possibly so large as to dwarf other forms of communications, it is relevant to end this article with Kennard's observation:

> The advent of Internet-based and other new technology-driven communications services will erode the traditional regulatory distinctions between different sectors of the communications industry.

While the four trends listed above still hold in that brave new world, his comments suggest that implementation will evolve over time.

6. Research Considerations

There is considerable research done constantly on all aspects of communications and public policy. Research in academic settings is done primarily by economists and political scientists. A great deal of their focus is on the effects of new technologies on a nation's citizens, and results frequently in policy recommendations. Lewis Branscomb (1993) reflects contemporary examples of this kind of work. The second source of considerable research and debate are the regulatory agencies themselves. In the United States, the FCC conducts much research on all aspects of rates for fees and taxes for each form of electronic communications. Their research is routinely published on its web site. In Western Europe, the OECD does similar research but in addition has taken a special interest in information privacy matters and the role of the Internet. Each year, throughout the 1990s, it sponsored conferences on all aspects of this issue; proceedings of each have been published on OECD's web site.

The Internet is the subject of much research all over the world. In the United States this is primarily being done by academics, with leading initiatives underway at the University of Texas, University of California at Berkeley, and at the Massachusetts Institute of Technology. As with other forms of technology, the issues being looked at focus on extent of deployment in the economy, possible government regulatory options, and effects on national policies. Both the FCC and OECD publish many white papers on narrow issues, written in a formal academic style with footnotes and ample bibliography. In addition to the books in the bibliography, each major regulatory agency in the world has an Internet site with public policy announcements, proceedings of conferences, and other studies. The US FCC and the OECD in Europe are the two best sources for material on a wide range of communications issues and technologies.

Telegraph

The telegraph was the outgrowth and application of advances in electrical science between about 1800 and 1840, particularly the discovery of galvanic electricity by Luigi Galvani and the invention of the electrical battery by Allesandro Volta around 1800, and research into electromagnetism by Hans Christian Oersted, Andre Marie Ampère, Joseph Henry, and Michael Faraday during the 1820s and 1830s. The first two telegraph lines opened in Great Britain in 1837 and the USA in 1844. The telegraph was the only form of electrical communication until the invention of the telephone in 1876, and it remained the mainstay of rapid long-distance communication until the development of practical long-distance telephony after 1900. After 1920, as long-distance telephone rates dropped and many countries introduced airmail service, telegraphy's share of the long-distance communications market entered a long decline. By 1970 the overland telegraph industry in the industrialized world was dead or dying. Submarine telegraphy survived longer; it was the only medium for rapid overseas communications until the advent of transatlantic radiotelephony in 1927, and it remained the cheapest and preferred medium until the installation of undersea telephone cables in the 1950s. After 1980 other technologies, such as facsimile and electronic mail, took over the role of long-distance record communications formerly supplied by the telegraph.

In technological and scientific terms, the telegraph was important for three major reasons. First, telegraphy was the first major application of discoveries in electrical science, and it was one of the first technologies with a firm scientific foundation. Second, telegraph electricians during the mid-nineteenth century helped to establish the discipline of electrical engineering. Finally, technical problems, especially in submarine telegraphy, stimulated major scientific advances in physics and oceanography.

Telegraphy was the first technology to sever the connection between communication and transportation. Because of the telegraph's ability to transmit information almost instantly, it affected many aspects of society, culture, politics, international relations, and economics after 1840. It helped to create integrated national and international markets, sped the dissemination of news, provided a model for new literary forms, aided Western imperialism, and spurred national governments to develop telecommunications and technology policies.

1. *The Telegraph in Great Britain*

In the mid-1830s William Fothergill Cooke developed a telegraph which indicated letters by using the transmitted electrical current to deflect magnetized needles at the receiver. During the same period, Charles Wheatstone conducted several important experiments on the long-distance transmission of electricity. In February 1837, the two men pooled their efforts and in June they obtained a patent for an electromagnetic telegraph using five wires to deflect five needles in order to indicate letters of the alphabet. They built their first commercial line in 1838 and 1839. In late 1842, Cooke patented an improved telegraph which used two wires and needles, instead of five, to indicate letters; this halved construction and installation costs.

During the early 1840s, railways were the major customers of the telegraph. In 1846 Cooke and a group of investors founded the Electric Telegraph Company to build a commercial telegraph system for the use of the press and businessmen. By 1855 its network encompassed nearly every important town in England and Ireland. For the next quarter century, the Electric company dominated the industry but competed with four other companies for business. During this time the industry shifted from the Cooke and Wheatstone two-needle instruments to various forms of printing or recording telegraphs.

By the mid-1860s, much of the British public, Parliament, and the civil service supported the nationalization of the telegraph industry, claiming that Post Office operation would reduce rates, expand the network, and provide better service. In 1868, Parliament authorized the purchase of the telegraph lines, and the Post Office began operating them in February 1870. Despite initial successes, it was soon apparent that the British postal telegraph faced serious financial obstacles, including an inflated purchase price, unremunerative press and railway rates, commercial rates which barely broke even, and competition from the privately owned telephone industry.

At the turn of the century, telegraph traffic peaked at some 90 million messages. Throughout the following decades, traffic dropped and losses mounted because of competition from the telephone and the letter post which delivered letters within the British

Isles within 24 hours of posting. The telegraph's heyday was over by 1920, and by 1970 the telegraph had ceased to be an important communications medium in Britain.

2. The Telegraph in the USA

In 1837 and 1838, Samuel F. B. Morse publicly demonstrated his electromagnetic recording telegraph to prominent scientists and government officials. Morse's system at this time comprised an alphabetic code of dots and dashes, a telegraph key to encode messages, and a receiving register which recorded signals on to a moving strip of paper. Morse believed that the federal government should own and operate his telegraph, and hoped to convince the American government to purchase his system. In 1843, Congress gave Morse $30,000 to build an experimental line between Washington and Baltimore. This line began operation in May 1844, but the government refused to fund an extension of the line northward to New York. In 1846, the government turned over the Washington–Baltimore line to private investors.

Over the next 15 years, the telegraph network spread rapidly; by 1850, lines reached every important point east of the Mississippi River, and by 1861, a transcontinental line reached California. The major change to telegraph equipment in this period was the elimination of the recording register; operators shifted to sound reception by deciphering the clicks of the receiving magnet. During the late 1840s and early 1850s, a confusing welter of several dozen companies sprang up to build telegraph lines, many of them poorly organized and short-lived. During the late 1850s, a cartel of six companies coalesced and provided stability to the industry. The end of the Civil War in 1865 sparked a final wave of consolidation, and Western Union emerged in 1866 as the country's telegraph monopoly.

During the remainder of the nineteenth century telegraph technology remained relatively static. The only major advance arose in the 1870s, Thomas Edison's invention of the quadruplex which allowed the simultaneous transmission of four messages on a single wire. Between 1866 and 1910, Western Union faced two major challenges to its dominant position in the American communications market. During this period, a vocal and vigorous movement arose to nationalize the telegraph and place it under postal administration, and Western Union officials spent much time and energy defending their private monopoly to the public and to Congress. The telephone, independently invented in 1876 by Alexander Graham Bell and Elisha Gray, was Western Union's second major challenge. Bell offered to sell Western Union his patent, but Western Union refused and established a competing telephone system in the late 1870s using Gray's and Edison's patents. Because of Bell's superior patent position, Western Union withdrew from the telephone market in 1879 in exchange for Bell's promise not to compete with Western Union's long-distance telegraph business. In the 1870s and 1880s, the telephone could not operate over distances longer than a few dozen miles. However, by about 1890 telephone engineers expanded the range of audible conversations to a few hundred miles, culminating in the establishment of Bell's transcontinental telephone service in 1915. As Bell's long-distance network expanded and rates declined, the telephone steadily eroded the telegraph's share of the long-distance communications market.

Under the leadership of Theodore N. Vail, American Telephone and Telegraph (AT&T), Bell's parent company, was powerful enough to acquire working control of Western Union in 1910. AT&T's control of Western Union demonstrated that the telephone had eclipsed the telegraph as the nation's preferred long-distance communications medium. AT&T voluntarily relinquished its Western Union holdings in 1914 to forestall federal anti-trust proceedings. Although short-lived, Vail's administration modernized Western Union's antiquated accounting and management structure and spurred the company to replace its Morse instruments with automatic telegraph equipment.

Between 1915 and the end of World War II in 1945, the telegraph's share of the long-distance communications market continued to decline because of competition from the telephone, government air mail service, and AT&T's teletype service inaugurated in the 1930s. During the War, the Federal Communications Commission forced Western Union to divest itself of its international cable network and to consolidate with its sole remaining competitor, the bankrupt Postal Telegraph Company, two moves which weakened Western Union's long-term financial position.

Following World War II, Western Union's managers attempted to modernize the company's physical plant and to preserve a market niche for record communications. Between 1945 and 1980, the company undertook three major modernization programs, the development of analog facsimile technology, the construction of a microwave beam network to replace its wires and cables, and the launching of communications satellites. Although these systems were technologically successful, they failed to reverse Western Union's declining market share with respect to the telephone; by 1990, Western Union was defunct except for its money-transfer service.

3. Telegraphs in Asia and Africa

The first telegraph in India, constructed by two British army officers, opened in 1851. During the 1850s, the British government encouraged the construction of a

government-owned telegraph network to link the major trading and political centers, and by 1856 India had some 7,000 km of telegraph line and 45 offices.

The French telegraph network in Indo-China was also an instrument of colonial control. France began telegraph construction in 1861 and by the turn of the century the Indo-Chinese network comprised about 12,000 km of land lines and cables connecting over 200 offices. After 1880 the colonial powers occupying Africa built land and cable networks to connect their possessions with the home countries. The Indian, Indo-Chinese, and African telegraph networks were primarily instruments of imperial control and only secondarily commercial systems.

The Chinese government regarded telegraphy suspiciously, as a tool of the Western powers to gain control of their country. During the 1860s, Russian, British, and French entrepreneurs and government officials began pressuring China for telegraph concessions. Chinese officials resisted until the 1870s, when they granted foreign companies limited franchises to build telegraph lines. In 1881, the government established an Imperial Telegraph Administration to build and to operate a national network, but officials continued to resist the wholesale construction of foreign-owned telegraph lines. However, several European countries used the Boxer Rebellion of 1900 as a pretext to extract political and economic concessions, including the right to build telegraphs, from the weakened Imperial Chinese government.

Whereas Chinese government officials sought to shield the country from foreign influences in the second half of the nineteenth century, in Japan the Meiji Restoration of 1868 brought to power an elite eager to modernize the country along Western European lines. Japan's new rulers embraced the telegraph and hired a British telegraph engineer in 1869 to build a line between Tokyo and Yokohama and gave landing rights to a Danish cable company. By 1872, Japan enjoyed direct telegraphic communication with Europe. During the next two decades, the Japanese telegraph network expanded rapidly. By 1891, Japan had over 400 telegraph offices connected by nearly 12,000 km of wire.

4. *Submarine Telegraphy*

The successful development of submarine telegraphy between 1851 and World War I established an international communications network and helped Western nations to pursue their imperialist and commercial ambitions in Africa, Asia, and Latin America. From 1850 to the early 1870s, engineers confronted and solved several problems in submarine telegraphy: insulation, cable-laying ships and equipment, signal distortion and attenuation, and sending and receiving apparatus. British scientists, engineers, and entrepreneurs played leading roles in all four areas.

In 1851, a British firm laid the first successful undersea cable between Dover, England, and Calais, France. British and American entrepreneurs and government officials soon began exploring the feasibility of a transatlantic cable. In 1856, the American Cyrus Field and the British telegraph engineers John Brett and Charles Tilson Bright headed a group of investors who started the Atlantic Telegraph Company. The company received subsidies and naval support from the American and British governments. After two failures in August 1857 and July 1858, the company successfully laid a cable between Ireland and Newfoundland in August 1858. The cable failed, however, after a few weeks of weak and intermittent signals. The 1858 cable failure, the straitened finances of the Atlantic Telegraph Company, and the American Civil War (1861–65) all combined to delay a renewed attempt until 1865. Under the leadership of John Pender, the newly formed Anglo-American Telegraph Company successfully laid two cables in July 1866, marking the start of uninterrupted electrical communication between the two hemispheres. During the last third of the nineteenth century, the Atlantic cables were instrumental in establishing global markets in news, agricultural commodities, and financial securities.

During the late 1850s and 1860s, British telegraph engineers and government officials sought to connect Britain with its possessions in India, southeast Asia, and Australia. In 1870, they successfully laid a cable from England through the Mediterranean, Red, and Arabian Seas to Bombay. In 1872, an extension from India provided direct telegraphic connection to Singapore and Australia. Between 1870 and 1914, several American and British cable companies competed for the telegraph business of the Caribbean and Latin America, a competition which mirrored and fueled the general commercial rivalry between the two countries in the region.

On the eve of World War I, about 500,000 km of undersea cables existed, over half under British control and one-fifth under American control. France, Denmark, Germany, and The Netherlands accounted for the remaining cables. This global submarine cable network helped Western nations to attain economic and political dominance of Asia, Africa, and Latin America. During World War I, British leadership in cable and wireless communications played an important role in the Allied victory over the Central Powers.

During the 1920s, demand for international communications boomed and the submarine telegraph industry reached its peak. Furthermore, AT&T introduced a major technological advance, inductively loaded cables which increased message-handling capacity by a factor of five. Western Union installed the first inductively loaded cable in the Atlantic Ocean in 1924, and the new cables ensured that submarine telegraphy would occupy a central place in global

communications over the next several decades. However, economic depression and World War II between 1930 and 1945 reduced demand for international communications generally.

After World War II, two new technologies, telephone cables and satellite communications, converged to make international telephoning easier and cheaper, and hence to render submarine telegraphy obsolete by 1980. AT&T laid the first transatlantic telephone cable in 1956, and by 1983 seven transatlantic cables provided over 11,000 voice circuits. During the 1970s, satellite communications reached maturity, and by the early 1980s satellites provided about 50,000 voice circuits. The installation of digital fiber-optic cables during the 1980s increased the number of international telephone circuits by an order of magnitude and reduced greatly the cost of overseas telephone calls.

Telephone

Since its invention in 1876, the telephone has become, literally, a fixture of everyday life throughout the industrialized world and much of the developing world as well. It is so commonplace that only its absence becomes noteworthy (such as in school classrooms and prisons). Too easily forgotten by laypeople and scholars alike is the miracle of being able at any time to place a call to any other subscriber worldwide. The enormous value of the telephone can be appreciated if one only considers the plight of a villager who wants to know if there might be work available in a nearby town, or who needs to summon aid for a sick family member.

Also easily overlooked are the ramifications of this global connectivity. By allowing us to transcend a variety of physical and social barriers, the telephone has led to a complex set of dispersed personal and commercial relationships. By any measure, the telephone has dramatically altered the social landscape. Cars and airplanes were adumbrated respectively by horse-drawn vehicles and birds. Yet, in human imagination the power of real-time interactive oral communication over great distances had been a power reserved exclusively for divine beings. Given this godlike power of the telephone it is little wonder that it has been one of history's most successful inventions. Little wonder, too, that some of earliest experiments with it were designed to ascertain whether the telephone could be used to communicate with the dead. (Perhaps not regrettably, the answer is that it cannot.)

1. Global and Microcoordination

Today, for a billion people, the act of making or receiving a telephone call in their home or business is a normal, often daily, occurrence. (Another billion, at the other end of the development spectrum, have in their entire lives never used a telephone.) For rapidly growing numbers of people worldwide, car driving and cityscape walking are becoming settings for making and receiving phone calls. In the United States, 200 or so billion calls are made annually from 100 million households, with many billions more generated from offices, mobile phones, and computers. Given the commonplace quality of the ordinary

telephone it remains hard for us to delineate, let alone appreciate, the telephone's ramifications throughout global societies and the interior world of individual psyches.

Although the telephone has numerous cumulative macrosocial consequences, most of them are predicated on its ability to support social interaction. An essential aspect of the telephone is its ability to allow coordination among geographically dispersed (or even locally concentrated) people. Numerous studies demonstrate that the telephone promotes business, sociality, democracy and information flow. For those who are physically handicapped or otherwise constrained, it opens vast arrays of contacts. (It is interesting and perhaps surprising to note that the telephone has increased greatly the social contacts and informational resources for the deaf, via TTY interfaces. This quality is particularly gratifying given Alexander Graham Bell's original interest in helping the deaf.)

The telephone allows convenient management over distance, and via voice messages, asynchronously. Upon its basis, extraordinarily large enterprises can be established and effectively controlled. As a corollary, those who would otherwise have greater independence find themselves circumscribed by those (sometimes literally) above them. The telephone has enabled the rapid conduct of large-scale financial transactions and has greatly assisted the formation of capital markets.

A collateral effect is that digital telephonic technology, including voice-mail systems, has been partly responsible for the elimination of huge numbers of middle managers and support staff throughout American industry. Ironically, many of these positions were created in the first place to deal with the communication flood created by the analogue telephone. This picture is also influenced by the answering machines, which of course allow the conveyance of telephone messages without human intervention. In former times, self-respecting managers, professors or other professionals would be reluctant to conduct their business without having a secretary on staff. (Indeed, much effort necessarily went into 'faking' the existence of a secretary to act as an intermediary.) Today, for many professionals, having a secretary would seem to be not only wasteful but also an indication to their clients that they are out of touch with current best practices.

The proliferation of digital answering machines also affects the tenor of professional events. For instance, it used to be the case that at a conference or symposium, the break-time would be used for social interaction and enjoying the 'here and now' aspects of the conference venue. Nowadays, however, attendees rush outside to use their mobile phones or crowd the payphone booths in an attempt to call their remote answering machines, collect messages, and return phone calls. In another context, the mobile phone and pager has led to a new form of social effrontery. While seemingly engaged in conversation, one coolly glances down and scrolls through messages on one's communication device, all the while nodding sagely as if heeding every word uttered by one's interlocutor. These are a few of the many faces of what Kenneth Gergen has termed 'absent presence.' People are seemingly at an event or socially engaged, but their attention and mental focus is elsewhere.

Telephones, especially mobile phones, increase the pace and efficiency of life. They also allow more flexibility and individual efficiency at business and professional levels and at those of family and personal life. Moreover, people can take action to allay the feeling they are not accomplishing enough. People can harness spare time, or time previously spent in tasks that do not require much attention (for instance, waiting on a shopping queue) to plan and coordinate with others, get information, or even shop remotely by phone while they also shop in person. On the other hand, those who treasure respite may find themselves pressured to replace otherwise excusable isolation with productive tasks. Once upon a time, being aboard an airplane excused an executive from having to interact with colleagues. No more, for the fax and phone now follow even at six miles high; nor are the seashore and mountaintop beyond their reach. An age of perpetual contact, at least in potential terms, is dawning.

Despite the many advantages to having the telephone available any time and anywhere, there are drawbacks to it as well at both the individual and social levels. The telephone can be a minor irritant or a conduit for crime. In terms of the former, many social critics of the late nineteenth century expressed irritation at the way the telephone seemed to destroy the orderly pace of life, the considerable pleasures of social propriety and as well those of solitude and reflection; the target has remained lucrative, and the frustrations of telephone use and abuse remain a staple of the screen, both large and small. The telemarketing solicitation, of which there is a rising tide, is also an oft-remarked-upon irritant. Telemarketers themselves use market research, so it is no accident that their calls seem to arrive at dinnertime or other exquisitely inconvenient moments. More serious, though, is that there are a large variety of swindles—some of which even use computer-aided dialing schemes—that prey especially on those with the least social resources. Stalking by telephone and obscene phone calls to both men and women are also serious problems. On the other hand, with advances in technology that give call recipients greater power to control access to themselves (such as increasingly popular caller-identification services) people are better able to manage their communication environment to suit their individual tastes and needs.

The increasingly nuanced technology available to callers and callees demands ever greater sophistication to achieve a flawless performance of the choreography of communication. Think of the dilemma of a shy but sedulous teenage boy who wants to ask a popular girl

to the school prom. Presumably he would not want to leave on her caller-identification box a perusable record of his forty or so attempted calls before finally reaching her. The degrees of freedom and maneuver are reduced with intriguing consequences that cannot be explored here. Suffice it to say that, sadly, it appears that there is an iron law of telephone contact: people generally get the most calls from those from whom they would least like to hear, and vice versa.

In all, though at times a source of irritation and adroit tool of criminal activity, the telephone has proven to be an important factor in increasing the pace, scope and intensity of business and management operations while simultaneously lowering the cost of engaging in these activities. It has had a parallel effect on people's levels of social interaction.

2. *Geographical Distribution*

The telephone has influenced substantially the distribution of people across the physical landscape. On the one hand, the telephone has allowed the massive vertical downtown urban center to survive then thrive. Without the telephone, the skyscraper would have been most difficult to build and manage. Further, it would be difficult for the structure to maintain its usefulness to its denizens without the telephone.

Some claim that the telephone has enabled one particular form of geodemographic dispersion, the suburb. However, detailed studies of transportation system development indicate that the telephone was not an important factor in this remarkable internal migration. Still, the telephone does allow many in rural locations to participate in business and social relations in a viable way, which without the telephone would not be possible. At the same time, those in extremely low-density areas have persistent difficulty getting even minimal telephone service; the situation is exacerbated by the fact that this populace is generally poor and remote from economic opportunities. This, unfortunately, is a social problem that will endure for decades. The telephone, though, has allowed those who choose isolation—and such people are often drawn from the middle and upper strata of society—to enjoy it without having to forego ready communication. Some seek to 'get away from it all' but still want employment as consultants, or at least to stay in convenient contact with friends, family, and emergency services.

3. *Economic Development*

It has long been an article of faith that the telephone promotes economic development and social welfare. This belief has had powerful repercussions on national telecommunications policies worldwide. These have ranged from subsidized rates for the poor, subsidized rates for everyone, and special incentives for telephone companies to modernize their systems or physically extend their services to remote areas. Certainly there has been a strong association between telephone lines and economic growth, particularly, as Hudson (1984) has shown, in developing countries. Researchers have demonstrated a logarithmic relationship between main telephone lines and national income on a per capita basis, although the direction of the causal arrow has not yet been established.

What is not in doubt is that the telephone itself fosters employment growth, not the least to serve itself as an industry. In the early days of mechanical switches, when telephone systems were growing dramatically, it was speculated that within a generation all young boys in America would have to be employed simply to connect phone calls. Although this scenario never materialized, phone companies have traditionally been enormous consumers of manpower, and are usually one of the largest employers of a region. Traditional telephone companies everywhere, though, are for the most part looking for ways to reduce their traditional workforces, heavily concentrated in jobs of installation or as operators. They are replacing vast numbers of these workers with smaller numbers of software engineers and technicians.

Yet even as the workers per 1,000 telephone lines decreases worldwide, employment in the wireless telephone industry has mushroomed. In many cases, the growth in the mobile phone sector has far surpassed the cuts in the traditional wireline companies (many of which were formerly government ministries of Post, Telegraph, and Telephone services or PTTs). As the expense of laying copper wire is far greater than erecting a radio tower, many people in developing countries are gravitating to mobile phones simply because they can get them more quickly than wireline ones. It is my guess that because the mobile phone are more flexible and can be used in more places, the economic impact of growth in mobile phones will be greater than that of the growth of their tethered counterparts.

Telephones can have other economic effects: they ease the job prospecting process directly, increasing economic efficiency by making it easier to change jobs. Also, by using the telephone as a sales tool, consumption is stimulated, which leads to job creation and economic growth. Staffing the sales force alone of course means that jobs will be created. To illustrate by the situation in the US, according to the Direct Marketing Association, spending devoted to telephone marketing is about $62 billion annually and comprises nearly 40 percent of the nation's direct marketing expenditures. The telephone's indirect employment impact in telemarketing is substantial; in 1998, employment in direct telephone marketing was estimated at more than nine million workers.

Although much of the prior discussion focused on macroeconomic effects, it is also worth mentioning

the two-fold microeconomic impact of the telephone. First, it allows individuals to run their own business, often from their home or voice mailbox. Thus, it encourages small enterprises. Yet, it also encourages large-scale enterprises as well since it allows firms to capture the benefits of large size without excessive coordination costs as discussed above.

4. *Polity and Politics*

Due to its ability to connect quickly remote areas, the telephone has helped foster national integration. At a structural level, it also serves to centralize exercise political authority while concomitantly circumscribing regional centers of power. Notwithstanding this structural aspect, the telephone has something of a reverse consequence for individual political empowerment. In this regard, Ball (1968) and Aronson (1971) argue that the telephone has been a politically democratizing instrument. There is much to this viewpoint, and studies have shown that, controlling for levels of economic development, in Communist countries of Eastern Europe there were equivalent numbers of TV sets when compared to their Western European counterparts. However, there were drastically fewer telephones. The presumed reason for this maldistribution is that the telephone enables two-way communication, whereas the TV allows controlled information to be sent in a one-way direction from centralized source to a passive mass audience.

The important role the telephone system could play in controlling the populace has not been lost on governments. In the late nineteenth century, France wanted a centralized, governmentally controlled telephone system because authorities anticipated that rebels might otherwise be able to seize control of it during an uprising. During the Soviet communist regime, the absence of telephone books in Moscow was legendary. Telephone tapping is a long practiced art that has been used to fight crime and enemies of the state.

Revolutionaries as much as police recognize that the telephone is the body politic's nervous system. Hence, it is the universal target for those seeking to subvert or protect the government. Lenin directed that the telephone and telegraph offices be initial targets of his Bolshevik seizure of power. As a contrary example, we point to the August 1991 coup attempt against Mikhail Gorbachev and his government. The plotters failed to seize the telephone system. Consequently, the anti-Communists were able to use it to rally themselves. Boris Yeltsin and his supporters, barricaded in the Parliament building, were able to make and receive calls from around the country and the world; they used this power to marshal and coordinate support. A report on Russianet even claims the parliamentary defenders were able to phone in their food orders to the Moscow Pizza Hut. The telephone facilitates the management of political campaigns and the operation of political organizations.

For well-organized campaigns, the telephone bank has become an important element in any contest. They can also be used to generate otherwise lethargic public interest in issues. In the United States, a neologism has been created to describe the abuse of this process. The term is 'astroturfing,' in honor of the artificial grass of the same name. Astroturfing is the process of using telephone banks to create the incorrect impression among politicians that there is a 'grass-roots' swell of public concern about an issue when in fact there is little or none. Instead, the outpouring of opinion on the issue had been catalyzed by a small group of telephone operators who 'pipe through' a citizen to her representative's office to recite a prepared message. This example provides further demonstration of the principle that telephone technology has an impact that is governed largely by the motive of the user.

5. *Societal Aspects*

Traditional sociological variables of age, social class, socioeconomic status, gender, and race/ethnicity influence people's relationships with the telephone. Young people are generally much more likely to adopt new technology than their older counterparts. Material resources, as measured by income, also have a noteworthy effect. Predictably, those at the very bottom of a society's income distribution are least likely to have telephone service. More surprisingly, as shown by Katz's (1999) research, people in the third income quartile are disproportionately represented among purchasers of enhanced telecom services. This may be because these services are perceived as entertaining or of high prestige. This noteworthy trend occurs in both Europe and the US; whether it obtains in other regions is unknown.

Since its inception, there have been speculations about the small-group and social interactional consequences of the telephone. Marvin (1988), in her path breaking study of the social reception of the telephone (among other nineteenth century electrical technologies), demonstrated that concerns over the impact of the telephone were reproductive of those the larger society. Among these were the erosion of family authority, race and social class barriers, and sexual and social propriety. Also of substantial concern was disrespectful and deceitful behavior. Victorian-era Americans believed, justifiably, that the telephone reduced social cues ordinarily conveyed in the richer channels of face-to-face interaction and written correspondence. By masking cues, such as the location and social status of the caller, the telephone denied important cues to assist in making judgments about the interlocutor. Thus, it would be easier to violate

social and legal codes. These concerns remain substantial even after a century of telephone use, and are born anew with contemporary communication technology such as the Internet.

The telephone plays a role in the conduct of gender relations and in the pursuit of sexual gratification. In contemporary, often suburbanized society, the telephone has become an important means by which teens socialize themselves, build and sustain their relationships, and amuse themselves in an historical period when they are defined as problematical non-adults Wynn and Katz 2000. Commonly, women run the 'social work' of maintaining family links and social schedules via the telephone. (All other things being equal, when both a man and a woman are in a room together, a woman is twice as likely to answer a ringing phone.) Rakow (1992) has documented the important role the telephone plays in women's relationships, and the ways it provides support for their independence despite various constraints and provides them with social resources they need to pursue their relationships and goals.

As in other areas, the telephone can enhance coordination in people's search for partners. The telephone's role in abetting prostitution has long been noted. (Indeed, a term-of-art, 'call-girls,' clearly refers to the role of the telephone.) While it is impossible to capture precisely the temporal, economic, or organizational magnitude of the telephone's role in the commercial sex industry, plainly large sections of the yellow pages and of urban newspapers are devoted presenting this information in a slightly hidden argot to knowing patrons. Phone booths in many countries are littered daily with miniature handbills enticing customers to one service or another.

The telephone can also serve as a less direct conduit for sexual expression. Indeed, the conduct of remote interactive sex is an entirely *de novo* mode of expression enabled by the phone. The remote as well as the disembodied aspects of a telephone call can have its sexual appeal, and in this regard one hardly need mention the candlestick design that characterized phones for a half century. By relying on its aural and fantasy capabilities, it can also serve as a safe and sanitary substitute for in-person sex. Recognizing this pent-up demand, an entire industry of 'pink services' has sprung up in any country where it is allowed. Definitive data as to its size are difficult to obtain, but an instructive dataset can be derived from the Austrian experience. Austrian law had forbidden phone sex historically. However, in 1991, a revenue-sharing arrangement was established so that offshore companies could benefit from premium international telephone tariffs. The Dutch Antilles became a center of such 'pink services', and numerous companies began placing ads in Austrian newspapers giving their Antillian numbers. The results were dramatic and instructive. For all of 1990, the total duration in minutes of calls to the Dutch Antilles from Austria was exactly 13,050. For the first nine months alone of 1991, the number of minutes of calls from Austria to the Dutch Antilles exceeded 1,600,000.

Not all telephone sex is predicated on a financial arrangement. Many millions of obscene calls are reported annually to authorities. Both men and women make obscene phone calls to obtain erotic stimulation from the reaction of their shocked victims. These types of calls seem to occur throughout the world wherever a telephone system is present. As a case in point, within six months after the first automatic telephone network was installed in Papua New Guinea, an obscene phone call was reported to authorities. A third class of sexually oriented telephone call is neither commercial nor inflicted on victims, but rather occurs by mutual consent. For decades, lovers have enjoyed erotic phone conversations, and the topic receives substantial treatment in literary and cinematic formats. Nevertheless, seldom has public attention to this private aspect of human behavior risen to the heights it did in 1998. As part of a larger relentless investigation, an incident of sexual gratification via telephone between US President Bill Clinton and his White House aide, Monica Lewinsky, was given protracted national media attention and related to Congress in an official report. Thus, presidents and perverts alike serve to demonstrate that the telephone, like every other communication technology—from the video camera to the car, and from the printed book to the web-enabled mobile phone—can be used by people as a context for sexual excitement and fulfillment.

Another striking aspect of the telephone is its use as a tool of personal empowerment. With emergency phone boxes set up on campuses, and especially with the mobile phone, people can feel safer in public areas. It has expanded the places and times that people, and especially women, can go to a variety of places, thus increasing people's freedom and mobility. It also permits parents to expand the privileges they give their children in terms of when and where they can go. This has the intriguing result of both increasing and loosening parental control.

The telephone also enhances individual autonomy by allowing people to live more successfully by themselves. Yet it preserves instant access between those experiencing a medical or police emergency and a variety of support services. In addition, a substantial variety of community and psychological services are available at any hour and often with complete anonymity.

As with any technology, the use to which it is put is influenced by the motives of the human user. Just as not all people are good, neither are all purposes to which the telephone is put benign. The telephone has offered new venues for monitoring individuals, invading their privacy, and harming them materially or psychologically. In terms of monitoring, the wireless revolution, particularly as it intersects with the tele-

phone, is increasingly affecting all aspects of social interaction, from the conduct of relationships to the receipt of medical care. These technologies will not only be used to deliver services but as well to monitor individuals. In the past telephonic monitoring has targeted parolees and the elderly. The number of citizens who are regularly and passively tracked will be increasing; this will be done through the data collected by systems used to regulate mobile phones and intelligent highways. Already mobile phone records are being used in civil (e.g., divorce actions) and criminal cases (e.g., the apprehending of kidnappers).

The telephone also gives individuals tremendous powers to affect others' lives at a distance. Though often used in pranks and practical jokes, the telephone has also been used to inflict protracted harassment and terror on others. Such practices include spreading malicious rumors, making harassing calls late at night, and even concocting identities in order to manipulate or frighten someone. In one case, a young girl pretended to be a nurse, and in this guise reported (falsely) to another girl that her lab test results indicated that she had AIDS and was pregnant. The girl victim attempted suicide and disaster was only narrowly averted. The culprit was caught using caller-ID.

Turning our attention to the underpinnings of social life, Fischer (1992) found that a social–psychological effect of the telephone was that it seemed to accelerate the pace of social life. His classic study, *America Calling*, found that the spread of the telephone in the US reduced isolation and increased social contact. A concomitant finding is that a good proportion of telephone users experienced anxiety or 'communication apprehension.' Many citizens also feared excessive social contact, becoming the subject of telephone gossip, and being subjected to unwanted calls. However, he found no support for more extreme claims that it brought people to a constantly heightened sense of alertness and anxiety over the potential summoning outcry of the telephone's ringing bell. Fischer concludes that the telephone cannot be implicated and the emergence of 'psychological modernity,' that is, the contemporary sensation of free-floating anxiety and dehumanization. Rather, he concludes that on the whole, people readily and comfortably assimilated the telephone into their lives. They used it as 'the conscious product of people employing things, not of things controlling people.'

6. *Technological Convergence*

It is impossible to speak of today's telephone exclusively in its formerly traditional wireline configuration. Mobile phones, discussed below, are but one aspect of this telephonic reconfiguration; it extends to all aspects of voice communication. One salient aspect is the way people manage their calls. For instance, in the US, the majority of telephone subscribers also have some form of answering machine. This device changes how people use their phones, e.g., to monitor before picking up the receiver, and which in turn affects the behavior of the caller ('I know you're there! Come on, pick up.'). Having the telephone answered by a machine was until 1987 seen by the majority of the US population as an act of rudeness to callers. It was emblematic of the fear that 'robots would take over,' and that people were losing control over their daily lives. (This also ties into the above point about the importance of having a secretary to handle one's calls.)

Today opinion surveys show that the majority judges it an important courtesy that should be extended to callers. Some even go so far as to say that it is rude not to have an answering machine or voice mail. Still, the answering machine/voice mail is but one of the ever-multiplying ancillary service that are being added to the formerly black 'one-size-fits-all' telephone. These include built-in faxes, caller-ID, three-way calling, call-waiting, and call-trace; together they are changing what a telephone is and how it is used, as well as the subterfuges that are used to work around the telephone's expanded capabilities.

Even as the telephone becomes more powerful and capable, it is becoming tetherless. Not only is the home phone increasingly likely to be cordless with reception to a $\frac{1}{2}$-kilometer from base, but people are increasingly subscribing to mobile telephone services that will allow them to range across continents. Moreover, some people are abandoning their wireline phones entirely; in the US, about four percent of subscribers have done so already and their numbers are increasing. Among other things, this trend means the loss of geographical meaning to area codes. Conversely, the physical telephone line is for most Internet users their primary access mode; but mobile telephones are also becoming Internet enabled. Although currently most users access the Internet via the computer, it seems inevitable that soon the majority will be doing so from enhanced mobile phones.

Computers themselves are increasingly encompassing the features of the telephone, becoming Internet phones and answering machines and voice chat messaging units. Personal digital assistants are beginning to act as both mobile phones and portable computers. Platform capabilities are becoming intermixed, that is, telephone conversations can occur virtually anywhere with anybody via any machine. One consequence of this technological advance is that, without too much hyperbole, it appears that there is arising a new sense of 'perpetual contact.' This new state will allow better co-ordination, improved business operations and enhanced kin and social relations. It will also introduce new conflict over the appropriate norms for, and possible constraints on, people's public behavior. To cite an instance, there are now mobile phone-free rail cars and restaurant sections.

Already, however, the proliferation of mobile phones has created a brouhaha over their use in public places, most especially while driving cars. Though some of the controversy revolves around manners and appropriate levels of sensitivity, the larger issue of the use of and conduct in public places is only beginning to be addressed. It remains an unsolved puzzle for social scientists and the architectural profession to create public spaces that can amenably coexist with privatizing mobile telephonic behavior. However, the much more powerful issue is the question of safety. Mobile phones mean not only that lives can and will be saved but also that—because there are those who elect to use it while driving—lives will be lost. Sadly, there is a growing toll of people killed by mobile phone using drivers. Those who are affected by such tragedies will be fostering legislation to restrict the use of mobile phones in cars.

7. *The Telephone as Synecdoche for the Modern Condition*

The telephone has had substantial impact on the structure and quality of human existence, from business to sex, and on the conduct of war and peace from the international to the intra-family level. Never has so small a device been used so easily by so many to do so much to so many.

The use and abuse of the telephone encapsulates and expresses the dimensions of social scientific perspectives on modern life. What happens in the larger canvas of life is reproduced within the ambit of life on the telephone. The telephone's impact stems from the inherent qualities of a technology that allows easy, inexpensive real-time interaction by voice over both short and great distance. People have investigated aggressively and exploited this technology's potential. Through this unrelenting effort, there has been an isomorphism between what the technology can achieve—as its capabilities become more sophisticated—and the needs and desires that exist within mankind's biological and social framework.

The telephone system has been used in ways as broad as the human imagination, many times in ways that were never envisioned (or were even opposed) by telephone company system designers and marketers. Telephone systems have been used to broadcast operas and provide wakeup, dial-a-joke, and dial-a-prayer services. Psychological and emergency services, astrological advice, and interactive matchmaking services are among its staples. Users themselves have created a variety of 'work-arounds' to beat the telephone system (e.g., tone generating boxes that allowed caller to bypass toll charging mechanisms). None of these uses or innovations was foreordained. Rather, as shown by Coopersmith (1991), far from a calculated manipulation of telephone company executives, some innovations as enormously successful as the fax and answering machine were at various points in their development opposed and thwarted by telephone company executives.

No dictator, the telephone has become a servant to those pursuing profit and pleasure. The picture after more than a century and a quarter is quite unlike those sketched originally by hand-wringing dysutopians, such as Mark Twain. These critics saw the technology as depleting social capital, killing social relationships, and inducing depression (a view similar to today's critics of the Internet).

On balance, the telephone has clearly done far more to liberate humanity than enslave it. This observation is not meant to downplay the harm that can be and is inflicted telephonically. Like two other communication technologies—the airplane and the car—the telephone can be used for both good and evil. It can be used to wreak suffering and terror; it can be used to carry messages of love, hope, and redemption beyond the vast oceans. In this context, then, we should recall the lessons of the Bible and the Greek myths that even the existence of a powerful god is not without frustration.

Televangelism

Televangelism refers to what used to be called the 'electric' or 'electronic church,' which is the religious programming sponsored by evangelical Christians using commercial television time with the purpose of bringing individuals to salvation. Televangelism as a term was first developed in *Prime Time Preachers: The Rising Power of Televangelism* (1981), which explores the rise of the phenomenon in the USA. The term is also fairly interchangeably used with 'electric' or 'electronic church' as defined by Ben Armstrong (1979) to define the use of broadcast media, first radio, then television, to deliver church messages. Schultze presents the 'electronic church' as a construct defined by its 'business values, experiential theologies, media-derived formats, faith in technology, charismatic leaders, and spin-off ministries' (1990, p. 42). Either term refers to both the broadcast itself and the institution and norms that are created within it to demonstrate its values (Frankl 1987).

1. *The Development of Televangelism*

The technological development, adoption and regulatory environment surrounding the advent of radio and television in a given society is critical to the development of televangelism and for that reason televangelism varies across nations, depending largely on the degree and type of control over media programming. The creation and tone of televangelism in the USA is very closely tied to the rules governing programming in the early days of radio and the ways in which evangelical Protestants took advantage of shifts in media regulation.

1.1 *Televangelism in the USA*

In the early days of radio regulation in the 1920s, the Federal Communications Commission (FCC) required broadcasters to provide free access to the airwaves in the form of public service broadcasting (Finke and Stark 1992). The networks then turned to the Federal Council of Churches as a way of streamlining the work of picking groups that would be allowed access to the airwaves. The Council of Churches, however, represented 25 mainstream denominations (Bruce 1990) and created guidelines to promote mainline denominations, shut out fundamentalists and encourage local churches to share time in ecumenical broadcasts. Because the churches that made up the council quickly monopolized the available free time, only a couple of the largest evangelical churches were able to obtain time through the public service broadcasting avenue. In addition, little opening existed for purchasing time (Bruce 1990).

Protesting evangelical organizations formed their own pressure group for lobbying the networks; this group eventually became the National Religious Broadcasters (NRB) in 1944 (Bruce 1990), after the Mutual Broadcasting Company announced new policies that made it even more difficult for evangelicals to reach the airwaves (Hadden 1993).

The NRB was successful in obtaining access to paid time for its members. For over a decade following its founding, the NRB made significant strides in increasing the visibility of evangelicals on the air and by the late 1960s 'dominated the religious airwaves' (Hadden 1993, p. 116). The theological emphasis on salvation dovetailed neatly with the necessity of evangelical broadcasters to ask for money to support these programs. Hadden asserts that televangelists offered viewers the 'product' of salvation and then asked them to contribute in order to help the broadcasts to continue to reach new (and unsaved) viewers (Hadden 1993, p. 117). Through being forced to pay for air time and thus offer programming that viewers were willing to support financially, evangelicals were well positioned for the changes to come in FCC policy. In 1960, the FCC ruled that broadcasters did not have to give away time for it to count as public service time; time previously given to the mainline churches could now be sold, not given, to them under this policy (Hadden 1993, p. 118). While the mainline denominations protested this change, they were unable to maintain their access to free airwaves and evangelicals moved in to purchase time from local stations. In addition, videotape made it possible to for broadcasters to distribute their programming inexpensively for simultaneous airing in multiple markets (Roof 1997). These two developments in policy and technology, coupled with the programming savvy of the evangelical broadcaster positioned them for the airwave dominance that they maintained until the scandals and political activism of the late 1980s and early 1990s.

While televangelist scandals are well known for landing one broadcaster in jail and ending several television ministries, the effect of the political activism embraced by the broadcasters is less frequently mentioned. The political stances and eventual presidential bid of Pat Robertson and the activism of Jerry Falwell are correlated with the stagnation of their audience share (Hadden 1993). Since the dramatic expansion of cable wiring in the 1980s many televangelist broad-

casters have embraced cable and broadened their programming to include not just services, but also other 'family friendly' programming such as reruns of early network sitcoms.

1.2 Televangelism in Sweden and African Countries

While the experience of televangelism in the USA has been rather high profile and well documented by journalists and scholars alike, it is worth considering the development of televangelism in other cultures to understand more fully the influence of the intersection between religion, technology, and policy, and the development of media programming. Comparative work on religious broadcasting in the USA and Sweden by Linderman (1996) notes the differences in the religious environments in the two countries. Where the USA has a tradition of pluralism that in the case of religious broadcasting was for a time dominated by mainline churches, the Church of Sweden is the Lutheran national state church within a nation of religious freedom. Other religious bodies are the Pentecostal movement and the Mission Covenant Church, which vie with the national church for airtime. The Swedish Broadcasting Corporation allocated 75 percent of time for morning services and all major holidays to the national church and the rest of the time was allocated to the council representing the free churches. However, the Swedish Broadcasting Corporation eventually came to believe that it should regulate not only the time for religious broadcasting, but also the format and content. Their view was that 'religious radio should be more open, and able to communicate the general Christian message to people outside the churches—thus in a way being more "evangelistic" compared to the view of the churches' (Linderman 1996, p. 102). In addition to the broadcasts from Swedish religious organizations, the expansion in the number of channels received by viewers in Sweden also brought televangelists from the USA to Swedish airwaves, including the 'Hour of Power' with Robert Shuller (Linderman 1996).

Work on televangelism in Africa includes discussion of the early entry of international televangelists from the USA and European countries into the African media and debate over the appropriateness of the format. Hackett finds that early televangelism in Africa consisted of broadcasts of American televangelists with broadcasts in Ghana of Oral Roberts from the late 1970s to 1982, and Nigerian broadcasts of Pat Robertson's CBN news in the 1980s (1998, pp. 262–3). Hackett also notes that the development of televangelism and the dissemination of mediated religious messages is tied with the development of the megachurch through the charismatic leadership of evangelical churches in the region. In addition to the radio and television broadcasts, tapes are marketed and shared among family and friends, and thus further disseminated throughout the community. However, the development of televangelism is criticized by some clergy as inappropriate in a region with so much poverty (Asuzu 1987).

2. Approaches to the Study of Televangelism

Televangelism involves media, religion, sociology, history, political science, and economics, thus, is under examination from a variety of disciplines. Frequently cited for their work in documenting the development of televangelism both as a form of mediated religion and as cultural construct are Hadden and Swann (1981), who coined the term televangelism and extended interest in televangelism beyond religious circles to involve sociology and economics. In addition, Bruce's *Pray TV: Televangelism in America* (1990) revisits the history and the current issues in televangelism and asserts that the audience figures for televangelism are overestimated; this debate will be explored more fully later. Some analysis of televangelism has focused on the confluence of the economic and religious marketplace (Finke and Stark 1992). Historians have chronicled the role of religious broadcasters in political debates (particularly Father Coughlin in the l930s) as well as the struggles between religious factions for control of the airwaves.

2.1 Televangelism as Ritual

Other researchers have considered televangelism as a ritual informing the lives of viewers, connecting them with a broader community of believers. These scholars claim that the ritual transforms the everyday world into the symbolic and through reflection provides a base for guiding one's everyday life (Alexander 1997). Televangelism may serve to legitimize the messages performed in the course of the program. This concept of the ritual within televangelism connects it to the interest in the audience for such programming. Study of the televangelism audience takes many forms, from the interest in how believers approach the form as a ritual to analyses of a market share and ratings. Hoover's *Mass Media Religion* (1988, p. 112) examines *The 700 Club* audience in terms of how viewers' histories intersect with their experience as viewers both as individuals and as a community formed as an audience. Comparative research on the reception of re ligious television in Sweden found that US evangelicals differed greatly from Swedish evangelicals in terms of how they perceived the program's believability, pointing out the possibility for future exploration of how media and religion in differing cultures produce these outcomes (Linderman 1996).

2.2 Debates Over the Size of the Audience for Televangelism

As previously alluded to, questions over the size and scope of the audience for televangelism has fostered a

debate that includes not only scholars from a variety of disciplines, but also religious broadcasters. Early studies of this audience, most notably one supervised by the Yale Divinity School in 1955, attempted to delineate attributes of the audience correlated with religious programming and addressed the potential influence of level of religiosity, socioeconomic status and denominational affiliation (Parker et al. 1955). Hadden and Swann (1981) sought to balance the proclamations of the televangelists themselves and ratings by Arbitron by comparing systems of measurement in order to explain why the televangelists' numbers were so high and Arbitron's so low. They concluded that while Arbitron's figures may have been low because of the failure to include cable data, that the rating company's numbers were probably the most accurate. Hadden and Swann also concluded that while the numbers of viewers were not insignificant, the audience for televangelism had declined from 1978–80 by approximately two million viewers (1981, p. 55). Bruce (1990) noted that a 1987 study using data from both Arbitron and Nielson produced radically different audience figures, 13.3 million and 70 million viewers, respectively. These discrepancies, of course, point out major problems in comparing audience measurements based on differing assumptions, but they also call to question the power of televangelism as a force for mobilization. Hoover's discussion of the myths surrounding religious broadcasting labels the assumption that there is a large and 'significant' audience for televangelism as such a myth (1990). He notes that the funding formulas for televangelism differ considerably from that for standard commercial television and that audience size, donations to meet costs, and the ability of a program to stay on the air are not interdependent. Hoover also points out the importance of televangelism programming from within an evangelical group as opposed to the importance assessed by those from outside that community who may tend to overemphasize the significance of a program being on the air. Obviously, given the differing perceptions of those within and without the televangelism community and the differing means of audience measurement, this debate will not be easily settled and its continuation fuels other questions of secularization and the intersection of media, religion and culture.

3. *Future Directions in the Study of Televangelism*

As the media landscape has changed considerably, not only in terms of forms of media, but also the economic structure of media, the concept of televangelism is probably going to change with its environment. While the dramatic growth of the Internet with its potential for religious communities, dissemination of information and the creation of decentralized networks of individuals is certainly one avenue, more closely tied to the original development of televangelism is the structure of the mass communication industry. It appears that two intertwined avenues are likely for future investigation. The first, the economic structure of mass communication, has produced powerful conglomerates for distributing programming across a variety of media and with these changes comes a synergy, as a conglomerate uses its many venues to promote a certain media product. The second, closely related, change in the media environment comes from the production of messages to be disseminated across formats, from film to video to television to radio and print. Just as Disney promotes films and characters that are then presented in Disney World, Bakker used his television platform to promote his dream for a Christian values theme park. Colorado-based 'Focus on the Family' started with a radio broadcast by Dr. James Dobson and built an organization that now markets tapes, videos, magazines, and books to disseminate the organization's message not only in the USA but in multiple languages throughout the world. In addition, Big Idea Production's 'Veggie Tales' video series for children provides a marketing hook for the merchandising of toys, stuffed animals, workbooks, and tapes in the USA, Latin America and Saudi Arabia. Future studies of televangelism may find it increasingly difficult to address one television program or one televangelist in isolation; instead, work may need to focus on Christian media companies that produce a variety of formats for multiple audiences.

Television: General

Television has been the dominant mass medium in most Western countries since the 1950s. It has been studied in a great variety of ways, in a number of scholarly disciplines, from psychology and the social sciences to film studies and art history. In the 1970s and 1980s, precisely because the medium invites cross- and interdisciplinary approaches, the study of television was central to the establishment of new forms and institutions of scholarly inquiry and teaching on the borders between the social sciences and the humanities, media studies and cultural studies. So far, there are very few if indeed any university departments exclusively devoted to television studies.

The study of television is, thus, still organized in accordance with the general divisions between scholarly disciplines and between 'schools' within (mass) communication and media studies. But especially since the early 1980s there has also been a trend toward a form of eclecticism where it is recognized that useful work is done from a number of starting points, employing a number of methodologies and a variety of theoretical frameworks.

1. *The Medium and Modernity*

Williams suggested in *Television: Technology and Cultural Form* (1975) an understanding of television that focused on its social organization as a broadcasting medium, arguing that there is a functional fit between this form of communication and the conditions of modern society. Processes of modernization led on the one hand to centralization of resources and power, on the other to increased social and geographical mobility. Williams termed this latter aspect of modernization 'mobile privatisation,' referring to the relative social isolation of individuals and nuclear families literally and metaphorically 'on the move.' Broadcasting was simply a highly adequate institution in this social situation. It makes immediate distribution of necessary information to all citizens possible, and efficiently contributes to the construction of the 'imagined community' (Anderson 1983) of nation–states.

Historical research has demonstrated that television technology in itself had other possibilities as well. It was already envisaged in the nineteenth century as a new form of two-way communication. Companies such as AT&T experimented with 'picture-phones' in the 1920s, and amateurs started constructing simple transmitters and receivers. Also, the idea of video surveillance was explored at this time (Allen J 1983). A more serious alternative to broadcast TV was television as a theatrical medium for collective, public reception. Nazi Germany developed such a system in the 1930s, with hundreds of public television halls throughout the country (Uricchio 1989). Most people who experienced the first telecasts of the BBC in that decade did so in restaurants, at railways stations, and the like (Corrigan 1990).

But already in the 1880s, there is evidence that popular imagination played with the idea of broadcast TV, that is, the transmission of sound and images from some central source directly to people's homes, organized in genres such as news, education, art/entertainment, and advertising (Wheen 1985). In the 1890s, Thomas Alva Edison and others were striving to come up with a successful solution for broadcasting TV (Sklar 1976, p. 11), and the idea circulated throughout the Western world. All of this lends support to the idea that broadcast television to private homes is related to fundamental social structures and interests in modern capitalist societies, such as the division between the domestic and the public realms on the one hand and the need for socially and culturally integrative efforts on the other. Furthermore, processes of democratisation could obviously also be served by broadcasting media since they allow for a more equal access to resources of information, knowledge, and cultural experiences.

The development of multichannel systems of broadcasting via satellites and cable systems since about 1980 may thus be thought of as 'divisive' since they constitute numerous separate viewer-communities within a given nation. So-called postmodernist theorizations of television have consequently seen multichannel television's abundance of programs on offer at any time as a manifestation of a new, presumably 'decentered' social and cultural situation (e.g., Collins 1989). Relatively little empirical work has been done on the larger social and cultural consequences of the transition from one or a few to dozens or even hundreds of television channels. But

most viewers still spend much or most of their viewing time with a handful of channels, and watch discreet programs as much as they just zap around. Hence the continued existence of 'hit shows' and newscasts competing over ratings. Most channels still stick to the same genres of programming, have fairly similar newscasts, and address the same or similar issues. It can, thus, be argued that television has retained much of the socially and culturally integrative functions ascribed to it by Williams. Clearly, though, these functions are modified, first, by multichannel satellite and cable TV, and, second, by the already ongoing digitalisation and convergence with (other) digital media.

2. *Policies*

The history of television policies starts with the attempts to regulate radio broadcasting in the 1920s. The fact that the number of available frequencies was finite led to forms of public regulation that are unheard of for other mass media. While most European countries decided to organize broadcasting institutions as state-owned monopolies, financed by a license-fee, the US from the beginning regarded broadcasting as another business opportunity, where profits would come from advertising revenues. The US also had to regulate broadcasting in ways that made it a quite particular area of private enterprise. Frequencies had to be allocated to broadcasting organizations by some public agency, operating in accordance with a set of politically determined principles. The first comprehensive broadcasting legislation in the US, the 1927 Radio Act, made clear that those who were licensed to use radio waves, were required to serve 'the public interest, convenience, or necessity' (Hoynes 1994, p. 38). The Federal Radio Commission, which in the 1930s became the Federal Communications Commission, was therefore established. It has ever since played a pivotal role in political struggles over the development of broadcasting in America, with agendas shifting as political administrations have come and gone. Key issues have been the ways in which competition is to be ensured with a necessarily limited number of actors in the market place, and whether or how space and resources are to be provided for noncommercial, public TV. Underlying both issues is the question of what the notion of the 'public interest' which broadcasting is to serve actually means.

Regulations and the forms of funding clearly influence program output and thus the medium's social functions. Williams (1975) demonstrated in a simple quantitative comparison the differences both between programming in commercial and noncommercial channels and between the television systems in the UK and the US. In the US, public channels were without broadly popular drama or other entertainment, while network TV was lacking documentaries, one-off dramas, educational programming, etc. The result was a polarized system where the majority of viewers would in practice not encounter certain types of programs that might be important to them as citizens. In the British 'duopoly' system the characteristic differences between commercial and public channels were also observable, but the differences were considerably less pronounced so that the programming menu available to all viewers was more varied.

The BBC generally functioned as a model for European public service television. The definition of public broadcasting's mission formulated by the BBC's first Director General, Lord Reith, was thus programmatic for most or all of these institutions—they were to provide information, education, and entertainment to the entire population at a price affordable to all. Some critical scholars, especially in the 1970s, perceived the BBC as an elitist institution basically affirming the existing cultural and social hegemony in the UK. However, when commercial satellite television arrived in the 1980s such critique partly gave way to a view that emphasized the democratic qualities of the public service television tradition. Since the mid-1980s, the threats to public service television posed by so-called deregulation of broadcasting and the expanding commercial offerings have motivated lots of research into the traditions and conditions of this form of broadcast TV all over Europe, including comparative studies that clarify considerable differences between the various national systems (e.g., Syvertsen 1992, Raboy n.d.).

The European Union now decides much of the premises for broadcasting policies in Europe even if this is in principle an area where member states are to retain national sovereignty. On the other hand, the EU has officially decided that public service broadcasting is to be protected. The European Council of Ministers (which includes the EU member states but also all other European countries) has done the same and also defined 'public service television' in a way that very clearly sets it apart from and in opposition to purely commercial services. Many of the pertinent issues in research on public service broadcasting and broadcasting regulation in general now has to be of a legal and economic nature. Most crucial, however, is the question of what happens when digitalisation does away with spectrum scarcity, the legitimation of traditional broadcasting regulation.

3. *Production*

Research on television production ranges from studies of political regulations, ownership, and other aspects of the economics of the television industry, to participant observation in broadcasting institutions and independent production companies to theoretical discussions of the notion of 'authorship' in the context of the necessarily collective production processes in television.

The so-called 'political economy' tradition in mass communication research has always focused on the importance of economic forces and related social structures. Prominent representatives of this tradition are Schiller (1989) in the US and Garnham (1990) in the UK, both regarding television as part of the larger media system of capitalist societies. Networks and production companies are parts of huge conglomerates encompassing not just media and leisure industries but also any number of other branches of business. These enormous concentrations of capital exert considerable political and cultural power, both domestically and internationally. British scholars of the 'political economy' tradition have, moreover, been exploring the implications of Jürgen Habermas's theory of the 'public sphere' for our understanding of television and the media in general (see *Mass Media and the Public Sphere*; *Mass Media, Political Economy*; *Information Society*).

In-depth studies of television production practices and personnel are not many. Cantor's *The Hollywood TV Producer: His Work and His Audience* (1971) is a classic in the field, a piece of organizational sociology charting the space for creativity in television and describing three types of television producers—the 'filmmakers,' the 'old-line producers,' and the 'writer–producers.' The often well-educated writer–producers appeared as the only group that both take the medium seriously and expect the audience to accept more ambitious shows with social 'messages.' Newcomb and Alley (1983) represent a more traditional humanistic view of textual production in their *The Producer's Medium*, based on interviews with individuals they claim have managed to leave their personal imprint on the series they have produced. Gitlin's *Inside Prime Time* (1983) is a study also of top-ranking executives which demonstrates not least the space for personal agendas and preferences when decisions about programming are made. Executives may use results of audience research that support their intuitive preferences while setting aside those that do not.

A few studies of production are combined with textual analyses of products. An early example is a study of the independent company MTM Enterprises, which contributed to a renewal of US television drama with shows such as *The Mary Tyler Moore Show* and *Hill Street Blues* (Feuer et al. 1984). In Britain, Tulloch and Alvarado (1983) did a similar study of the BBC serial *Doctor Who*. Buckingham (1987) and Gripsrud (1995) are examples of studies that also add an analysis of audiences to the study of production and textual analysis, thus covering the entire communicative process.

4. Programs

Williams (1975) was the first to name and point out the importance of the way in which television's (and radio's) programs are presented as parts of a continuous 'flow.' This means, according to Williams, that the impressions and meanings of individual programs will tend to overlap and merge in the viewer's experience. Flow remains a fundamental feature of broadcast programming. The ordering of programs in certain sequences, so-called scheduling, is of great importance to any television channel. It represents a channel identity and can be use to attract and not least keep viewers for the channel's programs and ads. As Ellis (1983) pointed out, most programs also consist of *segments*, that is, sequences of up to about 5–7 min that are more or less self-contained in terms of meaning. This structure results in part from its practical advantages from a production point of view, but it is also related to the need to make programs accessible to viewers who arrive in the middle of a program. The 'program' unit is thus in a sense a troubled category, threatened by dissolution both by the 'flow' and by internal segmentation.

The limits of 'the program' as an object of textual analysis have consequently been discussed, including the problem of separating the program text from the ads that are inserted into it and the question of the status of a single program or episode in soap operas that run an ongoing story for decades (Feuer 1989, Allen R 1985). In practice, viewers have few problems in identifying their favourite show and distinguishing it from the ads, and a soap opera (as well as newscasts and other long-running programs) may be analysed by way of a more or less representative sample of episodes (Gripsrud 1995).

It is probably correct to say that most textual analyses of television have been preoccupied with questions of representation and ideology, that is, the representation of gender and sexuality, of race and ethnicity, class, social conflicts, political issues, etc. and how they relate to larger ideological patterns and struggles. To these ends, all the theoretical, more or less philosophically grounded approaches in textual analysis have been applied in a variety of blends—semiotics, psychoanalysis, phenomenology, hermeneutics, etc. While fiction and entertainment have provided most of the material for such work, also newscasts, talkshows, and documentaries have been analyzed, often interestingly demonstrating the ways in which such 'reality programming' is actually constructed in accordance with certain textual traditions and principles rather than relating directly the structures of external reality.

The most prominent of social science traditions in the field of program analysis is so-called quantitative content analysis, which defines certain elements of content and then proceeds to count their occurrences, most often across large samples of programs. Typically, the elements counted would be violent acts, sexual innuendo, women in powerful positions, etc. Such research may provide overviews of developments over time in certain dimensions of programming or

suggest the extent to which certain portrayals of social categories or issues have a dominant position in the total program output or in a certain genre. A prominent example of large-scale quantitative content analysis of television programs is that conducted by Gerbner and co-workers in the late 1960s and early 1970s, the results of which were central to the formulation of the so-called 'cultivation theory,' that is, a theory of television's long-term consequences for people's world view (Gerbner 1973). Their analyses indicated that (US) television, across genres and individual programs, presented a systematically distorted view of social realities in a number of areas such as family life, work and social roles, aging and dying, crime, and violence. Correlating content analysis with opinion surveys then seemed to suggest that viewers, especially heavy viewers, accepted this distorted view of social conditions as true.

5. *Audiences*

In line with the general history of research on modern mass media, worries over how the new medium affected especially children and adolescents were important starting points for the first studies of television in the 1950s. For example, Maccoby (1951) concluded that the medium undermined communication within the family, even if it made family members spend more time together. The same researcher later tried to show that television viewing had a negative 'escapist' function for children who were lacking real-life satisfactions (Maccoby 1951). Studies such as these were fraught with both conceptual and methodological problems, and marked by a prejudiced, negative attitude to the medium. Any viewing of dramatic fiction would for instance tend to be counted as 'escapist,' reflecting a somewhat shallow understanding of the uses of fantasy and art in general. Around 1960, large empirical projects both in the UK and in the USA tried to estimate the social and cultural implications, especially for children, of the nationwide introduction of television (Himmelweit et al. 1958, Schramm et al. 1961). The everyday lives of children in communities with and without television were charted in surveys and compared. The findings of these studies were quite complex and did not give a totally negative view of the medium's social and cultural role.

The above mentioned 'cultivation theory'—or, rather, hypothesis—is basically in line with critical theories of the structural, long-term power of the media to define social reality in ways that harm various disadvantaged social groups. Throughout the 1970s such perspectives on television were theorized and significantly renewed in work conducted by researchers at the Centre for Contemporary Cultural Studies at the University of Birmingham, UK. Hall (1973) applied concepts from semiotic theory to the process of communication, speaking of production as a moment of 'encoding' and reception as a moment of 'decoding,' thus theoretically demonstrating the possibility of complications in the 'transfer of messages' that were not simply due to 'noise' or misunderstandings. Hall suggested three main types of 'readings' of television programs—'dominant,' 'negotiated,' and 'oppositional,' that is, acceptance of the program's 'message,' partial agreement, and critical rejection. An empirical study of groups of viewers conducted by Morley and Brunsdon (Morley 1980) demonstrated how social class and political convictions might shape audience attitudes to television programs, making some groups more critical than others. In the wake of this study, audience research within or close to the British cultural studies tradition has repeatedly demonstrated how varied interpretations and evaluations of programs might be, both within and between social classes, races, genders, and nations. They have also described how television viewing is inscribed in people's everyday lives and the routines and power struggles that prevail there (e.g., Morley 1986, Seiter et al. 1989), how this came about historically in a wider social and cultural context (Spigel 1992) and, somewhat more abstractly, how television viewing has deeper social functions related to its psychological functions for viewers (Silverstone 1994, Ellis 1999) (see *Audience*).

6. *Medium*

Much scholarly writing and various sorts of research may be categorized as contributions to an understanding of television's specificity as a medium in terms of the ways in which it represents reality outside of itself and the ways in which it relates to its audiences. One of the first contributions of lasting significance on the latter theme was the article by social psychologists Horton and Wohl (1956) in which the authors coin the term 'para-social interaction' in a discussion of the 'intimacy at a distance' characteristic of the relations between viewers and television characters such as talk-show hosts. The term refers to the way in which viewers tend to establish pseudo-dialogical relations with television characters, 'talking back' to them, etc. These practices set television apart both from film and radio, and reflect the particular type of intimacy associated with this domestic audio-visual medium. They can, besides the domestic location of sets, be tied to the normal size of the screen, which renders close-ups of human faces close in size to those of interlocutors in the same room. Importantly, television's 'talking heads' often address viewers directly ('you'), simulating real conversation also in its preferred styles of speech. These features are shared by radio but have an even stronger effect when combined with moving images.

Furthering this line of thought, Meyrowitz (1985) argues that television has contributed significantly to a series of important changes both in the public sphere

and in the relations between people in general. Television has moved politicians and other public figures closer to the rest of the population by presenting them in close-ups and settings that make them appear more 'ordinary.' A new way of appearing in public has thus developed, in which the public/private distinction has become blurred. Meyrowitz terms this 'middle-stage' behavior, referring to Goffman's (1959) distinction between a 'front stage' and a 'back stage' set of conventions for self presentation. This has radically altered the conditions for all sorts of rhetorical practices. Moreover, television programs have provided children with insights into the world of grown-ups and boys and girls now know more about each other's intimate lives. For better or worse, television has thus reduced distances between various social categories and weakened certain hierarchical and authoritarian structures.

The capacity for simultaneity between a real event and its transmission and reception as audiovisual representation, that is, 'liveness,' is central to television's specificity as a medium and its social role. It shares a form of distribution (broadcasting) with radio, it shares subject matter also with newspapers, magazines, and books, and it shares the audiovisual form of representation with film. Early television was all 'live,' but now nearly all television programming is prerecorded. Television producers and broadcasters actively seek the impression of immediacy or 'liveness'; it is simply a key aesthetic value in television. This is related to what Barthes (1981) termed the 'photograph effect': when we see a photograph we (used to) know that what is in the picture has actually once been in front of a camera. Television wants this, and more: not just 'this really happened,' but 'this really happens, right now!' Studio debates, interviews, and variety shows will either be live—or try to appear to be. Pretaped shows like sitcoms will often inform us that they are 'taped in front of a live studio audience.' Liveness is particularly important to newscasts, since 'news' as a genre is based on getting as close to immediacy as possible. This is why reporters often talk to the camera—'live,' 'on the spot'—at a dark place where nothing is happening (anymore). What is at work here is an equation of 'live' with 'real': liveness means reality, or *truth*.

A medium that can give us 'reality in the raw,' unfolding as it happens, cannot lie, it would seem, and this ability tends to lend a particular quality of immediacy, realism, or truth to much more than live programming (cf. Heath and Skirrow 1977). 'Liveness' as an aesthetic value is, therefore, still important even if new technologies and styles of presentation progressively makes the medium *less* 'live' (cf. Feuer 1983). Caldwell (1995) has argued that television is more and more becoming a medium not about outside 'events' but about itself and its visual style. But there is still much live programming, and liveness as an effect remains important for the above reasons.

'Liveness' is furthermore a key to television's ability to establish experiential communities. It strengthens the general experience of collectivity in the act of viewing (cf. Rath 1989). Televised national events manifest and support national identity, and so the question is whether or to which extent globally televised events—rock concerts, Olympic games, royal weddings, or funerals—can contribute to the establishment of new sense of transnational community. Dayan and Katz (1992) argue that television's live broadcasts of major events function as rituals that not only reinforce existing symbolical orders but also create new ones. This is just one of the ways in which television continues to be of great political, social, and cultural importance (see *Media Events*).

At the start of a new millennium, television as we know it is, according to many, about to disappear. Digitalization leads to convergence with any and all other media of communication. The distributive model of broadcasting may appear to be replaced by that of the World Wide Web, that is, a system without designated centers, presenting unlimited choice of contents to consumers. These consumers must now be thought of as active individuals and hence the term 'audience' is no longer adequate.

It may, however, also be argued that such a total revolution is envisaged mostly on the basis of technological possibilities and that the outcome of an undoubtedly comprehensive process will be modified by social and cultural forces and interests that may sustain the further existence of broadcast television. Total fragmentation and individualization will be restrained by the need for community-forming, shared media experiences and the need for competent, reliable editorial services or guidance in the confusing mass of contents on offer. Commercial interests will no doubt seek to exploit such needs and strive to establish control of gateways to and routes within the new landscapes of electronic information and entertainment. Governments may seek to find ways of securing the production of identity and distribution of cultural resources represented by the classic broadcasting model, particularly in its public service versions. Historical experience with introductions of new media indicates that already existing media survive alongside the newcomers. Theater was not killed by film; film was not killed by television. Even radio survived television, and books and newspapers are still around.

The dynamics of the ongoing process present television research with a number of exciting, difficult tasks, even if the profession of prophets should not be confused with that of serious scholars. The situation calls for studies of the relations between technological developments, economic forces, sociocultural structures, and, not least, the space for political interventions. Such studies could well be motivated by an interest in how democracy is served by various media systems and structures. The link between theories of democracy and media is generally in need of sustained,

philosophically qualified reflection. The process of convergence and increased interactivity also calls for in-depth analyses of the uses and functions of new and old versions of television, not least the ways in which new and old forms relate to each other. Finally, digitalization opens a whole set of new aesthetic and rhetorical possibilities; new forms of representation, new ways of telling stories, new ways of persuading consumers and citizens. While all of these new areas of inquiry will no doubt require new theoretical and methodological tools, the experiences of some 60 years of television research are well worth keeping in mind. Re-inventing the wheel remains a waste of time.

Television: Genres

The most basic definition of genre is a 'type,' 'kind,' or 'sort', and when applied to television, it refers to specific kinds or categories of programming. The categories may distinguish broad program types such as fiction and nonfiction, or may create narrower delineations such as the division of fictional programs into soap operas, cop shows, sitcoms, and hospital dramas, and non-fictional ones into sports, news, religious shows, talk shows, and so on.

Genres forge a strong link between the television audience and the television industry, a direct connection between the consumption and the production of programs. For a commercial television system, such as that of the USA, this link is of the utmost importance.

The phrase 'television genres' has unique meanings and ramifications for different television systems and audience members in different areas of the globe, but the general notion of television genres has had a profound effect on structuring television the world over. Many television systems were born in the throes of enormous struggles over what types of programs would constitute the broadcasting of the nation. Would they be educational and informative or predominantly entertaining? Would they be religious or secular? Would they be high culture or popular? Would they be nationally produced or imported?

Even after the establishment of national television systems, heated debates over program types often emerged in establishing regulatory policies and shaping the future of the system. If systems were commercial, such as that of the USA, what would be the place of news, educational, or politically oppositional programming? If systems were state operated, such as those of many European, Middle Eastern, and Asian nations, what would be the place of entertainment, imported programs, and shows that might run counter to state policies or predominant religious beliefs?

Every national television system and their audiences need to be studied in great detail to determine exactly how genres have worked in their histories. A closer look at US television will detail some of the major ways that genres have participated in defining it along particular lines, in forging its commercial character, and in fashioning the culture of its viewers and nation. Because American television is currently imported in numerous countries of the world, a closer look at the functioning of genres in its operations will aid in understanding a great deal of television programming in circulation today, particularly from the point of view of its production. Such a look should also bring into focus various aspects of genre that can be compared and contrasted with the programming of other television systems in other areas of the globe.

1. Genre and the US Television Industry—A Historical Sketch

1.1 The Transition from Radio to Early Television

From the first flickers of the first cathode ray tubes in the living rooms of postwar America, the principle of genre was already at work in trying to create an audience for the new medium. By the early 1950s many popular radio shows of various generic categories appeared in television incarnations, including the western, *The Lone Ranger*, the quiz show, *Twenty Questions*, the soap opera, *The Guiding Light*, and the domestic comedies, *Beulah*, *The Goldbergs*, and *The Life of Riley*, to name only a few. This was because television inherited many of its programming and operating principles from US radio, which had developed over the previous 30 years into a thoroughgoing commercial system, dependent on advertiser dollars and governed by a ratings system for judging the popularity of shows.

Genres had become a major force in the economic workings of US broadcasting. Throughout their histories, the radio networks (NBC, CBS, and later ABC) and the television networks (NBC, CBS, ABC, and the short-lived DuMont) gradually sought to determine, through ratings mechanisms and statistical sampling (diaries kept by families 'scientifically' selected by ratings companies, and later by a combination of diaries and meters hooked up to home receivers), how many listeners or viewers were tuned in to what programs; to catalog specific listener or viewer demographics (primarily according to age and gender); and to rate programs based on which ones attracted the most audience members. The implications of this phenomenon were more far-ranging than they may at first appear: the programs (and consequently their genres) that attracted the most audience members of the right ages (those aged 18–49 generally came to be the most valued) became the ones that the broadcasting industry wanted to produce and reproduce; programs and genres that seemed popular because of their ratings were reproduced or cloned, while others fell into oblivion.

This dynamic has endured throughout the history of US television. Specific genres have proliferated at different periods (westerns in the 1950s and 1960s, detectives and spies in the 1960s, 'jiggle' shows in the 1970s, prime-time soaps in the 1980s, situation com-

edies in the 1990s, reality programs in the 2000s, and so forth) because television networks could minimize financial risk by renewing contracts for shows with high ratings and choosing new pilot programs that fell within the tried and true category of proven ratings winners. The recoiling from innovation by sticking with highly rated genres became one of the hallmarks of US television.

It took until the late 1950s for genre to achieve its full-blown status in the functioning of the television industry. Two other factors, the influence of the New York theater and the technology of live television, had significant impacts on the emerging television medium in the late 1940s and early 1950s. Each of these factors themselves had strong implications for the development of genres on television.

1.2 The Genre of Anthology Dramas

In the late 1940s and early 1950s, many New York playwrights and directors worked in the emergent medium of TV to produce the spate of anthology dramas that have come to be equated with the phrase of 'Golden Age' of American television. These dramas, such as the well-known *Requiem for a Heavyweight* by Rod Serling, *Marty* by Paddy Chayefsky, and *Thunder on Sycamore Street* and *Twelve Angry Men* by Reginald Rose, were aired on shows sponsored by individual advertisers and called anthology drama series, shows such as *Playhouse 90*, *Goodyear Television Playhouse*, *Studio One*, *Kraft Television Theater*, and *US Steel Hour*. Hundreds of these dramas or teleplays were produced during the 1950s—original plays every week for the numerous anthology programs on the air at the time. They were also produced live, on the sets of the three-camera television studios that came to epitomize one of the thrills of early television—viewers in their own living rooms seeing what was simultaneously happening in a distant space.

Although other programs and genres, some of them not live but shot on film such as the hugely popular comedy *I Love Lucy*, were attracting large groups of viewers, the anthology dramas constituted a genre of enormous critical and audience acclaim. By the middle of the 1950s, however, the anthology drama genre and live prime-time fictional programming as a whole was virtually obliterated.

As commercial enterprises, NBC, CBS, the young ABC, and corporate television sponsors struggled in the early 1950s to rationalize the television industry, to get it working in ways most profitable for their companies. This militated against anthology dramas in four ways. First, the dramas were too costly and too cumbersome to produce: each one required a new director and a new playwright who needed to conceive of an entirely new play. Second, the networks and advertisers began to consider the teleplays too controversial for national television, dealing as they often attempted to (though frequently muted by censorship) with serious social problems. Third, sponsors began to think of these dramas as non-conducive to advertising—their serious subject-matter was often considered too serious and their unglamorous, working-class characters too jarring to the spirit of consumption and the showcasing of products. Fourth, the live productions were not oriented toward future profits—they could not be rerun or exported.

1.3 Formulaic Filmed Genres

These business imperatives, which became more sharply formulated by the industry as the experimental years of the 1950s waned, led to the standardization of generic formulas and a factory-like system in American Television. Most entertainment programs, whether they were westerns, hospital dramas, police programs, situation or domestic comedies, came to develop narrative formulas with well-defined story premises and possibilities. (Even quiz shows, game shows, variety shows, newscasts, and sports programming gradually developed similar formulaic structures.) The programs had standard and repeatable characters (or hosts, reporters, anchors, and announcers), sets, wardrobes, and shot compositions. They were overwhelmingly shot on film (with the exception of news, sports, and daytime soaps) for maximal use in the rerun, syndication, and export markets. Equations were also made between different desired audience groups and different genres: men were drawn in with westerns, spy shows, cop shows, sports; women with comedies, hospital drama, and, of course, daytime soap operas; both men and women with quiz shows, variety shows, and game shows, and so forth. Filmed (and, from the 1970s on, some videotaped) formulaic genres thus came to serve as linchpins of the factory-like production process that dominated Network Era American television. They provided a way to control production costs and predict consumption patterns.

One popular genre, the quiz show, allowed the networks in the late 1950s to complete their corporate rationalization of the TV business by wresting the control of programming away from individual corporate sponsors—when a national scandal burst from the discovery that the producers of corporate sponsored popular quiz shows secretly provided answers to contestants, the networks argued that they (rather than the individual corporations who owned and sponsored the shows) were the only ones that could ensure the integrity of program content. NBC, CBS, and ABC effected a switch from a system in which individual companies sponsored individual programs (and therefore had the final say over a program's content, renewal, or cancellation) to a system in which individual companies could only buy advertising spots before, after, or in the middle of programs controlled

by the networks. From the later 1950s forward, therefore, the three major television networks could produce and reproduce formulaic genres in an assembly-line way with total control over their content, their longevity, and their cloning. Standardized genres came to have a powerful place in the operations of the entire American television system and its popular culture.

2. Genre and Television Audiences

2.1 Genres and Audience Pleasure

During the past 15 years, scholars have begun to analyse the reception by audience members of the type of delimited TV fare that the US system has, in fact, offered; and they have produced many intriguing studies of specific genres and their most avid viewers or fans. In his book *Television Culture*, John Fiske, the cultural theorist, examines the place of many different genres from soap operas to action adventure programs to game shows in the lives, fantasies, and pleasure domains of their many viewers. He strongly advocates (and has been criticized for taking too extreme of a position) looking at the ways viewers make use of television programs for their own enjoyment and even political empowerment, rather than focusing on the relationship of TV programs and audiences to the industry that produces and profits from them. Other scholars have taken a similar approach.

Henry Jenkins (1992), Constance Penley (1991), and Camille Bacon-Smith (1992), for example, have intensively studied fans of the science fiction genre, particularly those of *Star Trek*. They show how these fans take an industrially produced formulaic television genre and turn it to their own ends, making it part of their own lives and creative endeavors. Jenkins, for instance, chronicles the passionate investments of fans in the culture surrounding *Star Trek* conventions. Penley details the ways a group of women viewers rewrite *Star Trek* narratives with their own unique plots for their own illustrated fanzines. Jenkins' notion of 'textual poaching' has, in fact, been taken up by a number of cultural critics to describe the ways that viewers of commercially produced genres can 'poach' or rifle through these programs (programs produced by a capitalist culture industry) in order to derive pleasures that may have nothing to do with the intentions of the television networks and advertisers to generate audiences as consumers.

2.2 Genres and Society—Gender, Race, Sexuality, Nation, and the Family

Various facets of contemporary US society and its citizenry have been examined in relation to television genres. How, for example, do genres contribute to defining femininity and masculinity, race, ethnicity, sexuality, nationhood, and notions of the family? How, in other words, do genres contribute to shaping the norms of those social facets—to defining what 'normal' femininity or masculinity means, what it means to be white or black in a society such as the US? How, on the other hand, might viewers use TV genres to question or challenge dominant societal norms?

Scholars such as Tania Modleski (1984), Robert Allen (1985), and Dorothy Hobson (1982) analyse the ways that many women viewers (particularly those caring for small children in the home) have made soap opera an integral part of their everyday lives, pleasures, and friendship networks. Modleski elaborates upon ways that women viewers derive sometimes unpredictable meanings and pleasures from the soaps. She argues, for example, that some women viewers identify with the ubiquitous villainess characters in soap operas as a way of getting fictional revenge on a social system that minimizes women's power, work, and social contributions. Scholars studying sports programming are currently trying to analyze the ways that sports produce meanings of conventional (macho) masculinity but at the same time may engender in their male viewers nonconventional meanings of men being emotionally, tied to other men in overt displays of friendship, and so forth.

Julie D'Acci (1994), in a study of the popular crime drama *Cagney and Lacey*, demonstrates how TV genres contribute to the ways that masculinity and femininity are defined and actually lived out in society. This cop show, starring two women, became a women's program—a hybrid of cop show, soap opera, and comedy—in order to attract an audience of working women with the kind of genre fare TV executives thought such an audience wanted to see. The show also became part of a social movement for women's rights and equality, and an important rallying point for its many committed women viewers. Szu-ping Lin (2000) uses a similar approach in studying the importance of a Taiwanese genre called *Hsiang-Tu Hsi*. These nightly run melodramas have become an integral part of wide-ranging public debates on women's issues and rights in contemporary Taiwan.

In US television, black characters and stories have historically been confined to the genre of situation comedy and denied the range of representation and seriousness that dramatic shows can afford. Herman Gray (1995) has demonstrated how one of the most innovative programs on American television, *Frank's Place* (about an African American college professor who inherits his father's New Orleans restaurant), met with quick cancellation because it was genre transgressive, combining elements of the comic and the dramatic, a transgression that the TV industry found untenable given its history of corralling black characters and subject-matter in the comic terrain. How-

ever, Crystal Brent Zook (1999) chronicles the importance of African American writers and production teams in producing comedies for the FOX network that, although working within the confines of the stereotypical genre, deal in more progressive ways with black stories and characters. Tricia Rose (1997), for her part, argues that the music video genre has given voice to African American women artists and a sense of empowerment to African American women viewers. Gloria Abernathy-Lear (1992) illustrates the ways some African American women viewers make use of the primarily white-oriented daytime soap operas to, among other things, critique and lay bare the shortcomings of a dysfunctional white-dominated society.

From the point of view of sexuality, Ronald Becker (1998) has examined the spate of gay-themed comedies in the 1990s, discussing how these programs contribute to ongoing public debates about sexuality, and help explore the boundaries of sexual identity for their gay, lesbian, and heterosexual viewers. And from the point of view of nationalism, Michael Kachman (1999) has demonstrated how the television spy genre participated in defining 'America' and the American citizen during the Cold War along particular xenophobic lines.

Finally, researchers such as David Morley in *Family Television: Cultural Power and Domestic Leisure* and Ellen Seiter in *Television and New Media Audiences* have conducted ethnographic studies of TV viewers to show how TV programs affect both family life and children. Morley profiles, for example, how different genres become grounds of power struggle in the daily life of some British families, with possession of the remote control falling along conventional gender based lines—male 'heads' of households have the clicker and consequently the power to decide what genres the family will watch and when. (See *Audiences*.)

The work cited here represents only the tip of the iceberg of studies on the relationship between popular commercial television genres and social life in the world beyond the home screen. Much more research is already in print and under way. The importance of television genres as definers of societal norms and as rallying points for viewers becomes more and more evident.

3. *Television Genres—Theoretical Considerations*

In an influential article on television genre, media scholar Jane Feuer groups most theoretical work on TV genre into three different camps—the aesthetic, the ritual, and the ideological (Feuer 1992). According to her schema, the aesthetic approach includes attempts to define genre solely in terms of the artistic or formal components of a television program or 'text' (apart from its social or historical context), and particularly with deference to the 'author' of that text. The ritual approach, on the other hand, sees genre as intimately tied to its social context. It conceives of genre (and all television) as a 'cultural forum' that helps maintain the social order and aids it in adapting to change (see Newcomb and Hirsch 1983). Genres serve an important, though tacit, cultural function, in that they feed back to viewers important meanings about the culture at large, and thus become 'an exchange between industry and audience, an exchange through which a culture speaks to itself' (Feuer 1992, p. 145). According to this take, some workplace sitcoms of the 1970s (*The Mary Tyler Moore Show* and *Alice*, for example) aid viewers in adapting to the social change involving women's massive entry into the workforce at the time.

In contrast, the ideological approach 'views genre as an instrument of control.' Thus at the level of the television industry genres assure an audience for the networks and advertisers. At the level of the programs themselves genres serve to reproduce the ideology of the capitalist system. At the level of the audience, familiar genres help make it seem that the ideologies expressed in the programs are just plain common sense, the way things naturally are (rather than capitalist-based consumer-creating ideologies) (p. 145).

Feuer goes on to describe the ways that television scholars have begun to combine the ritual and ideological approaches to account for the active production of meanings by the viewers as well as the TV industry, and therefore the constant conflict (rather than the ease) in the reproduction of ideology. She also contends that such a combination has allowed TV and film critics to conclude that by means of genres, audiences unconsciously confront and grapple with many societal contradictions such as law and order vs. individuality (the gangster genre), nature vs. culture (the western), the work ethic vs. the pleasure principle (the musical), and so forth.

Rick Altman (1984) also incorporates a ritual and ideological approach when he uses a linguistic model to conclude that genres are comprised of 'semantic elements' (standard generic components such as cowboys, horses, guns, saloons, for a western) and a 'syntax' (the crystallized generic meaning of a western such as a white male hero as the 'necessary' bridge between nature and culture). This syntax develops over time and may express both a dominant ideology and the changes and challenges that bubble up in a culture. Many scholars stress that no matter which of these positions one espouses, genres develop historically and should be understood as fluid and changing rather than as fixed entities.

These various approaches are not necessarily incompatible. An 'integrated approach,' as exemplified here, conceives genre as operating at the intersection of the television industry, the audience, the text, and

the social context. Jason Mittell (2001) takes the integrated approach further and argues that most previous scholarly work on genre (such as that just recapitulated) proceeds too much from what he calls a 'textualist assumption'—an assumption that places too much emphasis on genre as equivalent to the program itself, as essentially a description of a particular kind of TV text. On the contrary, he argues, instead of examining genres as textual attributes, they can best be understood as cultural categories, belonging to specific historical moments and contexts.

For Mittell, genres are not comprised of the programs that they categorize, but by the practices of industries and audiences that use generic categories to define television programming. Thus when we want to study sitcoms, he says that instead of confining our analysis to the examination of sitcom texts (individual programs over time), we should explore how television networks schedule sitcoms, how audience members define their own tastes in terms of program choices, and how critics use particular standards to judge the genre—all strategies of definition, interpretation, and evaluation that link the sitcom to cultural norms, hierarchies, and relations of power. This shift in analytic focus looks beyond media texts themselves to understand their operation in the culture at large, and parallels a reconfiguration of genre within literary and film studies as well.

4. *Television Genre and the Future*

Since the break-up of the three-network domination over US television and the proliferation of cable channels that began in the mid-1980s, genres are playing a somewhat different role in American commercial culture. Now entire channels are founded on their generic status—a Sci Fi channel, a Romance channel, a Golf channel, a Comedy channel, a Cooking channel, and so forth. The confluence of television and the internet in the coming years, and the possibility of completely individualized regimes of viewing, similarly present many more possibilities for the interaction of genres and viewers' everyday lives. Likewise, the creation of global television markets and communities only underscores the importance of looking more closely at the way genres operate cross-nationally and cross-culturally. Robert Allen's *To Be Continued: Soap Operas Around the World* (1995) furnishes an exemplary model of this type of work.

Television: History

Forecast in novels and science journals since the late nineteenth century, television came to the USA and other developed nations in the decade and a half following World War II. Major manufacturers of radio receivers, led by Radio Corporation of America (RCA), as well as individual entrepreneurs had labored in the 1930s in the USA, Germany and the UK to perfect a device capable of receiving over the air clear images and sound. US companies had been especially anxious to perfect a receiver that could be mass produced. Military research during World War II had advanced their work.

In the late 1940s, the USA was best positioned to experience a 'television boom.' RCA and other companies were offering television sets that, though expensive, were not beyond the means of most consumers. At the same time, RCA established a nationwide network, National Broadcasting Company (NBC), that offered set owners regular programming. Another TV set manufacturer, Du Mont, similarly founded a TV network, as did the radio networks, ABC and Columbia Broadcasting System (CBS) (Du Mont ceased operations in 1955). The four chains provided programming to individual stations, most of which, because of federal regulations, were not owned by the networks. With TV stations operating in most of the nation's larger cities, consumers began purchasing sets. A strong economy allowed such consumption. So did the postwar boom in marriages and child-bearing, which left many young adults housebound, thus making television relatively cost-efficient home entertainment. Although high income was a strong predictor of set ownership in the first years of the television boom, family size soon became the stronger variable. By the late 1950s just under 90 percent of all US homes had one or more televisions. In time, owning a television became an expectation throughout the world. That said, television spread more slowly in poor countries because of the relatively high costs of receivers, the absence of electrical service and uneven TV production standards.

In contrast to what emerged in many other nations, the so-called 'American' system followed the US radio model of privately owned broadcast stations and networks carrying programs or series paid for and sometimes produced by advertisers. Oversight by the US Federal Communications Commission (FCC) was nominal. As the medium's patron, advertisers held enormous control over programs in television's first dozen years, especially because demand favored them over networks and stations. They normally sponsored entire shows, often including plugs of their wares. In most instances, advertisers sought the largest possible audience. This came to mean relying on a set of program 'genres,' most of which owed something to radio and motion pictures. That said, a few sponsors self-consciously cultivated a smaller, elite audience by underwriting musical, dramatic or news programs. Many advertisers and broadcasters initially assumed that the TV viewer was better educated and well to do. Partly because of this misidentification of the audience, which also occurred during the early years of radio, many network programs were culturally ambitious. Original dramas, produced in New York, the nation's theatrical center, appeared every night. Critics later insisted that the USA had experienced a 'Golden Age of Television.' However, the fare most identified with the Golden Age could not, over time, compete for viewer favor with other, less pretentious efforts.

In the late 1950s, US television underwent a series of changes that established industry practice for the remainder of the century. As television spread into smaller communities, demand for dramatic and comedy programs that had followings in the larger cities collapsed. Individual comics like Milton Berle and Sid Caesar, whose humor resonated with eastern viewers, were unable to sustain their early success. The larger, more representative audience preferred filmed programs, including westerns and detective dramas, that were inexpensive imitations of motion pictures. This shift in demand encouraged the movement, already underway, of TV production from New York to California. Television increasingly took on the look of Hollywood as opposed to Broadway. At the same time, a sharp increase in advertiser demand gave the networks and larger stations the upper hand over advertisers in programming decisions. By the mid-1960s, most television programs had multiple sponsors.

Outside of Latin America and the Caribbean, much of the world actively sought to avoid taking up the US system. Much as they had disdained US motion pictures, political and intellectual elites abhorred what they construed to be the vulgarity of US television. As a result, few broadcasters enjoyed the autonomy of their US counterparts. Communist and many third-world countries tightly controlled television's development and production. The Soviet Union and other regimes regarded television, like radio, as state instruments. Other countries, notably in Western Europe, followed the corporation model of the British Broadcasting System (BBC). Under the British model, the government created an independent broadcasting authority that relied on receiver fees rather than advertising. In the mid-1980s, about two-thirds of Europe's television authorities derived their revenues from receiver fees, as did about half of all African and Asian systems. Most of the time, BBC was free of direct government interference. The UK did permit commercial television in creating the Independent Broadcasting Authority (IBA) in 1955. But commercial TV in the UK, as in many other nations, was subject to far more regulations than in the USA. In the UK, non-government TV endured an excess profits tax that had the effect of encouraging more elaborate

cultural programming that rivaled the self-conscious, educational efforts of BBC. The Japanese Broadcasting System (NHK), in contrast, gave commercial TV far greater freedom. Although former British colonies initially embraced the BBC model, political anxieties caused the leaders of most newly independent countries to take up more direct, state control akin to that of the Soviet Union. Then, too, the relatively high cost of starting television service and the absence of domestic commercial investors partly explained the adoption of the statist model in most poor nations. Some third-world leaders sought to put off TV's development indefinitely, only to relent under pressure from urban elites who had encountered television in the West.

Although many if not most nations sought to avoid the US system, few could resist its programming. In the early 1980s, UNESCO reported that most nations, including those with totalitarian or Islamic fundamentalist regimes, offered more entertainment programming than any other type. This tendency created an enormous opportunity for US producers. US-made entertainment series, especially those that emphasized action or broad humor, proved immensely popular. As in the case of motion picture assembly, US television producers had a huge comparative advantage in the emerging global market for programming. The switch of US networks to filmed series created a substantial inventory of exportable entertainment. The USA possessed unequaled production facilities in southern California, as well as the movie industry's large reserve of on-camera and production talent. A large domestic audience and advertising demand, as well as the sale of syndication rights as 'reruns' to individual US stations (and eventually, cable outlets), meant that successful US programs were profitable before they were distributed overseas. They could thus be offered relatively inexpensively. British television production, with somewhat similar advantages, was a distant second as an exporter of TV programming. Most other nations simply could not produce programming of the same standard and appeal. This was especially true in less developed countries where, Elihu Katz and George Wedell estimated in the mid-1970s, imported series constituted just over half of all programming. Indeed, viewers in some countries, Katz and Wedell noted, frequently could select from different US programs aired by competing channels at the same time. One scholar of international communication concluded in 1988, 'A kind of sameness fills TV screens just about everywhere.' Revealingly, a 1999 NATO air strike against a communications center in Belgrade, Yugoslavia, destroyed 123 episodes of three US series.

The Americanization of television throughout much of the world had its critics. One of the first, Herbert I. Schiller, regarded the US's export of programming as part of a conscious attempt by the nation's political and business elites to extend the USA's influence via communication. 'The "have-not" nations,' he wrote, 'stand practically defenseless before a rampaging Western commercialism.' More likely, Katz and Wedell argue, market forces and the law of comparative advantage, and not sinister calculation, accounted for the US's impact on television globally.

In its first decade and a half, US commercial television presented relatively little news programming, very little of which elicited controversy. News programs lost money and drew few viewers. The networks considered informational programming a way of placating influential political and cultural leaders as well as of meeting the FCC's modest public service standard. In receiving TV frequencies or licenses for a fixed term, stations promised to devote a minority of its overall schedule to programs, including news, 'in the public interest.' In theory, license renewal hinged on stations meeting this 'minority interest' standard. In practice, the FCC very rarely scrutinized individual licensees' public service schedule. Nonetheless, station managers were not prepared to ignore the agency altogether. Not surprisingly, television news tended to be uncritical of those in power and, as Nancy Bernhard has argued, supportive of America's Cold War with the Soviet Union.

By the 1960s, US networks and many stations were profiting from certain types of informational programs, specifically early evening newscasts. These were not as popular as some contemporary observers assumed. In the late 1960s, one survey indicated, just over half of all US citizens watched no network evening newscasts during a two-week period. Yet television news did command the attention of many influential US citizens, who assumed its primacy; TV newscasts also drew increasing advertiser interest. Indeed, nightly newscasts became stations' largest single source of revenue. In the 1970s, the network evening 'magazine,' CBS's *Sixty Minutes*, with its mix of exposes and features, started winning viewers For the first time, a network news program actually competed against evening entertainment shows in popularity rankings. Imitations on other networks followed. Although none could generate the following of *60 Minutes*, because they were less costly than entertainment series, the networks earned more money carrying such programs. All told, the realization that news shows could, in fact, be even more profitable, caused broadcasters to seek more viewers by adopting a less serious news agenda. The line separating news and entertainment blurred.

The first great test of US television news came with the US intervention in the Vietnam war. The medium earned at best a low pass. Popular mythology, perpetuated by surviving correspondents (and their critics), insists that TV brought the war's horrors home every evening to a people glued to their sets. Television reporters, according to this wisdom, criticized the conflict itself and thus helped to end US involvement. Subsequent scholarship by Daniel Hallin and others

has largely discredited this self-serving history. As already noted, newscast audiences were never as vast as some imagined. Nor did TV news, for a variety of reasons, show much combat footage. Relatively few reports were carried live. And in the initial years of the US build-up, 1964–66, reporters and news anchors (or readers) passively if not enthusiastically relayed the positions of the US military and civilian leadership. After 1966, some TV correspondents did challenge, ever so mildly, the progress of the war. Yet television was hardly, as some later asserted, leading public opinion or the news media generally. Other news organizations, specifically the hugely influential *New York Times*, had already started to express skepticism about the Vietnam commitment. And television news failed, Todd Gitlin has contended, to take the budding anti-war movement seriously.

As the USA withdrew forces from Southeast Asia, network television had to cover an even larger crisis. These involved criminal activities associated with the June 1972 break-in of the Watergate apartment complex in Washington DC, by figures tied to the re-election campaign of President Richard M. Nixon. The TV networks, especially CBS, covered the Watergate story. Still, they did not do so with nearly the rapidity and thoroughness of some newspapers. Herbert J. Gans' study of the evening network newscast production in the 1970s stressed the extent to which NBC and CBS depended on the *New York Times* for their news agenda.

US television remained primarily an entertainment medium, and TV's staple product began to change. A 1970 FCC regulation restricted the networks' ownership of entertainment programming. This gave producers more freedom, and some sought to convey the more relaxed cultural climate. To many critics, this shift fostered a second 'golden age.' Shows like *All in the Family* and *The Mary Tyler Moore Show*, in violation of industry practice, dealt with contemporary issues like race relations and the sexual revolution. Dramatic series in the 1980s and 1990s, usually involving law enforcement or medicine, similarly took a more realistic tone.

Despite renewed critical respect for some shows, network television's hold over the US viewer slipped in the latter decades of the century. In the 1950s and 1960s, most US citizens received their TV service over the air. The finite size of the radio band limited the number of on-air stations the typical set could receive. And until the late 1970s, the three networks in effect determined what US citizens watched. Most TV stations remained affiliated with a network. On a given evening, nine out of every ten televisions were tuned to a network program. In the 1980s, however, the networks began losing some of their audience. Although the presence of more independent stations cut into the networks' share, the spread of cable proved the far more decisive blow. By subscribing to a cable service, consumers could greatly augment their choices, originally from four to 12 to 30 or more channels. By 1997, the average US cable system provided 47 channels. This much larger array of choices proved too tempting for most consumers. The percentage of homes with cable rose from 7.6 percent in 1970 to 49.4 percent in 1988. By the late 1990s, up to 70 percent of all households had cable. Others had satellite signal receivers that afforded them even more services; such systems were more common elsewhere in the world. The US network audience shrank to about half of the total evening audience.

Cable's rise had several significant effects on the television. Providing many more channels greatly weakened an original justification—scarcity of service—for broadcast regulation, as did a larger disillusionment with the efficacy of business oversight. The FCC relaxed most rules regarding public affairs programming and eventually, network ownership of entertainment programs. The growth of all-news cable channels—along with the end of the Cold War—caused the network news divisions to reduce their coverage of more serious political and international news in favor of stories more likely to attract viewers. At the same, competition from cable channels caused the established networks to forsake their traditional observance of US prudishness. Trying to hold viewers, some network program producers took more risks in their handling of sexuality and crude language. Compared with their predecessors, broadcasters worried less about offending some viewers, who could always turn to a cable channel rerunning an innocuous 1960s situation comedy. In planning a racy police drama, *NYPD Blue*, producer Steven Bochco recalled being told by an ABC official in the early 1990s 'to come up with something that would at least begin to compete with cable.'

Cable channels offered a range of programs and formats. Even so, one of the ironies of cable's growth was that the most popular cable channels relied excessively on reruns of series originally telecast on the networks. These were accompanied on some channels by professional wrestling and variety shows that targeted young men who delighted in bad taste. Many cable channels practiced 'narrow-casting,' that is, they presented programming intended to engage only sports fans (ESPN) or pre-adolescents (MTV). Although the popularity of no one cable channel could compete with any of the networks, combined the cable outlets constituted a regiment of Lilliputians tying down the three Gullivers.

The networks were also wounded by the entry of new rivals in the 1980s and 1990s. None proved more successful than Fox, whose programs usually ignored industry practice and middle class proprieties. 'We were free from the hereditary constraints at the other networks, the decades of doing things a traditional way,' a Fox vice president explained in 1997. Along with still more networks, WB and United Paramount Network (UPN), Fox frequently violated another

industry rule by playing to subgroups of the national audience, that is, younger or African–American viewers.

Although the advent of more TV channels mainly on cable complicated their routines, advertisers in many ways benefited from the more competitive television. Promoters of products more appealing to a specific subgroup, like adolescents or women, welcomed the efficiencies of cable narrow-casting. At the same time, cable's growth restored some power to advertisers in their dealings with the networks. Because younger viewers were thought to be more likely to try new brands and services, product makers in the 1990s were prepared to pay more – sometimes significantly more—to co-sponsor a TV program with the 'right' demographics. That is, they began basing more of their 'media buys' on who rather than how many watched a given show. All in all, this represented an unprecedented shift by the networks' underwriters, most of whom had heretofore prized the size rather than the composition of the audience.

Amid such industry upheaval came dramatic changes in industry proprietorship. After several generations of stable ownership, all three established networks changed hands in the 1980s. Capital Cities, owners of TV stations and newspapers, purchased ABC in 1985 and then sold the network to the Disney entertainment conglomerate in 1995. In 1986, General Electric took over RCA and NBC; investor Laurence Tisch bought CBS. Westinghouse, an electronics company, secured CBS in 1995 only to allow itself to be combined with Viacom, another entertainment concern, in 2000. Meanwhile, individual stations, some of which had been controlled by the same company or family for several generations, were sold and resold through the 1980s and 1990s. Such franchise transfers increased all the more when Congress passed the Telecommunications Act of 1996, which lifted or weakened FCC regulations, including restrictions on the number of stations individual companies could own.

With only with a few exceptions did US television remain the mass medium that it had been in 1960 or 1975. Annual rituals like the National Football League's Super Bowl commanded huge audiences, as did momentarily popular shows like *Who Wants to Be a Millionaire* and *Survivor*. Otherwise, even top-ranked network programs like NBC's comedy *Seinfeld* had to settle for a much smaller percentage of the total television audience than had comparably ranked shows a generation earlier. The future offered more of the same. The spread of the Internet into more US homes at the century's end portended ever more individualized media services.

1. *The Historiography of Television*

The history of television has only begun to command serious scholarship. Until the 1990s, most research on the medium has consisted of highly specialized studies conducted by social scientists testing theories of media influence. The first wave of this research is ably summarized in Leo Bogart's *Age of Television* (1972). Historians, except for those tied to programs focusing on the film or journalism, have all but avoided the medium, despite its immense popularity and seeming influence. Their reluctance is understandable. Few are familiar with the constantly ballooning research on media effects. Moreover, evaluating mass culture itself, as opposed to its influence, has always been a tricky endeavor, much simpler for newspaper columnists than academics. It became all but impossible in the latter decades of the twentieth centuries, as scholars in the humanities and sociology dismissed cultural hierarchies altogether as hopelessly subjective, if not indicators of class and educational attainment. Historians who could pass these obstacles faced more logistical roadblocks. In the USA, corporations have been the major players in the medium's history, and relatively few have opened their records to scholars. Then, too, the sheer volume of TV programming over the years has all but compelled historians to limit their inquiries to case studies (see, e.g., Balio 1990, Spigel and Curtin 1997). Relying on middle-class sources, Lynn Spigel has sensitively examined how US citizens sought to adapt themselves and their families to television. There have been more ambitious histories, notably by Asa Briggs (1961–95)of the BBC and Erik Barnouw's more episodic treatment of US broadcasting (1970). Paul Rutherford has written a very competent history of Canadian television (1990, see also Levy 1999).

Meanwhile, many gaps will need to be closed, including far more examinations of ethnicity and gender. Virtually no systematic investigations have been conducted on advertisers' complex and changing relationships to the medium. Much more research needs to be attempted measuring the relationships between TV news and those in power.

Finally, the tendency of program producers to take up concepts first developed overseas needs to be explored. Successful US series had many imitators over the years. Still, the phenomenal success at the end of the twentieth century of ABC's *Who Wants to be a Millionaire* and CBS's *Survivor*, both modeled after European programs, demonstrated that even US program producers have occasionally engaged in plagiarism. CBS modeled its long-running *Sixty Minutes* after a Canadian program. British programs inspired such popular US series as *All in the Family* and *Sanford and Son* as well as some far less resilient endeavors.

J. L. Baughman

Television: Industry

The television industry, by the close of the twentieth century, had grown into an economic force generating mass media's greatest revenues, costs, and profits. In the USA the production, distribution, and broadcasting of television (and later cablecasting and delivery directly by satellite) has long been dominated by a few vertically integrated networks, which produce much of their own programming, and often own broadcast stations, cable systems, and satellite-to-home divisions. While a variety of state-controlled or semi-independent publicly funded television systems have existed around the world, by the end of the twentieth century, more and more TV industries outside the USA were deregulated, that is privatized, and began to look increasingly like the American commercial television industry model.

1. The US Television Industry

From its innovation after World War Two to the middle 1980s, in the USA three national systems of interconnection or networks dominated the TV business. Then came cable TV's 100-plus networks, and in the 1990s even more offerings through satellite-to-home delivered direct TV or DBS. This choice among hundreds of channels seemed to signal an open, competitive industry. Just the opposite was the case.

Seven corporations dominated. A seeming plethora of TV choices collapsed to seven conglomerates all built around organizations producing programming allied with other parts of the same company that determine the program scheduling. In most cases the entertainment programs were made in Hollywood in a deal with a studio such as Disney or Paramount. These corporations also own TV networks which broadcast, cablecast, or deliver shows via satellite to the home. Executives with the same company make programming decisions either aimed at mass audiences, the so-called traditional networks such as Disney's American Broadcasting Company (ABC), or more and more to niche networks, such as Disney's growing number of cable channels.

1.1 US Broadcast TV

The television industry in the USA started, like all others in the world, broadcasting signals over the air. From the late 1940s to the 1980s, three networks dominated American television—NBC, CBS, and ABC. In the 1990s came three more—United Paramount, the WB, and Fox. Five companies owned them as the twenty-first century commenced: Disney's ABC, Viacom's CBS and United Paramount Network, AOL Time Warner's WB, News Corporation's Fox, and General Electric's NBC. These six networks—all parts of vast corporations—defined what most US watchers viewed. The actual local TV stations in the USA simply functioned as spigots, drawing their programming from these networks plus a smattering of syndicated fare, and three or four hours per day of locally produced news.

By the close of the twentieth century, all the networks—save NBC—were tied directly to Hollywood-based companies. Broadcast television became a classic case of vertical integration. The networks had long produced news and sports; by 2000 their Hollywood parents were creating all forms of programming, from comedies to dramas, from reality shows to news reports. They produced the show, distributed it through their own networks, and then showed it to much of the nation on their increasing number of owned and operated stations (by 2000 covering more than a third of all US households).

The Australian media baron Rupert Murdoch introduced the Hollywood vertically integrated TV network system when in 1985 he bought a studio (Twentieth Century Fox), then purchased Metromedia TV stations (for his owned and operated group), and then launched the first new TV network in 30 years—Fox. During the 1990s, Viacom followed

Murdoch's lead and fashioned its United Paramount Network (supplied by its Paramount studio), and Time Warner created the WB network. Disney underscored the importance of this new broadcast network economics when in 1995 it acquired ABC. In 1999, Viacom purchased CBS and so by 2000 owned two broadcast networks.

1.2 Cable TV

As late as 1980, most viewers in the USA watched solely broadcast TV, but then more and more households began to subscribe to cable television. As the twentieth century ended, about two-thirds of Americans paid monthly fees to a local cable monopoly. After the passage of the 1996 Telecommunications Act, cable franchises consolidated, and in 1998 AT&T acquired cable franchises representing about a third of all customers in the USA. AT&T's CEO Michael Armstrong bet his corporation's future on cable, based on two principles. First, cable was a legal monopoly, reminding Armstrong of the old phone company. Second, Armstrong saw that cable's broadband wires could offer not only offer television but also Internet access.

At first glance there seemed to be a plethora of cable networks. There was BET for African Americans, TNN for fans of country music, and ESPN for sports fans, to name but three of an estimated 150 cable networks. Yet of all these choices, most were owned in part (or completely) and/or operated by one of the major TV media conglomerate companies noted above as controlling broadcast television. These companies desired to own networks so that their local franchises could be guaranteed popular programming. In 1999, AT&T controlled through its corporate partner, Liberty Media, the Discovery Channel, The Learning Channel, BET, and a half dozen others, while AOL Time Warner, the second-top owners of cable franchises, owned and operated Superstation TBS, the network piped into most cable homes, plus TNT, and three CNN services.

But not all cable networks were controlled by these vast, vertically integrated media conglomerates. An alternative tactic, reasoned a few Hollywood moguls, concluded that it was not necessary to spend billions of dollars to wire local cable franchises, but simply to produce desirable programming, and TV viewers would find and pay for those channels, regardless of who was their local monopoly cable franchise. Disney, Fox, and Viacom executives, for the three leading examples, concentrated in creating programming to feed cable networks such as ESPN, The Family Channel, and MTV, respectively. They did not vertically integrate.

In sum, cable networks add no dominant new owners to the list of TV powerhouses described above. As a consortium, these very media corporations financed C-SPAN as a public service, as well as to insure access to the US Congress. Indeed, only one of the top 20 cable networks could be called independent—Landmark's Weather Channel. It is more efficient to think of the dozens of cable networks as simply outlets for Disney, Viacom, AOL Time Warner, The News Corporation, AT&T, and General Electric. Indeed, to think of separate broadcast TV and cable TV industries no longer makes sense from an ownership perspective. The aforementioned major companies all own sizable broadcast and cable television production studio properties. They also dominate pay-TV—Viacom's Showtime and the Movie Channel, and Time Warner's HBO and Cinemax—as well as the creation and distribution of movies on rented and sold video.

1.3 Satellite Delivered Television

The 1990s did introduce a whole new means of gaining access to television— direct broadcast satellite (DBS), that is, satellite-to-home direct delivery. After 1994, many new DBS entrants flooded in; one in ten of US television households signed up before the century ended. Paying more, DBS subscribers could access up to 200 channels, principally around the clock pay-per-view movies, and sports broadcasts from all regions of the USA and around the world. DBS pioneers took direct aim at TV's junkies. Until the final month of 1999, however, DBS subscribers could not get local broadcasts; then the US Congress removed this restriction, and in most places in the USA subscribers to DBS were able to access all channels available on cable as well as a hundred more.

By the time the law was changed in November 1999, though, the world of DBS competitors had been winnowed to one dominant player. DirecTV, owned by Hughes Electronics, a division of General Motors, possessed more than 90 percent of the market, with tiny EchoStar and its DISH Network struggling to stay in business. In nearly all markets across the USA DirecTV alone was positioned as the alternative to the monopoly cable company.

DirecTV thus completed the list of the seven dominant TV companies in the USA, and indeed the seven major multinational TV industrial giants around the world. These seven dominant companies—General Electric, Viacom, Disney, News Corporation's Fox, AOL Time Warner, AT&T, and DirecTV—defined TV's oligopoly. The world of the TV industry in the USA had expanded from three broadcast networks to seven key corporations. The big change was that for cable- and satellite-delivered TV one had to pay. But the oligopolistic seven did not offer all forms of programming. Within each genre of TV programming, they picked their spots to compete. So for 24-hour news, for example, a customer had three choices: AOL Time Warner's CNN, NBC's MSNBC, or News

Corporation's Fox News. The other four conceded this genre, and concentrated on becoming the top player in other program categories.

2. *The Rest of the World*

As the twenty-first century began, the major TV conglomerates relied more and more on exporting programming around the world. Yet Hollywood-made TV by no means monopolizes the world's television. For example, in Latin America, Brazilian and Mexican TV industries were successful in regionally exporting TV programming. In Europe, French and German companies did the same thing. Still, overall Hollywood functioned as the leading maker and exporter of TV entertainment. Its influential trade association—the Motion Picture Association of America—smoothly paved the way for export by lobbying both the US Department of State and governments around the world to keep TV trade open and unrestricted. Foreign governments resented US pressure, and formally and informally struggled to protect their domestic TV industries.

While much of the TV industry outside the USA started as an extension of government, by the 1990s deregulation had eliminated most regulations, and the TV industries in wealthy nations in Europe, the Americas, and Asia looked more and more like mini-versions of Hollywood. The TV industries of Japan, Brazil, France, and Canada, as typical examples, for the key variables of industrial analysis would include (a) geography, particularly land mass; (b) economic development, particularly following the collapse of the Soviet Union; and (c) long-term cultural differences, whereby some countries continue to see the TV business as having formidable externalities (i.e., benefits to the national state). In Canada, for example, the Canadian Broadcasting System is strongly supported by the nation–state to ward off the overwhelming of the Canadian culture by US interests. As the twentieth century closed, the differences among larger developed nations—save for the pressure from the Big Seven—had narrowed, as all adopted some amalgamation of advertising-based and pay television, delivered by broadcast, cable, and satellite.

Small countries—such as The Netherlands and Belgium, and any African state—even if economically well developed, more than ever needed strong state support and subsidy. Undeveloped nations—where TV was important, but feeding the nation far more vital—increasingly saw their native TV industries struggle against the vast multinational invasions. Indeed, throughout developed and underdeveloped Asia, Rupert Murdoch's Star TV network brought in news coverage that shattered government monopolies, and introduced US and European cultural products into cultures that could offer only minimally financed alternatives.

European nations banded together as the European Community to challenge the multinational TV industry giants in order to preserve local and native culture. With the percentage of European households owning and using TV sets increasing dramatically as the twentieth century ended, no governmental monopoly could satisfy new channel demands, particularly once cable TV and DBS were introduced. With more TV use, and less national control, concern rose about foreign influences, and a united Europe struggled to set up quotas so Europeans could watch European-made TV shows, not simply more and more from Disney, Viacom, and the other vast multinational TV conglomerates. This sort of nation–state collective action will continue as long as the structure of TV industries around the world insures that economies of scale result in the costs of Hollywood programming being less than costs of local programming.

Some nations have stakes in multinational success, such as the United Kingdom with its Pearson PLC, Germany with its Bertelsmann AG, Australia with its News Corporation, and Japan with its Sony. Spain and Italy have tried following the same model, but with less success. The big unanswered question of this assistance to multinationals comes from emerging national powers such as India, Indonesia, and China, all with vast populations, but all still emerging from colonialism or communism and still finding a place for domestic industries in the face of the world's multinational companies. For all TV industries outside the USA, change will remain the order of the day as media conglomerates merge and states seek the resources to protect their native cultures.

3. *Analytical Perspectives on the TV Industry*

There are several leading approaches to the analysis of television as an industry. Critics on the left have long seen the television industry as an increasingly influential cultural industry no different from other industries in monopoly capitalism. For example, Edward Herman and Robert McChesney (1997) focus on the inevitable rise and continuation of giant corporations, and the lack of true TV alternatives that challenge the dominant political–economic structure. Even with the increasing number of cable channels, one strains to find any progressive alternatives to corporate voices that sing largely in unison. The dominant TV powers have continuously increased their power as they fashion a global media presence. In particular, the innovation of space satellites as the dominant means of distribution—replacing coaxial cables and microwave relays—enables the images and sounds of television to flow easily from anywhere to anywhere else. Critics such as Herman and McChesney argue that the dream of TV as a means of mass education and democratic enlightenment has turned into a system devoted almost wholly to selling

products and avoiding controversial presentations which would inform citizens.

Conservative neoclassical industry analysts, in contrast, deny the cultural homogeneity of which left-wing critics complain. Such analysts as Benjamin Compaine insist that TV shows face competition from many sources of popular culture. Defenders of the status quo, like Bruce Owen and Steven Wildman (1992) agree with TV executives who claim they face a highly contested domain with ever-changing forces of supply and demand. They stress that no global television producer or network can force anyone to tune in. With more channels being offered by cable and directly by satellite, one can hardly argue there exists little diversity or choice in the current configuration of the TV industry. Genres of TV fare—from docudramas to science fiction, from news magazines to news reports 24-hours a day—see their ratings rise and fall. With the rise of new TV technologies like the VCR and DVD, for example, the TV fan can take charge of their set, and program their own favorite shows. As profit-seeking companies making up the TV industry add more and more channels, viewers will continue to be better and better off, argue neoclassical economists and industry owners.

Both camps come to their studies with predetermined assumptions. Leftists know the system does not work; neoclassicists know it does. A third group, industrial organization economists, perhaps start from a less ideological base. They instead seek to show how different industry structures lead to different forms of firm and industry conduct. As Gomery (1993) has pointed out, TV industries are not all the same, nor are their social and political effects either uniformly good or uniformly bad for the public welfare. The industrial organization economists describe and analyze the structure, conduct, and performance of each industry—stating up-front, not simply assuming what values might constitute good or bad performance. If the refusal of industrial organization economists to begin with a normative orientation is a strength, it weakens their grounds to promote particular public policy recommendations, apart from accepting the terms or performance criteria that policy makers themselves bring to the table. Industrial organizational analysts can bring alternative policy recommendations to the table, but cannot argue that they have the best solution to industrial problems critics might raise. They can offer only fixes on the margin, accepting (indeed assuming) that capitalism rarely offers the best media policy left unfettered, and a radical alternative to capitalism seems not to promote a more enlightened, educated citizenry.

Temperament and Human Development

Because temperament refers to the early-appearing dispositions upon which personality is based, it can be studied in infants and nonhuman animals as well as older children and adults. It offers an important place to begin in understanding human development. Rather than seeing individual differences in personality and social behavior as solely the result of socialization, temperament research identifies basic dispositions toward affect, arousal, and attention that will be further shaped by experience in development.

1. A Definition of Temperament

Temperament has been defined as constitutionally based individual differences in emotional, motor, and

attentional reactivity and self-regulation, demonstrating consistency across situations and relative stability over time (Rothbart and Derryberry 1981). The term 'constitutional' stresses links between temperament and biology. Over the long history of the study of temperament, individual differences in temperament have been linked to the constitution of the organism as it was understood at the time. The term 'reactivity' refers to the latency, rise time, intensity, and duration of responsiveness to stimulation. The term 'self-regulation' refers to processes that serve to modulate reactivity; these include behavioral approach, withdrawal, inhibition, and executive or effortful attention.

2. *History of Temperament Research*

Temperament study has an ancient history: individual differences in temperament were described in the fourfold typology of the Greco-Roman physician Vindician, who linked temperamental characteristics to Hippocrates' model of the humoral constitution of the body (Diamond 1974). The term 'temperament' derives from the Latin *temperamentum*, a proportionate mixture, denoting the relative preponderance of one or more of the body humors. In Vindician's typology, the melancholic person, quiet and moody, was seen as having a predominance of black bile; the choleric person, touchy, aggressive, and active, a predominance of yellow bile; the sanguine person, sociable and easygoing, a predominance of blood; and the phlegmatic person, calm and even-tempered, a predominance of phlegm. Ideas about the fourfold typology of temperament persisted throughout the Middle Ages and the Renaissance, and were found in the writings of Immanuel Kant.

Early in the twentieth century, major schools in Europe and the UK contributed to temperament research (Rothbart 1989). An Eastern European tradition began with I. P. Pavlov's observations of individual differences in his dogs' behavior in the laboratory. On the basis of the dogs' reactions, Pavlov and his followers posited characteristics of the nervous system, including strength or weakness of excitation and inhibition, and nervous system lability. This was nevertheless a conceptual nervous system; the nervous-system characteristics were based on behavioral observations. Work in Eastern Europe continued in Nebylitsyn's studies of individual differences in the laboratory, with adults as subjects. In the late twentieth century, due to a lack of consistency across stimulus modalities and response systems in the laboratory, questionnaire assays of individual differences have been undertaken.

In Central Europe, research on temperament in The Netherlands was to become highly influential. Heymans and Wiersma, in 1908, asked 3,000 physicians to observe a family (parents and children) and to fill out a temperament/personality questionnaire on each person. When the more than 2,500 responses were analyzed, three factors were identified: activity (the tendency to act out what is thought or desired), emotivity (the tendency to show body symptoms, to be fearful and shy), and primary vs. secondary process (the tendency to react immediately or in a postponed and more organized way). This research, which involved a wide range of subjects, was followed by European research on temperament in early development, with intense longitudinal observation of infants. Wallon in France and Meili in Switzerland investigated infants' muscle tension and emotionality, and Meili reported stability across time in infants' irritable or anxious responses to standardized stimuli. Meili's contributions showed a similarity to later research in the USA on temperamental emotions and behavioral inhibition (G. Balleyguier, personal communication, September 8, 1996).

In the UK, factor-analytic studies of individual differences in temperament and personality were carried out using adults' self-reports. Early work yielded factors of introversion–extraversion, emotional stability–instability (later called by Eysenck 'neuroticism'), and volition or will (Rothbart 1989). Eysenck added a physiological base to the temperament factors by relating them to cortical excitation and inhibition, and the functioning of the limbic system. Still later, Gray revised Eysenck's theory by positing individual differences in behavioral activation and inhibition, as well as tendencies to fight and flight. He also related these individual differences to an underlying neurophysiology. At the turn of the twenty-first century, Gray's theory was one of the major psychobiological models of temperament, along with models put forward by Panksepp, Cloninger, DePue, and Zuckerman.

In the USA, there were multiple contributions to the study of temperament. Allport used temperament in his trait-based theory of personality, and Cattell and Thurstone carried out early factor-analytic research on temperament and 'vectors of mind.' These would later be followed by research on the Big Five personality factors in adults (Digman 1996). Nevertheless, in early research on child development, temperamental dispositions were rarely discussed. Instead, social-learning theories stressed the importance of reward and punishment in shaping behavior and accounting for individual differences. The study of cognitive development would also become much advanced before the study of emotional development and temperament became popular. Only in the late twentieth century did research grow and flourish in temperament and development. This renewed interest has been linked to the realization that the direction of parent–child influence is not only from parent to the child, but that the infant and the young child also bring much to shaping the interaction (Bell 1968). Interest in temperament has also been linked to advances in neuroscience, with knowledge of indi-

vidual differences in temperament providing links to genes and neural networks, as well as to social interaction.

3. Current Research

In the USA, the New York Longitudinal Study (NYLS) by Thomas, Chess, and colleagues formed the basis for much of the recent research on temperament in children (Thomas and Chess 1977). Parents of infants between the ages of two and six months were interviewed about their children's behavior across a wide variety of situations. A content analysis of interview information on the first 22 infants yielded nine dimensions of temperamental variability: activity level, rhythmicity, approach-withdrawal, adaptability, threshold, intensity, mood, distractibility, and attention span-persistence. The goals of the NYLS were chiefly clinical, and no attempt was made conceptually to differentiate these dimensions from one another. Nevertheless, numerous parent-report questionnaires were developed based on the nine NYLS dimensions.

As a result of more recent research, however, major revisions to the NYLS list have been proposed (Rothbart and Bates 1998). Both factor-analytic research using NYLS items, and research following a more rational approach such as that of Rothbart, have identified a shorter list of temperament dimensions. These dimensions include positive affect and approach (extraversion or surgency), fearfulness, anger/frustration, attentional orienting, and executive attention (effortful control). These dimensions are particularly interesting because they are evolutionarily conserved affective-motivational and attentional systems. They serve adaptive functions, and can be seen in nonhuman animals as well as in the human species (Panksepp 1998).

In factor-analytic studies of parent-reported temperament in childhood, three to four broad factors are frequently found (Rothbart and Bates 1998). The first of these is surgency or extraversion, which includes activity level, sociability, impulsivity, and enjoyment of high-intensity pleasure. The second is negative affectivity, including fear, anger/frustration, discomfort, and sadness, and the third is effortful control, including attentional focusing and shifting, inhibitory control, perceptual sensitivity, and low-intensity pleasure.

Current research on temperament in childhood makes use of parent-report questionnaires, laboratory assessments of children's behavioral and psychophysiological responses to standardized stimuli, and observations of children's behavior in the home or school. With this information, it has been possible to study the development of temperamental systems, and to relate temperamental functioning to other important outcomes. These include the development of empathy and conscience, the development of behavior problems, children's adaptations to the classroom, their susceptibility to drug and alcohol abuse, and their accident-proneness.

Developmental research also indicates that the emotional systems of temperament and reactive attentional orienting are in place before the development of executive effortful attention (Rothbart and Bates 1998). In the newborn, individual differences in irritability and orienting can be observed, and by two to three months, infants demonstrate clear positive responses to stimulation. Early forms of what will later be called extraversion or surgency are present in the smiling and laughter and rapid approach of infants, and measures of approach tendencies and smiling and laughter at this early age predict children's extraverted tendencies at seven years. Throughout early development, children who are more extraverted also seem to be more susceptible to anger and frustration.

At four months, individual differences in infants' distress and body movement to stimulation predict later fear and behavioral inhibition. By six months, it is also possible to predict seven-year-old children's parent-reported frustration and anger by the infant's responses to toys out of reach or behind a plastic barrier. Infants' behavioral approach tendencies are also manifested at six months in their latency to reach and grasp objects.

The onset of fear or behavioral inhibition in the last quarter of the first year of life appears to work in opposition to the infant's approach tendencies, so that some infants who formerly rapidly approached novel objects are now slowed in their response to novel stimuli, and may not approach at all. They may also show distress to possibly threatening objects. As with approach tendencies, individual differences in fear-related behavioral inhibition show considerable stability across childhood and even into adolescence (Kagan 1998). Longitudinal research has reported stability of fearful inhibition from two to eight years, and from the preschool period to age 18.

Fear-related control of behavior can be seen in the early development of conscience (Kochanska 1997). Fearful children are more likely to show early signs of conscience. In addition, fearful children whose mothers use gentle discipline, presumably capitalizing on the child's tendency to experience anxious states, develop highly internalized conscience. More fearful infants also later tend to be empathetic and susceptible to guilt reactions. Fear can thus be seen as a basic control mechanism that is importantly implicated in socialization.

Beyond the inhibitory control provided by fear, a later-developing attentional system makes a crucial contribution to socialization. As executive or effortful attention develops in the second or third year of life and beyond, individuals can voluntarily deploy their attention, allowing them to regulate their more re-

active tendencies (Posner and Rothbert 2000, Ruff and Rothbart 1996). In situations where immediate approach is not allowed, for example, children can limit their attention to the rewarding properties of a stimulus, thereby resisting temptation and delaying gratification. Similarly, when faced with a threatening stimulus, children can constrain their fear by attending to environmental sources of safety as well as threat. In both of these examples, individual differences in attention allow children to suppress their more reactive tendencies, take in additional sources of information, and plan more efficient strategies for coping. These capacities have been referred to as effortful control, and they refer to temperamental characteristics that are distinct from extraversion/surgency and the negative emotions. Research indicates some stability of individual differences in effortful control during childhood. For example, the number of seconds delayed by preschool children while waiting for rewards that are physically present has predicted children's parent-reported attentiveness and ability to concentrate as adolescents.

In older children and adults, temperament is often studied through self-reports, allowing analysis of internally experienced feelings as well as behavior. The self-report method is also frequently used in the study of adult personality. In adult research, highly differentiated scales assessing temperament have been factor analyzed, yielding factors very similar to those found in Big Five or Five Factor Model research on adult personality (Rothbart et al. 2000). The Big Five personality factors have been derived from research using trait-descriptive adjectives, following the hypothesis that significant individual differences will be represented in the lexicon, that is, in the words people use to describe others and themselves. The Five Factor Model emerged from factor analyses of large numbers of personality self-report items. There is now considerable agreement for five broad factors of per sonality derived from this method, including extraverversion, agreeableness, conscientiousness, neuroticism, and openness to experience.

In research using adults' self-reports to scales assessing temperamental reactivity and self-regulation, three resulting factors are similar to those found in children and to measures of the Big Five personality factors. These include temperamental surgency or extraversion, positively related to personality extraversion; negative affectivity, related to neuroticism; and effortful control, related to conscientiousness. In addition, self-reported temperamental orienting to external and internal stimuli is related to personality openness to experience, and temperamental affiliativeness to personality agreeableness. Thus, the structures emerging from temperament research—using basic psychological processes of affect, arousal, and attention—and from personality research—using a lexical or personality-scale analysis—are closely related. Because temperamental individual differences are based upon fundamental psychological and neural processes and are present early in life, these findings suggest that early temperamental predispositions may form a core around which the later-developing personality will be built.

As noted above, temperamental systems are evolutionarily conserved. It is interesting that recent research has attempted to apply 'personality' constructs to studies of nonhuman species. A review of factors identified in studies of twelve nonhuman species has found support for factors of extraversion, including energy and enthusiasm; neuroticism, including negative affectivity and nervousness; agreeableness, including altruism and affection; and openness, including originality and open-mindedness (Gosling and John 1999). These are seen in the chimpanzee, monkey, hyena, dog, and cat. Several species tested did not give evidence of attentional openness, and evidence for individual differences in conscientiousness was reported only in chimpanzees. It seems likely that these studies, although labeled studies of personality, are getting at the evolutionarily conserved temperamental systems studied in human temperament research. In addition, since not all capacities appear to be shared across species, especially conscientiousness or effortful control, we can recognize important phylogenetic *differences* in temperament. For example, the capacity for effortful control, when linked with language, provides opportunities for self-regulation of reactive systems in humans that are not present in other species.

Advances in neuroscientific imaging technology and in our knowledge of brain networks underlying the emotions and attention have been an additional source of information for students of temperament and development. There is now detailed knowledge of networks subserving fear as well as both reactive orienting and effortful attention (Rothbart and Bates 1998). Because imaging studies allow researchers to identify tasks that activate these brain networks, it is possible to adapt these tasks to children of different ages in order to study the development of a temperamental system (Posner and Rothbart 2000). This marker-task approach has been used in the study of the development of attentional orienting and effortful control, but it is likely that marker tasks can be used to assess many additional individual differences. In late twentieth-century research, marker tasks of effortful attention in the laboratory were positively related to parents' reports about children's ability to control attention and emotion.

4. *Methodological Issues or Problems*

The usual issues and concerns about psychological measurement apply to the study of temperament. Because the focus of study in temperament is individual differences, it is important to design measures that will demonstrate variability. It is also important

that the tests are reliable, giving consistent measurement, and valid, reflecting something meaningful about the child's dispositions. The latter is often demonstrated in a psychological measure's convergence with other measures.

In temperament research, researchers have often been skeptical about using parents as informants about their children's behavior. It has been felt that parental biases or lack of knowledge will yield measures that are invalid, with direct observation seen as a preferable method. However, considerable evidence indicates convergence between parent report and observational measures (Rothbart and Bates 1998). In addition, laboratory observations have their own limitations. For example, it is difficult to collect extensive information about children's emotionality in the laboratory when one emotional experience has carryover effects on another. Fearful children may also behave differently in a strange laboratory situation than less fearful children, because expressions of temperamental dimensions are not independent of one another.

5. *Probable Future Directions of Theory and Research*

Temperament is a basic integrative construct within psychology, and improvements in temperament concepts and methods will be critical to advances in understanding development. One goal will be a thorough understanding of the basic processes of temperament, including the components of positive affect/approach, fear, frustration, affiliation, and attention, and how they develop. Understanding the affects and attention will benefit the understanding of temperament, just as temperament analyses will benefit our understanding of the affects and attention. Many advances will come from areas of affective and cognitive neuroscience, where much progress has been made in understanding the emotions and attention. Progress in the study of brain structure and its relation to molecular genetics will also be of great importance.

At the same time, improved assessment methods are needed at multiple levels: measures of behavior in the laboratory, including marker tasks for the development of brain structures, behavior in naturalistic daily contexts, physiological measures, informant reports, and self-reports. Increased use of the laboratory, using marker tasks, brain imaging, and recording, is likely to provide further links with underlying neural systems. Questionnaire measures involving self-report will continue to be important.

To further understanding, it will also be necessary to continue to develop the theory of temperament and its development. Because temperament encompasses organized systems of emotional and attentional processes, rather than separate traits, studies of relationships among temperament variables allow a much richer view of development. In this approach, continuity and change within systems, as well as developmentally changing links among the systems, must be considered. Studies of developmental pathways between early temperament and later personality outcomes will be complex, because childhood and adult individuality unfolds in the context of social relationships, and continuity and change cannot be understood without considering the developmentally changing impact of social experience. To understand developmental pathways, it will be necessary to disentangle complex interaction effects among early temperament predispositions, socialization processes, relationships, and culture.

Because of those complexities, temperamentally different children may arrive at similar or equivalent outcomes via different pathways. Pathways of temperamentally different children may converge over development. For example, Kochanska (1997) has found that fearful toddlers whose parents used gentle discipline, and fearless toddlers whose parents capitalized on positive motivation in a close relationship, attained comparable levels of conscience. Temperamentally similar children's developmental pathways may also diverge as a result of different experiences within relationships or varying cultures.

We have entered a very exciting era in developmental psychology. With support from flourishing neuroscience, genetics, developmental psychopathology, and behavioral research in development, the twenty-first century promises to offer new understanding of the uniqueness of pathways of individual growth. Temperament research will make major contributions to this understanding.

Temperament: Familial Analysis and Genetic Aspects

Individuals differ from birth in their reactivity to stimulation and how they regulate their physiological arousal and emotional states. These temperamental differences are expected to be due to physiological differences that, in turn, may be partly caused by genetic differences. This article reviews the findings genetic studies of behavior that have estimated the heritability of temperamental differences in Western cultures by comparing temperamental traits between members of the same family.

1. Temperament

The concept of temperament as a part of personality that is primarily biologically based, observable already in infancy, and stable throughout the life span, is deeply rooted in prescientific views of human nature. For example, the Hippocratic typology of four temperamental types (sanguine, melancholic, choleric, phlegmatic) was highly influential throughout the Middle Ages and the Enlightenment. In the twentieth century, three main strands of temperament research emerged that later became interconnected (see Strelau and Angleitner 1991).

Soviet and Eastern European research began in the 1930s with Pavlov's observation of differences among dogs in his conditioning experiments. Animals with a 'strong nervous system' responded with increased intensity to increases in stimulation whereas animals with a 'weak nervous system' failed to respond above some threshold. The Pavlov school also introduced the concepts of strength of inhibition, balance between activation and inhibition, and mobility (the flexibility of the adjustment to changing conditions). This approach was developed further in England by Gray (1982) and has influenced particularly physiological and clinical research on adults. According to Gray, individuals differ on two main temperamental dimensions—inhibition and impulsivity. Inhibited individuals react more strongly to conditioned signals of novelty and punishment than uninhibited individuals. Impulsive persons react more strongly to conditioned signals of reward than unimpulsive persons.

A second research tradition was based on self-descriptions of temperament in questionnaires. British factor analytic studies, which were begun in the 1930s by Burt, were taken further by Eysenck who identified two major dimensions of temperamental differences, extraversion–introversion and emotional stability–emotional lability (or neuroticism). Eysenck (1967) was of the opinion that these two dimensions of self-described temperament directly reflected physiological differences in arousability. According to this highly influential theory, extraverts need more stimulation than introverts for optimal arousal, and introverts are sooner overstimulated than extraverts (Pavlov's idea of the weak nervous system). Eysenck attributed these assumed physiological differences to an arousal system in the brain stem. A similar, less developed theory attributed differences in emotional stability to the differential arousability of the limbic system. However, attempts to test this theory in psychological experiments have met with only limited success (see Strelau and Angleitner 1991).

A third research tradition is the study of temperamental differences in infants and young children (Rothbart and Bates 1998). The pediatricians Thomas and Chess initiated the highly influential New York Longitudinal Study on early temperamental differences (Thomas et al. 1963). They repeatedly interviewed parents about their infant's behavior in specific contexts. These descriptions were sorted into nine dimensions of temperament: activity level, approach/withdrawal, adaptability, mood, threshold, intensity, distractibility, rhythmicity, and persistence. Subsequent research showed that some of these nine dimensions were strongly correlated, and parent or teacher questionnaires were designed that assess fewer, less correlated dimensions of infants' or children's temperament. For example, the Colorado Childhood Temperament Inventory assesses five dimensions: (negative) emotionality, activity, persistence, shyness, and sociability.

In recent years, these three traditions have become increasingly interrelated. Gray (1987) showed that his

model of inhibition–impulsivity can be translated into Eysenck's model of extraversion–neuroticism at the level of self-description. Windle and Lerner (1986) developed a questionnaire for the assessment of temperamental dimensions from childhood through adulthood. Halverson et al. (1994) pointed out how temperamental dimensions are related to the more general five-factor model of personality description. By and large, temperament refers to the first two factors of this model, extraversion and emotional stability, which were already identified by the British factor analytic tradition, with age-specific additions particularly for infants and younger children.

Therefore the working definition of temperament for this article refers to individual differences in basic psychological processes that constitute the affective, activational, and attentional core of personality (Rothbart and Bates 1998), and which are mainly related to the first two factors of the five-factor model of personality description, extraversion and neuroticism.

2. *Estimation of Heritability*

The genetic influence on temperamental differences in a human population can be studied both directly and indirectly. The direct method tries to establish a statistical relation between the frequency of variants of a gene in the population (its alleles) and temperamental traits. This method provides estimates of the influence of specific genes on specific traits and requires molecular biological knowledge about which genes and alleles can be distinguished. This direct method became feasible towards the end of the twentieth century as the relevant knowledge became increasingly available.

The present article reviews results from familial analyses conducted in the field of behavioral genetics, a subdiscipline of population genetics (see Plomin et al. 1997 for an overview). This indirect method estimates the overall genetic influence on a specific dimension of temperament relative to the overall environmental influence on this dimension through analyses of the temperamental similarity of members of the same family such as twins, adoptive siblings, and their parents. This method requires only basic knowledge about rules of inheritance, not molecular biological knowledge about genes and their alleles. However, the method is based on certain assumptions that may not always be valid.

The indirect method is based on the fact that the genetic similarity of family members varies from 0 percent shared alleles in the case of adopted siblings or adopted children and their nonbiological parents, to 50 percent shared alleles in the case of biologically related siblings, nonidentical twins (dizygotic twins), and their biological parents, and 100 percent shared alleles in the case of identical twins (monozygotic twins). Siblings, nonidentical twins, and their parents share 50 percent of their alleles on average because half of children's alleles stem from the mother and the other half from the father. Identical twins are an exception because they develop from the same original cell that only later splits into two different individuals; they are therefore genetically identical.

Two basic assumptions of the indirect method are: (a) influences on temperamental differences in the population can be either environmental or genetic, and (b) the overall impact of the environment, relative to genes, is identical for siblings, adoptees, and twins. Therefore, differences in their similarity can be fully interpreted as genetic effects. Thus, if identical twins are more similar in a specific temperamental trait than nonidentical twins, or biologically related siblings are more similar than adopted siblings, this difference in similarity can be genetically interpreted. The larger the difference in similarity, the stronger the genetic influence on the temperamental trait. Thus, there exist two main indirect methods of estimating genetic influences: comparing identical twin pairs with nonidentical twin pairs (twin method), and comparing biologically related sibling pairs with adopted sibling pairs (adoption method). As a result it is possible to crosscheck the results of these two methods with one another. Other indirect methods compare the similarity between identical twins that are reared apart as opposes to those reared together, or the similarity between parents and their biological children as opposed to their adopted children.

The strength of the genetic influence on temperamental differences can be quantified by the heritability coefficient h^2. This coefficient can be interpreted as the proportion of variance in a specific temperamental trait in the population that is due to genetic differences: $h^2 =$ genetic variance/total variance. It can be estimated on the basis of differences between intraclass correlations. In the twin method, the intraclass correlation between nonidentical twins (a measure of their similarity) is subtracted from the intraclass correlation between identical twins. Because this difference estimates $100 - 50$ percent $= 50$ percent of the genetic influence (identical twins share 100 percent of their alleles, and nonidentical twins 50 percent), it is doubled; this double difference is h^2. In the adoption method, the difference between the sibling correlation and the adopted sibling correlation is doubled because it estimates $50 - 0$ percent $= 50$ percent of the genetic influence (adopted siblings do not share alleles).

The heritability coefficient can vary between 0 and 100 percent. Zero heritability would be found if the variation of the temperamental trait in the population is only due to environmental differences. In this case, adopted and biologically related siblings are equally similar in this trait, as are identical and nonidentical twins. A heritability of 100 percent would be found if the variation of the trait in the population is only due to genetic differences. In this case, adopted siblings

would be as dissimilar as children from different families, and identical twins would perfectly match each other in the trait; normal siblings would be moderately similar.

The concept of heritability is a relativistic concept because it estimates the amount of genetic influences relative to environmental influences. Therefore, heritability can vary between populations and between different traits within the same population. Thus, the heritability of adolescent shyness can be higher in the USA than in African cultures, and adolescent shyness can be more heritable than adolescent sociability in the USA. Furthermore, heritability depends on the variability of genes and environments in a given culture. If the genetic variability is increased (e.g., through genetically dissimilar immigrants), or if the environmental variance is decreased (e.g., through compensatory education), the genetic influence can increase; if the genetic variance is decreased (e.g., through a virus that kills people with particular alleles), or if the environmental variance is increased (e.g., through an unjust political system), the genetic influence can decrease.

The heritability of a trait depends not only on the trait, the population, and its culture, but also on age. The genetic influence on a trait may decrease with age because more and more environmental influences accumulate. On the other hand the genetic influence may also increase with age because more and more genes become relevant for the trait or because older children and adults are more able than young children to select their environment according to their genetically influenced interests and motives (such selection would decrease the environmental variance). All in all, heritability is a highly relativistic concept with regard to the target trait, culture, and age.

3. *Heritability of Temperamental Traits*

Empirical studies on the heritability of temperamental traits are nearly exclusively restricted to North American and Western European samples. Therefore it is unknown whether the following findings can be generalized to other cultures. Because heritability can vary with age, the findings are discussed separately for different age groups. Because the findings also vary considerably with the estimation method used, twin studies and adoption studies are discussed separately.

In twin studies of older infants and children, two groups of traits can be distinguished with regard to their heritability (see Goldsmith et al. 1997). A first group of traits (activity, emotionality, sociability, impulsivity, approach/withdrawal) is characterized by a high similarity of identical twins (intraclass correlations approximately 0.60) and a dissimilarity of nonidentical twins (correlations close to zero), suggesting the odd result of more than 100 percent heritability for some of these traits. A second group of traits (inhibition to strangers, adaptability, mood, distractibility, rhythmicity, intensity, persistence, and threshold) is characterized by an equally or even higher similarity of identical twins along with a moderate similarity of nonidentical twins, suggesting 40–60 percent heritability. Adoption studies for this age range have resulted in zero or even negative correlations for adopted children and somewhat more positive correlations for biologically related siblings, suggesting 10–50 percent heritability.

Whereas in all these studies a moderate to strong genetic influence on temperamental traits was found, one twin study found no genetic influence for 5 different observed temperamental traits in 4-day-old infants (Riese 1990). Together with findings of a low stability of temperamental differences over the first months of life, this result can be attributed to strong environmental influences around birth that obscure genetic effects (e.g., perinatal and postnatal difficulties that transitionally influence the infants' emotional and attentional reactivity).

For adolescents and adults, most studies have focused on extraversion and emotional stability (or the reverse trait, neuroticism). Loehlin (1992) reviewed these studies. For twin studies, the results were similar for both traits: approximately 65 percent genetic influence, based on moderately high correlations between identical twins and low correlations between nonidentical twins. For adoption studies, extraversion showed a higher heritability of approximately 50 percent than neuroticism (only approximately 15 percent heritable).

In a large study of Finnish twins, Viken et al. (1994) found a decrease in the heritability of both extraversion and neuroticism between late adolescence and the late twenties and no change in heritability thereafter. It should be noted that this study relied on cross-sectional analyses that compared the results for different birth cohorts. Therefore, the age effects may reflect cultural changes rather than age-related changes. Only longitudinal studies that follow the same persons over a long time can disentangle age-related changes from historical changes.

Overall, there is clear evidence for genetic influence on temperamental traits at all ages except close to birth, but the findings are far from being consistent between the twin and the adoption method. Possible reasons for these inconsistencies are discussed in Sect. 4. When the results are compared to the findings for other individual differences such as intelligence, conscientiousness, or agreeableness, the heritabilities are not higher (see Loehlin 1992, Plomin et al. 1997). Thus, variations in temperament do not seem to be more genetically influenced than other variations of personality and intelligence.

4. *Methodological Problems*

Both the twin method and the adoption method are affected by multiple problems that can bias their

results. For temperament-related traits, the main problems seem to be contrast effects and non-additive genetic influences. Contrast effects make twins and siblings more different, and can occur in two different forms. First, they can be due to sibling rivalry (e.g., one becomes more dominant and the other more submissive in their interaction, and these tendencies generalize to other relationships). In this case, twins and siblings are more different than one would expect on the basis of their genes and other environmental influences. Such contrast effects are expected to decrease with increasing age differences between the siblings; thus, they should operate particularly in the case of twins.

Second, contrast effects can affect personality judgments by family members because the parents or the siblings contrast a child with his or her siblings. For example, the parents may overestimate differences between two siblings' aggressiveness if one is moderately aggressive relative to peers and the other one is not aggressive because they perceive one as 'the aggressive one' and the other as 'the non-aggressive one.' These judgmental contrast effects are expected to increase with increasing dissimilarity of the siblings. Therefore, they are expected to underestimate most strongly the similarity of adopted children, and moderately strongly the similarity of biologically related siblings; for identical twins they should be particularly small.

Saudino et al. (1995) studied contrast effects for parental ratings of temperament. They compared the similarity of identical twins, nonidentical twins, siblings, and full, half, and genetically unrelated siblings in stepfamilies. This approach enabled estimation of the strength of contrast effects. They found significant contrast effects for all temperamental traits. These contrast effects may explain both the odd finding of more than 100 percent genetic variance for many temperamental traits in twin studies (the difference between identical and nonidentical twins is overestimated because the nonidentical twins are judged to be less similar than they really are) and the very low or even negative correlations for adopted siblings (they are judged to be less similar than they really are). It should be noted, however, that after controlling for contrast effects, significant genetic effects remained for all traits in this study.

The second main methodological problem is that the influences of different genes on a temperamental trait may not necessarily be additive. For example, the mere presence of the alleles A and B may not in itself increase the risk for high emotionality but the simultaneous presence of both alleles may. Because identical twins share all alleles, they share 100 percent of all genetic effects, including such non-additive effects, and adopted siblings share neither additive nor non-additive effects. However, nonidentical twins and siblings share 50 percent of the additive effects but a smaller percentage of the non-additive effects because these require that they share combinations of alleles. For example, the probability that they share alleles A *and* B is only 25 percent. If non-additive effects exist, the difference between identical and nonidentical twins estimates more than 50 percent of the genetic effects. Therefore, the heritability coefficient *over*estimates genetic influences. Similarly, the adoption method *under*estimates genetic differences because the difference between biologically related and adopted siblings estimates less than 50 percent of the genetic effects.

In the case of non-additive effects, the genetic estimates from the twin method and the adoption method are biased in opposite directions (overestimation vs. underestimation). This principle applies also to other problems such as the genetic similarity of the parents due to partner preferences (their homogamy), or a genetic similarity between adopted children and their nonbiological parents due to nonrandom assignment to families by the adoption agencies (selective placement). Therefore, it is possible to control these problems by the simultaneous analysis of similarity data from both twins and adopted children. This combination method requires complex statistical models (Neale and Cardon 1992) but circumvents most methodological problems of both the twin and the adoption method. It is even possible to estimate the strength of the various biases (e.g., separate estimations for additive and non-additive genetic effects). Thus, although there are many problems with these indirect estimations of genetic influences on temperament, most of them can be controlled.

5. *Misinterpretations of Heritability Estimates*

Often heritability estimates are misinterpreted as general estimates of 'the' genetic effect on temperament. In contrast, it was pointed out above that heritability estimates depend on (a) the specific temperamental trait, (b) the population of interest, (c) the historical period in its cultural development, and (d) the age of the participants. Another serious misinterpretation is the assumption that genetic effects on temperament can be altered only by changing the genes themselves through gene technology. This widely shared view is not correct because genes and environmental influences often interact in affecting personality. For example, the effects of pathological alleles such as the one that causes phenylketonuria can be minimized through environmental intervention (in this case: keeping a particular diet in the first years of life; see Plomin et al. 1997). Although the alleles that are relevant for temperament-related traits are as yet largely unknown, it is possible that their effects on temperament might be modifiable through diet, medication, specific parenting, or education. Heritability does not necessarily imply non-modifiability.

6. Conclusion

Indirect estimations of the overall genetic influence on temperament indicate significant genetic effects. The many methodological problems of these estimations can be controlled to a great extent through adequate study designs and statistical models. The estimates inform us whether temperamental differences in temperament among peers of a particular population are partly due to genetic differences. Because all temperament-related traits show significant genetic influence, at least in Western cultures beginning with later infancy, it seems promising to search for the specific genes that are responsible for these genetic influences.

Temporal Lobe

The temporal lobe subserves disparate functions. The dorsal (or superior) part is involved in the perceptual processing of auditory signals including speech. The primary auditory area is located at the central part of the lower bank of the lateral fissure, with higher

Figure 1
The extent and gyrus composition of the temporal lobe. 1, temporal pole; 2, superior temporal gyrus; 3, middle temporal gyrus; 4, inferior temporal gyrus; 5, fusiform gyrus; 6, lingual gyrus

auditory areas circumscribing it. Visual information processing about objects spreads from the ventral part of the occipital lobe to the posteroventral part of the temporal lobe. The most anterior and anteroventral parts are essential for the memory and retrieval of the semantic knowledge of objects.

1. Borders and Gyrus Composition

The temporal lobe is separated from the frontal lobe and the anterior part of the parietal lobe by the lateral (or Sylvian) fissure. Its borders with the occipital lobe and the posterior part of the parietal lobe do not have clear delimiting sulci. On the lateral surface, an imaginary line drawn from the temporo-occipital incisure (or the occipital notch) at the inferior margin of the hemisphere to the posterior end of the parieto-occipital sulcus defines the anterior border of the occipital lobe. Another imaginary line drawn orthogonally to this first line, from the point at which the lateral fissure turns upward, defines the border between the temporal and parietal lobes on the lateral surface. On the ventromedial surface, an imaginary line drawn from the temporo-occipital incisure to the point at which the parieto-occipital sulcus merges with the calcarine sulcus defines the border between the temporal and occipital lobes. The most medial part of the ventral surface of the hemisphere, medial to the anterior part of the calcarine sulcus and the anterior part of the collateral sulcus, is often treated as a part of the limbic system. The temporal lobe does not border with the parietal lobe on the medial surface.

The anterior end of the temporal lobe, the temporal pole, does not have sulci. The lateral surface of the temporal lobe has three anteroposteriorly elongated gyri separated by two sulci. Going from the more dorsal to the more ventral, these are the superior temporal gyrus, the middle temporal gyrus, and the inferior temporal gyrus. The superior temporal sulcus separates the superior and middle temporal gyri, and the inferior temporal sulcus separates the middle and inferior temporal gyri. The dorsal surface of the temporal lobe, which is concealed in the lateral fissure, is composed, from anterior to posterior regions, of the planum polare, the transverse temporal gyrus (or the transverse gyrus of Heschl), and the planum temporale. From its medial to lateral extent, the ventromedial surface of the temporal lobe is composed of the lingual gyrus, the fusiform gyrus, and the inferior temporal gyrus. The collateral sulcus separates the lingual and fusiform gyri, and the occipitotemporal sulcus separates the fusiform and inferior temporal gyri. The lingual gyrus continues anteriorly to the parahippocampal gyrus, which is the gateway to the hippocampus and related structures implicated in explicit memory (see *Hippocampus and Related Structures*). Both the lingual gyrus and the fusiform gyrus continue from the occipital lobe to the temporal lobe with no marks.

2. Auditory Functions

Because microelectrode recordings in human cortex are possible only in very rare clinical cases, and in vivo tracer studies are not possible, the current knowledge of the structure and function of the auditory cortical areas in the temporal lobe is largely due to results obtained in experimental macaque monkeys. Fortunately, the location and basic organization of auditory cortical areas is very similar in humans and macaques, insofar as the available data indicate.

2.1 Primary Auditory Cortex

The dorsal surface of the monkey temporal lobe does not have a transverse gyrus, but has an anteroposteriorly elongated annectant gyrus. This annectant gyrus in the ventral bank of the lateral fissure shows the histological features of primary sensory cortex such as densely packed granule cells, and dense reactivity to the cytochrome oxidase and calcium-binding protein parvalbumin. Studies with microelectrodes show that cells in this region respond well to pure tones, showing relatively sharp selectivity to a tone's frequency. These studies have permitted the identification of two separate tonotopically organized areas, named A1 and R. A1 occupies a large part of the annectant gyrus, and R occupies a smaller area anteriorly adjoining A1. Frequencies are mapped from lowest to highest in the anterolateral to posteromedial direction in A1, and the reverse in R. Both areas receive strong fiber projections from the main part (ventral division) of the medial geniculate nucleus (MGv). Although the histological features of primary sensory cortex are more pronounced in A1 than R, R is thought to be parallel to A1 in signal flow because responses of cells in R to pure tones survive ablation of A1.

In the human temporal lobe, a region with the histological features of primary cortex is located in the transverse temporal gyrus within the ventral bank of the lateral fissure. MEG (magnetoencephalography) and functional MRI (magnetic resonance imaging) studies consistently show tonotopy in the transverse temporal gyrus; frequencies are mapped from lowest to highest in the anterolateral to posteromedial direction. This mapping orientation is the same as in monkey A1. Some studies have also shown a second tonotopic mapping in the transverse temporal gyrus, which may correspond to R in the monkey. Bilateral damage to these primary auditory areas results in a profound deficit in sound detection, although the deficit usually recovers within several weeks to several months.

2.2 Higher Auditory Areas

The monkey auditory areas in the dorsal part of the temporal lobe are composed of three or four serial

stages (Kaas et al. 1999). The primary auditory areas constitute the 'core.' Axonal fibers from the core strongly project to regions in the 'belt,' which circumscribe the core in all directions except posteromedially. The belt regions are confined to the lower bank of the lateral sulcus. Fiber projections from MGv to the belt are weak, while there are moderate projections from the dorsal (MGd) and medial (MGm) divisions of the medial geniculate nucleus to the belt. There are at least three subdivisions in the belt as determined by distinct tonotopic mapping and histochemical and connectional properties. Cells in the belt tend to respond more strongly to narrow band noises and more complex sounds than pure tones, and their response tuning to pure tone frequencies tends to be broader than in the core (Rauschecker 1998). There is no consensus on the relative contribution of serial inputs from the core and direct inputs from MGd and MGm to the auditory responses of belt cells, but it is at least known that responses to pure tones in a part of the belt disappear after ablation of A1.

The belt strongly projects to the laterally adjoining regions on the lateral surface of the superior temporal gyrus. These regions have been named the 'parabelt.' The projections from the core to the parabelt are weak. Thus, there is a more or less serial projection stream from core to belt to parabelt. Like the belt, the parabelt receives projections from MGd and MGm, but in addition, the parabelt receives projections from other thalamic sites: the suprageniculate, limitans, and medial pulvinar nuclei. The parabelt projects extensively to more rostral and caudal parts of the superior temporal gyrus, adjoining regions in the superior temporal sulcus, prefrontal cortex, parietal cortex, and other brain sites. There are no projections from the core, and only weak projections from the belt, to these fourth-stage regions. Tonotopic mapping has not been found in the parabelt. The parabelt receives projections from the belt in a rostral-to-rostral and caudal-to-caudal manner. Thus, there are at least two serial pathways in parallel. There are some data on the cellular response properties that suggest that the two pathways correspond to the two main pathways in the visual system; the caudal auditory pathway corresponding to the dorsal, or spatial visual pathway, and the rostral auditory pathway to the ventral, or object visual pathway (Rauschecker 1998). Most cells in the rostral parabelt are more selective for sound properties, while cells in the caudal parabelt respond to pure tones of wide frequency ranges. Unlike rostral parabelt cells, most cells in the caudal parabelt, respond only to sounds from contralateral space. Some are more responsive to sounds from moving sound sources, sometimes with sensitivity to the direction of the source motion.

Available data in humans also suggests serial auditory stream (Kaas et al. 1999). Electroencephalogram (EEG) and MEG recordings of auditory evoked potentials show progressively longer response latencies at more distant locations from the primary auditory area. Functional MRI and PET studies have found a few tonotopic maps on the surface of the superior temporal gyrus. As for stimulus selectivity, functional MRI studies have found that complex sounds including human voices more strongly activate these surrounding regions than scrambled voices with matched power spectra (Belin et al. 2000, Scott et al. 2000). A bilateral lesion of the surrounding regions with the primary auditory areas spared is known to cause 'auditory agnosia,' a deficit in perceiving meaningful sounds including phonemes, elements of spoken words, and nonvocal familiar environmental sounds. Left-lateralized damage causes a specific deficit in perceiving phonemes (pure word deafness), while right-lateralized damage causes a less specific deficit in perceiving nonvocal, familiar environmental sounds, for which the term auditory agnosia is sometimes specifically used. In any case, a lesion of the surrounding regions leaves the detection of sounds intact. All these findings suggest that auditory information is processed serially in humans as it is in macaques—from the primary auditory areas located within the transverse temporal gyrus, to the surrounding regions at the planum temporale and the lateral surface of the superior temporal gyrus.

Apart from pure word deafness, there are patients who show a deficit in both the perception and vocalization of words. In the latter case, named 'Wernicke's aphasia,' spontaneous speech may be fluent but includes nonsense words or words with syllabic errors. These patients cannot repeat words or sentences spoken by other people. It is assumed that the phonetic memory of words or its access by phonemic inputs is damaged. The posterior third of the left superior temporal gyrus was originally proposed to be involved in this symptom, thus this region is often referred to as 'Wernicke's area.' However, the lesions in patients with permanent Wernicke's aphasia are larger and include the posterior half of the superior and middle temporal gyri or the white matter under Wernicke's area.

3. *Visual Functions*

In macaques, the middle and inferior temporal gyri are mostly dedicated to the purely visual associations involved in object vision. These regions are the latter stages of the ventral visual pathway. Their bilateral ablation causes a specific deficit in performing and learning tasks requiring visual object discrimination and recognition (Gross 1994). Single cell recordings have shown that cells respond to various complex features of visual object images (Tanaka 1996). Some of the cells specifically respond to views of faces.

In humans, however, purely visual functions appear to be restricted to the posterior part of the ventral temporal lobe. Both 'visual agnosia,' in which the

patient cannot retrieve semantic knowledge including the name of visually presented objects, and 'prosopagnosia,' in which the patient cannot retrieve the identity of visually presented faces, are caused by damage to the regions around the border between the occipital and temporal lobes on the ventral surface. These patients retain semantic knowledge of objects and individual persons, which they can retrieve via inputs of other modalities. More anterior parts of the ventral temporal lobe are thought to be essential for the semantic knowledge of objects and persons, with their names localized mostly in the left hemisphere.

Reading can be also specifically degraded (pure alexia) by damage around the border between the occipital and temporal lobes. Classical cases had combined damage to the left occipital lobe and the corpus callosum splenium (the posterior part of the corpus callosum), in which the deficit was explained by the disconnection of the language centers in the left hemisphere from the spared visual cortical regions in the right occipital lobe. However, a similar deficit is caused by a more localized damage to regions around the border between the occipital and temporal lobes in the left hemisphere. The patients have no deficit in writing words. Many patients can read words by picking up letters one by one. Therefore, the deficit is thought to be due to degraded perception of shapes composing words, especially global features covering the whole word. Among Japanese people, who use both visually complex ideograms (Kanji) and relatively simple syllabograms (Kana), there are rare cases in which reading Kanji is specifically degraded. The damage in these patients involve the most posterior part of the inferior temporal lobe in the left hemisphere.

Functional MRI studies have shown that the posterior part of the ventral temporal lobe is activated by the passive viewing of object images (Tanaka 1998). Parts of the fusiform gyrus are more strongly activated by viewing faces than other objects. The surrounding regions in the rest of the fusiform gyrus and the inferior occipital gyrus are more activated by non-face objects than faces. There are reports that views of towns, including houses, and views of rooms specifically activate the posterior part of the parahippocampal gyrus (Epstein and Kanwisher 1998).

4. *Semantic Knowledge*

There are aphasic patients with symptoms that appear to be due to damage or loss of the semantic knowledge of objects. These patients show impaired understanding of spoken words and sentences. Their spontaneous speech is fluent, but their vocabulary is poor. They also have difficulty in naming visually presented objects. Oral repetition of spoken words and sentences is intact, but without understanding. These patients have left-lateralized or bilateral damage of the middle and inferior temporal gyri and temporal pole. This symptom is a subtype of 'transcortical sensory aphasia,' but it is also called 'semantic dementia.' Semantic dementia is more often observed in 'Pick's disease,' a progressive genetic disease manifesting atrophy of cortical neurons, rather than vascular problems. The atrophy usually starts in both temporal and frontal lobes, but in the limited cases in which the atrophy starts in the temporal lobe, the patients show pure semantic dementia. The knowledge of objects at finer classification levels (individual and subordinate levels rather than categorical levels) tends to be lost first. As the infection progresses to the frontal lobe and the medial aspects of the temporal lobe, the symptoms develop into a more general dementia.

Semantic dementia may show category specificity (Caramazza and Shelton 1998). Three categories may be selectively impaired: animals, tools, and individual persons. Damage to the temporal pole impairs knowledge of familiar persons. In particular, the left temporal pole is important for the association of names with biographical knowledge, while the right temporal pole is important for the retrieval, based on various inputs, of biographical knowledge other than names. Damage to the anteroventral part of the left temporal lobe causes difficulty in naming animals based on various inputs. The conceptual and nominal knowledge of tools is degraded by damage to the posterior region of the lateral surface of the occipital, temporal and parietal lobe junction. Functional imaging studies (PET and functional MRI) show activation patterns in normal subjects consistent with the previously mentioned results obtained from brain-damaged patients (Damasio et al. 1996). In these studies, the subjects named objects from their pictures or made semantic judgments on pictures or visually presented words.

Tense, Aspect, and Mood, Linguistics of

The English sentences *He is asleep* and *He was asleep* differ in tense: the former is in the present and the latter in the past tense. In a similar way, *He opened the window* and *He was opening the window* are said to differ in aspect, and the verbs *wish* and *were* in the sentence *I wish I were dead* are said to differ in mood. Tense, aspect, and mood, traditionally labeled grammatical categories, play an important role in the grammar of English and most other languages.

It should be noted from the outset, however, that tense, aspect, and mood do not usually come neatly lined up as separate categories in grammars. Temporal, aspectual and modal properties are commonly interwoven in the same forms. Conversely, distinctions which would traditionally be thought of as belonging to the same category may be expressed in very different ways, for instance, by inflectional forms on the one hand and auxiliary constructions on the other. For this reason, many linguists prefer to see tense, aspect, and mood as one large domain within which various grammatical distinctions may arise.

Recent typologically oriented work has shown that although there is great variation among languages as to their systems of tense, aspect, and mood, the elements of those systems may be reduced to a relatively small number of types, each with its characteristic meaning and typical way of expression, developing historically by processes of grammaticalization. Such processes usually start with phrasal constructions involving lexical morphemes. Future markers may, e.g., develop out of constructions involving motion verbs such as 'come' and 'go,' or modal verbs with the meanings of obligation ('shall, must') and volition ('want'). Later on, inflections may arise through the coalescence of earlier free morphemes (auxiliaries or particles) with the stem of the main verb. The elements of a tense-aspect-mood system in a language may be at different stages in these grammaticalization processes; how far they have advanced determines both their form and their meaning. Thus, only a few of the types described below typically show up in inflectional distinctions, while the others tend to be expressed periphrastically.

The basis for the distinctions between forms traditionally subsumed under the category of tense is the time-dependence that characterizes the overwhelming majority of statements in natural languages. A sentence such as The *baby was asleep* does not make very much sense as long as we do not know what time we are talking about—that is, at what time the baby was asleep. In English, the tense of the verb gives us some indication about the time—we know that the speaker is referring to some point in the past. However, the exact location of that point is not indicated explicitly and has to be retrieved from the context. In many languages, e.g., Chinese, no distinction would be made between *was asleep* and *is asleep* here—in those languages, the identification of the 'topic time' or 'reference time' is left wholly implicit.

Nevertheless, the identification has to be made, in order to make sense of the statement. Thus, the way in which sentences are interpreted is similar whether or not a language makes the grammatical distinction between present and past tense. Notice also that tenses are not complementary to time adverbials, as is often assumed. Languages that lack tense distinctions do not, on the whole, use time adverbials more often than languages that do not. This is because time adverbials are used whenever the contextual temporal information is insufficient. Tenses, on the other hand, being more or less obligatory grammatical elements, are used whether or not the information they contain is necessary for the communication.

In the most straight-forward cases, the choice of tense depends on the relationship between the topic time and the time of speech. Time as experienced by a person is naturally divided into present, past, and future; these are also the three basic tenses of traditional grammar, although it is common for languages to have only a simpler, two-way distinction in their grammar: either between past and non-past or between future and non-future. In English, only the past tense (*he called*) differs from the present (*he calls*) morphologically; what is traditionally referred to as the future (*he will call*) is an auxiliary construction, although inflectional futures are far from uncommon in other languages (e.g., French *il dormira* 'he will sleep'). It is common for languages to have several ways of marking the future grammatically, often differing in subtle modal nuances (cf. English *will* vs. *is going to*). The common modal coloring of future tenses has led many scholars to deny the future status as a tense. Many languages distinguish grammatically degrees of remoteness in the past and sometimes also in the future. In many Bantu languages one thus finds 'today pasts,' 'yesterday pasts' and 'remote pasts' expressed by different verb forms or by auxiliaries.

A distinction is customarily made between absolute and relative tense, depending on whether the point of departure is the time of speech or some other time point. The tenses of finite verbs in main clauses are usually absolute—past tense means that the topic time

precedes the time of speech. Non-finite verb forms such as participles, gerunds and infinitives may also show tense distinctions, but these predominantly mark relations of simultaneity or temporal sequence relative to the time of the next higher finite verb, as in the sentence *She lived in London, working for a large company* where the gerundial clause is understood as being about the same time as the main clause (which, in its turn, is understood as preceding the point of speech). Finite verbs in subordinate clauses may follow varying principles. In clauses expressing reported speech, the verb is in many languages in the same tense as it would have in a direct quote; in English and some other European languages, the tense of such clauses depends on the tense of the matrix main clause. This phenomenon, exemplified in a sentence such as *John said that he was ill* (cf. *John said "I am ill"*) is traditionally referred to as 'sequence of tenses'; there is disagreement among scholars about its nature.

In some languages, special narrative tenses are used to express an event that takes place directly after another.

The sentences *He opened the window* and *He was opening the window* were said above to differ in aspect. Many traditional characterizations of aspect are formulated in terms of the perspective or viewpoint a speaker takes towards what happens or takes place in the sentence. Alternatively, we may say that aspectual distinctions involve different ways in which an event, process or state may be related to a point or period in time. Grammatical distinctions subsumed under the category of aspect are related to the different ways entities such as events, processes and actions are anchored in time, or, if we like, to the different perspectives we may take to these entities. In languages which express aspectual distinctions in their inflectional systems, the most common distinction is between perfective and imperfective aspect. Perfective aspect is used talking about completed events and processes and tends to be restricted to events that took place in the past, or sometimes either in the past or the future. Imperfective aspect, which is more independent of time reference, is used for states and processes that hold or are going on at the topic time but also for habitually occurring events.

A typical example of the intertwining of tense and aspect in an inflectional verb system is found in written French, in which perfective aspect is represented by the so-called passé simple or simple past (*il chanta* 'he sang'), while the present (*il chante* 'he sings/is singing'), the imparfait or imperfective past (*il chantait* 'he sang/was singing') and the future (*il chantera* 'he will sing') represent combinations of the imperfective aspect with various tenses.

Aspect may also be expressed by periphrastic or derivational means. Progressives, as exemplified by the English construction *I am/was/will be singing*, are a common type in languages and are almost exclusively expressed periphrastically. With regard to their meaning, they resemble imperfective aspect but have a more restricted domain of use in that they are only marginally used about states or habitual events. Historically, progressives are a common source of imperfectives.

Special habitual inflections are not uncommon; these may be used for events that take place regularly (*I used to visit him on Sundays*) but also sometimes for generic statements such as *Dogs bark*.

In many languages, the aspectual character of verbs may be modified by derivational processes. In contradistinction to inflectional aspect, these processes tend to be idiosyncratic and restricted to smaller sets of lexical items. A typical distinction expressed by derivational aspect is that between semelfactive or punctual on one hand and durative on the other, as in Hungarian *köhintett* 'he coughed once': *köhögött* 'he coughed (for a longer or shorter time).' The famous aspectual systems of Russian and other Slavic languages are derivational in origin but have over time been regularized and received many features that make them seem more like inflectional aspect.

The English perfect, as in *He has sung*, represents a cross-linguistically common type the semantics of which defies the traditional classification in that it cannot be unambiguously subsumed under either tense or aspect. Perfects are used of events that took place in the past but have a more restricted domain of use than ordinary past tenses. A common way of formulating the meaning of perfects is to say that they imply 'current relevance' of the event related in the sentence. Another way of putting this is to make a distinction between the 'time of event' and the 'topic time' (or reference time): in the perfect, the time of event is in the past but the topic time is equal to the time of speech. In the pluperfect (e.g., *He had sung when I arrived*) the time of event also precedes the topic time but here both points are in the past. Within the semantic domain typically covered by perfects, we also find more specialized forms and constructions. Resultatives express the resulting state of some event (e.g., *He is gone* in English); they are usually restricted to verbs that denote change. Historically, they are often extended in meaning to become perfects. Experientials, such as the Japanese *koto ga aru* construction (*Nihon de hataraita koto ga aru* 'I have worked in Japan') are used to express that some type of event took place one or more times within a period in the past.

The distinctions pertaining to the traditional grammatical category of mood cover only a relatively small part of the wide conceptual domain of modality. Moods are commonly said to express the speaker's attitude to a proposition or to its truth-value. However, a typical grammatical mood, such as the subjunctive in English, French, or German, is rather used to mark certain clause types, which are normally non-asserted and grammatically subordinate. Thus, in French, the subjunctive is obligatory in the complement clauses of verbs meaning 'want, desire, hope.'

The subjunctive thus marks these clauses off against plain main clauses, which are the unmarked, indicative mood (*Il est parti* 'He has left' vs. *J'espère qu'il soit parti* 'I hope that he has left'). Another common function of moods is to distinguish between possible and counterfactual situations in conditional constructions (cf. *If he is ready*, *we can go* vs. *If he were ready*, *we could go*, where the latter sentence contains the obsolescent subjunctive form *were*).

A form usually subsumed under mood is the imperative, whose primary use is to express speech acts such as commands, requests etc.

Many languages make grammatical distinctions on verbs which carry information about the kind of evidence the speaker has for a statement.

Territoriality: Geographical

Territoriality in humans, or human territoriality, is the act of delimiting and controlling an area of space—a territory—in order to control people and things. Human territoriality pervades our actions at all geographic scales, and undergirds socio-cultural power. It is a strategy that can be turned on and off. This, and the fact that human territoriality requires particular conceptions about space, make its use in humans different from its use in animals, where territoriality appears as an instinct that is often associated with aggression. Conceiving of human territoriality as an offshoot of animal instinct (Ardrey 1966, Montagu 1968) has resulted in misconstruing the problem. The most fruitful approach to human territoriality is through its relationship to non-territorial strategies; its connections to geographical place and space; and the advantages (and disadvantages) it provides.

1. Geographical Strategies of Control

Consider a hypothetical example of a father and his two small children at home in their kitchen. The father is trying to cook a meal and take care of the children, and they want to help. The father enjoys their company but they are too young to help, and run the risk of injury as they try to touch a knife or dish. The father wants to limit their access to these things, and he has two geographic strategies. One is for the father to rush around the kitchen placing the knife and dish out of reach and to restrain the children physically. Here the father intends to alter or control their spatial actions directly. The other strategy is indirect and territorial. It arises if the parent decides simply to restrict the children's access to things in space by telling them they 'may not enter the kitchen at this time.' That is, the kitchen for now is 'off limits.' Here the children's access to things is being limited by the parent's assertion of control over an area. (Sack 1986, p. 16) In the case, the area or territory was there to begin with; the parent took the opportunity to invoke it, and, after the meal is prepared, the territorial unit may recede into the background. Alternatively, the parent could

have created a new territory by delimiting and asserting control over part of the kitchen. Whether creating a new territory or invoking the power of a pre-existing one, human territoriality is a strategy that can be turned on and off, and when it is not used, we then rely on direct spatial interactions to affect or control the flows and access to things in space.

This example points out that territoriality is found in everyday life and at even the smallest geographic scales. But territoriality is most commonly understood to involve political activity and state control, and leads to concerns of sovereignty and jurisdiction. At an in-between scale, we find territoriality to be conjoined with such things as zoning, or with (often private) ownership of land. These and countless other instances of the control of area are examples of territoriality; not to recognize this is to overlook how territoriality provides humans with advantages that make it a necessary geographical expression of power. These advantages are outlined in Sack's theory of human territoriality (1986).

2. *Theory of Human Territoriality*

The theory builds on the definition of human territoriality 'as the attempt by an individual or group to affect, influence, or control people, phenomena, and relationships, by delimiting and asserting control over a geographic area [where the area is called the territory]' (p. 19) by pointing to three interrelated implications of this definition that reveal how and why territoriality works as an effective strategy. They are that territoriality:

(a) involves a form of classification by area, as opposed to classification by kind;

(b) that it must contain a form of communication by boundary; and

(c) it must rely on power to enforce control over the area. In shortened form, territoriality involves classification, communication, and control.

2.1 *Classification by Area*

Classification by area refers to the fact that when we assert control of an area, we are also using the area as a means of delimiting and defining the things we wish to control. Territorial control could mean that anything and everything inside the area is under someone's or some group's control. The things controlled do not have to be defined or enumerated. The father can tell his children to leave the kitchen or to not cross this particular threshold; in so doing he would be asserting control over any and everything within the area without telling the children what it is he does not want them to touch. In contrast, a non-territorial form of control would have to enumerate or disclose the objects and relationships that are to be controlled.

2.2 *All Territorial Units are Bounded*

The boundary may be thin and precise or thick and vague—more like a zone of transition than a precise line—and boundaries can be more or less porous. Some boundaries let very little in and out, while others allow a great deal to flow through. Regardless of its form, the idea of a boundary must be successfully conveyed to others for territoriality to work. This is because the boundary acts as the primary means for communicating territoriality. The father would not be able to use territoriality in the kitchen if the children were not old enough to know what a boundary means.

2.3 *Territorial Control*

For territoriality to work, the territory must be backed up by authority and power that are recognized and respected. If the signs of the boundary and the authority backing it up are not recognized, then territoriality would vanish and we would have to employ non-territorial direct spatial interaction. If the children were to ignore the father and not leave the kitchen, or promptly re-enter it, the father would have little choice but to pick up the children and remove them, or remove all of the knives and plates.

Each instance of territoriality incorporates all three facets, but the effectiveness of territoriality stems from the fact that one or more of these provides advantages. For example, not enumerating what it is that one wishes to control can be advantageous when we do not know all of the things to which we will need access, or when we do not wish to, or cannot, disclose what we want to control. Not being able (or not wanting) to enumerate the things we need is common for most of our activities. Even a relatively simple place like a building contains mixes of conditions taken for granted such as light, heat, and acoustics, which may be just right for the task but which could not have been enumerated before hand. This is even more the case for complex and open-ended activities such as politics, and explains why political behavior is often the most territorial of all. Territorial sovereignty provided by the nation state is an effective strategy of controlling innumerable and potentially important things for political processes that are open-ended.

Communicating through a boundary is simpler than communicating through a variety of symbols, each indicating a particular relationship to people and objects. In the case of the father in the kitchen, the children may be too young to understand the difference between a sharp and a blunt knife, and so there may be no choice but to use the boundary.

In the case of using power, it may be more efficient to enforce territorial control than to follow all of the interactions between people and objects. Fences and 'no trespassing' signs are often more efficient to deter transgressions than is the non-territorial strategy of following people around. Similarly, it may save effort

to have prisoners behind bars than to assign guards to follow them.

These three aspects of territoriality, which are found in all cultures and at all scales, provide advantages that can be taken up as reasons to use territoriality. However, different combinations of the three generate further advantages which only occur in particular historical contexts. For example, the territorial effect of defining things by area can impose new forms of social relationships when territory is used to classify and control people. An empire or a modern state may establish an administrative district which is then used to tax and conscript. People who before had nothing in common are now part of a new social entity. Colonies and post-colonial nation states are more complex examples. These uses of classification by area to define social relations and identities—a territorial definitions of social relations—is often contrasted with a social definition of the people and the place (Soja 1971).

Another complex consequence of territoriality is that it can lead to a container view of place or space. That is, once a territory is created, and if its contents have not been stipulated, or if its most important contents are not yet in place, it comes to be seen as an 'empty' space, even though there are still things in it. A room without occupants or furniture is 'empty,' even though it still contains air, heat and other aspects of nature. In this way, territoriality can help us to think of space as though it were content-less or empty. This container view of space reinforces and is reinforced by modern mapping which has us think of space as a geometric structure—a series of coordinates that describe space itself, independent of things, and it reinforces the idea that space can be bought, sold, and held as empty lots or parcels for speculation.

These advantages of territoriality can turn into disadvantages when conditions are not right. If the father employed territoriality too often, the children may never learn what it is they are not supposed to do. Stipulating what the right conditions are for taking up a territorial strategy is part of the theory of territoriality.

3. *Territory, Place, and Space*

Rooms, buildings, farms, factories and nation states are all territories and they are also places. What then is the distinction between territory and place? Place is a broader term, but one of its meanings merges with that of territory. 'Primary place,' as it is termed in a theory of place developed in *Homo Geographicus* (Sack 1997) or 'place-as-territory' is virtually the same as territoriality, though the two stress different qualities. Territoriality emphasizes how humans are served by boundaries that control what is in and out of place, while place-as-territory (or primary place) stresses how place is necessary for projects to be undertaken, and so focuses on the way place helps mix nature and culture to promote projects. Both point out that the boundaries and degrees of porosity of place, and the rules of what may or may not take place, affect the flows of things through space. These spatial flows and interactions then are generated and affected by territorial rules; and these rules of 'in and out' are in turn affected by the flows. The idea then of a socially constructed space should be understood to mean not that we construct physical space, but that the territories (and the places-as-territories) and the flows among them are created by us.

4. *Territory, Transgressions, and Identities*

Part of the effectiveness of territories in everyday life is that when they function according to plan, they often recede into the background and are taken for granted. Since territoriality supports and instantiates power, it is important to understand 'who' or 'what' group is in charge. A challenge to power through some sort of territorial transgression can make the territory reappear, drawing attention to and calling into question, the entire fabric of social conventions and power (Cresswell 1996). Sometimes this transgression seems to be playful or even without purpose, as in cases of graffiti. More deliberate transgressions of territorial rules for the sake of disclosing and changing power are found in pickets and sit-ins. Extreme cases of transgression are found in violations of territorial sovereignty and in acts of war.

5. *Territoriality, Globalization, and Scale*

Territories are always being transformed, dissolved, and created anew. However, modern conditions of a world economy and the electronic transmission of information have led to speculation that territories in general, and national territories in particular, are being radically transformed and may even be obsolete (Morley and Robins 1995). Instead of places and interactions through space, perhaps the proper description might be that of a constantly shifting set of nodes and networks. Many believe however, that national territories may not be facing wholesale dissolution (Newman and Paasi 1998). In the global economy they provide varying mixes of opportunities for capital and thus help mute economic crises (the 'spatial fix' according to Harvey 1982). The same mix of opportunities may also be provided by a constantly changing hierarchy of territorial scales within the state (a 'scaler fix' as in Brenner 1998, though he does not use this term.) Others see the nation state as remaining a vital means of expressing cultural and ethnic autonomy. Perhaps the greatest and most persistent challenges to territorial state sovereignty do not come from the economy but from ideas about world community and a common humanity that encourages individuals to care for distant strangers.

Whatever is the fate of nations, countless places-as-territories will exist and continue to be constructed because we cannot undertake projects without them. For now, the nation state is the most powerful one. But to ignore the fact that its powers to contain are permeable and changing is to fall into what Agnew (1994) calls the 'territorial trap.' We run the risk of falling into a different territorial trap when we ignore the power of territories and places-as-territories to mold events, for we might then observe that all kinds of actions seem to have bounded and spatially accordant geographies while being ignorant of the fact that they are shaped by a common territorial structure.

Terrorism

The term 'terrorism' refers to the systematic use or threat of violence to communicate a political message rather than defeat an opponent's military forces. Thus the targets of terrorism are symbolic. Victims of terrorism represent a wider audience. To achieve maximum shock effect, terrorist violence is usually dramatic and provocative. Typically small numbers of extremists who otherwise lack the capacity to challenge those in power resort to terrorism. However, the term is also used to describe clandestine violence in support of the state or by the state. A defining characteristic of terrorism is that its users expect rewards that are out of proportion to both the resources they possess and the risks they assume. Terrorism is, furthermore, a strategy that is not restricted to any particular ideology.

1. Historical Development of Terrorism

As a strategy of resistance to the modern state, terrorism emerged some half century after the French Revolution, when the term originated as a description of the state regime of terror. In the late nineteenth century, 'terrorism' became a strategy of opposition. Russian revolutionaries and anarchists in France, Spain, Italy, and Germany established terrorism as a central mechanism in attempts to overthrow established regimes, most of which were autocratic. In 1881 the assassination of the Czar of Russia horrified European governments while it inspired revolutionaries and nationalists from Ireland to India. Terrorism in Russia focused on selective assassinations of key political leaders. Anarchists introduced the concept of 'propaganda of the deed,' the idea of an outrageous action, such as a bomb thrown indiscriminately into a public gathering, that would frighten the ruling classes and arouse the masses. Irish republicans added to the repertoire by organizing attacks in London, outside the immediate theater of conflict. This formative era of terrorism ended with World War I, sparked by the assassination of the Austrian archduke by a Serbian nationalist.

In the interwar period right wing extremist movements adopted terrorist tactics in their struggles for power. The period is best known, however, for the practice of totalitarian terror from above in Germany and the Soviet Union. After World War II, terrorism figured prominently in some national liberation struggles of the 1950s and early 1960s, such as in Cyprus and in Algeria. As the colonial era ended, social scientists expected terrorism to disappear with it. Yet at precisely this moment terrorism was transformed into a major international phenomenon. In the late 1960s, Latin American revolutionaries and Palestinian nationalists independently conceived of a new tactic of terrorism: the seizure of hostages in order to compel governments to concede to their demands. Violence escalated when foreign states who supported these local regimes, such as the USA, also became targets. Hijackings of aircraft in the Middle East and diplomatic kidnappings in Latin America, for example, became routine. The 1972 seizure of Israeli athletes at the Munich Olympic games demonstrated

the immense publicity value of hostage-taking as well as the spillover of Palestinian terrorism to Western Europe.

By the mid-1970s, left wing and separatist terrorism came to pose serious internal security problems for liberal democracies, especially in Western Europe. In Germany and Italy, for example, terrorism emerged in the wake of student protest movements. In the Basque regions of Spain and in Northern Ireland, ethnonationalist organizations mounted prolonged separatist campaigns, which lasted to the end of the century. Outside of Europe, India and Sri Lanka also faced chronic terrorism from secessionist ethnic minorities in the 1980s (continuing through the 1990s in Sri Lanka). Furthermore, in Latin America, after revolutionary terrorism had ended in Argentina, Brazil, and Uruguay, the Shining Path movement rose to challenge the regime in Peru in the 1980s.

The Iranian revolution of 1979 and the Israeli invasion of Lebanon in 1982 stimulated the growth of yet another type of terrorist actor, as radical anti-Western Islamic groups formed in Lebanon, Palestine, Egypt, and, by the end of the decade, Algeria. The seizure of US hostages in Lebanon, as well as the advent of massive vehicle bombs, such as the attack on the American Marine barracks in Beirut in 1983, continued to focus attention on terrorism in the Middle East. Palestinian groups also remained active, for example, in the hijacking of the Achille Lauro cruise ship in 1985.

State-sponsored terrorism became another new issue of the 1980s, initially because of the Iran hostage crisis. In 1986, the USA, convinced that Libya was responsible for terrorism against Americans, retaliated with military force. This in turn provoked Libya to take revenge in the mid-air bombing of Pan Am 103 in 1988.

Terrorism continued to shock governments and their publics in the 1990s. High-casualty terrorism in the United States was an unprecedented development. Its origins were both domestic, as individuals associated with the US far right bombed the Oklahoma City federal building, and international, with Islamic militants organizing the bombing of the World Trade Center in New York. A second emphasis in the 1990s was the fear of terrorism involving weapons of mass destruction, a fear inspired not only by the 1995 sarin gas attack on the Tokyo subways by a religious cult but also by the prospect of the proliferation of nuclear, chemical, and biological weapons. In the Middle East, radical Islamic groups used terrorism to oppose the peace process initiated between Israel and the Palestine Liberation Organization (PLO), while the Gulf War and the subsequent US military presence in Saudi Arabia inspired Islamic militants to attack American interests. In 1998 simultaneous bombings of the US embassies in Kenya and Tanzania provoked the USA to retaliate militarily against targets in the Sudan and Afghanistan.

2. *Explanations of Terrorism*

Interest in the study of terrorism has paralleled the historical evolution of the phenomenon. Until the 1970s, little was written on the subject. Typically terrorism was treated briefly as the first stage of internal war, to be abandoned as insurgents moved to guerrilla warfare and then on to conventional war. By the 1990s, the literature contained thousands of specific citations to terrorism, including contributions by historians, political scientists, economists, legal scholars, criminologists, sociologists, psychologists, philosophers, and anthropologists. Nevertheless, there is no comprehensive unifying theory of terrorism. Nor is terrorism a central element in major theories of war and conflict. The importance of the concept is determined by the political significance of terrorist actions, rather than by intellectual context.

Terrorism is a contested concept that resists precise definition. Since the term is both elastic and emotionally powerful, it lends itself to subjective interpretations driven by political rather than analytical purposes. It is also difficult to distinguish terrorism from other forms of violence, such as, for example, guerrilla warfare or criminal activity. Must the victims of terrorism be noncombatants, for example? If so, are attacks on military targets acts of terrorism? If terrorism is defined in terms of the intentions behind the action, is it possible to know those intentions? What is the relationship between religion and terrorism? Furthermore, terrorism occurs so frequently and in so many different historical and cultural settings that it is difficult to make comparisons or draw general conclusions. Analysts of the subject even dispute basic questions of fact, such as whether or not terrorism is becoming more lethal or whether it is more likely in democracies.

2.1 *Why Does Terrorism Happen?*

Terrorism occurs in situations of conflict. Divided societies, repressive governments, economic inequalities, or ideological rivalry among states, for example, create the grievances that generate terrorism. In other cases, conditions are permissive. Democracies, for example, may be susceptible to terrorism because they tolerate dissent and allow an open news media. Yet few of the individuals who are dissatisfied or even actively engaged in social protest movements move on to participate in terrorism. Thus understanding the causes of terrorism requires knowledge of psychological motivations, at the individual or small group level. Research points to the dynamics of group relationships rather than specific personality types or mental pathologies. Once established, underground groups may struggle primarily to maintain group solidarity and cohesion. They bind together individuals with different backgrounds, skills, and levels of political commitment.

At the same time, terrorism is purposive behavior, a conscious strategy to gain attention, attract recruits, mobilize popular support, and provoke government repression. The policy of no concessions adopted by the US government in the early 1970s rests on the premise that terrorism is a rationally chosen strategy: if governments deny reward and guarantee punishment, terrorism will decline. When governments blame the news media for publicizing terrorism, they are assuming that terrorism would not exist without the reward of media attention.

The use of terrorism by states against their external enemies may also be related to inequalities of power that force the weaker party to be deceptive rather than open. Internal regimes of terror are due to the desire not only to crush but to forestall resistance. It is worth noting that insurgent movements may also govern by terror in territories they hold.

Terrorism also depends on opportunity, especially the availability of targets and of resources. In a modern world of industrialized states, with sophisticated transportation and communication networks and dense patterns of social, political, and economic interaction, both targets and weapons are in plentiful supply. Government efforts to defend specific points of vulnerability, such as civil aviation or embassies in high-threat countries, may produce a displacement effect, as terrorists substitute easy targets for hard ones. The development of the modern news media, especially television, permits terrorists to reach a worldwide audience almost instantaneously.

2.2 Forms of Terrorism

Bombings constitute the most common form of terrorism. Since the late nineteenth century and the invention of dynamite, terrorists have targeted public buildings and crowded public spaces. Although most bombings do not cause casualties, terrorists are capable of organizing spectacular high-casualty violence, facilitated by technological improvements in both explosives and timing devices. However, the capacity for high-casualty bombings does not depend on sophisticated technology; extremely powerful devices can be constructed with common fertilizer, for example. The same principle applies to potential terrorism using weapons of mass destruction: simple techniques could still be quite deadly.

Armed attacks on unsuspecting civilian targets, such as airline passengers or tourists visiting historic sites, are also part of the terrorist repertoire. Over time assassinations of individual government officials became less frequent, perhaps because of the availability of alternatives or the inaccessibility of public figures, who are now heavily guarded. Nevertheless, the second half of the twentieth century includes the assassinations of important leaders; Anwar Sadat, Indira Gandhi and Rajiv Gandhi, and Yitzhak Rabin number among them. (Not all assassinations can be defined as terrorism; the attack must be linked to an organized conspiracy or oppositional movement.)

The seizure of hostages is an explicit way of bargaining directly with governments. The tactic includes hijackings of airliners and even cruise ships, individual or group kidnappings, and armed takeovers of buildings such as embassies. Hostage seizures as a form of international terrorism had become less common by the end of the twentieth century, but kidnappings have continued, especially in domestic conflicts such as the ongoing insurgency in Colombia.

2.3 The Effects of Terrorism

Does terrorism succeed? It attracts the attention of the news media and the public, and the issue ranks high on the agendas of many governments and international organizations. However, does recognition of the threat or even of the grievances behind terrorism produce favorable political outcomes? Despite widespread publicity, the political effectiveness of terrorism is generally short-term and limited in scope. Terrorism may intimidate jurors or dissuade tourists, but it cannot compel popular majorities to give in to minority demands. Both the Irish Republican Army and the PLO eventually renounced terrorism. Terrorism polarizes opinion by mobilizing support and hardening opposition. In this way, it can inflame existing conflicts and disrupt peace processes, but it rarely changes fundamental attitudes.

Test Administration: Methodology

The meaning of an individual's score on an educational or psychological test depends on the test being administered according to the same specified procedures, so that every test-taker faces the same situation. A test administered under specified conditions is said to be standardized. Without standardization, scores from the test will be less accurate, and comparability of test scores will be uncertain. Details of administration depend on the format and content of the test.

1. *Standardization*

Standardized directions help to insure that all test takers understand how much time will be allowed to complete the test, whether it is permissible, or advisable, to omit responses to some test items, how to make the required responses, and how to correct inadvertent responses. Multiple choice items merely require the test taker to choose among a set of alternative answers. Constructed response items may require the test taker to write a short phrase or sentence as a response, or may require a more extended written response. Performance assessments will often require the test taker to perform some task, possibly using some equipment, under standardized conditions, with the performance evaluated by a test administrator, or recorded for later scoring. In general, a quiet environment, free of distractions, will promote appropriate test performance.

Instructions for paper-and-pencil tests are simple; multiple choice items may require the test taker to mark the answer on a separate answer sheet whereas short-answer items require writing a response on the test paper. Test takers are more likely to need practice in responding to tests that are administered by a desktop or similar computer. Items are displayed on the computer display screen, and the test taker responds by means of computer keys, a 'mouse' or similar indicating device. In some instances, the test-taker is asked to respond to constructed response items by typing a word or short phrase with a computer keyboard.

Test takers may need practice in navigating a computer-based test. Usually, the screen shows one item at a time, and does not proceed until some response has been made. One of the response options may be to skip or postpone the item, in which case the computer will offer the item again after the remaining items in a section have been answered. Sometimes the test taker has the option of flagging the item for later reconsideration. Item review, which cannot be controlled on paper-and-pencil tests, is more complex with computer administration and may not be permitted. Test takers prefer to have the option, but those who make use of it seldom change their previous response. When a change is made, however, it is more often a change from wrong to right than from right to wrong. The net effect of item review is an occasional score improvement, weighed against time spent in making the review. When the test is timed, and if further new items are available, the candidate would, in general, be better off attempting the new items rather than returning to items that have previously been answered.

Computer administration permits the use of items that are not feasible with paper-and-pencil tests. Most involve some aspect of temporal control or measurement. Short-term memory can be tested by presenting some material, and then asking questions about it after it is removed from the display. Some aspects of response time can also be measured. Also, test material can include moving displays, including short segments of televised scenes or activity.

1.1 *Accommodations and Test Modifications*

Persons with disabilities may be at a disadvantage in the testing situation. Persons with limited vision may have trouble seeing the test material; others with motor impairment may have difficulty making the required responses. Special test administrations may be offered to accommodate such persons (Willingham et al. 1988). Printed tests with large type, or large fonts on the computer display may help persons with limited visions. A person or a computer system can read verbal items to the test taker, although items with diagrams and graphs pose more challenging problems of communication. Persons with certain motor disabilities may need help in making the appropriate responses. Persons with attention deficits, dyslexia, or similar disorders may easily be granted additional time on timed tests.

When persons are tested under nonstandard conditions, the validity of the score becomes suspect. Much validity evidence is empirical, and depends on standardized test administration. If only a few persons are offered a certain accommodation, it becomes difficult to determine whether their test score has the same meaning as a score from a standardized test. Most such evidence requires substantial numbers of cases in order to be evaluated. Opinions differ about the suitability of using test scores from accommodated tests. In large-scale operations, a score from a special accommodation may be marked, or 'flagged' to indicate its special status. It may be deemed appropriate to indicate the nature of the accommodation, but not the nature of the disability, although it will often be impossible to report one without revealing the other. In some venues, revealing the nature of a person's disability may be seen as a violation of individual rights, and may be illegal.

Persons whose primary language is not the language of the test will probably be at a disadvantage in taking the test. In some circumstances, it may be appropriate

to provide the test in their primary language, although test translation is not an easy matter, and requires extensive test development. An intelligence test or a questionnaire about health may elicit more valid answers if translated. On the other hand, an employment test for a position where a certain language is used as a part of the job would be appropriately given in the language of the job. (For more detail on this and other topics see American Educational Research Association et al. 1999.)

2. *Test Security and Cheating*

Test scores are often used to compare individuals with each other, or with established performance standards, with important consequences to the individual test taker. Some test takers may attempt to gain an advantage by obtaining knowledge of the test questions before the test is given. Thus, procedures for safeguarding the test materials before, during, and after the testing are an important aspect of test administration. Generally, test takers are forbidden from taking notes; any scratch paper or other material that they may have used during the test must be disposed of.

Obtaining advanced knowledge of items is but one way of gaining an advantage over other test takers. Test administrators may be asked to check identities through photographs, fingerprints, or other means of personal identification to preclude the possibility of a candidate arranging for someone else to take a test in their stead.

A variety of statistical checks may be made of test responses in an effort to detect various forms of cheating. If several persons are found to have exactly the same responses to many of the items, further investigation may be warranted. A person who answers many easy questions wrong, but who correctly answers many difficult items has, to say the least, an unusual pattern of responses, triggering further checking. If a test is offered on several occasions, and a person has taken the test more than once, large differences in the person's scores from one time to the next would be suspicious.

2.1 *Test Preparation*

Testing programs with high stakes have spawned a number of organizations offering special tutoring in how to take the test. Such short term preparation ('coaching') may involve having clients take pseudotests that contain items like those that might be expected on the actual test. Methods are taught for coping with particular types of items. Sometimes, a variety of suggestions are offered that are not content-related, but that stress how to detect the correct alternative by special clues, such as 'the longest alternative is probably the correct answer'. Studies of the effectiveness of these commercial test preparation programs have had mixed results, but the best estimate is that the advantage of a two- or three-week course is from about 0.1 to about 0.3 standard deviation units, which is roughly equivalent to one or two additional questions answered correctly. Longer preparation has a larger effect; multiweek courses amount to further instruction in the subject of the test, and may more properly be viewed as education.

Large testing programs, concerned lest commercial preparation courses give well-to-do candidates a special advantage, have made preparation materials available to all test candidates. This may simply be older, retired forms of the test, together with general test-taking advice. Many also offer, for small cost, computer software to provide the sort of instruction that the 'coaching' schools provide. Still, some candidates put themselves at a disadvantage by not using such material, being overly confident of their own proficiency.

3. *Test Scoring, Norms and Performance Standards*

Test standardization extends to test scoring. Responses to paper-and-pencil tests can readily be scored by computer. Constructed responses can sometimes be scored by computer, but these responses usually are scored by human scorers. In some instances, computer programs are being used to score extended written responses and essays. Preparing a detailed scoring rubric, which spells out the detailed criteria by which responses are to be evaluated, can facilitate consistent scoring, by human or computer. Human scorers can be trained on the use of the rubric, and are monitored through a variety of checks, including occasional rescoring of some responses, and statistical comparisons.

Test scores usually consist initially of simply counting up the number of correct responses, or summing the scores given to items when the responses are not scored simply 1 or zero. Sometimes, a penalty is imposed for incorrect answers, in an attempt to correct for the possibility that a test taker might mark the correct response to a multiple-choice item by chance. Despite voluminous evidence, no definitive statement can be made as to whether the penalty for wrong responses improves or harms the validity and reliability of the resulting scores. Omitted responses are generally given no credit, i.e., treated the same way as wrong responses (see *Classical (Psychometric) Test Theory*).

Scores based on item response theory involve combining information from item responses by a more complex statistical method. In effect, more credit is earned for correct answers to more difficult questions, and more penalty is imposed for incorrect answers to

easier questions (an exception is the scoring of fixed-length nonadaptive tests using the one-parameter, or Rasch, IRT model, in which case the number correct is a sufficient statistic for estimating the person's proficiency).

Test scores have little meaning without additional information. Norms are statistical distributions of test scores made by defined groups of test takers, and provide one normative standard of comparison. External performance standards can be set with reference to test content. Some tests are designed to provide scores understandable only by professionals; with only broad categories of performance being revealed to the test taker (Angoff 1971).

4. *Test Equating and Calibration*

Well-established testing programs generally have several equivalent forms of the test. Each test form has different items, but all forms are constructed according to the same set of test specifications, or test blueprint, which indicates topics to be covered, item difficulty, item formats, and other aspects of item content. Still, test development procedures cannot insure score comparability; some adjustments are necessary in the scores from a new form to make them comparable to scores from old forms. The statistical process of making scores comparable is called test equating (Feuer et al. 1999). Linear equating involves giving two forms of the test to equivalent groups of test takers, and then adjusting the score distributions to have the same mean and standard deviation. Equipercentile equating uses the same data but adjusts the score distributions to have the same shape, so that for any given test score, the same proportion of test takers earn scores that are below that score value in both tests. Anchor test equating involves administering a common segment of along with both tests, to form the statistical link.

5. *Adaptive Testing*

The use of computers to administer tests has led to the development of computer-based adaptive testing (CAT) (Wainer 1990, Sands et al. 1997). In CAT, the selection of items presented to a test-taker is shaped by the test-taker's own responses to the test. Normally, the first question is of medium difficulty. Those responding correctly to the item will be given a more difficult item; those giving a wrong response will get an easier item. The same principle continues until a fixed number of items has been administered, or until some other criterion is reached. The net result is that each person is asked questions appropriate to his or her own proficiency level. Time is not wasted asking persons of low proficiency items that are too difficult for them, and high scorers are not asked questions that are too easy for them. The level of accuracy of scores on a traditional test can be achieved in a adaptive version of the test with from 30 percent to 50 percent fewer items.

The idea of adaptive testing can be traced to Binet, the originator of the intelligence test. Some current tests of intelligence for children follow a similar procedure, adapting the level of question to the demonstrated ability of the test taker to respond correctly. Such tests are administered individually, so the test administrator can readily select subsequent items according to a specified protocol. Individual administration is impractical with large-scale testing; group administration is more efficient, but all test takers must take the same test. The use of a computer for administration means that tests can again be tailored to the test taker, without the need for a trained administrator.

CATs get favorable evaluations from test takers. In a CAT, each candidate faces items that are challenging but not overwhelming. Persons who usually do poorly on ability tests are surprised at how easy the test appeared to be. The better candidates find a CAT harder than they expected, but engaging.

5.1 *CAT Procedures*

Different CAT systems use different procedures for administering a CAT. Algorithms differ in how the first item is chosen, how subsequent items are chosen, when to stop the test, and how to score the test. With different test takers receiving tests of different difficulty, the score cannot be the traditional 'number-right' of paper and pencil tests, since most test takers get about the same number of items correct on a well-designed CAT. Current CAT's rely on item response theory (IRT) for scoring the test responses, as well as for choosing items to present. IRT is based on the premise that all the items are measuring the same underlying proficiency. While each item is to some extent unique, the items also share some common elements. The IRT model accounts for item interrelationships with a model that specifies the form of the relationship of each item to the dimension of proficiency being measured.

CAT requires a large set of items, called collectively an item pool, or item bank. Each item is characterized by one or more parameters indicating the item's difficulty, strength of relationship to the proficiency being assessed, and propensity of low proficiency test takers to guess correctly the right answer. The item characteristics, called 'item parameters are estimated statistically from data obtained from administering the items to a group of test takers that serves as the reference group. Since an item bank contains from 200 to 1000 or more items, all items cannot be administered to a single group of persons. Instead, an elaborate design can be used to administer the items to equiv-

alent groups, and to calibrate all the items to a common scale. The statistical calculations necessary to score a CAT can be done in the blink of an eye on modern computers, so a test score is available as soon as a person has completed taking the test. Of course, if constructed response items are included, the computer program must include an algorithm for scoring such responses immediately. Such algorithms are rapidly becoming the state-of-the-art.

Item selection in CAT is usually done one item at a time, but may also be done by selecting groups or items, in stages. Selection in general depends on a preliminary estimate of the test taker's proficiency, based on the item responses already made. The next item, or group of items, is selected to be maximally informative, given the current performance. Often, many other factors must also be considered. Traditional tests that are prepared professionally conform to a detailed set of test specifications, having mainly to do with item content. Such specifications are especially important for achievement tests, which measure the extent of mastery of some domain of knowledge. Each constructed test is expected to have the same balance of content and coverage of topics. By using codes for various content and format characteristics of an item, the item selection algorithm for a CAT can strive to select items so that the content specifications are met as well as possible, as well as finding items of the appropriate difficulty for the test taker.

With CAT, the problem of security is daunting, because persons are scheduled to take the test at different times. Groups of test takers can team up to each remember a few items, and later pool their memorized items. The remembered items can then be offered, possibly for profit, to persons who have yet to take the test. To diminish the effect of foreknowledge of a few items, CATs may be furnished with very large item pools, so that the chance of encountering any particular item will be very small. More elaborate strategies involve using several different item pools, formed from very large collections of items ('item vats'). Studies show that the effect of foreknowledge of a few of the items in a large pool will, on average, provide very small improvement in test scores.

Test Anxiety and Academic Achievement

In contemporary, achievement-oriented societies, test anxiety is a ubiquitous phenomenon. Test anxiety is educationally important because it may influence learning, achievement, health, and personality development. Among a number of emotions relevant for students' academic development, test anxiety has been studied most often. Exam-related anxiety had already been discussed by psychoanalytical writers in the 1930s. Large-scale empirical research started at the beginning of the 1950s (Mandler and Sarason 1952), and since then, more than 1,000 studies have been published (Hembree 1988, Zeidner 1998).

1. Concepts And Measures of Test Anxiety

Test anxiety may be defined as anxiety which subjectively relates to tests and their consequences (the term 'test' being used in a broad way and including exams as well). Typically, being afraid of failing a test, and of the consequences of failing, is at the heart of this emotion. Test anxiety can be experienced both before and during the taking of a test. Seen from the perspective of trait-state conceptions of anxiety, such anxiety is a state emotion when it relates to a specified test and is experienced before or during that test. As it is experienced habitually over extended periods of time and for dispositional reasons, test anxiety is a situation-specific type of trait anxiety. Trait test anxiety may be an important part of a student's personality.

The term 'achievement anxiety' has sometimes been used interchangeably with 'test anxiety.' Achievement anxiety, however, may also relate to situations normally not defined as being tests (e.g., situations at work or in sport which, like tests, imply the possibility of failure, but do not imply test-taking). Anxiety related to such situations may be similar to test anxiety. An example is competitive anxiety in sport.

At the beginnings of empirical research, test anxiety was defined as being one-dimensional. Early measures such as Mandler and Sarason's (1952) Test Anxiety Questionnaire assumed unidimensionality. However, the items of these measures already referred to distinct affective, cognitive, and physiological components of test anxiety, and early factor analyses repeatedly showed that these scales were made up of more than one factor. Therefore, Liebert and Morris (1967) proposed to distinguish affective-physiological components (which they called 'emotionality') from cognitive components (which they called 'worry'). Since then, a number of additional distinctions have been introduced, including I. G. Sarason's (1984) differentiation of affective tension, bodily symptoms, worry, and test-irrelevant thinking. Today, there is common agreement that test anxiety typically comprises (a) affective tension (feeling uneasy, nervous, and tense); (b) physiological activation (including symptoms such as increased heartbeat, sweating, etc.); and (c) cognitive worries relating to threat of failure, to the consequences of failure, to a lack of personal competence, etc. Contemporary measures of test anxiety like I. G. Sarason's (1984) Reactions-to-Tests Questionnaire and Spielberger's (1980) Test Anxiety Inventory (TAI) reflect these distinctions by comprising subscales relating to different test anxiety components.

2. *Test Anxiety, Learning, and Academic Achievement*

2.1 *Empirical Evidence*

The effects of test anxiety on learning and achievement have been studied in a large number of laboratory experiments and nonexperimental field studies (cf. Hembree 1988, Zeidner 1998). Experimental laboratory research has shown the following:

(a) dispositionally test-anxious subjects often perform less well at complex and difficult cognitive tasks than their less anxious counterparts. They tend to perform equally well or even better at tasks characterized by low levels of complexity and difficulty;

(b) the detrimental effects of dispositional test anxiety are more pronounced when an experiment is announced as being test-like and involving ego threat (e.g., when it is declared as being an intelligence test);

(c) state test anxiety experienced when performing complex and difficult tasks is also negatively related to performance. The relation is stronger for cognitive components of test anxiety (e.g., worries) than for affective-physiological components.

In line with experimental findings, test anxiety and academic achievement tend to correlate negatively in normal student populations. Average correlations reported in two meta-analyses were $r = -0.29$ (in grade 4 through postsecondary education; Hembree 1988), and, for mathematics achievement, $r = -0.23$ (Schwarzer et al. 1989). However, the range of correlations across studies also included zero and positive coefficients. Correlations did not differ significantly as a function of gender (Schwarzer et al. 1989). However, they were near zero at the beginning of schooling and then increased over the elementary school years (Hembree 1988).

2.2 *Theoretical Explanations*

One traditional explanation for this pattern of empirical evidence is that cognitive components of test anxiety consume cognitive resources (attention and working memory capacity): worrying about impending failure prevents one from concentrating on the task. This would explain why performance at complex and difficult tasks needing such resources is reduced, whereas performance at easy tasks may be left unaffected. Attention-deficit models using such assumptions have been part of early theories of test anxiety (e.g., Mandler and Sarason 1952) and continue to be one dominant theoretical paradigm.

More recent alternative explanations refer to effects of anxiety on other mediators of achievement, and to alternative ways of causation. Beyond cognitive resources, anxiety may affect students' motivation and learning strategies underlying their achievement. For example, anxiety may reduce interest in the subject matter and intrinsic motivation, since anxiety may be incompatible with positive affective engagement implied by intrinsic motivation. On the other hand, anxiety may well produce extrinsic motivation to invest effort in order to avoid impending failures. Simultaneous operation of such opposing mechanisms would imply that the motivational effects of anxiety on overall motivation and resulting effort may be ambivalent. In addition, effects on learning strategies may be complex as well. For example, anxiety may impede the use of creative cognitive and metacognitive strategies such as elaboration and organization of learning material or flexible time management. On the other hand, it may facilitate the use of more rigid strategies such as simple rehearsal (Pekrun 1992a, Pekrun and Hofmann 1999).

Beyond effects of anxiety on achievement, anxiety/achievement relations may also be produced by the effects of low achievement and low ability on the development of test anxiety. For example, experiences of failures may induce test anxiety, which would imply that negative anxiety/achievement relations may be produced by the effects of achievement on anxiety, instead of the reverse (developmental model; cf. Meece et al. 1989, Pekrun 1992b). In addition, performance deficits in test-anxious students may be caused by

reduced ability, implying that test anxiety might be a reflection of low ability instead of being causal in producing performance decrements (skill deficit model; Everson et al. 1989).

These different explanations may be regarded as being complementary instead of mutually exclusive. In many students, test anxiety may be generated by low ability and failures in the first place. Performance deficits in such test-anxious, low-ability students may then simultaneously be caused by low ability and by high test anxiety implying attention problems, motivational problems, and low-quality learning styles. This would imply multiple mechanisms mediating the effects of anxiety on achievement as well as the reciprocal causation of anxiety and achievement over time.

A number of studies have shown that effects of anxiety on achievement may indeed be due to different cognitive and motivational mechanisms (cf. Pekrun and Hofmann 1999, Zeidner 1998). Multiple mechanisms implying ambivalent cognitive and motivational effects may also explain why some studies found zero or positive correlations between test anxiety and achievement instead of negative relations (Hembree 1988, Schwarzer et al. 1989). Finally, the results of a small number of longitudinal field studies corroborate that anxiety and achievement may in fact be linked by reciprocal causation over the school years (Meece et al. 1990, Pekrun 1992b).

3. Development and Antecedents of Test Anxiety

3.1 Developmental Courses

In many students, the development of achievement-related anxiety can be traced back to the preschool years. Psychodynamic assumptions suggest that high parental expectations and negative parental judgments producing feelings of dependency, guilt, aggression, and anxiety may play a major role at this age (S. B. Sarason et al. 1960). Nevertheless, in early elementary school average levels of test anxiety are still relatively low. Mean values increase over the elementary years, which is congruent with emerging experiences of cumulative scholastic failures in many students, and to the related decline of average self-concepts of ability (Hembree 1988). Simultaneously, correlations between anxiety and achievement tend to become stronger during this time period, indicating that factual performance and affective experiences begin to be linked as suggested by developmental models of anxiety/achievement relations.

After the elementary years, average levels of test anxiety seem to be fairly stable throughout secondary school and college. Nevertheless, there may still be significant positive or negative developments in individual students, thus indicating developmental plasticity. One important mechanism is individual transitions between schools or classes implying changes of relative achievement positions within reference groups, which in turn affect the level of achievement-related anxiety (cf. Zeidner 1998).

3.2 Individual and Educational Antecedents

Empirical research has identified a number of antecedents which can be made responsible for the development of test anxiety (cf. Pekrun 2000, Zeidner 1998). Important individual antecedents are: (a) expectancies of failure, attributions of failures to low ability, and negative self-concepts of ability; and (b) an exceedingly high subjective sense of the importance of failures. The typical test-anxious student believes that it would be of the utmost personal importance to prevent failure at school, but that they are probably not able to do so, implying threats to self-esteem and future life.

Parent, teacher, and peer behaviors influencing such failure-related beliefs and, thereby, the development of test anxiety are: (a) high achievement expectancies and pressure for achievement; (b) competition within classrooms; (c) feedback of failures (as implied, for example, by low grades); and (d) punishment after failure. Parental and teacher support, on the other hand, might theoretically be assumed to be protective factors, but have repeatedly been shown to be uncorrelated with students' test anxiety. This paradoxical finding may be due to the ambivalent effects of support, which may imply hidden messages of pressure for achievement in addition to offering help. Finally, at the level of educational institutions and systems, important factors leading to anxiety may be competitive goal structures, social comparison standards of giving feedback, and educational career structures implying negative long-term consequences of early failures.

4. Therapy and Educational Prevention of Test Anxiety

In numerous studies it has been shown that test anxiety can successfully be alleviated in many students. Test-anxiety therapy may aim at: (a) reducing the experience of anxiety directly (e.g., by methods of relaxation); (b) breaking up habitual ties between situational triggers and the experience of anxiety (as in methods of behavioral therapy such as systematic desensitization); (c) changing belief structures such as expectancies, self-concepts, and achievement values underlying test anxiety (cognitive therapy); and (d) building up competences to learn and perform more efficiently in order to attain success (skills training). Studies suggest that treatments combining different approaches may be most efficient (cf. Zeidner 1998).

In contrast to therapy, ways of prevention have been studied less often. However, prevention might be both more humane and financially more effective than letting test anxiety develop in the first place and then

trying to alleviate it by individual therapy. Judging from the available developmental evidence, important educational strategies suitable for the prevention of test anxiety may be: (a) reduction of excessive demands for achievement; (b) the use of mastery-oriented, individual, or cooperative standards of grading instead of (or in addition to) competitive standards, thus giving low-ability students the opportunity to experience success; (c) adequate help instead of punishment after failure; and (d) adequate design of educational career structures.

Changing parent and teacher behavior, designing educational systems, and fostering school cultures along such lines may produce complex, multiple effects, some of them perhaps unwanted. Therefore, more long-term field studies exploring ways of preventing negative affect in students, as well as fostering positive emotions, are needed.

5. *Directions for Future Research*

Future test-anxiety research should explore in more detail the multidirectionality of causal pathways, and the multiplicity of mediators linking anxiety to learning and achievement. Furthermore, individual differences concerning mediators and causal pathways should be explored, thus producing evidence on students' individual affective life instead of relying on sample statistics as in most test anxiety research to date (Pekrun and Hofmann 1999). In addition, more studies on educational strategies to prevent test anxiety are needed.

Finally, research on students' academic emotions has thus far focused on test anxiety. As a result, not much is known about students' negative emotions beyond anxiety (such as anger, boredom, or hopelessness in achievement situations), or about their positive emotions (enjoyment of learning, hope for success, etc.; cf. Weiner 1985, Pekrun 2000). In many students and academic situations such emotions are probably no less important than anxiety. For example, deactivating negative emotions such as boredom or hopelessness may be even more detrimental to academic achievement than test anxiety has been proven to be, and positive emotions such as enjoyment of learning may be of primary relevance for students' intrinsic motivation and long-term engagement in learning. Therefore, future investigators should transcend test-anxiety research by analyzing other learning-related and achievement-related emotions as well.

Test Bias

Of all of the issues in modern testing and assessment, none generates more controversy and heated debate than the issue of 'bias' in testing. Tests are important instruments of public policy. They figure centrally in determining a child's readiness for schooling, in placing children into classes for the educable mentally retarded and into classes for the academically gifted. They have been used for years in European countries and in Japan to determine the class of occupations that students will enter as adults. Tests have become important in the United States in determining who will graduate from high school. For almost a century, professionally developed measures of scholastic aptitude have played an important role in determining who will be admitted to what colleges and who will be employed in what jobs. In the past half-century, tests have played an increasingly determinative role in certifying individuals to practice their chosen profession.

All of the above are serious test uses involving 'high stakes' decisions for individuals. Small wonder that when social, cultural, or ethnic minorities are assigned pejorative classifications or denied life opportunities on the basis of tests, the charge of unfairness and discrimination arises.

Although test bias is discussed generally in the context of bias against cultural and ethnic minorities in a given society, the concept (as well as the methodologies used to investigate it) is quite generic. Following conventional usage, in this article the group against whom a test is suspected of being biased will be referred to as the 'focal group.' The group with which test results of the focal group are compared will be called the 'reference group.' Thus, if a test is suspected of being biased against female examinees, they become the focal group, and males become the reference group. If the test is suspected of being biased against an ethnic minority (e.g., African-Americans), they become the focal group, and European-Americans become the reference group.

1. *What Test Bias is Not*

It is sometimes useful and instructive, although somewhat inefficient, to begin the examination of a concept by describing what it is *not*. On a test of upper body strength, a random sample of men will almost surely have mean scores that are higher than a random sample of women. It would be foolish to label such a test 'biased against women.' In fact, such a difference in performance between the sexes so accords with what we know to be true, that were no such performance difference observed, we would hold the test suspect. A less obvious though equally apt example is the persistent finding in many societies of differences among cultural and ethnic groups on measures of cognitive functioning, scholastic ability, and academic achievement. The existence of such differences, some of which are substantial, is interpreted by many to indicate bias in the measures themselves.

To appreciate the fallacy of such an inference, one need only consider a random sample of, say, African-American and White students in the city of Chicago. When measures of academic achievement are administered to these two groups, the typical finding is that White students as a group score significantly above their African-American counterparts. Again, to conclude that the test itself is therefore biased against African-American students would be erroneous. One would have to systematically rule out a plethora of rival causes of mean score differences (and there are many) before it could be safely concluded that the test itself was in some way deficient.

2. *Internal Sources of Test Bias*

There are many definitions of 'test bias' (cf., Flaugher 1978, Jensen 1980) and in the limited space available we will be able to discuss in some depth only the major sources of concern. We do not cover the extensive literature on possible sources of test bias emanating from individually administered tests of intelligence, such as administrator/examinee differences in race or dialect, nor such factors as differences in motivation and test anxiety. We will restrict treatment here to sources of test bias that are traceable to aspects of the measuring instrument itself and to sources of bias resulting from the use of tests in selection and prediction.

2.1 *Bias as Unintended Multidimensionality*

Most paper and pencil, multiple-choice tests are intended to measure a more or less unidimensional construct. To be sure, this intention is rarely ever met. Few tests actually measure a single ability. Even a test of simple addition involves multiple abilities at some atomistic level. What is meant my 'unidimensional' is that only one ability contributes to score variance. 'Reading comprehension,' for example, entails a certain minimum vocabulary and the ability to decode words. But in most applications these abilities do not contribute significantly to score variance because the vast majority of examinees are sufficiently adept at lower-level skills that such differences as exist do not contribute to test score variance.

A familiar and common example of bias as multidimensionality, also known as construct bias, is a test of quantitative reasoning that contains word problems. For examinees whose first language is not the language in which the test is written, the test may well reflect differences in familiarity with the language of the test, rather than the intended construct, quantitative reasoning. Bond (1981) provides a vivid example of bias as unintended multidimensionality in the verbal domain. Imagine a teacher who wished to assess the verbal analogical reasoning of her class of 14- and 15- year-olds. She constructs an analogies test that contains an unusually large number of terms familiar to rural students, say, but relatively unfamiliar to urban students. A typical item on the test might be:

pig:sty::chicken:_____
(a) barn (b) table (c) turkey (d) coop (e) dinner

Because students raised on a farm are more likely to know the meanings of the words in a given analogy, they would be at a tremendous advantage over urban students on such a test. The typical urban student is penalized because of his or her unfamiliarity with the very words that make up the analogy. For these students, the test is as much a test of vocabulary as it is one of analogical reasoning. For rural students, the test is a 'purer' measure of analogical reasoning, uncontaminated by large differences in exposure to the words composing the analogies.

Bond noted that as a practical measurement matter, it is impossible to separate 'vocabulary' from 'verbal analogical reasoning.' Conceptually, however, the two constructs are different. Although there is no way to avoid this problem in constructing a test, there are ways to control statistically for such differences. The procedure involves giving a separate test of vocabulary, then comparing only those students on the analogies test who have the same vocabulary scores.

An often overlooked source of unintended multidimensionality arises from response processes that a test is intended to assess and those that are actually employed by examinees. For example, if a test is intended to assess mathematical reasoning, it is important to ascertain whether examinees are, in fact, reasoning about the material instead of following a standard, taught algorithm. Different groups may well be differentially exposed to solution routines, or they may systematically employ different strategies of unequal effectiveness. Laboratory studies of the response process by subgroups of the population can assist in determining the extent to which capacities irrelevant or ancillary to the construct may be differentially affecting performance.

Before turning to other conceptions of test bias, brief mention must be made of the continuing debate over the relationship between bias and what has come to be called the 'IQ controversy.' Many people believe that if tests of 'intelligence' are shown to be free of construct bias (i.e., they measure the same construct(s) in different groups), then there is strong evidence for the notion that mean differences on such tests have a substantial genetic component. This is an unfortunate and misguided notion. The demonstration that a test is measuring essentially the same or similar attributes in two groups has no *a priori* implication for the source of any group differences that emerge. The many possible reasons for such differences (including differences in exposure, opportunity to learn, motivation, and so on) must be investigated as a separate matter.

2.2 Bias as Differentially Functioning Items

Not all items on a test are of equal overall quality, reliability, and validity. As noted earlier, the wording of some items may systematically confuse examinees who do not speak, as their first language, the language in which the test is written. In multiple-choice tests, clues as to the correct choice may be inadvertently introduced, so that some items may put certain examinees at a relative advantage over others. In achievement tests, some examinees may have received specific instruction on a particular procedure, while others received no such instruction. Such items are said to exhibit differential item functioning, or DIF, a neutral term that the measurement profession now prefers over the more value-laden term, 'item bias.' (The astute reader will note that one source of DIF is unintended multidimensionality on a smaller scale.)

The methodological and statistical machinery to identify items that function differentially for different groups has reached a state of considerable sophistication over the past 20 years (see Holland and Wainer 1993). In this article, three of the more common approaches (chi-square, Mantel–Haenszel, and item response theory) will be described. Of historical interest, since it was the first attempt to formalize a procedure for identifying biased test items, is the method based on relative item difficulty known as the delta method of Angoff and Ford (1974). The logic underlying the method is that even if groups differ in their overall mean on a test, the rank order of item difficulties within the focal and reference group should be approximately the same. The method involves an inverse normal transformation of item difficulties within the two groups of interest. (The transformation is an inverse one because of the unfortunate historical practice of defining item difficulty, p, as the proportion of examinees who respond correctly to the item, rendering it an item 'easiness' index!). Specifically, the delta (Δ) for the ith group for the jth item is $\Delta_{ij} - 4\pi_{ij} + 13$, where π_{ij} is the z score that cuts off p_{ij} in the unit normal distribution. The arbitrary constants, 4 and 13, are used to place the deltas on the difficulty scale of the Educational Testing Service, with a mean of 13 and a standard deviation of 4. The two sets of

delta values can be plotted against each other and the swarm of points so formed should cluster tightly around a 45° line that passes through the origin. Biased items are indicated by points that are beyond some prespecified distance from the line.

A major shortcoming of the delta-plot method is that excellent items (in the sense of validly discriminating between high and low scorers on the test) will erroneously appear to be biased when the reference and focal groups differ on the trait being measured. A second problem with the Angoff and Ford approach to DIF is that it leaves unanswered the central question in any evaluation of differential item functioning: do individuals of equal proficiency, ability, or knowledge on the construct being measured (regardless of their group membership) have the same probability of answering the item correctly?

Two general methods for investigating the above question (one based on classical test theory principles, the other on item response theory) have evolved. The former uses the total score on the test itself to match members from each group on ability. The summed chi-square methods (Scheuneman 1979, Camilli 1979) first divide the distribution of raw scores into J ability levels. A 2×2 frequency table of right/wrong responses is formed for each item with the groups constituting the rows of the table, say, and the item response (1, 0) constituting the columns. These are then combined in a $2 \times 2 \times J$ contingency table across the J ability levels. The test statistic used to determine the existence of item bias is the familiar chi-square test of association. Scheunamen's χ^2_{correct} statistic takes into account only the correct responses. The more appropriate Camilli full information χ^2_{full} statistic considers both correct and incorrect responses.

By far the most popular method for investigating DIF using classical test theory principles is the measure of association developed by Mantel and Haenszel (1959) and adapted for DIF research by Holland and Thayer (1988). Like the chi-square methods, the Mantel–Haenszel (M–H) procedure divides the score scale into J levels. The procedure uses the *odds* of getting an item correct, p/q (where $q = 1-p$), by members of each group. The ratio of these odds, α_j, is combined across levels and weighted by cell frequency. For computational and interpretive convenience, the natural log of the odds-ratio, rather than the odds-ratio itself, is used. The M–H log odds-ratio, β_j, is a signed index, with positive values signifying DIF in favor of the reference group, and negative values indicating DIF in favor of the focal group. A chi-square test for the M–H index may also be calculated.

Differential item functioning has also been investigated extensively using item response theory (IRT), a powerful and elegant test model that attempts to model, in probabilistic terms, responses of examinees to individual items. Each item on a test can be represented by an item characteristic curve (ICC), an S-shaped item response curve, based upon the logistic function, that specifies the probability that persons of a given ability, θ, will answer the item correctly. The ICCs for each item may be estimated separately for each group. In IRT, ability matching is achieved as a by-product of the rather complex estimation procedures themselves. Once examinees are placed on the same θ scale, if no DIF is present, the two ICCs should overlap within measurement error.

Figure 1
(a) An item exhibiting uniform DIF. (b) An item exhibiting nonuniform DIF

Figure 1 depicts two examples of differential item functioning using item response theory. In both cases, the ICCs are for the same item estimated separately for the two groups. In the first example, the item is biased against the focal group because, for fixed θ, members of that group have a substantially lower probability of getting the item right than members of the reference group. The second example depicts a relatively rare but real occurrence, 'nonuniform' DIF: the item is biased *against* high scoring members of the focal group, but biased *in favor of* low scoring focal group members. The opposite pattern occurs for reference group members. It should be noted that classically-based procedures cannot distinguish between these two forms of DIF.

3. Bias in Selection and Prediction

When a test is used to predict some future criterion such as success in school or performance on the job, the test may not do so equally well for different groups. For example, when the regression line for male candidates or the regression line from combined male and female candidates is used to predict the college performance of female students, the predictions tends to be systematically too low. That is, female students tend to perform better in college than would be expected from their SAT scores. To the extent that an institution's admission policy adopts a 'top-down' strategy, the test would be systematically biased against women.

3.1 The Classical or Regression Model

The definition of selection or prediction bias that has attained some measure of agreement among measurement specialists is that due to Cleary (1968). Known as the 'classical' or 'regression' model of selection bias, the model states that 'a test is biased for members of a subgroup of the population if, in the prediction of a criterion for which the test is designed, consistent nonzero errors of prediction are made for members of the subgroup' (p. 115). In this definition, if a given test score is associated with the same level of future criterion performance, regardless of group membership, then the test is 'fair' or unbiased, and to the extent that selection is based solely on predicted performance, the selection system is fair. Statistically, selection bias is indicated when, in the regression of criterion performance on test scores, either the regression lines or intercepts differ for focal and reference groups. When the regression lines coincide, or more precisely, when the regression lines do not differ to a statistically significant degree, the test is said to be unbiased.

Thorndike (1971) was the first to point out an unfortunate difficulty with the regression model. In passing, we note that his reasoning figured prominently in the US National Academy of Science report on fairness in employment testing (Hartigan and Wigdor 1989). The situation is illustrated graphically in Fig. 2. In the figure, we make the usual assumption that there is a 'cutoff' score on the test (defining selection) and a cutoff score on the criterion (defining 'success' and 'failure'). The quadrants of the resulting 2×2 table comprise four distinct groups of individuals. Those who are: *True Positives*: selected and successful (quadrant I); *False Negatives*: rejected but would have succeeded had they been accepted (quadrant II); *True Negatives*: rejected and would have 'failed' had they been accepted (quadrant III); *False Positives*: selected and unsuccessful (quadrant IV).

The regression lines for the focal and reference groups coincide, so that the test is fair according to the regression model. The difficulty with the model arises from two sources. First, the two groups differ in mean scores on the test (a typical finding). Second, the test is never perfectly reliable and is always imperfectly correlated with the criterion. These two conditions together result in the percentage of focal group members who were improperly rejected (quadrant II) being substantially larger than the comparable percentage of reference group members. Hartigan and Wigdor (1989) state the case succinctly, 'The undoubted effect of imperfect prediction when social groups have different average test scores is to place the greater burden of prediction error on the shoulders of the lower-scoring group' (p. 258).

Figure 2
Effects of imperfect prediction on the false negative rate when there is no prediction bias according to the regression model

Before turning to alternative selection models, it should be noted that the apparent unfairness of the regression model, when its conditions for fairness have been satisfied, result not necessarily from any inherent deficiency in the test itself. Nor are these effects inextricably bound up with race, ethnicity, social class, sex, or some other defining feature of the groups. Rather, the 'unfairness' results solely as a statistical result of the two groups having different means on the test. The effects would be as clearly in evidence within the focal or reference group were its members divided into high and low scoring subgroups.

3.2 Alternative Models of Fair Selection

Alternatives to the classical model have been proposed by Cole (1973), Darlington (1971), Einhorn and Bass (1971), Gross and Su (1975), Jensen (1980), Linn (1973), and Thorndike (1971), among others. In a

seminal and influential paper, Petersen and Novick (1976) analyzed and evaluated the models of Cleary, Cole, Einhorn and Bass, Gross and Su, Linn, and Thorndike in terms of the degree to which they were 'internally consistent.' Their analyses of the models will be briefly described here, but a thorough review of all of the models cannot be undertaken in the limited space available. The reader is advised to consult the original sources as well as other in-depth discussions found in Jensen (1980) and the special issue of the *Journal of Educational Measurement* (1976) edited by R. M. Jaeger.

Thorndike drew a distinction between fairness to individuals, which the regression model assures, and fairness to groups. According to Thorndike,

> The qualifying scores on a test should be set at levels that will qualify applicants in the two groups in proportion to the fraction of the two groups reaching a specified level of criterion performance (1971, p. 63).

Fairness to the group consists of selecting equitable proportions of members from each group. Different cut scores, x_i, are possible, in fact likely, for the two groups. Assuming a minimum level of acceptable performance on the criterion, y, a selection test is considered fair according to the Thorndike model if the cut-score x^* for the two groups is such that

$$T = \frac{\Pr(X \geqslant x_F^* | \pi_F)}{\Pr(Y \geqslant y^* | \pi_F)} = \frac{\Pr(X \geqslant x_R^* | \pi_R)}{\Pr(Y \geqslant y^* | \pi_R)}$$

where T is a constant for the reference population (π_R) and the focal population (π_F) and x^* and y^* are cut scores for the test and criterion, respectively. Following Peterson and Novick, this model has come to be called the Constant Ratio Model.

Cole (1973) proposed a model of fair selection, the Conditional Probability Model, that assures to any individual, regardless of group membership, an equal chance of being selected, provided that he or she would have been successful if selected. That is, for anyone who can achieve a satisfactory criterion score ($Y \geqslant y^*$), there should be the same probability of selection regardless of group membership. The Cole model specifies that a test is fair when cut scores are set for the two groups such that

$$C = \Pr(X \geqslant x_R^* | Y \geqslant y^*, \pi_R) = \Pr(X \geqslant x_F^* | Y \geqslant y^*, \pi_F)$$

where C is a fixed constant for both populations.

It is noted that in most situations where the focal group mean on the selection test is below that of the reference group, both the Thorndike and Cole models will result in a greater proportion of focal group members being selected than would be the case with the regression model. The downside from the selecting institution's point of view is a less than optimal mean overall performance of those selected.

In the usual selection situation, the 'given' information for each applicant is not his or her future state of being (success or failure) in relation to the criterion variable, but rather his or her present observed standing on the selection test. That is, a fair selection test, it can be argued, should be based upon the conditional probability of success, *given* selection. Such a model has been suggested, though not necessarily advocated, by Linn (1973). The model essentially reverses the Cole model above. For a test to be fair, cut scores for the two groups are set so that the following equality holds, where the notation is as before:

$$L = \Pr(Y \geqslant y^* | X \geqslant x_R^*, \pi_R) = \Pr(Y \geqslant y^* | X \geqslant x_F^*, \pi_F)$$

Associated with each of these ostensibly fair and plausible alternatives to the regression model is a different index which must be constant across groups. Yet, in general, they all result in different cut scores and different proportions of individuals from the focal and the reference groups being selected.

In an influential paper, Petersen and Novick analyzed the competing and contradictory models by applying a test of 'internal coherence.' Briefly, the three models above focus attention on those who would be successful. Fairness is discussed in relation to these individuals only. But the same logic, the same perspective on fairness and bias, can be applied to individuals who were *not* selected and who would have been *unsuccessful* if selected. It turns out that when questions are phrased with these individuals in mind, the above models contain a logical contradiction. For example, the Thorndike model can be restated as follows: the qualifying scores on a test should be set at levels that will *reject* applicants in the two groups in proportion to the fraction of the two groups who *fail* to reach a specified level of criterion performance. The reformulated, converse model then becomes:

$$T' = \frac{\Pr(X \leqslant x_R^* \pi_R)}{\Pr(Y \leqslant y^* | \pi_R)} = \frac{\Pr(X \leqslant x_F | \pi_F)}{\Pr(Y \leqslant y^* | \pi_F)}$$

The models proposed by Cole and Linn may be similarly reformulated. Petersen and Novick prove that only in rare and unlikely circumstances will the three converse models result in the same cut scores as the original models. Different individuals will be selected depending on whether one formulates fairness with selected, successful individuals in mind, or whether one focuses on rejected, unsuccessful individuals. The three models are internally incoherent.

By contrast, the regression model and a model proposed by Einhorn and Bass (1971) are internally coherent. The Einhorn and Bass model sets the cut score for each group in such a way that the criterion score for persons with test scores greater than the cut score will be above the minimum acceptable criterion

with probability at least equal to some specified value. It is then required that this probability (or conversely, risk) be the same for all groups of interest, hence its designation as the Equal Risk Model.

4. Conducting Remarks

Measurement specialists can contribute importantly to discussions about the technical adequacy of tests and the importance of adopting models that meet specific requirements. Of course, matters of test use in education and employment will not be decided by measurement specialists and statisticians. Matters of test use and testing policy will ultimately be decided in the public, legislative, and judicial arenas. It is nevertheless hoped that technical analyses of differential item functioning, of the various sources of internal test bias, and of the consequences of adopting a particular selection model will inform the public, legislative, and judicial debates.

Test Theory: Applied Probabilistic Measurement Structures

Psychological test theory invites the formulation and testing of methods of assigning numbers to individual's attributes, such as degrees of skills or personality traits. Measurement theory is the formal and logical theory of necessary and sufficient conditions of attributing measures to objects or events (see *Measurement, Representational Theory of*). It is astonishing that test theory is not usually treated as a special area of measurement theory. Test theory (modern test theory, item response theory, IRT) is probabilistic and concerned with the relation of response probabilities to latent traits. It usually neglects the measurement principles (relations and operations, homomorphisms) necessary to represent observations by numbers and their relations (with the exception of the principle of specific objectivity, see below). Usually a representation by an analytical model (see below) is postulated and statistical tests are given to test the adequacy of the representation of empirical data by the model (item characteristic function, parametric IRT). Measurement theory usually is deterministic and axiomatic and concentrates on relations and operations. The relations typically are qualitative or ordinal. How can measurement theory be made probabilistic? (See *Test Theory: Applied Probabilistic Measurement Structures*.) How can test theory be made concerned about logical relations and homomorphisms (structure preserving representations)?

The more recent development of nonparametric IRT (Hemker et al. 1997, Holland and Rosenbaum 1986, Irtel and Schmalhofer 1982, Junker 1993, Junker and Ellis 1997, Mokken 1971, Rosenbaum 1984, Scheiblechner 1995, 1998, 1999, Stout 1987, 1990) is closer to measurement theory. The authors specify empirically (statistically) testable criteria necessary for unidimensional representations of psychological test data.

Typical psychological tests consist of a set of items ($i = 1, 2, \ldots, k$) which are supposed to 'measure' a common (unidimensional) psychological trait (e.g., verbal, numerical, spatial … intelligence; neuroticism,

depression,…), and to which the subject ($v = 1, 2, \ldots, n$) chooses one answer out of several ordered categories ($h = 0, 1, 2, \ldots, m$). In most cases the test performance of a subject is summarized by the Likert score (simple integer score) or the trivial scoring function: all answers are weighted equally with constant weights for categories and the weights are summed over items. A major advance over this naive procedure was made by parametric rating scale models inspired by Rasch's measurement theory. A well-known parametric IRT model for ordered response categories is the rating scale model (RSM).

$$P(x = h \mid v, i) = \frac{\exp(h(\theta_v - \beta_i) + \varpi_h)}{\sum_{x=0}^{m} \exp(x(\theta_v - \beta_i) + \varpi_i)}$$

$$\beta_i = \sum_l a_{il}\eta_l + c$$

(Andersen 1977, Andrich 1978, Masters 1982) where x is the response category of the answer ($x = 0, 1, 2, \ldots, h, \ldots, m$), θ_v the subject (ability) parameter, β_i the item (difficulty) parameter (with possibly a linear model with respect to basic components η_l) and ϖ_h the response category (attractiveness) parameter (with the normalizations for uniqueness of parameterization $\sum_i \beta_i = 0$, $\varpi_0 = \varpi_l = 0$, $c = 0$).

Models like this are an improvement over simple integer scoring because the fit of the model can be tested by a conditional likelihood ratio statistic (and the fit of the linear item parameter model can be tested by an additional likelihood ratio test). Thus we may detect, for instance, that no such psychological trait as conjectured does exist (in the sense of the model) or that not all items belong to the same psychological trait, or that the scoring of the categories may depend on the item and so on. However, the logistic form of the category characteristic curve (CCC, the function describing the probability of choosing category x; Hemker et al. 1996), the existence of three scales (subjects, items, categories) and their additive concatenation, the response category as scoring function (factor h or x in the exponent) are postulated all at once, and if the model does not fit there is no (or little) evidence as to which assumptions are failing (the situation is much better concerning the linear model for the item parameter assuming that the basic model fits).

An essential advantage of the probabilistic measurement theoretic formulation of such models is that no such risky assumptions are necessary simultaneously in advance, that each step can be tested separately, and that those axioms can be identified which are possibly responsible for lack of fit. The test of the logistic form of the CCC and of the adequacy of the scoring function are rendered unnecessary by a measurement theoretic test model because no analytic CCC is assumed and there is no need of a scoring function (beyond an ordinal scale). The existence of ordinal scales for subjects and items can be tested separately from each other and independently of the postulation of an additive conjunction of interval scales for subject and item parameters (see for instance the exponent of the CCC of the RSM). Should the test of additive item and subject parameters be successful, we could then test an additive conjunction with an appropriately constructed scoring function (an interval scale for the response category scale). Independently of the outcome of the latter test, and separately from each other, we can test additive models for the item and subject parameters. In short, the advantages of measurement theoretic test models are the stepwise construction of a hierarchy of gradually more complex models, and an exact specification of the level at which the construction of the models possibly might fail.

1. *Making Deterministic Axiomatic Structures Probabilistic*

A successful translation of the deterministic axioms of a measurement structure into a probabilistic version grants the formal rigor of measurement structures while being at the same time probabilistic, i.e., provides a statistical theory for testing the validity of the model. Some possibilities of probabilization of axiomatic measurement structures are expounded by Heyer and Nideree (see *Measurement Theory*: *Probabilistic*). A version of a probabilistic additive conjoint structure will be given below (ADISOP, CADISOP). The most basic proposition of most measurement structures is that an object a is in some respect larger, more attractive, etc., than an object b, symbolically, $a \gtrsim b$, where the objects and the relation are assumed to be empirically observable and deterministic (for example, two weights and the turning of the scale of an idealized balance). How could this be translated into the single, inconsistent qualitative reactions (right–wrong, strongly refuse–strongly prefer) of subjects to single items? Falmagne (1976, 1979) suggested replacing $a \gtrsim b$ with the probability $P(a \gtrsim b)$ of observing a 'larger reaction' (for example, the judgement a is louder than b) upon repeated presentation of the pair (a, b) (or of observing a larger median reaction time, etc.). This is feasible for some psychophysical tasks, but totally impractical for usual psychological intelligence and personality tests where individually identifiable items reasonably can be presented only once to subjects (a repetition would change the meaning of the item). For these I suggest replacing the larger relation $a \gtrsim b$ or the probability of a larger relation $P(a \gtrsim b)$ with the relation of two probabilities, $P(X \leqslant x \mid a) \leqslant P(X \leqslant x \mid b)$, where $P(X \leqslant x \mid a)$ is the probability of observing a specified or 'smaller' reaction than x (for example, a predominantly right answer) on presentation of a. If there are more than two graded responses (rating scales, polytomous

Table 1
Stochastic dominance of variables, $F \gtrsim T \gtrsim P \gtrsim U$ (cumulative distribution functions: 1, positive; 2, moderately positive; 3, moderately negative; 4, negative)

	Rating			
Category	1	2	3	4
U	0.417	0.778	0.972	1.000

T	0.064	0.278	0.714	1.000
F	0.063	0.175	0.588	1.000

ordered response categories) available for items I suggest using the concept of stochastic dominance (see below and *Majorization and Stochastic Orders*). The probabilities are an intermediate layer intervening between the empirical and numerical relational system of a measurement structure (Roberts 1979, p. 274) and even estimates from single observations turn out to be sufficient for statistical testing of larger restrictive measurement structures (for example, if a subject 'moderately agrees' to an item his cumulative probabilities of 'disagreeing' or 'moderately disagreeing' are set to 0 and his probabilities to 'moderately agree' or 'agree' are set to 1).

A stochastic variable W dominates a stochastic variable V, if the probability that W is smaller/equal than an arbitrary value x is smaller/equal to the probability that V is smaller/equal to x for all x, that is:

Definition. Stochastic dominance $\gtrsim$.

$$W \gtrsim V \Leftrightarrow F_w(x) \leqslant F_v(x) \quad \text{for all } x$$

where $F(x) = P(X \leqslant x)$

Definition. Strict stochastic dominance $\succ$.

$$W \succ V \Leftrightarrow F_w(x) \leqslant F_v(x) \text{ for all } x$$

and

$$F_w(x) < F_v(x) \quad \text{for at least one } x.$$

If $W \gtrsim V$ we also write $F_w(x) \gtrsim F_v(x)$ for the cumulative distribution functions (CDFS) and similarly for $\succ$.

As an example, the students of a lecture on statistics rate their attitude (preference/aversion) towards the usefulness of statistics for the understanding of psychology (U) (high/low), the importance of statistics for professional success (P) (important/unimportant), the time needed to learn statistics (T) (acceptable/annoying), and the work with formulae (F) (fascinating/disgusting) on a four point scale. The students reject formulae most, the time requirements for learning statistics next, and think more positively about the importance of statistics for professional success, and most for understanding psychology (Table 1).

If the preference (aversion) for one option stochastically dominates the preference (aversion) for another option, then the probability that the first option is accepted (rejected) is always greater than or equal to the probability that the second option is accepted (rejected) if the ordinal scale is dichotomised (transformed into a binary scale) at an arbitrary position. This invariance makes the stochastic order relation independent of a great variety of different empirical operationalizations (experimental arrangements for the determination of larger relations).

If the deterministic order relations are made probabilistic by the concept of stochastic dominance, then the concept of empirical verification and falsification of single relations by single observations must be replaced by statistical testing of order relations (Bartholomew 1983, Robertson et al. 1988) and by the likelihood principle of model testing. Suppose we want to test the validity of the above order relation $F \gtrsim T \gtrsim P \gtrsim U$ for all subjects of a specified population. Then there are many nonparametric tests to test the null hypothesis of no differences and we can test the hypothesis of the same (similar) order of items for all subjects by testing samples from all relevant subpopulations of subjects; we can also calculate the likelihood of all possible orders and choose the maximum likelihood order.

2. *The Construction of Ordinal Scales for Subjects and Items: the Isotonic Probabilistic (ISOP) Measurement Structure*

The most basic level of the hierarchy of models for the construction of unidimensional scales for psychological traits is the construction of ordinal scales for subjects and/or items. The construction of two scales simultaneously for two sets of objects (e.g., subjects and items) has been referred to elsewhere as biscalability or biorder (Guttman scale, see *Ordered Relational Structures*). Because these concepts are not probabilistic or appropriate only in psychophysical contexts they are not reported here (but they presumably could be made probabilistic).

In the example of rating different aspects (items i) of a negative attitude towards statistics each subject v generates a response vector $\boldsymbol{x}_v = (x_{v1}, x_{v2}, x_{v3}, \ldots)$ of ratings of aversions for items 1, 2, 3,…. The subjects possibly are characterized by a unidimensional latent trait 'aversion against statistics.' The response distributions of the response variables X_{vi} of subjects $v = 1, 2, \ldots, n$ and items $i = 1, 2, \ldots, k$ can be ordered by stochastic dominance;—but how can the subjects (items) be ordered? The response vectors of the subjects give no simple order of the subjects with respect to aversion against statistics. The order relation on the set of subjects (items) has to be defined by

a new concept. We can say that one subject dominates another (with respect to aversion against statistics) if all his/her ratings are larger than or equal to the ratings of the other subject. Of course, many pairs of subjects will not be ordered by this relation (the order is partial). The subjects cannot be compared directly, but by means of their response vectors, i.e., by means of the items as instruments; and therefore the measurement structure is called an instrumental probabilistic pair comparison system (Irtel and Schmalhofer 1982; bioorder, see *Ordered Relational Structures*).

The set of observed multidimensional polytomous response vectors $\boldsymbol{x} = (x_1, x_2, x_3, \ldots)$ ordered by the relation

$$\boldsymbol{x} \text{ dominates } \boldsymbol{y} \equiv x \gtrsim y \text{ iff } x_i \geqslant y_i \text{ for all } i$$

is a multidimensional coordinatewise partial order.

If several variables are stochastically ordered and their order coincides with a scalar parameter of their distributions then they are said to be *isotonic* (similarly ordered) in that parameter. That parameter may represent a known attribute of the variables or a scale value on a latest dimension (for example, aversion in Table 1).

Definition. Isotonicity. A family of variables X_i or distribution functions F_i depending on a parameter p_i is isotonic in p_i if $X_i \prec X_j \Leftrightarrow F_i(x) \geqslant F_j(x)$ for all x of $p_i \leqslant p_j$.

In order to be able to construct ordinal scales for the set of subjects and items we now extend the concept of isotonicity to a two-dimensional array of variables X_{vi}, for example the aversions of several subjects for a set of attitude items or the preferences of visitors for various holiday arrangements. This is achieved by the axioms of the ISOP measurement structure.

Let A be a set of subjects $v, w, \ldots$, and Q a set of items $i, j, \ldots$,. We associate with the Cartesian product $A \times Q$ a family of random variables X_{vi} with distribution functions $F_{vi}(x) = P[X \leqslant x \,|\, v, i]$ defined on the set $X = \{x, x', x'', \ldots\}$ of categories (values) of an ordered dependent ('achievement') variable X.

Definition. A system $\langle A \times Q, F \rangle$ where F is a family of distribution functions on $A \times Q$ is weakly, independently ordered (an ISOP model) iff the following axioms are valid.

Axiom W1. *Weak subject independence* holds if the response distribution of subject v dominates the response distribution of subject w at item i, then the response distributions of v are not dominated by w at any other item j.

Axiom W2. *Weak item independence* holds if the response distribution of item i dominates the response distribution of item j for some subject v, then the response distributions of i are not dominated by j for any other subject w.

Axiom LI. *Local independence* holds if the probability of the response vector of a subject v is the product of the probabilities of the single responses

$$F(x_{v1}, x_{v2}, x_{v3}, \ldots \,|\, v) = F(x_{v1} \,|\, v)\, F(x_{v2} \,|\, v)\, F(x_{v3} \,|\, v) \ldots$$

(Scheiblechner 1995, 1998).

We can write W1 in the form 'if $F(X_{vi}) \succ F(X_{wi})$ for some i, then $F(X_{vj}) \gtrsim F(X_{wj})$ for all j meaning that the stochastic dominance relations between subjects are similar (isotonic) for all items. Analogously for W2, the stochastic order of items is similar for all subjects and therefore independent of subjects (except for ties: Scheiblechner 1995, 1998). The pair $\langle A \times Q, F \rangle$ is called an instrumental probabilistic pair comparison system. Axiom W1 orders subjects by the stochastic order of their distribution functions of reactions to items and states that the orders are independent from the specific items used, except for possible ties (subjects are similarly ordered by items). This independence of the orders of subjects of the items is the basis for the construction of the latent unidimensional subject ordinal scale or person parameter. Axiom W2 similarly states that the stochastic order of items is independent of subjects and this is the base of the item ordinal scale or item parameter. The axioms are independent and can be statistically tested independently of each other.

If the system of variables is an ISOP, then the distribution functions can be ordered, and there exist ordinal scales $\varphi_A(v)$ on the set of subjects, and $\varphi_Q(i)$ on the set of items, such that the distribution functions of the family X_{vi} of random variables are functions of the two ordinal scales (Scheiblechner 1995):

$$F_{vi}(x) = F(x \,|\, \varphi_A(v), \varphi_Q(i))$$

where $\varphi_A(v)$ and $\varphi_Q(i)$ are ordinal scales.

The two ordinal scales are 'order independent relative to subsystems' (Scheiblechner 1995), that is, the ordinal scale for subjects does not depend on the set of items and the ordinal scale for items does not depend on the set of subjects, both except for ties (the corresponding property is called specific objectivity or sample independence in the logistic Rasch model; Andersen 1995, Rasch 1960)

The following implications of ISOP can be tested:

(a) the validity of axiom W1 for each item and for the total test (= set of items);

(b) the validity of axiom W2 for each response vector (subject) and for the total sample;

(c) the validity of the coordinatewise partial order of response vectors for each subset of items of the test and for the total test;

(d) the validity of the coordinatewise partial order implied by one part of the test for another part of the test; and

(e) the validity of a large number of manifest partial and linear isotonicities.

Especially the facility to test separately the single axioms of the measurement structure and the separate

tests for different parts and aspects (formal relations) of the data are a measurement theoretical advantage of the ISOP measurement structure.

3. The Construction of Interval Scales for Subjects and Items: the Additive Conjoint ISOP (ADISOP) and the Complete ADISOP (CADISOP)

The axioms of the ISOP model are sufficient for the construction of two separate unidimensional ordinal scales on the sets of subjects and items. We now strengthen the ISOP model by additional axioms in order to derive ordered metric/interval scales for subjects and items. First the ADISOP model is considered which is an ISOP model with a cancellation axiom added that relates the subject and item factors.

Definition. A probabilistic pair comparison system $\langle A \times Q, F_{vi}(x)\rangle$, where $F_{vi}(x)$ is a family of cumulative distribution functions defined on $A \times Q$, is an ADISOP iff the axioms of the ISOP model and the following axiom are satisfied.

Axiom Co. Validity of cancellation of subjects and items up to order o.

(Similar structures are the PACOME models, Falmagne 1979). An explanation of cancellation up to order o is given in Scheiblechner (1999) and Scott (1964). It means that a reduction of the item parameter by an amount δ can be compensated by an increase in the subject parameter by the same amount δ. The subject and item parameters 'cancel.' Or if we attribute real values to subjects and items then the order of their sum is isotonic in the order of their distribution functions. For example, if the 'ability' parameter of subject v plus the 'easiness' parameter of item i is larger than or equal to the sum of the ability and easiness parameter of subject w and item j, then the distribution functions are isotonic in the sum, i.e., $F_{vi}(x) \gtrsim F_{wj}(x)$ and the reverse.

If the system $\langle \boldsymbol{A} \times \boldsymbol{Q}, \boldsymbol{P}\rangle$ is an ADISOP model then the order of the CDFs is identical to the order of the sums of the subject and item parameters, i.e., there exist real functions ϕ_A, ϕ_Q on A and Q and $\psi_{A\times Q}(v, i) = \phi_A(v) + \phi_Q(i)$ on $A \times Q$ such that for all (v, i), $(w, j) \in A \times Q$

$$\phi_A(v) + \phi_Q(i) < \phi_A(w) + \phi_Q(j) \Leftrightarrow F_{vi}(x) > F_{wj}(x)$$

for some x or $\Leftrightarrow F_{vi}(x) \prec F_{wj}(x)$

The scales ϕ_A, ϕ_Q are unique up to positive linear transformations, i.e., they are interval scales if Axiom Co is valid up to arbitrary order o, and they are ordered metric scales if Co is valid up to the finite order $(\min\{n, k\} - 1)$ where n and k are the number of elements of A and Q, respectively. Ordered metric scales are unique up to monotonic transformations which leave invariant the order of the (finite number of) intervals. Ordered metric scales are approximations to interval scales. The cumulative response distribution functions on the product set of subjects and items

$$F_{vi}(x) = F(\varphi(x);\ \varphi_A(v) + \phi_Q(i))$$

are antitonic (do not increase) in $\psi_{A\times Q}(v, i) = \phi_A(v) + \phi_Q(i)$ and isotonic (do not decrease) in $\varphi(x)$, where $\varphi(x)$ is an arbitrary strictly isotonic function of x (i.e., is an ordinal scale). The functions $\phi_A(v)$ and $\phi_Q(i)$ are interval scales (ordered metric scales) with an arbitrary origin (additive constant) and a common unit (scale factor).

The ADISOP model can further be strengthened to a model where the response category parameter also is additive to the item and subject parameter. The axiom W3 strengthens Co and extends cancellation from subjects and items to include subjects and instrumental variable (response category) and items and response variable.

Definition. A complete ADISOP (CADISOP) model is an ADISOP with axiom (W3) (and RS) replacing axiom Co:

Axiom W3. Weak instrumental variable independence holds if:

$F_{vi}(x) < F_{vi}(x')$ for some v and some i, then $F_{wj}(x) \leqslant F_{wj}(x')$ for all w and all j

Axiom RS. Restricted solvability. Certain restrictions apply to the solution of stochastic dominances.

The weak instrumental variable independence axiom W3 is an independence axiom like W1 and W2 and makes the factor of the coding of the response variable X independent of the experimental factor of subjects and of the factor of items (for each value x of the instrumental variable the biorder of subjects and items is the same). It makes the coding of the instrumental variable another additive factor. Cancellation is no longer restricted to subjects and items but includes the response variable factor (an increase of the response category parameter by an amount c can be compensated by an equal increase in the subject or item parameter). Axiom RS grants that the system of equations and inequalities representing stochastic dominances has a solution under certain restrictions (e.g., if the CDF of subject v at item i and category x is between the CDFs of subjects u and w at item j and category x, then there is a subject s whose CDF at j and x' is equal to the CDF at (v, i, x); similarly for the item and category factors (Roberts 1979 p. 218).

If the pair comparison system $\langle A \times Q, P\rangle$ is CADISOP then there exist scales ϕ_A on A, ϕ_Q on Q and ϕ_X on X such that for all (v, i, x), $(w, j, x') \in A \times Q \times X$

$$\phi_X(x) - (\phi_A(v) + \phi_Q(i)) \leqslant \phi_X(x') - (\phi_A(w) + \phi(j)) \Leftrightarrow F_{vi}(x) \leqslant F_{wj}(x').$$

The scales are interval scales with a common unit (scale factor). The 'system characteristic function'

$$F_{vi}(x) = F(\phi_X(x) - (\phi_A(v) + \phi_Q(i)))$$

is strictly isotonic in its argument (Scheiblechner 1999).

4. The Integration of Linear Models for Item and Subject Parameters in Additive Models: Linear ISOP, ADISOP, and CADISOP Models

The ADISOP can be combined easily with an additive model for the item parameter:

$$\varphi_Q(i) = \sum_l a_{il}\eta_l$$

where a_{il} are known coefficients specifying the frequency or amount of 'basic components' l present in item i, and η_l are the (easiness, attractiveness) parameters of the basic components.

The matrix A with the coefficients a_{il} is termed the (item) model matrix. The estimation of the linear item model can easily be integrated into the algorithm for fitting an ADISOP model (Scheiblechner 1999).

It is interesting to note that the coordinatewise partial order of items implied by the model matrix A can be tested in ISOP model with only ordinal scales for items (and subjects) available. The full linear model for items with interval estimates for the basic parameters, however, requires interval scales for items (and subjects) and thus an ADISOP. Thus in a model with latent scales and latent concatenations the question of additivity of item components cannot be separated completely form the question of additivity of item and subject parameters.

It is possible also to include an additive model for the subject parameter

$$\varphi_A = \mathsf{B} \cdot \delta$$

where φ_A is the column vector of subject parameters, B the (n, k) matrix of 'dosages' of (basic) treatments which were given to subjects and δ the column vector of 'gains' (increments of the subject parameter) caused by the treatments (the first column of B may be a column of 1s for an additive constant). The necessary supplements of the estimation algorithm are similar to the inclusion of the item model. Both extensions can be performed in a CADISOP model, of course.

The linear ADISOP/CADISOP models with the inclusion of linear models for items and/or subjects can be tested versus the respective unrestricted models by likelihood ratio tests.

5. Discussion and Future Directions

Probabilistic measurement models are known in psychophysics and utility theory, for choice behavior and pair comparisons, for decision making under uncertainty, and measurement of subjective probability. Not much attention is usually placed on estimation of parameters (probabilities and scale values) and statistical testing of fit (a rare but well-known and unsatisfactory (biased) example is Mosteller's test of fit for pair-comparison data). The probabilistic version of the additive conjoint measurement structure by Falmagne (1979) is a noteworthy psychophysical example for the statistical treatment of measurement models. Some statistical principles of estimation and testing could be borrowed and adapted from isotonic regression (Dykstra 1983, Robertson et al. 1988). The tests concern stochastic (probabilistic) transitivity or consistency. The ISOP model is a weak stochastic transitivity model for a product structure ($A \times Q$) and satisfies the statistical standards of probabilistic test theory. There are many statistical tests for various assumptions (axioms) in various parts of the data (see above, end of Introduction). The tests are based on generalizations of Goodman and Kruskal's index for ordinal association (1954, 1959, 1963, 1972). The U-model by Irtel and Schmalhofer (1982) is ISOP for dichotomous items and is its immediate precursor. The authors suggest an optimal contrast test for the bi-isotonic model (based on Robertson et al. 1988).

It is possible to specialize the ISOP model so as to pair comparison data (and to compare it with other probabilistic measurement models; Fishburn 1973). It is possible also to generate probabilistic polynominal conjoint measurement structures (Roberts 1979) by exactly the same steps as with ISOP structures (there is little use for those structures at present because no interesting empirical procedures for gathering corresponding data are known). Finally, it is possible to apply ISOP structures to geometrical measurement structures (multidimensional scaling, Kruskal 1964a, b).

A permanent problem in psychological test theory is the modelling of the speed–accuracy trade-off for items where the speed and accuracy of the response are recorded at the same time. This problem can be attacked along the lines of isotonic probabilistic measurement structures whereby some interesting new problems arise.

Text Comprehension: Models in Psychology

Models of text comprehension are concerned with how people understand and remember the verbal information they see or hear. The need for models of text comprehension arises from over 40 years of research on how people comprehend and learn from text. Early work focused on what people remembered from different kinds of texts (e.g., stories, lectures, newspaper articles, and encyclopedia-type articles). This early work showed that some kinds of texts (e.g., stories) were easier to understand and remember than others (e.g., encyclopedia-like articles). Researchers investigated ways to make texts easier to understand and remember, with variable success. These studies brought to light the role of task demands and reader characteristics. For example, memory tasks placed different demands on the comprehender than did problem-solving tasks. Furthermore, comprehension differed depending on reader characteristics such as prior knowledge, reading and listening strategies, attentional resources, purpose, and interest. Current models of text comprehension attempt to account for how text is processed and the relationship between how it is processed, the memory representation that is created, and performance on memory, problem solving, learning, and decision-making tasks. Models of text comprehension are tested by how well they predict behavioral data and through computational modeling. (For further discussion, see Britton and Graesser 1996, Goldman and Rakestraw 2000, Graesser et al. 1997a, 1997b, Kintsch 1998, Weaver et al. 1995.)

Text comprehension involves many cognitive processes that relate the elements in the text to one another and to prior knowledge so that the result is a coherent mental representation. An important issue for models of text comprehension is the contribution of prior knowledge of the text topic and structure to the formation of coherent representations. Texts are seldom completely explicit with respect to the connections among text elements so comprehenders often have to make inferences to bridge these 'gaps.' Inferences sometimes are made just from the text information and sometimes involve elaborative processes that rely on prior knowledge.

The outcome of text comprehension is a memory representation that reflects the meaning the comprehender has constructed. The representation may reflect the surface text itself, the meaning constructed from the text elements (e.g., words, phrases, and sentences that were actually in the text), and/or meaning elements derived from prior knowledge. The representation often goes beyond the meaning of the text (the textbase model) to reflect a model of the situation described by the text. Prior knowledge plays a greater role in the situation model than in the textbase.

In general, models of text comprehension seek to describe, explain, and predict various processing activities and their representational consequences. A lower bound on the adequacy of models of text comprehension is that they provide explanatory accounts of the behavioral data. Currently, models of text comprehension provide more adequate descriptions and explanations than predictions of behavioral phenomena. Furthermore, most models do not deal adequately with all of the empirical findings. Most models selectively focus on some subset of empirical findings, although they increasingly attempt to be comprehensive (see, e.g., Britton and Graesser 1996, Gernsbacher 1997, Kintsch 1998, O'Brien and Myers 1999, van Oostendorp and Goldman 1999). The remainder of this article discusses current and future directions in the study of text comprehension models.

1. Approaches to Studying Models of Text Comprehension

Text comprehension research has required the development of methods for systematically analyzing and describing characteristics of the text, the comprehender, and the processing and representation demands of various comprehension tasks. Researchers examine these 'input' variables in relation to two types of dependent measures, namely those that assess processing as it is occurring (on-line measures) and those that assess the results of the processing (memory representation measures). Computational models have been formulated to give more precise explanatory and predictive power to models of text comprehension.

1.1 Text Analysis

Texts are often described at the level of the individual ideas (microlevel) as well as the more global organization of these ideas (macrolevel). Origins of modern text analysis systems typically represent the ideas as propositions. Although the specific details of propositional notation differ somewhat across systems, a proposition is a theoretical unit that contains a predicate (e.g., a verb or adjective) and associated arguments (e.g., nouns, embedded propositions). Arguments have a functional role such as agent, object, or location (for discussion, see Graesser et al. 1997a, Goldman 1997).

Consider the first sentence in a hypothetical paragraph: Mike drove to the gas station and got out of the car. There are two ideas linked together by an and. Mike is the agent of both driving and getting out of the car and the location of both actions is the gas station. The ideas in subsequent sentences would be similarly described and attempts made to link them. Suppose the next several sentences relate details of Mike's attempt to rob the gas station, including the fact that the attempt was foiled when the car stalled as Mike was making his getaway. The global organization would reflect an attempted robbery theme, provided that the comprehender had prior knowledge of robbery scenarios. Ideas more central to the robbery theme would have greater importance, be more central, and be at a more superordinate level in the representation.

Empirical research has shown that propositions are a useful way to characterize text and prior knowledge. Recent challenges to propositional representations contend that there is more to meaning than the symbolic form, i.e., the word (Glenberg 1997). Clearly this is the case, but it does not seem to deny the usefulness of propositional representations for text research.

Although prior knowledge can guide the organization of ideas in a text, the surface text itself contains cues to the underlying semantic organization. Relationships among ideas may be signaled by repetition of specific concepts, either in exactly the same form (e.g., car) or through synonym (e.g., jalopy for the stalled car in the Mike example). Rhetorical devices (e.g., The key idea is, The first point is) and graphic cues (e.g., paragraph indentations, boldface font) can help readers recognize and create connections among ideas (Goldman and Rakestraw 2000, Zwaan and Radvansky 1998).

1.2 Comprehender Characteristics

Several characteristics of comprehenders provide constraints on text comprehension. The most frequently

examined are prior knowledge relevant to the topic of the text and discourse forms, working memory, and interest.

1.2.1 Prior knowledge. Researchers have developed various techniques to assess the impact of prior knowledge on text comprehension and vice versa. Techniques for assessing domain-relevant concept knowledge include concept relatedness ratings, question answering, sorting, and cued associative responding. Assessments of discourse genre knowledge, and rhetorical structures include judgment tasks, their use in generated text, and patterns of on-line processing measures such as reading time and verbal reports. By comparing groups that differ in prior knowledge measures, researchers can assess the impact of knowledge on text comprehension. Researchers infer the impact of the text on knowledge from changes in measures of prior knowledge before and after comprehension.

1.2.2 Working memory. Although all humans have limited attentional resources, there are individual differences in working memory span for verbal material and these are related to text processing and memory. Daneman and colleagues (see Daneman and Tardif 1987) developed a technique for assessing working memory span. Working memory limitations mean that, in most cases, the whole text cannot be processed at once but must be processed in cycles. Ericsson and Kintsch (1995) proposed that one way of dealing with resource constraints is to construct retrieval structures in long-term working memory.

1.2.3 Interest. Personal interest in particular topic areas is assessed through self-report measures typically. Text comprehension is positively related to personal interest in the topic of the text. Situational, or text-based interest, is associated with specific information in a specific text and often is measured through ratings of each sentence in a text. Information with high situational interest, sometimes called 'seductive details,' is well recalled regardless of its importance to the overall theme of the text (see review by Alexander et al. 1994).

1.3 Analysis of Task Demands

Task demands are characterized in terms of the memory representation needed to perform on post-comprehension tasks and whether the tasks require that the comprehender just retrieve information or retrieve and reason with information. For example, comprehenders can do an excellent job of retelling a story so long as they have a good representation of the surface elements and textbase of the story. However, if they need to decide whether the main character acted ethically, they need to reason about the events in the story. The reasoning involves the situation representation.

Other analyses of task demands examine indices of processing difficulty (e.g., unfamiliar vocabulary or complex syntax) in order to compare different texts or task situations. Under conditions of high task demands, comprehenders should either take longer to process the text or end up with less coherent representations. The effects of task demands will be minor if comprehenders do not interpret them appropriately and strategically respond to them (Goldman 1997).

1.4 Assessing Online Processing of Text

Online techniques allow text processing to be assessed independently of the resulting representation and its subsequent use in memory or problem solving tasks. Online measures indicate what is active in working memory at the same time. This is important because limits on attentional resources constrain the amount of text and prior knowledge that can be active simultaneously. Simultaneous activation is necessary for forming links among text or prior knowledge elements, according to virtually all current models of comprehension (Britton and Graesser 1996, Kintsch 1998, van Oostendorp and Goldman 1999).

Some online techniques (e.g., eye movements, reading times, and inspection patterns) provide estimates of where readers look, for how long, and the order in which they look at specific information. Other techniques provide estimates of what information is active in working memory at specific points during the reading process (e.g., probe memory, priming, and think-aloud techniques). Several models and mechanisms have been proposed to account for observed patterns of processing and activation of prior knowledge and previously processed portions of text, including the structure building framework (Gernsbacher 1997), associative priming (Kintsch 1998), resonance (O'Brien and Myers 1999), constructionist theory (Graesser et al. 1994), and the memory-based processing model (O'Brien and Myers 1999). In addition, think-aloud protocols indicate that there are age- and skill-related differences in strategies that comprehenders use to form coherent representations of text, with more effective comprehenders using explanation-based strategies to a greater degree than less effective comprehenders (Chi in press, Coté et al. 1998, Trabasso and Magliano 1996).

1.5 Assessing Mental Representations

Obviously, mental representations are not directly observable. Researchers make inferences about mental

representations on the basis of observable indices of those representations, such as the information comprehenders produce when asked for the 'most important' information in a text or when asked to recall a text. Assessments of text representations are taken *after* the comprehender has read or heard the text, and thus differ from on-line measures.

Methods for studying comprehenders' representations are typical of those used to study broader issues of memory. A primary distinction is between recognition and recall or free response, techniques. Recognition memory is often used to determine the content and form of elements in the representation (e.g., surface, text, or situation). Recall or free response measures can be more or less open-ended. Comprehenders may be asked to recall the text, recall just the main ideas from the text, summarize the text, create a diagram of the important information from the text, or answer questions about presented and potentially inferred information.

Assessments of mental representations have established a number of important findings, summarized here. Ideas that are more important, more causally central, or more superordinate are remembered better and more frequently included in summaries than are subordinate ideas. Generally, this is the same information that receives more extensive processing. In addition, the more coherent the text, the better the recall, especially for comprehenders who are 'low knowledge' with respect to the topic of the text. Finally, interest affects what is remembered. When interest value is pitted against importance, interest wins.

2. *Computational Models*

Computational models simulate text comprehension on a computer. Computer models must be extremely specific and precise with respect to the hypothesized processes, representations, and interactions. The fit of the simulated output can be compared with the output of humans for a comparable task to provide a basis for validating and updating models of text comprehension. Likewise, mathematical models quantify precise patterns of processing times, memory scores, ratings, and other psychological data. Failures of fit can be as informative as good fits because these discrepancies can lead to new insights about the limitations of existing models (Goldman et al. 1996, Graesser et al. 1997a).

Computational models of text processing have been influenced by symbolic and connectionist cognitive theories. In symbolic theories (Anderson 1983), actions are linked to specific conditions under which they might occur. These are called production rules and take the form of If ⟨condition⟩ Then ⟨action⟩. When the condition side of a production is satisfied, the production 'fires' and the action occurs. When new input enters working memory, all production rules are evaluated to determine which ones have conditions that are satisfied, and one is selected to fire, completing a cycle. On successive cycles, the input to working memory dynamically changes, and different productions are satisfied.

Connectionist theories (Rumelhart and McClelland 1986) distribute representations and processes among a large set of simple units analogous to neural units. Each word, concept, or proposition has a corresponding ensemble of neural units. The units are connected with one another through weights that are excitatory, inhibitory, or neutral and form a neural network. During comprehension, a particular set of units that matches the input is initially activated and activation spreads throughout the network consistent with the excitatory and inhibitory links. Activation continues spreading until there are relatively minimal changes in the activation levels of the units and a stable pattern of activation is achieved. This pattern of activation captures the meaning of the input.

Most models of text comprehension are hybrids of symbolic and connectionist theories. Currently, the two most influential models are those of Just and Carpenter (1992) and Kintsch (1998).

2.1 *Just and Carpenter's Collaborative Activation-based Production System (CAPS) Model*

The CAPS architecture (Just and Carpenter 1992) is a production system architecture augmented by two characteristics that give it a connectionist flavor. First, the collaborative aspect of CAPS results from removing the restriction that only one production fires on each cycle. Rather, all matched productions are simultaneously fired. Second, the activation process is not all or none. The condition sides of productions accrue levels of activation. The collaborative and changing activation characteristics of CAPS combine to generate a process in the connectionist spirit: productions fire in parallel, gradually changing the activations of working memory elements by an amount proportional to the activations of other elements. When the activation of a particular element falls below a threshold activation level, that element is no longer noticed by the system and is unable to participate in further processing. Just and Carpenter constructed a comprehension-simulation model within the CAPS architecture, READER. It was designed to process a short, expository passage on flywheels. Lexical, syntactic, and semantic representations were built simultaneously due to the parallel firing of all productions that matched on a given cycle.

Just and Carpenter (1992) embellished the CAPS model with the assumption of an activation limit ('cap') on working memory. The capacity-constrained architecture (3CAPS) means that productions com-

pete for available activation. When fired production rules request more activation than is available, the 'cap' has been reached. Processing at the 'cap' results in a graceful loss from working memory of productions that are not participating in processing, and an overall system slowdown.

2.2 Kintsch's Construction–Integration model

The Construction–Integration (CI) model (Kintsch 1998) represents the input as propositional nodes in a network of linked nodes. The node is a symbolic representation of the content that has a weighted link in the connectionist manner to other nodes in the network. The model simulates the construction of a text-base representation and the incorporation of prior knowledge to form a model of the situation described by the text. The model proceeds in two phases. During Construction, propositions are linked based on argument (concept) overlap to create an initial representation. Additional links can be specified depending on assumptions about causality, temporality, and logical relations. Prior knowledge is also activated 'indiscriminately' and some irrelevant information may be included as part of the network representation. Kintsch (1998) uses the Latent Semantic Analysis (LSA) model of knowledge representation (Landauer and Dumais 1997) to simulate prior knowledge activation. In LSA, knowledge is represented as vectors in a high-dimensional 'semantic space.' Concepts in the input text are located in the semantic space and neighbors are activated.

During Integration, activation spreads through the network of nodes. Activation flows out of nodes with few or weak connections and to nodes that are richly connected, until the network reaches a stable state. During Integration, relevant knowledge associations tend to maintain activation and become part of the representation, while irrelevant associations tend to lose activation and drop out of the representation. At the completion of a CI cycle, each text node has a particular strength value and link strengths for each node to which it is connected. At the conclusion of comprehension of the entire text, each node and link in the network has a cumulative strength value, reflecting its cumulative activity during all cycles of comprehension. These values are used to create long-term memory strength values that can be used to predict the relative likelihood of remembering a particular node or relationship.

The CI model takes into account working memory limitations in that input propositions are processed in cycles and only the most active are held over for processing in subsequent cycles. The number that are 'held over' is a parameter in the model. Propositions not held over can be reinstated in subsequent comprehension cycles. Kintsch (1998) uses the theory of Long-term Working Memory (Ericsson and Kintsch 1995) to elaborate the relationship between working memory and long-term memory. This theory postulates that expert performance for tasks such as reading is accomplished by having highly organized and easily accessible knowledge structures in long-term memory. During processing, working memory utilizes 'pointers' to these structures, which makes them quickly and easily accessible, thus accounting for the fast and accurate application of prior knowledge under conditions of normal comprehension.

2.3 Other Activation-based, Dynamic Models

The CI and 3CAPS models have spawned a 'family' of models that share assumptions about fluctuating activation of elements and dynamic behavior of the representations. One model, Capacity Constrained Construction Integration (3CI), combines CI and 3CAPS by replacing the fixed-buffer working memory of the CI model with the dynamic, fixed-capacity working memory system of 3CAPS (Goldman et al. 1996). 3CI allows all propositions that are currently active after a CI processing cycle to be carried over to the next processing cycle. Loss of activation is a natural result of processing when the 'cap' is reached. 3CI results in an enhanced ability to establish coherence across sentences by having more propositions potentially participate in the same processing cycle, thereby increasing the link strength between them. Simulation results show that for texts that have hierarchical organizations (such as a premise and examples), the 3CI model is able to assess the global discourse structure and relate specific information to that global structure more effectively than the CI model.

Other models in the activation-based family focus on the nature of the links among text elements (Britton and Graesser 1996, van Oostendorp and Goldman 1999). For example, Langston and Trabasso (1999) implemented a model in which causal relatedness drives the creation of links between clauses and is responsible for text coherence. The model accounts for a variety of narrative processing phenomena such as reading time, importance ratings, and the contents of think-aloud protocols.

Van den Broek et al. (1999) focus on different kinds of information and connections among nodes. They proposed a 'Landscape' model in which a text representation is constructed from information that is activated from the text in the current reading cycle, the text in the preceding reading cycle, information earlier in the text, and from prior knowledge. Different types of connections carry different weights, and a limited capacity working memory provides constraints on the amount of information that can be processed in any particular cycle. The Landscape model can account for both the order and the content of free recall.

3. Issues for the Future

Conceptual advances in models of text comprehension require that they continue to focus on knowledge activation and inference making, especially for learning from text in content and technical domains. Optimal learning from text occurs when individuals who vary in their prior knowledge of the text topic are 'matched' to texts that vary in conceptual difficulty. While this observation is not novel, Wolfe et al. (1998) provided evidence that LSA provides a reasonably convenient way to establish a range of texts on the same topic that differ in conceptual complexity.

Models of text comprehension also need to expand their focus in a number of ways. First, they need to include the processing of the surface text, including parsing, knowledge of discourse structure and genre, and the impact these have on the creation of propositional representations. Advances in techniques for processing natural language make it more feasible for computational models to take surface text input rather than a researcher-parsed list of propositions. This expansion of computational models will permit more detailed understanding of interactions between surface structure characteristics of the discourse and interpretations that comprehenders construct (Goldman et al. 1996).

A second expanded focus concerns the impact of new input on existing knowledge structures (O'Brien and Myers 1999). This is important for learning in content domains and is important in the everyday conduct of human activity. Adults are resistant to updating information they have read in newspapers and magazines when contradictory information is published subsequently. Whether updating occurs appears to depend on the combined impact of strength and explicitness of the contradiction (see chapters in van Oostendorp and Goldman 1999). Future research on updating needs to examine domain-relevant prior beliefs and knowledge because these are likely to affect readers' judgments about the plausibility of the original and updating information.

Models of text comprehension also need to expand the nature of the texts they examine. In response to the ubiquitous nature of new multimedia technologies and the information resources they make available, individuals are comprehending an expanding array of texts. Research is beginning to examine models of text comprehension in some of these new venues, such as hypertext and hypermedia environments, particularly with respect to scanning and inspection strategies. Comprehenders are accessing multiple sources of information quickly and easily, sometimes in response to self-assessment of comprehension. We know a little about the processing, representation, and integration of information from different sources (Perfetti et al. 1999). We need to know more.

Finally, models of text comprehension need to move beyond the single reader and deal with the social construction of meaning. Text comprehension, like other aspects of cognition, is situated in particular social, historical, and cultural contexts that impact the interpretation process (Bloome and Egan-Robertson 1993, Goldman 1997). What individuals regard as important and meaningful in texts is governed by their interactions with others, as well as by their interactions with the text. Models of text comprehension need to examine the impact of such contexts on the psychological processing and representation of meaning.

Textbooks

The textbook remains today what Altbach calls a 'virtual icon of education' (Altbach 1991, p. 242), yet controversy surrounds nearly every aspect of its production, dissemination, and use, and its prospects for survival are uncertain in a high bandwidth, digitized, and wireless world. Textbooks in modern society function simultaneously as surrogate curricula, cultural artifacts, and commercial objects. Their development over the past two millennia has been driven by the evolution of formal schooling and of the printing arts, as wells as by the development, particularly since the start of the twentieth century, of educational psychology. Important differences in textbook form and use, and of the issues surrounding these areas, exist across the schooling levels—elementary, secondary, and tertiary; curricular areas; and countries. The form that textbooks will assume in the future is projected to change with the fuller integration of information and computer technologies in schooling.

1. Definition and Evolution

1.1 Definition

Textbook usually is interpreted in a general sense, referring to texts that are especially prepared for the study of a subject. The prototypic textbook has as its core a sequence of topics that are arranged to lead a student through a subject or course of study, accompanied on the periphery by occasional guiding statements, summaries, or the like, exercises for practice, questions for self-assessment, and assistance for the instructor. All textbooks possess the core element but differ in representation of the periphery. Primary level textbooks tend to possess all of the peripheral attributes; secondary level ones, most, and tertiary level ones, fewer. Nevertheless, all textbooks are viewed as surrogate curricula, defining a prescribed codification of knowledge.

1.2 Historical Development

Until at least the Enlightenment, textbooks for advanced study were either original works, such as the grammars of Donatus and Pricisian, Boethius's *Geometry*, and Ptolemy's *Mechanisms of the Heavens*, or abridged compendiums of these works, such as Martinus Capella's *The Marriage of Mercury and Philology* (Cubberley 1920). For children, specially developed materials originate with the *Orbis Pictus* of Comenius (1658/1887), which was the first illustrated schoolbook published for introductory learning. By the end of the seventeenth century primers for teaching reading were published in Europe with the alphabet, lists of syllables and words, as well as religious material: the Lord's Prayer, the Creed, and so on. From the influence of Rousseau and Pestalozzi came, by the second decade of the nineteenth century,

carefully sequenced materials for learning, along with occasional suggestions for the instructor. With the adoption of tax supported schooling, particularly in Europe and North America, both the market and the need for textbooks expanded dramatically, leading to changes in both size and content. Coincidentally, improvements in printing technology and paper making throughout the nineteenth century were also reflected in textbooks. With the rise in educational psychology, beginning at the end of the nineteenth century, instructional approaches became more differentiated and more scripted, leading by the post-World War II period, to separate teacher manuals to accompany many elementary and secondary level textbooks.

2. *Surrogate Curriculum*

According to Altbach and Kelly (1988, p. 3), '(Textbooks) constitute the base of school knowledge, particularly in third world countries where there is a chronic shortage of qualified teachers.' But even in industrialized countries textbooks are the primary codification of school knowledge and the principal guide for teachers. Teachers at the elementary levels, who are responsible for teaching a broad curriculum in self-contained classrooms, choose out of necessity to use textbooks, along with workbooks and teacher guides. At higher levels of schooling the textbook is as much a prop for students, a *vade mecum* for a course, as it is a guide for the instructor.

2.1 *Grade Level Differences*

Although textbooks are used at all levels of education and in all subjects, their importance varies not only across countries but also across grade levels and curricular areas. At the primary levels their use is limited primarily to literacy, at least until the students, on average, can read well enough to gain meaning from other content area texts. In many school systems language arts and mathematics texts may be the only ones commonly used prior to the fourth or fifth year of schooling. Then, through the first years of graduate school, textbooks tend to be the basis of instruction for most subject areas.

2.2 *Subject Area Differences*

Thomas Kuhn has pointed out in *The Structure of Scientific Revolutions* that at the college level textbook use varies dramatically by field of study. Music, the graphic arts, and literature typically are taught through direct exposure of the student to artists' works, textbooks playing only a secondary role. In history, philosophy, and the social sciences, textbooks have a more significant role, but students usually are also assigned readings from the classics and from contemporary research reports. In contrast, the natural sciences are taught almost exclusively from textbooks (Kuhn 1970). Within the natural sciences, textbooks are rewritten after each paradigm shift (or 'revolution,' in Kuhn's terms), with the revolution obscured and the past reinterpreted to show only its connection to the issues of the new paradigm.

2.3 *Use of Textbooks by Teachers*

How teachers use textbooks is a matter of concern for educational administrators. In developing countries where teachers may not be well trained, close adherence to the sequence and directions of the textbook is desired. In other countries, reliance upon textbooks, particularly at the primary levels, is not viewed positively. Studies of teaching practices, however, have tended to show that high percentages of elementary teachers do use textbooks as their primary guide for instruction (e.g., Shaver et al. 1979, Weiss 1987). But other studies have shown that teachers, in general, do not follow their textbooks slavishly (e.g., Stodolsky 1989).

2.4 *Control of Textbook Content*

In most countries a central ministry of education determines the general content of textbooks but the actually writing of the texts may be performed by persons outside the ministry, as in Russia, or within the ministry, as in Singapore. In the US, Canada, and Germany control over textbook content is vested at a provincial or state level, although the actual texts are produced by the private sector. In many developing countries, where indigenous textbook industries generally are not yet developed, multinational textbook companies exercise some control over content. French produced textbooks, for example, are used in many West African secondary schools (e.g., Togo); some of these texts portray sex roles and other culturally sensitive matters that are alien to West African cultures (Biraimah 1988).

2.4.1 Imported textbooks. At a postsecondary level and especially in technical subjects, textbooks are relatively expensive to produce, due to the cost of illustrations, complex diagrams, formulas, and the like. Many countries, including the smaller industrialized ones such as The Netherlands, Finland, and Luxembourg, must import textbooks for these levels, and the majority of the these texts are written in English. A further factor that affects the content of textbooks worldwide, but particularly at a secondary and tertiary level, is that a small number of highly industrialized countries dominate knowledge production and dissemination. Countries like the US invest large amounts of money in all fields of research and development, including educational research,

and tend, therefore, to set many of the tertiary level standards worldwide for curriculum and assessment. Through academic institutions, research laboratories, libraries, and professional journals, countries like Britain, Germany, and the US exert both direct and indirect influence over textbooks in most of the rest of the world. That this knowledge is shared freely is offset partially by the reduction in cultural autonomy that results.

2.4.2 International concerns over content. Even within a world that recognizes, at least in principle, the right of each country to design and teach its own curriculum, cross-national conflicts over curriculum content have occurred. One example is the concern expressed by a number of countries to specific national treatments of twentieth-century history and particularly of World War II and the Holocaust. In 1982 The People's Republic of China and South Korea protested changes in Japanese history books that removed references to the Japanese massacre in Nanking and watered down the language previously used to describe other Japanese behavior toward conquered territories (Ketcham 1986). More recently, an Austrian publisher of a high school history series was forced, through pressure from other countries, to stop referring to Nazi concentration camps as 'punishment camps.' History texts in the US have been attacked for over a half century for lack of fairness and objectivity in describing wars (Walworth 1938), for being bland and condescending (Sewall 1987), and for failing to attribute blame to individuals (FitzGerald 1979). Similarly, science texts have been criticized for their handling of evolution (Skoog 1984).

3. *Cultural Artifact*

3.1 *The Latent Curriculum*

The table of contents and index of a typical textbook define, to a large degree, the manifest curriculum offered by the text. But on top of this curriculum are a secondary set of messages, reflected by commission and omission, that constitute the latent or hidden curriculum (Cronbach 1955). In part, this is what Williams calls the selective tradition of society (Williams 1980). A mathematics textbook that constructs its word problems around interests of a consumer society—goods to be purchased, interest on loans, fees paid for services—conveys a different message from one that presents the same mathematical challenges built around revolutionary themes—distribution of land to the poor, triumph in sports over capitalistic societies, and so on. In China, for example, mathematics textbooks during the Cultural Revolution conformed to the prevailing ideology; with a shift in politics, mathematics textbooks by 1980 were stripped of all praise for the Gang of Four and their policies (Kwong 1988).

3.2 *Class Structure*

Texts for teaching reading have been studied worldwide for different aspects of their latent curricula, including gender roles (e.g., Lorimer and Long 1979–1980, Zimet 1972, Biraimah 1988), need for achievement (e.g., McClelland 1961), moral/ethical values (e.g., de Charms and Moeller 1962), and sociocultural ideologies (e.g., Ahier 1988, Apple and Christian-Smith 1991, Luke 1988). Drawing on Paulo Freire's claim that pedagogy for literacy, by definition, requires an educational ideology, some of these latter authors argue that in countries such as Britain, the US, and Canada, literacy textbooks are as much concerned with maintaining class structures and political hierarchies as they are with imparting reading and writing. Although there is a surface validity to these claims, as demonstrated particularly by textbooks from the 1950s and 1960s, they are difficult hypotheses to test on modern textbooks in industrialized countries, given the pressures on publishers to produce textbooks that are unbiased toward any sex, race/ethnicity, age, country of origin, or political belief. Texts today could be attacked as much for failing to promote cultural continuity as for over-representing any particular class or belief in society.

4. *Commercial Object*

In almost every country that has formal schooling, textbooks have some relationship to the commercial sector. In Singapore, for example, textbooks are designed and written by a Ministry of Education, but copublished with private sector firms. In the USSR, prior to its breakup, the Ministry of Education or a State Committee for Public Education designed the content of textbooks but authors were selected through public competitions and paid royalties for their efforts, which were published by state controlled printing houses. In Mexico, where textbooks have been provided free to the six grades of public and private elementary school, government support has been provided to develop what World Bank researchers have called 'the most dynamic private sector publishing industry in Latin America' (Neumann and Cunningham 1982).

4.1 *Concentrations of Expertise and Production Capacity*

Textbook publishing and marketing require expertise in subject matter and pedagogy, along with capital, production and distribution capacity, and access to

paper. These resources are found primarily in the major metropolitan centers of North America, Asia, and Europe, and are increasingly being dominated by the larger European conglomerates—Pergamon and Pearson in the UK, Bertelsmann in Germany, and Hachette in France. Even in the US, few major textbook publishing houses have remained independent. The rest of the world lies in the periphery of textbook publishing, even though many other large countries such as India, China, Mexico, and Egypt produce many if not most of their own textbooks and the latter two export regionally to smaller developing countries (Altbach 1991).

4.2 Physical Characteristics

The appearance of textbooks—the quality of paper, typography, illustrations, bindings, and cover stock—are a function of printing technology, different national economies, grade level, and national (or regional/local) educational policies, such as the adoption cycle. In all school systems primary level textbooks usually are done on the cheapest paper, often with paper covers and limited use of color for illustrations. Russia textbooks, which the former Soviet government subsidized, were produced to last 2–3 years and were done with cheap paper, cover stock, and bindings. In contrast, textbooks in the US are produced to last 5–7 years and due to market factors have far more expensive components. But they also cost almost 10 times as much as their Russian counterparts (Mehlinger 1991).

4.3 Authorship

Authors of secondary and tertiary textbooks generally write the works that bear their names. At the elementary level, on the other hand, writing houses or other anonymous writers often do the majority of the development. The authors usually are involved in planning and review, and may even draft a few model lessons, but their main function is to impart validity to the resulting product, through their professional reputations, affiliations, or their race/ethnicity, age, or sex. In the US, most elementary reading textbooks in the eighteenth and nineteenth centuries were authored by single individuals, with a few having two authors, or (rarely) three. By the early part of the twentieth century, most readers had two or three authors, by the 1950s, four, and by the 1970s, as many as eight authors and instructional consultants (Woodward 1986).

4.4 Marketing and Adoption

In many countries, including some with national ministries of education, textbooks compete in a partially open marketplace. The selection of textbooks for schools, however, is often enshrouded in a complexity of national, regional, and local politics. In the US, where local control of schools and lay control of the school curriculum are fundamental tenets of the educational process, school board prerogatives for textbook selection often clash with particular citizen interests as well as with state and national politics. State-wide adoption practices, initiated originally for both economic and political reasons, have led to several heavily populated states (e.g., Texas, California) exerting unwarranted influence over the entire elementary and high school textbook trade.

5. The Future of Textbooks

In a science fiction classic entitled *A Round Trip to the Year 2000 or a Flight through Time*, written by Cook (1903), news and novels in the year 2000 are no longer printed. Instead central 'bureaus' transmit voice recordings upon request from phonographic records. However, textbooks still exist and specific mention is made of a 'text-book on Applied Psychology which has a place in every school in the nation' (Cook 1903/1974, p. 109). Whether the projected survival of textbooks was considered as a positive or negative factor by the author is not known; however, while daily newspaper reading has declined steadily since the early 1950s and the novel has been declared dead at various times over the past decades, textbooks have continued to thrive at all levels of education and in all countries where formal education exists.

In the 1960s the main threat to the existing form of textbooks was the programmed textbook, a dull, tedious approach to sequencing subject matter in baby-sized bites, based on the behavioral conditioning studies that the psychologist B. F. Skinner performed with pigeons and rats (Reid 1969). In the 1980s computer-assisted instruction was offered as a high-tech alternative to textbooks and to teacher directed instruction, with the promise that each student could progress at his or her own pace—a goal that was seldom challenged by educators. Today the World Wide Web (WWW), hypertext, and inexpensive, book-sized computers that can display texts on high quality displays, are the assumed replacements.

For the developing world, which is still struggling to recruit and train sufficient numbers of teachers and to provide adequate buildings for schooling, the provision of textbooks written in the national languages and appropriate for their cultures remains a challenge. Similarly, smaller industrialized countries would like to find inexpensive approaches for producing or adapting tertiary textbooks to their languages rather than importing them. Finally, for the historian, the preservation of textbooks remains an issue. Few, if any major research libraries are willing to invest resources in preserving and cataloging textbooks,

particularly elementary and secondary ones. Fortunately, a number of newer research centers and projects for the study of textbooks have been funded, including the Japan Textbook Research Center, The Teaching Resources and Textbook Research Unit in the Faculty of Education at the University of Sydney, Australia, the UNESCO International Textbook Research Network (in cooperation with the Georg Eckert Institute in Germany), and the Textbook Colloquium in the Open University Faculty of Arts in the UK.

Thematic Maps in Geography

As the name implies, a 'thematic map' addresses a specific theme, such as health or climate. The theme can be narrowly focused, as for a map showing infant-mortality rates for a specific year, or comparatively broad and complex, as for a map relating health-care delivery and mortality. In both function and content, thematic maps are fundamentally different from navigation maps, which serve the way-finding needs of drivers, pilots, sailors, and tourists, and general-purpose or reference maps, which portray a diverse set of basic features such as coastlines, rivers, terrain, cities, transport routes, and political boundaries (Robinson and Petchenik 1976). (For a discussion of other types of maps, see *Ethnic Conflict, Geography of*). Comparatively rare at the outset of the nineteenth century, thematic maps as a group have become more numerous, varied, and intellectually richer than either of these other two types (Robinson 1982). This article examines the distinctive elements of thematic maps, including principal strategies and pitfalls.

1. *Elements of Thematic Mapping*

Thematic maps have two main components: a thematic overlay, and a base map. Typically, the base map is already available in a cartographic database or collection of general-purpose maps, whereas the thematic overlay consists of data from a noncartographic source, such as field observations, a government census, or a thematic database. After selecting or specifying a base map with an appropriate geographic scope, map projection, scale, and reference features, the map author adds the graphic symbols and labels that portray the map's unique theme, as shown in Fig. 1. Consisting largely of structural and background information, the base map is usually less visually prominent than the thematic overlay, which focuses on a specific distribution or relationship.

1.1 *An Appropriate Map Projection Is Essential*

Because the earth is spherical and most maps are flat, the base map distorts the geometry of boundaries and other reference features (Maling 1992). The amount of distortion depends in a large measure on the map's 'scale,' defined as the ratio of distance on the map to distance on the earth. On a 'large-scale' map covering a neighborhood, an archeological excavation, or other small area for which the earth's curvature is minimal, the distortion can be negligible. By contrast, a 'small-scale' map covering a continent, a hemisphere, or the entire world must distort large shapes as well as most distances and directions, and might also distort areas and angles. But by selecting an appropriate projection, the map author can avoid distortions likely to mislead readers.

The world map in Fig. 1 illustrates the distortions of the '*plate carrée*,' or 'plain chart,' a map projection for which locations are easily reproduced on a sheet of graph paper. This particular perspective is 'developed'

Figure 1
A thematic map consists of a base map and a thematic overlay. On this base map a *plate carrée* projection affords true scale along the equator and all meridians

Figure 2
The Peters (upper right) and Goode's (lower left) projections are 'equivalent' projections, which preserve areal relationships. In contrast, the Mercator projection (upper left), which is 'conformal,' preserves angles and small shapes but severely distorts the relative areas of continents and countries. The Robinson projection (lower right), which is neither conformal nor equivalent, offers low distortion of angles and areas, except in relatively unpopulated polar regions

by shrinking the earth to a globe, and then projecting meridians, parallels, and other features onto a cylinder wrapped around the globe and tangent at the Equator. The globe establishes the projection's 'stated scale,' which for most 'cylindrical projections' is valid only where the cylinder is in contact with the globe, in this case along the Equator. Distinctively the *plate carrée* also provides true scale along all meridians, so that north–south scale is constant, and the parallels, like the meridians, are uniformly spaced. Because the meridians do not converge, as on a globe, the east–west scale grows progressively larger with increasing distance from the Equator, so that the map not only inflates the areas of Europe, North America, and other middle-latitude regions, but also portrays Antarctica as twice the size of South America, which is appreciably larger. Even so, the projection offers a comparatively reliable portrait of Africa, which straddles the Equator.

Base maps with severely distorted areas can misrepresent seriously the extent and importance of thematic information (Monmonier 1993). For instance, the *plate carrée*, if used for a map of fertility, automobile ownership, or other phenomenon with marked differences between mid-latitude and tropical countries, will overstate the incidence of patterns occurring in North America, Europe, and Australia, while underrepresenting patterns in Latin America, Africa, and southern Asia.

The Mercator projection (in the upper-left part of Fig. 2) fosters even more egregious areal distortions. Designed to render lines of constant direction as straight lines—sailors and pilots can plot a course as a straight line, and read its bearing with a protractor—the equatorially-centered Mercator projection increases the poleward separation of the parallels steadily so that Greenland looks as large as South America. Because the north–south scale increases to infinity at the poles, which are never shown, the grid in Fig. 2 is truncated at 80° N and 80° S. (More potentially misleading versions of the projection show

only half of Greenland and omit Antarctica altogether.)

Area distortion can be especially troublesome for a 'dot-distribution map,' on which equal-sized dots represent a fixed number of people, hogs, or hectares of wheat. On this type of map, closely spaced dots indicate a higher density than widely separated dots. An accurate portrayal of relative density thus depends upon a base map with little or no areal distortion (Monmonier 1996). For example, if regions A and B, in different portions of the map, each contain a hundred evenly spaced dots within a square centimeter, viewers will assume their densities are similar. But on an inappropriate base map, this apparent similarity could be an artifact of the map's projection: for example, if a globe shows region A, notably farther from the Equator, as only half the size of region B, the exaggerated relative size of region A on the map will have spread its dots farther apart and reduced the apparent density.

Map authors can avoid misleading impressions of density and relative importance by choosing an 'equivalent' projection, designed to preserve areal relationships. 'Equivalency' is one of several properties with which map projections avoid specific kinds of distortion (Snyder 1993). Although all map projections distort most distances, 'equidistant' projections show true distances along straight lines converging on a point at the center (often but not necessarily one of the poles). Although map projections distort most directions, an 'azimuthal' projection displays true relative bearings for all shortest-distance, 'great-circle' routes converging at its center. Although map projections typically distort angles, 'conformal' projections show true angles as well as true shape within very small neighborhoods of every point: a property useful on small-scale weather maps, where angles between fronts, equal-pressure lines, and wind arrows are especially important, and on large-scale topographic maps, which cover small areas in detail and need to minimize distortion of shape and distance. Unfortunately, 'equivalency' and 'conformality' are mutually exclusive. Moreover, equivalent projections distort shape severely on world maps, whereas conformal projections (such as the Mercator projection in Fig. 2) greatly distort area.

The other three projections in Fig. 2 illustrate the trade-offs confronting a map author who needs to choose a world base map for a thematic overlay. The Peters projection (upper-right part of Fig. 2) is one of many equivalent projections with a rectangular grid. Although touted by pro-Third World and human rights groups in the 1970s and 1980s (Crampton 1994), its distinctive combination of severe east–west stretching near the poles and marked north–south stretching near the Equator yields gaunt, noticeably distorted shapes for Latin America, Africa, and most tropical countries, but provides comparatively accurate renderings of the UK, Germany, and other countries closer to 45° N and S. By contrast, Goode's homolosine equal-area projection (lower-left part of Fig. 2) is a composite of 12 locally centered projections that interrupt the oceans in order to describe more accurately the shapes of continents and other land features. A distinctly different trade-off is apparent in the Robinson projection (lower-right part of Fig. 2), which is neither equivalent nor conformal. By tolerating small amounts of areal distortion, mostly near the poles, the Robinson map lessens the distortion of large shapes without interrupting the oceans.

1.2 Appropriate Visual Variables Are also Essential

Verbal and graphic languages are complementary. Words in a thematic map's title, key, and caption link the symbols to natural-language terms and concepts, and are no less important than the lines, 'fill patterns,' and other graphic marks representing features, categories, and data values. But because map readers are almost always more skilled in the conventions and vocabulary of verbal communication, the map's effectiveness often hinges on its author's understanding of fundamental graphic concepts, particularly the appropriate use of visual variables.

Jacques Bertin (1983), a French semiologist who proposed a formal theory of graphic language, recognized eight visual variables: the two 'locational variables' (X-Y coordinates) for describing position on the paper or computer screen, and six 'retinal variables' for portraying a feature's character or category: size, shape, orientation, texture, hue, and value. Of the six, the latter three require clarification: 'texture' refers to the spacing of individual elements in a dashed line or set of parallel lines, 'hue' concerns readily apparent distinctions among blue, green, orange, red, and other named colors, and 'value' pertains to the relative lightness or darkness of a color or gray-tone. Although cartographers employ other retinal variables, such as numerousness, movement, and duration, Bertin's original six account for most symbols on thematic maps (Dent 1999).

Whether a symbol is appropriate depends in part upon whether the data are qualitative or quantitative. For countries or neighborhoods, area symbols varying in hue can be most efficient for qualitative themes such as dominant religion, native tongue, or type of agriculture, whereas a light-to-dark sequence of gray-tones is generally more effective for quantitative differences, as on maps showing local proportions of dairy farms, Roman Catholics, or Francophones. On a map of language regions, for instance, red for English and blue for French underscore differences in kind by looking quite different, at least to viewers with normal color vision. By contrast, shades of gray rely on the ink-intensity metaphor whereby a gray-tone representing 51–65 percent, for example, is at least noticeably darker than a gray-tone representing 36–50

Figure 3
Comparative treatments of count (left and center) and intensity (right) data with symbols varying in size (left) and value (center and right). Misuse of intensity symbols for count data on the center map yields a misleading pattern, In this example, a visibility base map affords clearly readable symbols for Delaware, Rhode Island, and the District of Columbia

percent. Among the retinal variables, hue and shape are better suited for qualitative differences, while size and value are more appropriate for quantitative differences. Orientation is best reserved for showing differences in direction, as with flow lines on a traffic map (Szegö 1987) or wind arrows on a weather map, while texture can reinforce or mimic value, as when closely spaced parallel lines make a fill pattern look darker than a similar symbol with more widely spaced lines.

Quantitative variables require a further distinction between count data and intensity data. Gross national product, tons of steel, and numbers of infant deaths are examples of count data: magnitudes represented most effectively by symbols varying in size so that bigger means more. By contrast, national income per capita, the percentage increase in steel production between 1990 and 2000, and the infant mortality rate are examples of intensity variables, better served by the darker-means-more metaphor of ordered gray-tones or single-hue colors.

Figure 3 illustrates the need to distinguish between count and intensity data. All three maps address infant mortality in the eastern half of the USA. At the left, proportional circles describe differences in the number of infant deaths; a bigger circle unambiguously represents more infant deaths than a smaller circle. In the center, a gray-tone treatment of the same data yields a potentially misleading map with dark, ominous-looking symbols for states with relatively large numbers of deaths and comparatively light symbols for states with few deaths. Stark differences in gray-tone thus suggest a health crisis in New York, Florida, and other relatively populous states, and comparatively benign conditions in moderately populous states like Alabama and Mississippi. By contrast, the gray-tones in the right-hand map offer a far more accurate portrait of geographic variations in the infant mortality rate, which adjusts infant deaths for the number of live births. On this last map, dark symbols for Alabama and Mississippi reflect two of the highest infant death rates in the nation, while New York and Florida register markedly lower (although moderately high) rates.

2. *Principal Cartographic Strategies*

Although thematic maps constitute a rich cartographic genre, any moderately conscientious examination of atlases, government publications, and scholarly books and articles will confirm the prevalence of a small number of graphic strategies, collectively appropriate for most needs (see *Cartography*). This section of the article identifies the more common varieties and their primary uses.

Aside from location maps, which are more topographic rather than thematic, the most common thematic map is the 'choropleth map,' in which area symbols representing specific categories completely fill the boundaries of countries, provinces, census tracts, and other areal units. Although some choropleth maps are qualitative, most are quantitative, largely because censuses and other systematic surveys have generated

Figure 4
Area cartograms adjust the size of areal units according to a transforming variable such as population. Contiguous cartograms may distort shape severely, whereas non-contiguous solutions preserve shape but lose contiguity

enormous amounts of numerical data for areal units. As the rightmost map in Fig. 3 illustrates, quantitative choropleth maps require intensity data as well as a coherent, light-to-dark series of ordered gray-tones or colors with little, if any, variation in hue. A principal exception is the map showing rates of change, for which contrasting hues, such as red and blue, can distinguish efficiently increases from decreases, while a variation in value differentiates larger rates from smaller rates (Brewer 1997). Because different classifications of the data can yield radically different spatial patterns, the efficiency and effectiveness of a choropleth map depends heavily on its categories (Evans 1977). A wise practice, often ignored, is the use of inherently meaningful category breaks, such as zero on a map of migration rates, or the national mean on a map of per capita incomes by province (Monmonier 1993).

Other common symbols for displaying quantitative data include proportional circles (as in the left-hand map of Fig. 3), 'pie charts' (circles divided into sectors representing subcategories with different hues), and small, equal-sized dots. On a dot-distribution map, each dot represents the same amount, ideally chosen so that the dots barely coalesce in the most dense area. On transportation maps, line symbols describe routes or flows, line width reflects volume of traffic or relative importance, and hues distinguish among highways, railways, and pipelines.

Some thematic maps demand specially tailored base maps (Southworth and Southworth 1982). For London, New York, and many smaller metropolitan areas, 'linear cartograms' of subway or bus systems represent individual routes with highly generalized lines varying in hue. By altering the map projection radically, linear cartograms afford greater detail in the central city, where routes converge and stops are closer. By contrast, on an 'area cartogram', the symbols representing countries or provinces vary in size according to population, wealth, military strength, or some other transforming variable. As Fig. 4 illustrates, contiguous area cartograms may require severe distortions of shape, whereas non-contiguous area cartograms sacrifice contiguity for shape (Olson 1976). In addition to dramatic demonstrations of international disparities in wealth or defense-spending, population cartograms provide a 'demographic basemap' useful for choropleth maps of public health and socioeconomic data (Dorling 1994). Adjusting the base map for differences in population diminishes the exaggerated impact of large units with small populations and ensures visible symbols for small, densely populated places. Another strategy, not based on population, is the 'visibility base map' (illustrated in Fig. 3), which merely provides readable symbols for small, otherwise obscure areal units.

Theory: Conceptions in the Social Sciences

1. The Main Postwar Ideal—The Deductive–Nomological Notion of Theory

The notion of theory plays a crucial role in social science, as in any science. But few social scientists have discussed the term in a philosophy of science framework. Even fewer have asked whether the term has the same meaning in all social science. Instead, tense debates have raged, with opponents implying—but not explicating—different understandings of theory. Attempting a classification, we find one ideal notion of theory together with four different understandings of theory, all of which have been influential in the social sciences.

The ideal notion of theory dominated postwar science. It originated from early twentieth century positivism. It generalizes the procedures of experimental natural science, physics above all. Two elements are crucial: first, the idea of logical deduction in axiomatic systems: theorems are deduced from a limited number of axioms. Second, a correspondence criterium of truth: empirical sciences depend on correspondence with facts (sense data), which represents a mind-independent external reality (philosophical realism). The deductive system generates hypotheses that are potential universal laws.

Given the laws, it is possible to specify a set of initial conditions under which a predicted result should follow. In an experiment, these conditions are established. If the result confirms the prediction, the hypotheses (laws) are strengthened. The experiment shows that the law represents general knowledge on how the initial conditions cause an outcome. This is also called the covering law model of explanation: the law is the black box that transforms causes into effects. Theory is a set of such laws. Theory is compact knowledge: many regularities can be subsumed under the same general law, making research systematic and cumulative. Such a notion of theory provides a clear-cut criterium of demarcation: testing of law-based deductions. Explanations, which do not satisfy this criterium, are *ad hoc* explanations and must be avoided.

Theory is thus an ever more complete system of universal laws. At the extreme end lies the vision of a complete unity of science possessing nomological knowledge of reality in its entirety. There are nuances between various 'positivist schools,' including very complicated philosophical disputes concerning the notion of causality, which cannot be dealt with here.

In the postwar period, the critical rationalist version of the deductive–nomological ideal, first argued by Karl Popper, has dominated: no theory can ever be verified, only falsified. Theories are not just generalizations; they are hypotheses on universal relations that have so far not been falsified. In later decades, the force of the deductive–nomological notion has been

Table 1
Four notions of theory in social science

	Law oriented	Idealizing	Constructivist	Critical theory
Committed to the deductive-nomological ideal	+	+	÷	÷
Accepts that sciences studying human actions are distinct from generalizing natural sciences	÷	+	+	+
Accepts that ethical fundamentals matter for social science theory	÷	÷	÷	+

weakened, even in the natural sciences. Philosophers of science now discuss much more sophisticated criteria of demarcation; it is also admitted that the notion tells us little about nonexperimental natural sciences like evolutionary biology. However, it seems that in the social sciences, the original and very restrictive notion has retained its status as a regulatory idea.

This is a paradox, since the results of social science's search for universal laws have been disappointing. Merton's (1949, p. 108) statement is as relevant today: 'sociologists (including the writer) may discuss the logical criteria of sociological laws without citing a single instance which fully satisfies these criteria.' If an instance is quoted, Durkheim's statement on the relation between social cohesion and suicide is probably the most frequent choice. But it remains contested whether that 'law' has served social research on suicide in ways that can be compared with the ways in which laws on gravity, thermodynamics, etc. have served natural science. This notion of theory may be sustained if social science could be reduced to natural science. We cannot here specify the various forms of reductionism (physicalism, biologism, psychologism), but if the joys, sorrows, memories, identity, and free will of humans could in some way be analysed as 'no more than the behavior of a vast assembly of nerve cells and their associated molecules' (Crick 1994, p. 3), then social scientific statements could be reduced to natural scientific statements. Although some scholars hold that such a reduction is in principle possible, very few claim that it can be achieved in practice. This topic, however, will not be discussed further here.

As long as no such reduction has been achieved, we must be aware of the paradoxical influence of the deductive–nomological ideal: it has had an enormous influence as a regulative idea, but there is hardly a single example of its successful application in social science. In practice, social scientists adhering to the ideal have applied two different modifications of the ideal: we shall name them the law-oriented and the idealizing notions of theory. Opposed to these notions are the constructivist and critical notions of theory, implied by scholars who do not accept the deductive–nomological ideal.

These four notions have all been influential and involved in applied social science research in the postwar period. Besides their differing commitment to the deductive–nomological ideal, Table 1 shows how they differ on two other counts: on the question of whether the fact that the social sciences study human actions makes any difference, and on the question of whether ethical foundations matter for theory.

2. *The Law-oriented Notion of Theory*

This notion retains a nomological focus at the cost of deductive rigor. This solution can be related to an ambiguity in Popper's original discussion. Despite his support for the covering law model, Popper was critical of the unity of science program. He rather accepted the distinction between generalizing sciences and history. Causal explanations in history relate to singular events, and universal laws here prove empty.

> For the theories or universal laws of generalizing science introduce unity as well as a point of view; they create, for every generalizing science, its problems, and its centres of interest as well as of research, of logical construction, and of presentation. But in history, we have no such unifying theories; or, rather, the host of trivial universal laws we use are taken for granted; they are practically without interest, and totally unable to bring order into the subject matter (Popper 1942, p. 264).

Popper notes particularly that such trivial laws do not define the initial conditions. Popper mostly classified social science together with the generalizing natural sciences. But at times he also regarded social sciences as specifying. The law-oriented notion of theory emerged as a response to this dilemma. The deductive–nomological ideal is retained: social science is seen as generalizing, distinct from the historians' focus on singular processes. But it is admitted that universal laws in the social sciences have proven trivial. Social science must still generalize, but given the absence of truly universal laws, we should focus instead on regularities that apply only within specific contexts. Such a notion of theory as a collection of 'law-like regularities' or 'quasi-laws' is less strict than the deductive–nomological ideal.

In this understanding, the difference between a theoretical hypothesis and inductive generalization evaporates, as does the distinction between 'theoretically based' and '*ad hoc*' explanations. Law-like or bounded regularities are difficult to separate from boundary conditions, since these conditions themselves enter into the definition of the law-like regularities. It is thus hard to devise decisive experiments, even in cases with no ethical obstacles to experiments involving fellow humans. If a theory (a set of quasi-laws) does not explain (is falsified), it will always be possible to argue that slightly different initial conditions applied. In addition, such bounded regularities are also more easy reconcilable with statistical generalizations than the strictly determinist notion of a covering law is.

Merton (1949), one of those who sense the gap between his own methodological ideals and the ways in which social scientists really proceed when they explain something, introduced the notion of middle range theories for such explanations. Middle range theories were legitimated by reference to the deductive–nomological ideal, but allowed contextual explanations unrelated to universal laws. This was the main methodological conviction in all branches of variables-oriented social science in the postwar period.

The dissonance between the deductive–nomological

ideal and real-life explanatory strategies Merton solved by treating middle range theories as temporary. He claimed that the social sciences were still too young. When they matured, as physics already had, the body of middle range theories would converge into a system of universal laws on the model of experimental natural science. Until social science matured, he concluded, it should give priority to middle range theories, deliberately avoiding universal theory. On this notion, the social sciences would be weak on deductive rigor and parsimoniousness, but strong on contextual explanations.

3. *The Idealizing Notion of Theory*

All through its history, the social sciences have been haunted by debates on methods, always returning to the question of whether the subject matter of the social sciences—human action, intention and meaning—require a specific approach to theory. This line of argument made possible another modification of the deductive–nomological ideal, one that retained deductive rigor by replacing law-orientation with idealization.

As a human being, the social scientist has the capacity to understand motives involved in actions and interaction. But these motives cannot be conceived as universal laws without exceptions. Even the simplest economic regularity—that demand increases when the price decreases—has its exceptions. Trying to transcend the dichotomy between nomothetic and ideographic approaches in the German *Methodenstreit*, both Max Weber and Georg Simmel emphasized that laws in the social sciences are ideal types, idealizations of human motives.

These idealizations are often formalized in axiomatic systems. In the law-oriented notion of theory, emphasis was on the experimental criterium of correspondence to facts. In the idealizing notion, the emphasis is rather on the other feature of the covering law model: deduction in axiomatic systems. While law-oriented researchers want to retain a notion of laws by specifying all conditions, idealizing researchers hold that it is impossible to describe 'all the sets of circumstances' (Boudon 1986, p. 65) in which an idealization applies.

They thus focus on the conditions that establish the ideal situation. Under such stylized conditions, human interaction can be understood via mathematical modeling of parametric and strategic rational action (game theory) (Elster 1983). This is the way the most prestigious postwar branch of social science, neoclassical economics, has always gone about. The program of rational choice theory—particularly influential in political science and sociology since the 1980s—strives to generalize such procedures in the other social sciences. This is often formulated as a program for 'methodological individualism,' according to which the human actor is the basic unit in social science explanations.

In these idealized models, the researcher is she who is in extensive command over the initial conditions, notably the preferences that are plugged into the models. These idealized conditions are 'theoretically interesting,' but they do not occur frequently (Boudon 1986, p. 67). It is thus crucial to distinguish social science models from natural science laws: the former yields predictions in an idealized world (classical economists often regarded this as a 'natural order'), but only in a very limited number of real situations. In contrast, the law of gravity applies very widely and in cases of flying objects such as birds or airplanes, the physicist can readily define the conditions for this deviance. 'A law applies to all cases, a model to ideal, that is, to particular cases' (Boudon 1991, p. 68).

Parsimoniousness and deductive power here comes at the cost of a gap between models and the real world. By constructing idealized models, social scientists use their skills in calculating, inferring, idealizing, and guessing with respect to human intentionality. If the model is to be fully idealized, perfect knowledge must be assumed. The scientist assumes perfect knowledge of the knowledge possessed by the actors of her model world. Both the scientist and the actors in the model world are omnipotent. A dilemma in this approach to theory is thus that these very strong assumptions must be relaxed if the model is to claim any empirical relevance. This relaxation makes the models highly complex.

This gap between model and explanation seems even harder to bridge than the theory–explanation gap of the law-oriented approach. But scholars who are concerned about explanatory relevance try to bridge it. They then end up in a methodological compromise quite similar to that of middle range theories (cf. recent discussions on the concept of mechanisms, starting with Elster 1983). The move to the middle range level mostly also implies relaxed assumptions about knowledge, sometimes bringing them quite close to the constructivist position, which shall be presented below.

The two modifications of the deductive–nomological ideal—law-orientation and idealization—have different advantages. But often, the distinction between them is not made, and scholars strive to have it both ways, that is to discover law-like regularities through idealized models. Such attempts (e.g., Elster 1983, Goldthorpe 1996) should be regarded as attempts at synthesis, and be judged with reference to the differences between generalization and idealization, as traced above. In addition, other differences between the two modifications should be taken into account: they also differ with respect to their implied notions of causality. Models of parametric and strategic rationality are mostly simultaneous equation models. While it may be claimed that any equation implies a causal relation, such general interdependence is a looser

notion than the mechanical notion of causality—requiring temporal asymmetry—implied in the law-oriented understanding of theory.

4. The Constructivist Notion of Theory

The term constructivism has many meanings. In philosophy, it is related to a long tradition of skepticism, in our century known under labels such as pragmatism and phenomenology. In the social sciences, more special schools are called constructivist. For the purpose of this survey, a constructivist notion of theory is defined with reference to its questioning of any foundation for the social sciences: Not only is the deductive–nomological ideal rejected, it is also implied that no alternative ethical foundations can be found (Table 1). It should be noted that this constructivist position has not been systematized to the same extent as the deductive–nomological notion of theory. What follows, then, is a synthetic presentation based on several statements that may differ with respect to important details.

Compared with the law-oriented and idealizing notions of theory, the constructivist approach entails a very different notion of knowledge. The deductive–nomological ideal provides a strict separation between scientific knowledge and everyday knowledge. According to the constructivist position, in contrast, the line of demarcation between science and everyday knowledge is 'fuzzy.' Social science theory is not in principle different from everyday knowledge! It may differ in degrees, but since scientists are themselves human beings, their knowledge is also embedded in their everyday life. This is because also science is a human collective, research groups are communities, and their knowledge is the bounded knowledge attained by interacting human beings. Any demarcation of social science is seen as a result of social processes, and thus relative.

Originating in skepticist epistemology, such a notion of knowledge has been implied by many schools in the sociology of knowledge. More recently, interdisciplinary cognitive science has also been a major inspiration to constructivism. Such a notion of theory does not draw its main notions from the routines of experimental natural science, but from the study of knowledge, communication and information in society at large. It also has a strong relationship to applied studies of social problems, which study how social processes define the problems and risk perceptions that create demands for social science research.

Science cannot be easily demarcated, so social processes define (construct) certain realms of knowledge as science. Attempts to apply strict demarcation criteria implies a focus on testing of theories, while constructivists mainly focus on theory formation, studies of the disciplines and professions into which knowledge production is organized, and of continuing struggles to define what science (theory) is. Relations of trust, authority, tacit knowledge, processes of exclusion, and rhetorical strategies influence the scientific community. As Kuhn (1970, p. 21) emphasized, the explanation of scientific discoveries must 'be psychological or sociological … a description of a value system, an ideology, together with an analysis of the institutions through which that system is transmitted and enforced.'

Certainly scientists work in a social subsystem which encourages analytic rigor, systematization, quest for consistence, democratic access to research results so that they can be replicated, etc. But still science is not qualitatively different from everyday knowledge; not something normatively sacred pursued independently of society at large. A sociologist of knowledge may study the deductive–nomological ideal of theory as a powerful rhetorical figure in the contest on how to define science.

We have seen that there was a particularly strong connection between economics and the idealizing notion of theory. The constructivist notion of theory has a particularly strong affinity to anthropology. It is critical of methodological individualism, emphasizing the crucial role of shared knowledge. A strong version of the constructivist position argues that any normative definition of 'science' is in principle not different from the myths found, e.g., in tribal societies studied by anthropologists.

In our everyday interaction, we agree on a view of reality. Such is the case among scientists too: physicists, for instance, use a number of concepts which cannot be 'seen' as facts in reality (force, field, atoms, electrons, quarks). These entities are studied through complex experimental equipment, e.g. particle accelerators. But scientists agree on the reality of these entities. Thereby, they retain their culture, just like other human communities. In tribal societies, people believe in other kinds of entities, but the claim that these entities are real, is quite parallel (Barnes et al. 1996, p. 84). Even in the hardest of sciences, the process of discovery implies visions, analogies and other features that are also found in religious or mythical world views.

Kuhn's famous notion of paradigms is in line with such a view: paradigms are exemplars, synthesizing in them theoretical discussion, experimental practice and instrumentation. It is a 'disciplinary matrix' with three main components: a specific symbolism that allows formalization, specific models for connections in the research field (from heuristic analogies to causal claims) and master examples, exemplary solutions derived from experimentation and research. The members of specific research communities are socialized into such a matrix via education and recruitment procedures (Kuhn 1974).

Theory is here understood in continuity with the formation of everyday knowledge. Observing some-

thing unfamiliar, we try to understand it in the light of what we already know. We use analogies, extending these to new areas. Such an extension always also implies adjustments. A famous case from the history of science is Darwin, who formulated his theory of natural selection by extending an analogy based on a view of the market mechanism implied in Malthus' theory of population.

Social science has often seen debates on which analogies to allow: the idealizing notion of theory prefers game-theoretical and mathematical analogies, and has been quite skeptical of functionalist theories that extend analogies based on the biological organism. Constructivists rather emphasize that a much larger diversity of analogies exists to be extended in the service of better explanations of social affairs. Interestingly, even Merton notes that middle-range theories start from some notion and its 'associated imagery.'

The idealizing notion of theory emphasized the similarities between social science and history. In the constructivist notion, not only history, but all of the humanities are seen as highly relevant to theory formation in the social sciences. History is the specifying science of singular events, tracing complex causal chains involving both intentions and social structural forces. These chains are reconstructed as narrative sequences, unpredictable in advance but understandable in retrospect (Ricoeur 1986). The historian's craftwork is to interpret the motives of the actors in their historical context, that is to imagine the everyday reality of historical actors. Similarly, the majority of anthropologists define their task as 'thick description' (Geertz 1973) of how everyday action is embedded in more or less local cultures. The various phenomenological, ethnomethodological, and symbolic interactionist (Glaser and Strauss 1967) strands within sociology share such a perspective.

In addition, most poststructuralist approaches imply a constructivist notion of theory: the basic structure of everyday knowledge is here conceived as discourses, which are analyzed by means of analogies drawn from linguistics. Social science theories are embedded in such discourses. As parts of such discourses, the social sciences influence the practices of institutions, media, professions and disciplines of our modern society.

Constructivists agree with the idealizing approach that social science study meaningful human action. Meaning is irreducibly linked to human interaction, which is crucially mediated by symbols and language. The social sciences thus face a challenge that does not bother natural science: how to access the symbolically mediated meaning, motives, preferences, identities of interacting human beings. The idealizing position tackles this challenge by making strict assumptions about knowledge. In contrast, the constructivist focus on everyday knowledge implies that knowledge is always limited, and so rationality is always bounded. The notion of theory is not linked to the ideal of perfect knowledge. Theories do not take the form of axiomatic models, but of contextual understanding of interacting motives (as, e.g., in Goffman's notion of an interaction order). Social science theories are social products; they are sometimes drawn into complex social constellations where other individual or collective actors pursue their own strategies. Theories may influence real developments, but they rarely predict them!

In this notion of theory, the gap between theory and explanation, between models and their empirical application, is minimized. Since all knowledge is limited, any theory is 'middle range'! That label is unnecessary since there is no assumption of a complete, full range theory. Since we do not possess coherent deductive theories accusations of *ad hoc* theorizing are misplaced. Theories are processes (Glaser and Strauss 1967), they cannot be accumulated as a stock of knowledge; they are not specific enough for direct application and they change over time. They do not provide clear-cut accounts of an external reality, since—even if we assume that such a reality is 'out there'—any such allegedly unequivocal representations will eventually be contested. At the extreme end of the constructivist spectrum are positions such as ethnomethodology and poststructuralism, that question any effort to establish theories above the level of the specific case. In particular, poststructuralists attempt to deconstruct any theory in order to celebrate relativism. Other scholars that fall under our broad heading of constructivism hold more moderate positions. Some have even adopted the term realism— e.g., 'pragmatic' and 'non-representational realism' (Pickering 1995, p. 181)—to emphasize this difference.

The deductive–nomological ideal, in this view, leads social science astray by implying that science should converge towards complete knowledge of the laws governing an external reality. Quite the contrary, social science has never seen anything like, e.g., the theory of relativity, social scientists tend to use the modest label 'a theory of … .' Constructivists argue that this plurality of theories should not be regretted, more theories would lead to better explanations (Glaser and Strauss 1967).

The constructivist approach—which we have here defined very broadly—does not generate very parsimonious theories, but by resisting any kind of decontextualization, it often proves strong on explanation. The lesson is that careful consideration of context and motives—structure and action—can never be dispensed with.

5. *Critical Theory*

The constructivist notion of theory is frequently accused of relativism: by devaluing the correspondence to an external reality, constructivism allegedly

implies that the most influential groups in the social system define what scientific theories are. This view is a provocation to the covering law tradition, whose notion of theory was actually designed to expose as pseudo-science fascist theories about such things as the 'fate of a people.' But with the role of nuclear physics in developing nuclear arms, and more broadly, the use of science as legitimation of technocratic rule, criticism rather turned against those who wanted to base social science methodology on the model of experimental natural science.

In this context, J. Habermas (1970) and others revitalized the interwar (Frankfurt School) program of critical theory. This position agrees to the rejection of the deductive–nomological approach, but insists that constructivism must be cured of its relativism by reference to an ethical foundation defined by communicative ethics. This internal linkage of theoretical and ethical reflection sets critical theory apart from the other three notions of theory (Table 1).

The social sciences are related to human interaction, involving understanding based on language. Since it should in principle be possible to agree peacefully in disputes between human beings, a communicative ethics is implied in all social interaction, the social sciences included. The evolution of modern society has enlightened the humans, equipping mankind with a set of human rights. Wherever these are not respected, social movements may form, legitimating their strategies with reference to solid ethical principles. Habermas regards this consensus–criterium of truth as an alternative to the mainstream criterium of correspondence. Social science is defined not by its stock of universal laws, but by its commitment to universal ethical principles. Since the reality studied by social science consist of interacting humans, the truth of its theories cannot be determined by correspondence to the present state of affairs, since social mobilization may prove this state of affairs to be unjust. Since also the social scientist is a participating actor, she cannot139 refrain from making her own judgment on this question.

The mobilization of social movements creates increased public attention to the life situation of certain social groups, supporting claims of equality (universal suffrage, equal social rights, etc.). The standard example is the labor movement, which according to classical nineteenth century Marxism was the 'critical subject' whose interests coincided with the universal interests of mankind. Marx himself, in fact, combined a sociology of knowledge with a law-oriented approach: he exposed 'bourgeois' economists by claiming that their theories were constructions based on the special, nonuniversal interests of their class. Only scientists who related to universal interests could provide an 'objective' understanding of the manmade world, of the 'laws of motion' of contemporary society. Later Marxist philosophers of science and others who try to fuse inspiration from the sociology of knowledge with anti-constructivist realism (Bhaskar 1978, Bourdieu 1990) have taken up this idea. In this survey, however, the features that unite critical theory and constructivism are emphasized.

In the postwar twentieth century, several feminist theorists claimed that the women's movement at that time played a role similar to that of the nineteenth-century labor movement. Fusing such an emphasis on women's 'standpoint' with a phenomenological focus on everyday knowledge, Smith (1990) criticized the male bias of all established sociological theories, using the common female experience of housework and child-rearing as a standard.

This position was countered by feminist theorists who link up with poststructuralism (Scott 1988), claiming that the idea of a standpoint serving as a basic foundation of theory is in itself a construction, as relative as others. More generally, the whole dispute between modernists and postmodernists in contemporary social theory—dating at least back to Habermas' (1985) attack on the poststructuralists, and on Foucault in particular—can be seen as a controversy between critical and constructivist notions of theory.

Critical theory has focused more on ethical foundations and less on concrete paradigms involved in the explanatory efforts of applied social science. Habermas (1968) distinguishes the action sciences from empirical–analytical (natural) sciences and historical–hermeneutic sciences. These are driven by different 'knowledge interests': technical dominance (natural science), maintenance and extension of intersubjective understanding (historical sciences), and liberation. The latter, critical knowledge interest implies that to the extent that social sciences discover law-like regularities, these are evaluated through collective reflection on their legitimacy.

Habermas argued that adaptations of the deductive–nomological ideal of universal laws by social engineering-oriented social scientists turned science and technology into ideologies. The law-like regularities are reinterpreted: the very point that social science laws can never be universal is not regretted, but given an 'offensive' meaning. Their nonuniversal nature means that they can be changed by social action. Later, Habermas (1981) linked technocratic world views and also mainstream economics to the systemic imperatives of modern societies, while critical theories were connected to the defense of *Lebenswelt* against the system's 'colonizing efforts.'

Unique to critical theory is its explicit reflection on the ethical foundations of social science theory. Like constructivism, critical theory is weak on parsimonious theories, but in addition it is mostly also weak on applied explanations. In the latter respect, it may at times converge with the constructivist focus on unique historical sequences, at other times with the law-oriented approach, emphasizing the changeable nature of quasi-laws.

6. Conclusion

We can conclude that there are clear ties between substantial theoretical perspectives and notions of theory in the social sciences. A number of the fundamental debates on social science—between constructivists and realists, between critical theorists and constructivists, between methodological individualism and 'collectivism,' between rationalists and empiricists—in fact imply debates between different understandings of theory and of knowledge more generally. This should not surprise us: social science research is after all in itself a social activity.

The discussion of understandings of theory in the social sciences has brought us around a vast rectangular field. Two varieties of a very strict, formal, and demarcation-focused notion occupy the corners at the one end. A ratr loose, substantial, and middle range notion of theory is found in a third corner and an ethically conscious version in the last corner. Representatives of each side and even of the third and fourth corner in between them are mostly so mutually suspicious that possibilities of coexistence and even interaction are seldom considered. Disputes also tend to interact with distinctions between the separate social sciences. For instance, economists almost exclusively work with an idealizing notion of theory, while anthropologists mostly prefer a constructivist notion. Still, it is striking that the law-oriented approach focus on theory testing, the idealizing approach on modeling, the constructivist approach on theory formation and the critical approach on ethical reflection. Possibilities of crossfertilization cannot, however, be specified here. While one must not gloss over fundamental differences, such possibilities should be explored.

Theory in Archaeology

Archaeological theory is a vibrant tapestry of competing approaches and agendas which mutually constrain and enable one another. Some of these approaches have been imported wholesale from the humanities, social, and natural sciences, while others represent novel reformulations, or extensions, of ideas originally developed in these fields. There have even been some attempts to devise theory that is unique to archaeology. Because of this eclecticism, archaeology stands in a special relation to other disciplines as a testing ground for exploring the articulation of different theories and this is a source of archaeology's strength. This view of archaeology as multiplex implicitly challenges the popular idea that the discipline has developed in a simple linear fashion through a series of stages—for example, from culture-historical, to processual, to post-processual (Preucel and Hodder 1996). Indeed, it suggests that more nuanced and historical studies are needed.

1. The Archaeological Record

What is the archaeological record? This seemingly simple question masks a set of rather complicated philosophical issues which have been and continue to be debated within archaeology. Does the archaeological record consist of the material remains of past societies?; Is it comprised of samples of those remains discovered through survey or excavation; is it the written accounts of those discoveries; or does it refer to our conception of our relation to the past in the present? Three influential models have emerged in response to these questions—the fossil model, the behavioral model, and the textual model.

The fossil model is the view that the archaeological record is the repository of the physical traces of past human activity (Binford 1964). Artifacts, monuments, and buildings all potentially reflect the decisions of past actors and the workings of past social systems. This perspective is based upon the principle that human behavior is patterned, and that past behavior can be inferred, given prior knowledge of pattern-generating behavior. The transfer of meaning from a known context to an unknown one is facilitated by means of analogy (usually direct historical, specific comparative, or general comparative versions). This view is shared by advocates of culture historical archaeology as well as the early processual archaeology.

The behavioral model holds that the archaeological record is better understood as a distorted reflection of the past behavioral system. This perspective was developed by Michael Schiffer (1976), who identified two major kinds of distortions: a) n-transforms, or distortions due to natural processes, and b) c-transforms, distortions due to cultural processes. The assumption here is that after controlling for these distortions, explanation can proceed in a manner similar to the fossil model by identifying and making use of established correlates between pattern and behavior. Although this view has been critiqued on the grounds that the archaeological record cannot properly be viewed as a distortion of itself, it has drawn much needed attention to taphonomic processes (how the archaeological record is formed) and to middle range theory (how archaeologists establish logical connections between present statics and past dynamics).

The textual model was originally introduced by Ian Hodder (1986) and is ultimately derived from the philosopher Paul Ricoeur's idea of 'social action as text.' It regards the archaeological record as meaningfully constituted by individual actors in the context of negotiating their personal identities and social roles within society. In this case, artifacts, monuments, and buildings not only serve utilitarian functions, but they can also be seen to be symbolically charged, potentially encoding such social meanings as ethnicity, gender identity, and worldview. Additional implications of the textual approach are that there can be no final reading since each reading has its own validity and that the intent of the past actor is only one among a number of possible meanings (Tilley 1991). This model is primarily associated with advocates of post-processual archaeology.

2. Epistemology

Archaeologists typically make use of three methods of knowing the past: positivism, historical materialism, and hermeneutics. These methods are often represented in opposition to one another, but they actually differ with respect to their basic goals. Positivism has been used to establish causal explanations of cultural adaptation and behavioral change. Historical materialism has been adopted to understand social evolution in terms of changes in the forces and relations of production. Finally, hermeneutics has been used to provide interpretive understandings of social practices and meanings.

The introduction of positivism in archaeology is associated with the emergence of processual archaeology (also called the New Archaeology) in the early 1960s. The agenda of processual archaeology was to formulate and test general laws of human behavior. These laws were to be used to describe, explain, and predict (or retrodict) cultural similarities and differences represented in the archaeological record. Consistent with the tenets of positivism, unobservables such as ideology or belief systems, were deemed metaphysical (or paleopsychological) concepts and, therefore, of no explanatory relevance. In its zeal to ally itself with the natural sciences, processual ar-chaeology moved quickly to espouse the deductive-nomological (D-N) approach (e.g., Watson et al. 1971) and to a lesser degree structuralism. More recently, it has broadened to include statistical-relevance models (S-R), abduction, and neo-positivist models.

Historical materialism, developed by Karl Marx and modified by his followers, focuses upon the dialectics of the mode of production, traditionally defined as the opposition between the forces and relations of production. The productive forces are the elements of the production process. These include the means of production, the objective conditions of labor, and labor power. The relations of production are the conditions under which the productive forces exist. These are fundamentally based upon class relations with capitalists enjoying the ownership of the means of production and the ability to purchase labor power to create a surplus. Although it has never been a dominant perspective in the West, Marxism has a long legacy, particularly in Europe. For example, one of its most significant early advocates was V. Gordon Childe (1936). Several different versions of historical materialism have now been used including structural

Marxism, dialectical Marxism, and neo-Marxism (Leone and Potter 1999, McGuire 1992).

A hermeneutic, or interpretivist, approach was introduced in the early 1980s in reaction to the limitations of positivism. As in the social sciences in general, archaeologists challenged the artificial distinction between the 'context of discovery' and the 'context of justification' and the characterization of ideational factors as epiphenomenal (Hodder 1982, Shanks and Tilley 1989). A hermeneutic approach seeks to understand the meanings behind actions—why certain actions were taken in a particular case—rather than to explain them as an instance of a general process. It is thus an appreciation of context, rather than an attempt at retrodiction. This method is central to post-processual archaeology and today has diversified to include a number competing variants ranging from post-structuralism, to gender theory, to discourse analysis, to phenomenology.

3. *Cultural Change and Social Evolution*

Archaeology does not currently possess a unified theory of cultural change, similar to the theory of evolution in biology, and most practitioners take this to be a consequence of the complexity of archaeology's subject matter which includes the full range of past human behavior from the appearance of the first6 anatomically modern humans to the emergence of the modern world system. There are three basic approaches to explaining long term, cultural change and social evolution: adaptationalism, transformationalism, and selectionism.

3.1 *Adaptationalism and its Variants*

Adaptationalism is closely associated with processual archaeology and its ecosystemic approach. Following the anthropologist Leslie White, Lewis Binford (1962) defined culture as 'man's extrasomatic means of adaptation.' The principal way that cultures adapted to their environments was by means of economic, social, and ideological subsystems mediated by technology (hence his technomic, soeiotechnic, and ideotechnic categories). It was assumed that a culture's natural state was equilibrium and that this stability was achieved through the operation of social strategies which served as homeostatic mechanisms. Any change within the cultural system was viewed as an adaptive response to some external stress, usually seen as environmental degradation.

Optimality theory is based upon the principles of evolutionary ecology as developed by ecologists and modified by evolutionary anthropologists. It regards culture change as the output of individual organisms seeking to maximize the net rate of energy capture so as to enhance their reproductive fitness. In archaeology the most popular version of these theories is optimal foraging theory (see Bettinger 1991). Advocates typically regard this approach as a heuristic approach, useful in modeling evolutionarily successful behavior, but not sufficient, in and of itself, to explain all human behavior. Indeed, the model is often used to highlight deviations from predicted behavior and these deviations are then explained in terms of cultural factors.

A sophisticated version of adaptationalism is coevolution. This approach studies the interaction between social learning, cultural transmission, and biological evolution. These studies take their inspiration from the coevolutionary or dual inheritance theories of biological anthropology. They typically regard genes and culture as two distinct, but interacting, systems of information inheritance within human populations. Culture is seen to have its own mechanisms and properties and, in this sense, it can be said to have a 'life of its own.' On this view, continuity rather than change is the norm because of the inertial properties of inheritance systems. The most comprehensive application of coevolutionary theory has been the study of plant domestication (Rindos 1984).

Cognitive archaeology is a relatively new direction that seeks to understand the evolution of the mind by means of special human ability to construct and use symbols (Renfrew and Zubrow 1994). There is, as yet, no clear consensus on what constitutes cognitive archaeology and a variety of different approaches are being explored. Nonetheless, it is possible to identify two emerging trajectories as particularly promising. These are those approaches based upon cognitive psychology and those based upon technological choice. An example of the former is the work of Steven Mithen (1996) who has proposed that the evolution of human intelligence is characterized by oscillations between increasing modularity and increasing cognitive fluidity.

3.2 *Transformationalism: Marxist and Political Economy*

Transformationalist approaches regard the roots of culture change as internal to society. Some of these approaches borrow liberally from versions of Marxism and the development of society is assumed to occur through the unity of opposites in a dialectical process. Others have taken a political economic perspective, closer to classical economics, that has emphasized competition and finance systems in the emergence of political institutions.

Prestige goods exchange theory was originally developed by Jonathan Friedman and Michael Rowlands (1978) as one of the pathways of their epigenetic model of social evolution. A prestige system is one where social status is based upon access to the prestige goods necessary for social reproduction. A depen-

dency relation emerges between core and peripheral elites such that only the core elites can maintain centralized control over luxury goods. Elites on the periphery can access these goods only through establishing alliances with the core. The result is an increase in the intensity of exchange and in the quantity of goods produced. An increase in production specialization occurs because, as the core elites desire particular kinds of goods, demand is heightened and this can often lead to standardization. Friedman and Rowlands suggest that prestige systems are typically unstable because of the difficulty of maintaining a clear monopoly over long distances.

World Systems Theory (WST), developed by the political economist Immanuel Wallerstein, is a theory of the spread of capitalism. It explores the structural linkages between First and Third Worlds such that development in one area generates underdevelopment in another. The central process is one of exploitation as nation state cores extract goods from peripheries and redistribute them according to specific rules of allocation. This process is both dynamic and complex since the status of the cores may fluctuate over time, resulting in unstable and changing boundaries. WST has been especially attractive to archaeologists because of the scale at which it operates. It places cultural entities within their larger, historical, political, and economic contexts and is sensitive to the spatial dynamics of control. Archaeologists have been sharply critical of Wallerstein's premodern and modern distinction and argued that its applicability needs to be fully explored in particular cases of State formation with special attention paid to the units of analysis (Stein 1999).

Yet another approach is Peer–Polity Interaction (PPI), a model developed by Colin Renfrew (Renfrew and Cherry 1986) to explain the social dynamics underlying the emergence of State political economies. It identifies social structures (political institutions, ritual systems, and non-verbal language) as the products of long term interactions between adjacent early city states. He identifies three processes—competition, symbolic entrainment, and increased trade. Renfrew notes that both warfare and competitive emulation can lead to the emergence of leaders who establish their authority through gift-giving and feasting and to the intensification of production. Symbolic entrainment can lead to the adoption of writing systems and the institution of kingship. Increased trade can result in craft specialization and mass production aswell as new institutions and facilities to manage surplus goods. PPI has been widely used in both old and new world contexts.

Tim Earle, Terrence D'Altroy, and Elizabeth Brumfiel have established what might be called the political finance model. These scholars regard specialization, not as the result of the political economy adapting to a new problem, but rather as the outcome of elites seeking to solidify and strengthen their political and economic interests (Earle and D'Altroy 1989). This reversal of the standard adaptationalist argument shares strong similarities with prestige goods models (see above), but retains an implicit notion of agency. Central to this approach is the distinction between staple and wealth-finance. Staple-finance systems refers to States that collect and redistribute subsistence goods as part of their juridicial rights. Wealth-finance systems are those States that make use of some form of wealth that is paid out as currency and is exchangeable for subsistence goods in the marketplace. Although both systems are characteristic of complex societies, Brumfiel and Earle (1987) emphasize that it is wealth-finance systems that seem to be the primary force in generating political development.

3.3 Selectionism; the New Darwinian Synthesis?

Selectionism is a controversial new approach which minimizes human intentionality and promotes natural selection to a central position in explaining change in the archaeological record. This ambitious project, largely an American phenomenon, seeks to develop a single general evolutionary theory sufficient to encompass both cultural and genetic transmission in humans and other animals. As defined by Robert Dunnell, the leading proponent of this view, change must be understood as a selective, rather than a transformational, process. He further proposes that artifacts are the 'hard parts of the behavioral segment of phenotypes' and that differential frequencies of artifacts are thus explainable by the same process as those in biology (Dunnell 1989: 44). To date, there have been more theoretical expositions than worked case studies. The few case studies that do exist are focusing on engineering design and performance characteristics of material culture in the explanation of social transitions.

4. Theories of Practice

Dissatisfaction with both the adaptationalist and transformationalist perspectives has led some archaeologists to explore elements of a theory of practice. Practice theories are grounded in post-structuralist approaches in anthropology, sociology, and gender studies and they generally emphasize the interplay between conscious, or goal directed, action and social structures which generate routinized action.

One of the most influential theories of practice is structuration theory. This theory was created by the sociologist Anthony Giddens as a means of bridging the limitations of functionalism and structuralism. A key component of this theory is the recursive relationship between structure and agency such that, through their actions, individuals both shape and are shaped by social rules. Structure can thus be concep-

tualized as both the medium and outcome of social action, a property that Giddens (1984) calls 'the duality of structure.' Some archaeologists have critiqued Giddens's conception of agency, arguing that it is not a cross-cultural category and needs to be conceived as particular to a specific time period (Dobres and Robb 2000). This suggests that a historicity of agency is needed. Others have critiqued it on the basis of its implicit male focus. Most studies of agency have, in fact, tended to center on capacities for action of men, rather than women.

A second version of practice theory is that developed by the anthropologist Pierre Bourdieu (1977). This theory is perhaps best known for the term 'habitus,' the unconscious and durable predispositions that underly routinized practice. Structure is seen as the social conditions of the production of the habitus and conjuncture represents a particular state of the structure. Hodder (1986) has characterized habitus as a linguistic and cultural competence mediating structure and practice. He regards it as of special significance for archaeology because it links social practices with the cultural history of society. One problem that has limited its use in understanding processes of social evolution is that it fails to adequately account for the transformation of the habitus. Perhaps for this reason it has seen its greatest use in ethnoarchaeological studies.

Recently, a number of scholars have drawn attention to embodiment as constitutive of social practice. Meskell (1999) has distinguished two trends. The first is the tendency to treat the 'body as artifact.' Here, the body is manipulated in ways similar to material culture in the context of negotiating identities and meanings. This perspective is particularly characteristic of British and European archaeology. The second is the 'body as the scene for display.' This approach is associated with issues of posture, gesture, costume, and sexuality and is linked to Egyptian, Near Eastern, and Mediterranean archaeology. Meskell's own work has both been inspired by and critical of Judith Butler's (1993) work. For example, she critiques Butler's idea of 'gender as performance' arguing against the assumption that performance is always about the replication of a set of norms on the grounds that there can be no single experience of being a certain biological sex. Rather one must consider the materiality of the body, its social setting, the operations of sex/gender and the individual dimension of living one's own body.

5. *The Social Context of Archaeology*

One of the signal contributions of the recent theoretical debates is the foregrounding of the social context of knowledge production. Many archaeologists, following the conclusions of Michel Foucault and Jurgen Habermas, now accept that the idea of neutral or objective knowledge is a fallacy—that is to say, knowledge is always produced to serve social interests. What still remains controversial, however, is the degree to which specific social contexts shape the practice of archaeology. These issues are particularly well illustrated in the cases of nationalist, feminist, and post-colonial archaeologies.

It seems inescapable that the past has always been used for political purposes (Kohl and Faucett 1995, Meskell 1998). In recent history, perhaps the clearest example of this is the use of Gustav Kossina's work to support the Indo-Aryan origins of the Nazis. Another frequently cited example is the interpretation of the site of Zimbabwe as the product of a white race in an attempt to deny indigenous southern Africans their rightful heritage. These examples, both obvious abuses, are sometimes taken to mean that all political uses of archaeology are inappropriate. This perspective, however, is a convenient overgeneralization that seemingly seeks to preserve the status quo. Archaeology can be used to empower people by providing them with a deeper appreciation of their heritage as, for example, can be seen at colonial Williamsburg where new exhibits features slave life alongside that of the plantation owners. Tourism can thus be a vehicle of neocolonialism or one of empowerment.

Feminism denotes a basic political commitment to confronting and eliminating androcentrism in Western society. Since the mid 1970s, a large literature has developed spanning the arts, the humanities, and social and natural sciences that explores the multiple effects of this bias. The first explicitly feminist archaeology emerged in Scandinavia (Norway) in the 1970s. In the United States, the first widely circulated paper on gender and feminism dates to 1984 (Conkey and Spector 1984) and the first professional conference was held in 1988 (Gero and Conkey 1991). The reasons for this late development in archaeology have been traced to the dominance of positivism and its view of objective knowledge. A number of studies have now addressed equity issues, particularly those issues associated with employment, promotion, grants, and publishing (Nelson et al. 1994). Many feminists have adopted Sandra Harding's view that feminist politics is not only a practical necessity, but is, in fact, essential in order to do good science. The best science is, therefore, the science that is produced under conditions where women and men enjoy equal representation.

A convenient date for the emergence of post-colonial archaeologies on the global stage is 1986. This date is the year the World Archaeological Congress was held at Southampton, UK. This conference is particularly important because it showcased sharp ethical conflicts (between anti-apartheid and academic freedom) for an entire profession (Ucko 1987). At the same time, it provided post-colonial scholars with a valuable opportunity to participate in substantial numbers in an international conference. For the first

time, post-colonial and indigenous issues in archaeology were featured in a series of influential publications (Layton 1989a, 1989b). In the United States, the passage of the Native American Graves Protection and Repatriation Act (NAGPRA) in 1990 has empowered many tribes by providing them with a vehicle for the repatriation of human skeletal remains and associated funerary goods, objects of cultural patrimony, and sacred objects. Although there have been some notable disputes, (e.g., the Kennewick case), archaeologists and native peoples have successfully collaborated on numerous projects of mutual interest.

R. W. Preucel

Theory of Mind

The term 'theory of mind' was coined by US psychologist David Premack in a famous article (Premack and Woodruff 1978) reporting experiments carried out on the chimpanzee, Sarah. The question of whether and in what sense animals other than humans have a 'theory of mind' ability remains unsettled. Human beings, however, clearly attribute a wide range of mental states to each other, including intentions, hopes, expectations, imaginings, desires and beliefs. Psychologists have come to use the term 'theory of mind' to denote this everyday ability to attribute mental states to other people and to thereby interpret,

explain, and predict their behavior. Theory of mind concerns our ability, not simply to *have* beliefs as such, but to have beliefs *about* mental states, including the recursive ability to have beliefs about beliefs. Of the various mental states, at least three states appear to be basic to our commonsense explanations: *desires* (which identify an agent's goals), *beliefs* (which reflect what an agent takes the state of the world to be), and *pretence* (because people do not always mean what they do or say).

1. Theory of Mind and Cognitive Psychology

It is all too easy to overlook or take for granted our everyday cognitive abilities, even the most spectacular of them. The ability to think about thinking is a case in point. While our knowledge of cause and effect, space, time, number, object, and so forth have been the focus of intense philosophical scrutiny since classical times, the highly abstract concepts that form cornerstones of our *social intelligence* have until recently received much less attention. One of the most surprising aspects of theory of mind ability is just how early in life it begins to develop. One might have thought that concepts as abstract as desire, pretense, or belief could only be acquired late in life, long after many other more concrete concepts, extensive general knowledge, and sophisticated reasoning abilities are in place. It would be very hard to explain to a young child what a belief is, given that one cannot point at a belief or pick one up or produce an intelligible definition. Fortunately, one does not need to do any of these things because young children acquire the relevant concepts spontaneously. In fact, mental state concepts emerge rapidly and without formal tuition during the preschool period (Leslie 1987, 2000, Perner et al. 1987, Wellman 1990), appear to be universal across cultures (Avis and Harris 1991), and can be acquired even by children with a clinically diminished IQ (Baron-Cohen et al. 1985, Tager-Flusberg et al. 1998).

According to US psychologist, Henry Wellman, the concept of desire develops around two years of age (Wellman 1990). A related sensitivity to intention or goal of action seems to emerge even earlier, as shown by the 18-month-old child's disposition to imitate the action an actor intended to perform but, due to error, did not actually perform (Meltzoff 1995). The Scottish psychologist, Alan Leslie, has shown that the concept of pretending begins to be used by children between 18 and 24 months of age. Strikingly, when children first begin to pretend play by themselves, they simultaneously acquire the ability to recognize that another person is pretending and can even share pretenses with others (Leslie 1987, 1994).

The question at what age the concept of belief is first acquired has been more controversial and has attracted a great deal of study. It is generally accepted that to show a grasp of the concept of belief, the child should understand that what someone believes might be false. Working in Austria, Heinz Wimmer and Josef Perner developed a seminal task in which children are required to predict the behavior of a story character by attributing a false belief to the character (Wimmer and Perner 1983). They tested children between three and six years of age and found that it was not until the children were six years old that a majority of their subjects passed their task.

Subsequently, a British team, working in London, and comprising Simon Baron-Cohen, Alan Leslie, and Uta Frith, simplified the Wimmer and Perner task and found that the vast majority of four year olds whom they tested passed by attributing a false belief to the story character (Baron-Cohen et al. 1985). Since then, such simplified tasks have been found to produce successful performance in four year olds. The child is told a short story, with the aid of pictures or props, in which a character, Sally, has a marble. She places this marble in a basket and covers it. Sally then leaves and goes outside. While she is gone, naughty Ann enters the room, finds the marble in the basket, and moves it to a nearby box, and hides it there. The child is then asked two 'control' questions to test for basic comprehension: 'Where did Sally put the marble in the beginning?' and 'Where is the marble now?' Finally, the child is asked either directly about Sally's belief, 'Where does Sally think the marble is?' or the child is asked to predict Sally's behavior, 'Where will Sally look for the marble?' In order to answer either of the latter questions, the child must attribute to Sally a belief that is different from the child's own belief, and that the child considers to be false.

Baron-Cohen et al. (1985) also found that older children with Down's syndrome who had an average IQ of 64 (in the mildly retarded range) mostly passed this test of false belief. However, the majority of a third group of children, children with autism, failed the false belief task. The group of children with autism had an average IQ of 82 and were thus in the low normal range. Their failure could not therefore be accounted for by mental retardation.

Wimmer and Perner developed a further false belief task in which the child is shown a container which normally contains a well-known candy, and asked what is inside (Perner et al. 1987). After the child answers with the name of the candy, the container is opened and the child is shown that there is in fact a pencil inside. The pencil is replaced and the container closed once more. The child is then told that another person will be shown the container in the same way, and asked to predict what the other person will say is inside. Their findings showed that most four-year-olds could pass this task while most three-year-olds failed. Perner et al. (1989) found that a group of children with autism, despite having verbal mental ages in excess of seven years, nevertheless mostly failed this task. Children with specific language impairment, matched on verbal ability with the autistic group, almost all

passed. Subsequently, these patterns have been widely replicated: Normally developing four-year-old children and older moderate to mildly retarded children mostly pass false belief tasks, and most children with autism fail (see Happé 1995 for a review).

2. *Theories of Theory of Mind—Agreements and Disagreements*

The existence of these early developing yet highly abstract concepts raises the question: What is their origin? Are these concepts innate and, if so, how is that possible? Alternatively, are these concepts acquired and, if so, how is that possible? Either way, we have a challenge. If innate, how could such concepts be built into a cognitive system? If acquired, how could such concepts be gained by children with limited experience and ability? The concept of belief seems as abstract as the concept of the electron, and there seems to be as little direct everyday evidence for the existence of beliefs as there is for the existence of electrons. Thus, the child's theory of mind offers an intriguing case study of the nature of abstract concepts and their origins.

So far, two main answers to the above questions have been proposed. The first answer assumes that possession of abstract concepts depend upon possession of abstract knowledge. This reflects the traditional assumption that a concept is really a name for a packet of knowledge. In the case of theory of mind concepts, the knowledge packets are said to be commonsense theories (Gopnik and Meltzoff 1997, Perner 1991, Wellman 1990). This view of abstract concepts is referred to as the 'theory theory.' The second model assumes that possession of abstract concepts can depend upon a cognitive mechanism, rather than upon knowledge. This view is known as the theory of mind mechanism (ToMM) view (Baron-Cohen 1995, Frith and Frith 1999, Leslie 1987, 1992, 2000). The principle focus of debate has been around the concepts of pretense and belief. Before examining the knowledge versus mechanism dispute, we should outline points on which the two views agree.

First of all, while interpretations of the data differ, there are few disputes about the data themselves. Second, it is not disputed that even young children's theory of mind concepts are mentalistic rather than behavioristic in character. Behaviorist philosophers and psychologists have argued that mental states do not really exist and that talk of mental states is really just a confused way of talking about behavior. However, our common sense, rightly or wrongly, is undeniably committed to the existence of mental states and, whether or not mental state concepts are 'sound,' we certainly possess and employ such concepts. We naturally assume that Sally's behavior will be caused by her desire to find the marble in combination with her belief concerning its whereabouts. We use such belief-desire predictions ubiquitously and to good effect everyday. This suggests that our mental states concepts do refer to something real, probably to complex cognitive properties of agents. If concepts like pretending and believing are mentalistic rather than behavioral, then they cannot be a simple summary of sensory experience. And that will have implications for how these concepts can be acquired. A third point that is not generally in dispute is that the child's theory of mind has some kind of innate basis in a disposition to employ mentalistic concepts. And finally, there is no dispute that in the course of development, the child acquires more and more knowledge about people, about mental states, and about the role mental states play in causing people's behavior.

Beyond the four points above, however, there is much controversy. As we have indicated, the disagreements center on the nature of abstract concepts and the role of concepts in development. If a concept is the 'name' of a body of knowledge, then the only way to acquire a given concept is to acquire the appropriate body of knowledge. Another way to look at this is that possession of a given body of knowledge determines possession of a given concept. So, if this body of knowledge changes, then so too will the associated concept. Since everyone agrees that children's knowledge changes in the course of development, then so too, on this view, must their concepts change. Hence, a major topic in the study of development is the study of conceptual change (Carey 1985). A further implication of this widespread view is that if a given concept is innate, then its associated body of knowledge must also be innate. Often, it is assumed that if something is innate then it cannot change with development. However, some theory theorists have proposed that some knowledge (specifically, knowledge of some theories) is both innate and revisable (Gopnik and Wellman 1994, 1995). On this account, both the child's innate and acquired concepts can and do change.

According to the ToMM view, concepts do not name bodies of knowledge but instead directly represent properties in the world. This means that the representational relation between a concept (in the head) and the property (in the world) that it designates is subserved by a causal mechanism of some sort. For example, the concept 'red' is typically established and sustained by the neurocognitive mechanisms of color vision. Without color vision, it is hard to attend to and learn about redness. But nothing you will learn about redness changes the meaning of the concept 'red,' namely, the property of redness. On this view, concepts do not depend upon knowledge; on the contrary, they are a prerequisite for obtaining knowledge. Therefore, conceptual development is not the same thing as knowledge development. Consequently, innate concepts do not require innate knowledge, and acquired

concepts do not depend upon acquiring knowledge. Instead, on this view, we have the job of inquiring into the nature of the neurocognitive mechanisms that establish and sustain conceptual representations.

The above contrasting assumptions about the nature of concepts lead to very different interpretations of theory of mind development.

3. *Early Development, Normal and Abnormal*

As mentioned earlier, 18-month-old infants will imitate the goal of an action rather than simply the movements comprising the action. It is possible that they do so because infants have knowledge of a theory of goal-directed action. If so, the 'theory of goals' they have knowledge of needs to be discovered and specified. Alternatively, infants may not have knowledge of a theory at all; their imitation may instead simply reflect the operation of a neurocognitive mechanism. The 'mirror neurons' discovered by Rizzolatti in his investigations of cells in the ventral premotor cortex (area F5) in monkeys are suggestive in this regard. Neurons with similar properties are apparently involved in human imitation (Iacoboni et al. 1999). Such mechanisms with their sensitivity to the 'hidden' goals of an actor's actions may form the innate basis for the concept of desire.

Early pretending provides another example of an early social sensitivity where it is hard to imagine what the content of the infant's theory, in this case 'theory of pretending,' might be. Leslie (1987) drew attention to a key and long ignored aspect of early pretending, namely, that when the ability for solitary pretending first emerges, between 18 and 24 months, so does the ability to recognize pretending in other people. Leslie went on to argue that pretending should be understood as part of our theory of mind ability. Instead of proposing that the infant possessed innate knowledge of a theory, he postulated the existence of a specialized neurocognitive mechanism, ToMM, that forms the innate basis for theory of mind concepts, including the concept of pretending. A number of empirical predictions followed from the link between pretending and ToMM, including the prediction that autistic children, who do not develop spontaneous pretending, would be specifically impaired in their understanding of belief.

As we saw, this prediction has been confirmed. However, this confirmation in itself does not prove the link between autism and an impaired neurocognitive mechanism like ToMM. One alternative possibility is that children with autism have some kind of general processing difficulty, for example, with language, or with abstract reasoning, or with working memory, or with some other general factor that is demanded by false belief tasks. Any of these possibilities would provide an alternative explanation to the idea of a specific impairment caused by an impaired ToMM.

To test the alternative general processing explanation for autistic performance on false belief, Leslie and Thaiss (1992) adapted tasks devised by Zaitchik (1990). Zaitchik had developed a task in which a Polaroid photograph is taken of an object in a certain location. The object is then moved to a new location. Following control questions about where the object was when the photograph was taken and where the object is now, the child is asked to say where the object is in the photograph. The child does not get to see the photograph. After all, the child in the Sally and Ann task does not get to see Sally's belief! Zaitchik found that preschool children tend to fail or pass both the photographs task and the Sally and Ann task about the same age. This is not surprising given how similar both tasks are from the point of view of general problem solving. When Leslie and Thaiss tested a group of high-functioning autistic adolescents and a group of normally developing four-year-old children on similar pairs of photographs and false belief tasks, they found that the four year olds performed well on both sets of tasks. The autistic subjects, as expected, performed poorly on the false belief tasks, but their performance on the photograph tasks was nearly perfect. This result too has been replicated and extended. The failure of autistic children on false belief tasks cannot be attributed to the general problem-solving demands of the tasks. The photograph tasks make the same or similar demands and the autistic subjects passed these.

So far, we have considered only comparisons between autistic subjects who fail false belief tasks and normally developing four year olds or nonautistic developmentally disordered subjects who pass. But we should also compare autistic subjects with normally developing three-year-olds who also fail. Do the latter two groups fail false belief tasks for the same reason? The ToMM model predicts that they fail for different reasons. Only in the case of autism is ToMM neurologically impaired; in the typically developing three-year-old, ToMM should be intact, limited only by immaturity. One way to test this prediction is to examine whether ways that help three year olds to pass false belief tasks also help autistic subjects. Siegal and Beattie (1991) found a very simple way to help three year olds achieve better performance on the Sally and Ann task. Instead of asking, 'Where will Sally look for her marble?,' they asked 'Where will Sally look *first* for her marble?' Surian and Leslie (1999) found that while this small change did indeed help three-year-olds to calculate Sally's false belief, it had no effect on autistic performance, which remained just as poor. Other manipulations which help typically developing three-year-olds but which do not help older children with autism have been reported by Roth and Leslie (1991, 1998).

Finally, although the existence of the neurocognitive mechanism ToMM was originally postulated on the basis of purely cognitive findings, recent advances in

brain imaging techniques are beginning to reveal the neural systems basis of this instinct (Frith and Frith 1999).

4. Summary

The ability to detect the hidden mental states of other people is a remarkable cognitive power. It is tempting to assume that the idea of mental states must rest upon the same sort of foundation as many other highly abstract ideas, like electrons or inflation—that is, upon the capacity for scientific reasoning and theorizing. However, the speed and precocity with which ideas about mental states emerge in normal development, together with the patterns of normal and abnormal development reviewed above, suggest a different picture. The basic theory of mind that typically emerges during the preschool period is based upon an in-built mechanism that provides an intuitive and instinctual sensitivity to the mental states of other people.

Theory: Sociological

Sociologists share a map of the history of sociological theory in terms of phases. In the earliest phase, in the nineteenth and early twentieth centuries, a few individuals, working independently, produced massively influential works. By the middle of the twentieth century, these works were recognized as a common 'classical' heritage for the expanding discipline of

sociology. A second, synthesizing phase was initiated through efforts to build a body of general theory. However, advocates of alternative perspectives rejected these postclassic theoretical systems. Thus, a third phase of sociological theory emerged in which multiple paradigms continue alongside renewed efforts to consolidate theoretical ideas. In this article, central attention will be given to the postclassical phase, treating two major efforts of generalized theoretical synthesis and, in each case, a major alternative perspective. The works of the classic phase appear here as intellectual resources for these efforts, both the syntheses and the theoretical alternatives. The recent situation in sociological theory is viewed as it emerges out of this postclassic phase.

1. *Classical Theory and the Convergence Thesis*

The very term 'sociological theory' came to prominence only after World War II, especially in the influential writings of Talcott Parsons. In his classic prewar treatise, *The Structure of Social Action* ([1937], 1968), Parsons argued that a convergence had taken place in recent social theory. He analyzed the writings of four influential European social theorists (Marshall, Pareto, Durkheim, and Weber) with a view to demonstrating that these writers had expanded the scope of analytical social theory beyond the positivist and idealist traditions. Any analytical theory, Parsons argued, treats only selected aspects of a complex reality, formulating two kinds of conceptual schemes. One such scheme is structural in the sense of specifying parts and relations among them that are characteristic of a type of empirical system. The other kind specifies analytical relationships among defined 'analytical elements' or variables. Parsons' convergence thesis pertains only to structural analysis. What this means and how it led to a particularly influential body of writings will be explained below.

1.1 *Social Action Systems*

Parsons treats social entities such as groups as empirical systems of the type he calls social action systems (see *Action, Theories of Social*). The analysis of the structure of the general social action system attempts to delineate types of acts and types of relationships among them. Neoclassical economic theory employs a conceptual scheme of minimal structure. It analyzes a type of action system—a market or a system of markets—consisting of an aggregate of independent rational acts (decisions) by producers and consumers in a competitive setting. By contrast, the four writers that Parsons discussed developed more elaborate structural concepts. Pareto, for instance, starting as a neoclassical economic theorist, later embarked on a project devoted to general sociology with an analytical focus on nonrational components of motivation (e.g., 'sentiments'). But it was Durkheim and Weber who, partly through Parsons' analysis of their works, came to be regarded as the key founders of sociological theory.

In his writings, Durkheim defined some of the enduring concerns of sociological theory. In particular, his major works deal with the nature and types of social solidarity; the analysis of social reality as an emergent realm of social facts such as institutions; the explanation of social facts in terms of other such facts, exemplified in the explanation of variable suicide rates by reference to variable levels of social integration; and the genesis of emotion-laden collective representations and their role in creating and maintaining enduring bonds among people (see Giddens 1972). From Parsons' point of view, these works were key contributions in the extension of the scope of analytical social theory while at the same time their common focus is clearly social integration.

In his writings on religion and society, Weber presented empirical evidence for a historical instance—the rise of modern capitalism—of the general idea that a cultural ethic or value system could influence the direction taken by economic forces. Weber also took on the task of constructing the conceptual foundations of sociology. In doing so, he started from the concept of action, defined as behavior with subjective meaning. He noted a variety of types beyond the instrumental-rational type featured in the market model. Sociology is defined as a discipline dealing with the interpretation and explanation of social action, defined as action involving orientation to the actions of one or more other actors (see Heydebrand 1994). This was the most direct source of Parsons' own conception of society as a system of action.

1.2 *The Fundamental Dynamic Theorem of Sociology*

In arguing that there had been a convergence on a conceptual scheme that generalized economic theory, Parsons went on to suggest what he regarded as a core idea of sociological theory. Namely, a stable social equilibrium—social order—is contingent upon the existence of a system of common values that are institutionalized so as to control the play of economic and political interests. The psychological foundations for this idea were developed further in his postwar writings, leading to his 'fundamental dynamic theorem of sociology' in *The Social System* (1951): the stability of social equilibrium requires the institutionalization of a value system that is also sufficiently internalized in the personalities of members. This idea reflects emphases in the writings of Pareto, Durkheim, and Freud concerning the nonrational foundations of social order.

1.3 Functional Analysis

In Parsons' later work, functional analysis became very prominent in the form of the 'AGIL scheme.' (For the most elaborate statement of the AGIL scheme, see Parsons and Platt 1975, see also *Functionalism in Sociology*.) Any action system, the argument goes, has four functional imperatives: adaptation to its environment (A), attainment of its goals (G), integration of its parts (I) and what Parsons calls latent pattern maintenance (L). Functional subsystems of a society include an economy (social adaptation function), a polity (social goal attainment function for society), societal community (social integrative function), and a 'fiduciary' system (latent social pattern maintenance function). At any level of functional analysis, the other functional subsystems form part of the immediate environment of any one such subsystem. A society itself is one of four functional subsystems of an overall action system, namely, the action-integrative (I) functional system, comprised of institutional structures. Its action environment consists of instances of the three other subsystems of general action: cultural systems (L), personality systems (G) and behavioral systems (A). Parsons describes relationships among these systems in terms of theoretical ideas such as the fundamental dynamic theorem of sociology.

1.4 The Fundamental Problem of Sociological Theory

Through elaboration of numerous ideas in the context of the AGIL scheme, Parsonian theory became an extraordinarily comprehensive but also rather complex framework. The complexity arises in part because Parsons was working on at least three levels of theory: general action theory, social theory, and sociological theory. That is, there is an implied 'tree of theory' in which sociological theory is only one among a family of interrelated analytical theories. Call the root of the tree 'the general theory of action.' The idea that action is behavior with subjective meaning belongs at this level, as well as the notion that any action has both rational and nonrational elements. Then there are four branches, corresponding to the AGIL scheme. One branch is social theory, focused on the integrative functional subsystem of action, the social system. This level too has four branches, one of which is focused on the integrative functional subsystem of the social system. It is this branch that constitutes the core of sociological theory, in Parsons' action framework. It relates to the problem of integration of a system whose structure contains instances of collectivities, roles, norms and values. These structural parts may be quite differentiated, e.g., in values, leading to strains in intergroup relations, among other integrative problems.

This analytical view of sociological theory as focused on the problem of social integration leads to a specification of a fundamental problem: what holds society together? Alternatively, it has been framed as the problem of order. It also has a long history in social thought, as was pointed out by Ralf Dahrendorf (1959). He argued that the Durkheimian–Parsonian mode of addressing this question favors a reply in terms of common values, institutional rules, and socialized motivation that stabilizes a system. By contrast, he argued, a very different type of theoretical answer has been given in another stream of social thought, namely conflict theory (see *Conflict Sociology*). This type of theory is exemplified by Marx's theory: coercion and domination of some by others is what holds society together, but with a constant latent conflict relationship that may break out into more or less major episodes of social change. Where Marx focused on property relations as the structured basis of latent or actual conflict and change, Dahrendorf argued that a more general and analytical theory would make power relations central. Any organization, and not just the private enterprise of capitalism, is treated as a structure of power relations between actors with and without authority. Subsequently, Collins (1975) attempted a synthesis of Durkheimian theory with a Dahrendorf type of conflict theory.

Criticism of Parsons' theory came not only from those who favored a conflict theory alternative but also from theorists adopting other perspectives. Prominent among these was George Homans, and his ideas constitute another mode of generalized synthesis in sociological theory that also was met with critical reactions from alternative perspectives.

2. The Behavioral Foundations of Social Bonds

As equally devoted to generality and synthesis as Parsons, Homans focused more specifically on the second of the two types of conceptual scheme mentioned earlier—the analytical element type.

2.1 The Human Group as a Social System

In the first of his two major theoretical works, *The Human Group* ([1950], 1992), Homans argued that the creation of sociological theory should begin with a scope restriction to small groups, those in which each member could interact with every other. Just as Parsons had looked to major works of leading theorists to create his convergence thesis and to launch his own theory program, Homans looked to significant works of empirical research and to the more specific findings emergent from them. Homans asked: What makes customs customary? In other words, how do we account for order? But here, as in all his work, the focus is not on the problem of integration of distinct groups but the more elementary problem of the

construction, maintenance, or change of relationships among persons that constitute a human group.

In the book, Homans develops the theoretical answer in conjunction with a review of empirical cases: a work group, a street gang, the family in a preliterate society, a group of professionals, and even a small town. However, he also cites Durkheim and Pareto, drawing upon the latter's system idea. Order in the form of social integration is explained through an emergent 'internal system,' given external conditions. Social bonds among members and shared norms are generated by mechanisms that are described in terms of specific hypothesized linkages among analytical elements pertaining to activities, sentiments, and interaction. For instance, the more frequently people interact with each other, the more similar their sentiments, normative ideas, and activities become. Each hypothesis qualifies the others, forming a dynamic system. Clearly, Homans' theory is illustrative of the second of Parsons' two types of conceptual schemes and far more clearly than in Parsons' own work.

2.2 Reductionism

In his second major work, *Social Behavior: Its Elementary Forms* ([1961], 1974), Homans asked the question: If these sorts of analytical hypotheses or laws describe group dynamics and the build-up (or dissolution) of a group, what explains the laws? In searching for this more fundamental level of theorizing, Homans invoked a conceptual scheme from behavioral psychology. A typical element is the frequency of reward, and a key mechanism is reinforcement: the greater the frequency of reward, the greater the frequency of the rewarded behavior. As in his earlier system of hypotheses, each such fundamental behavioral proposition is qualified by the others; for instance, a satiation proposition says that as a reward is given repeatedly, each additional unit of it declines in value. As applied to interaction, the sources of the reward (or cost) are other actors. Hence, interaction is an exchange involving material and nonmaterial goods and social approval is a fundamental category of social reward (see *Exchange: Social*).

The basic theoretical aim is the explanation of social life from a nonsocial foundation. This is analogous to the explanation of molecular levels of existence from a purely atomic basis. That is, it is an explicit theoretical reduction program. But what if atoms only could have the postulated properties they have if these properties emerge out of molecular relations? Then there would be no sense to the reduction. Treating persons as social products implies just that conclusion. For this reason, many theorists deny the premise of 'methodological individualism' that Homans is here presupposing. But this denial, in turn, may rest upon a misunderstanding.

What Homans takes as his fundamental conceptual scheme does not involve the socialized individual of everyday life. It involves the concept of a behaviral act and principles about behavioral processes, such as reinforcement. Behavioral acts, not persons, are the basic theoretical units. The socialized individual and the social system are equally outcomes of complex interactive behavioral processes. Thus, Homans has his own implied tree of theory, with behavior theory as the root. Analyzing group processes is one branch of such a tree.

2.3 Mind, Self, and Society

In this interpretation, Homans can agree with the classical sociological theorist Charles Cooley ([1909], 1962) who argued that individual and society are 'twin-born,' in that the person is socially constructed in social interaction and that a society is a system of interaction. However, Cooley stressed the importance of the concept of the self, a notion that Homans employs without theoretical elucidation. It is a branch of his tree of theory that he does not climb out on. Another classical theorist, the philosopher George Herbert Mead—writing in the first third of the twentieth century—had argued that the self can only emerge in a symbolic environment in which interaction involves a common system of meanings (Mead 1934). This is another branch of Homans' tree that he did not explore. Homans presupposes but does not treat the capacity for symbolization that is part of the human condition. And his behavioral focus intentionally avoids any discussion of the 'internalized conversations' that make up the mind in Mead's view. Hence, 'mind' is another branch that went unexplored. In practice, then, Homans simply took mind, self, and symbols as givens in the pursuit of a pure theory that would formulate and explain group processes.

But this was not how other theorists viewed Homans' project. For them, it was a misconceived exercise in sterile behaviorism. They preferred the social behaviorism of Mead, as reinterpreted by Herbert Blumer (1969). Blumer stressed the existence of interpretive processes by which actors define each other's conduct and creatively develop actions in situations rather than merely automatically acting out pre-existing structural roles. This 'symbolic interactionist' approach won a considerable following within sociology after the 1950s, especially through the influential analyses of interaction produced by Blumer's student, Erving Goffman (1967) (see *Interactionism: Symbolic*).

2.4 Sociological Explanation Revisited

In taking the reductionist approach, Homans accompanied his work with a polemical argument. He took aim at Durkheim, who had argued that what explanation means for sociological theory is a causal account that remains at the level of social facts. For

instance, to explain varying rates of deviance in groups, Durkheimian theory would point to varying levels of solidarity: the greater the solidarity of the group, the lower the rate of deviance from its norms. What Homans argued is that an analytical law or proposition stated in terms of social facts itself requires scientific explanation. We cannot be satisfied with purely group-level laws. What Homans argued was that such a proposition, if it is true, could be derived logically from a behavioral foundation. For instance, in a highly solidary group, members experience or can anticipate receiving high costs for undertaking some deviation from the group's norms, while in a less solidary group, such costs are lower. This is so because 'solidarity,' when analyzed in behavioral terms, means that members value each other's social approval to a certain degree. Hence, the mechanism that explains why varying rates of solidarity lead to varying rates of deviance is behavioral and the Durkheimian law is explained.

3. *The Current State of Sociological Theory*

Subsequent to Homans' work, the philosophy of science and social theory itself underwent some basic shifts of viewpoint. Both were strongly influenced by Thomas Kuhn's *The Structure of Scientific Revolutions* ([1962], 1970) in which it was argued that a normal science is characterized by a shared paradigm but that there are also revolutionary episodes in the history of science involving paradigm shifts.

3.1 *Multiple Paradigm Science*

In application of the paradigm concept to sociology, commentators characterized the field as one with multiple paradigms. By the late 1970s, most texts reflected this consensus, featuring separate chapters on functionalism (Parsons), conflict theory (both critical theory and the Dahrendorf tradition), exchange theory (Homans), symbolic interactionism (Blumer), structuralism (French and US versions), and phenomenology (social constructionism and ethnomethodology). (See Turner 1998 for overviews of these and other perspectives in contemporary sociological theory.) To make the picture even more diverse, two other developments occurred. Feminists launched a wide-ranging critique of sociological theory and helped to make the study of gender a key research topic. Postmodernist sociologists attacked the project of sociological theory as a continuation of the Enlightenment's grand narrative with scientific pretensions that could not succeed. Critics respond by attacking the cognitive relativism of this approach (see *Relativism: Cognitive*).

Some commentators argue that there is no possibility of placing these paradigms under a common intellectual framework, thereby seeing the discipline as permanently fractured and at war with itself. Others regard the situation as a positive one, emphasizing the importance of diverse viewpoints that could be brought to bear on any particular feature of social life. Still others recognize the diversity but argue for integrative theorizing, as described below.

3.2 *The Spirit of Unification*

The two most prominent midcentury efforts in sociological theory—each aiming toward generality and synthesis—have failed on the criterion of acceptance as *the paradigm* of general sociological theory. Yet the spirit of what they tried to accomplish is not gone. We can call it 'the spirit of unification,' meaning a value-commitment to generalizing synthesis efforts in episodes of consolidating components of distinct theoretical systems (Fararo 1989). Robert Merton emphasized this idea in his often-cited paper 'On Sociological Theories of the Middle Range' (in Merton [1949], 1968). A middle range theory employs a general conceptual scheme with analytical elements, but it is scope-restricted to some abstractly specified class of empirical systems, e.g., thermodynamic systems. It cuts through folk classification schemes, explaining intuitively very different empirical systems using the same analytical elements and laws that do not exhaust the content of the empirical system. In short, a middle-range theory is an analytical theory. Its scope is limited, not in the sense of dealing only with a class of concrete entities as classified culturally, but in the sense of treating only a certain system of variables.

A value-commitment to the construction of limited scope but abstract theories coupled with a value commitment to a recursive process of unification of such theories may well be a plausible path for the advance of sociological theory. At present, this approach is most strongly institutionalized in the field of research known as group processes, in which theorists elaborate and integrate their theories over time in connection with the construction of experimental situations that provide opportunities for testing the implications of theories. (For examples of group process research programs in relation to theory growth, see Berger and Zelditch 1993.)

3.3 *Mutations and Innovations in the Paradigms*

Recent developments indicate certain mutations in the paradigms and the emergence of new paradigms. Parsons's theory has been transformed into what is now called 'neofunctionalism,' while Homans's paradigm has mutated into part of 'rational choice theory.' Neofunctionalism departs from Parsons in a number of ways that reflect the influence of cross-paradigmatic critiques, attempting to incorporate ideas from conflict theory and interactionism, for instance, so that its advocates regard it as a new synthesis (Alexander 1985). Rational choice theory has departed from the behavioral psychological foundation that Homans

advocated, often favoring a more mathematically tractable rational action model (see *Rational Choice Theory in Sociology*).

One of the new paradigms is social network analysis (see *Networks: Social*). Although social system theorists often employed 'network' as a metaphor for the relational systems they analyzed, they did not employ formal tools. The social network paradigm incorporates a strong mathematical and statistical foundation into a program of cumulative research on the properties of social networks. But critics argue that there is little actual specification of explanatory mechanisms in the research undertaken under this paradigm.

In terms of influence on empirical research, these three paradigms are not on an equal footing. Social network analysis has been incorporated into a great deal of ongoing research. Indeed, its focus on formal techniques for the description of networks implies that it can be employed as a tool along with virtually any other perspective. Neofunctionalism has had a limited following. Most macrosociological research avoids use of the function concept. A return to functionalism as a dominant approach appears unlikely at this point, although some conceptual breakthrough that reinvigorates it cannot be ruled out.

By contrast, rational choice theory created a considerable debate in the late twentieth century. Given that the classic writers and Parsons created ideas that were seen by sociologists as overcoming the scope limitations of economics, a 'return' to rational choice as a postulate seemed regressive and was criticized on that basis. Defenders of rational choice theory can point to its strong contribution to the formulation of micro–macro linkage. This is particularly clear in the formulation set out by Coleman (1990). Macrolevel systemic givens constrain and enable microlevel situations of actors. Making rational choices based on their internal preferences and the situational constraints, actors then collectively shape macrolevel outcomes. This is not equivalent to Homans' reduction program. Instead it is a working strategy for incorporating agency into any sociological explanation, a point emphasized strongly by other recent theorists who are nevertheless critical of rational choice as an explanatory mechanism (Giddens 1984, Bourdieu 1990, Boudon 1998; see also *Macrosociology–Microsociology*).

If the Parsonian notion is accepted, that the problem of social integration defines the core problem of sociological theory within the broader framework of social theory, the route through the middle-range strategy is not inconsistent with the more general project that Parsons and others have pursued. A key contribution of sociological rational choice theorists has been their sharp theoretical focus on variants of the basic problem, treating coordination, cooperation, and trust, as well as solidarity (see *Solidarity, Sociology of*). At the same time, the synthesis of the Durkheimian theory of solidarity with conflict theory undertaken by Collins (1975) provides a different middle-range perspective on the problem of social integration. Thus, given the centrality of the problem and the existence of explicit theories treating it, the topic may well constitute an important locus of episodes involving theoretical unification. Finally, some of this work illustrates the use of mathematical models in bringing precision and deductive fertility to sociological theory (Doreian and Fararo 1998). Such model building can fulfill a variety of goals, including the clarification of concepts, the representation of processes, and the specification of theoretical constructs that explain a variety of phenomena (Berger et al. 1962). Developments such as these are a major hope for the future of sociological theory.

Therapist–Patient Relationship

The therapist–patient relationship is accepted widely as a central aspect of psychotherapy, although there is less agreement on how this relationship plays a role in treatment. This article will examine the varying perspectives on the therapist–patient relationship in both historical writings on psychotherapy and in current research and theory. Methodological issues in attempting to study empirically the therapist–patient relationship will also be delineated, and speculations on future directions for research and theory will be offered. But first, the next section will attempt to define the therapist–patient relationship.

1. *Definition of the Therapist–Patient Relationship*

A 'relationship' is something that emerges when two or more people interact. However, with the therapeutic relationship, and perhaps any human relationship, it becomes difficult to think about or observe this 'emergent' property of the interaction independent of the contributions of each of the participants. Thus, the thoughts, feelings, attitudes, and behaviors of the participants, as well as the technical interventions of the therapist, all potentially play a role in the formation and maintenance of the therapist–patient relationship and need to be considered in any conceptualization of this facet of psychotherapy. In the broadest sense, then, the therapist–patient relationship is the emergent entity that is produced by the expectations, attitudes, thoughts, feelings of the participants about each other, as well as their behaviors towards each other.

Despite this broad and elusive definition of the construct, we know a good therapist–patient relationship, and a bad one, when we see it. A good therapist–patient relationship is usually evident when patient and therapist are acting in a warm, caring, empathic, and productive way towards each other. A bad therapist–patient relationship is characterized by distance, hostility, lack of respect, manipulation, or poor capacity to work effectively together.

The positive, 'reality' based aspects of the therapist–patient relationship are subsumed under the concept of the 'therapeutic alliance.' Bordin's (1979) definition of the therapeutic alliance in particular has had considerable influence in theoretical and research writings. The therapeutic alliance, according to Bordin (1979), consists of three elements: (a) agreement between patient and therapist on the goals of therapy, (b) agreement on the tasks of therapy, and (c) the affective bond between patient and therapist. While the bond incorporates the emotional aspects of the patient–therapist attachment, agreement on goals and tasks refers to expectations or cognitive elements of the relationship. To understand how these aspects of the therapist–patient relationship have come to be accepted widely and how they apply to the full range of different psychotherapies requires a historical perspective, given in the next section.

2. *History of Concepts of the Therapist–Patient Relationship*

Modern views of the therapist–patient relationship can be traced directly to Freud's writings. Freud considered the therapist–patient relationship to be a unique laboratory for observing aspects of patient's personalities that may have relevance to the patient's symptoms or psychopathology. Moreover, he utilized the relationship to effect change in the patient (see *Psychoanalysis in Clinical Psychology* and *Psychoanalysis: Overview*).

Freud described several components of the therapist–patient relationship. In terms of the patient's contributions to the relationship, Freud (1958) described both positive and negative transference reactions. Transference refers to the expectations, desires, thoughts, and feelings that are 'transferred' from a previous relationship on to a new relationship (e.g., the therapist). Positive transference was further divided into the reality-based 'friendly and affectionate aspects of the transference which are admissible to consciousness and which are the vehicle of success' (Freud 1958) vs. other positive feelings and perceptions (e.g., sexual feelings, strong dependency) that were not reality-based, originating instead from the patient's unconscious linking of the therapist with significant past relationships. Similarly, negative transference included negative feelings and perceptions that originated from past relationships and were not evident in the therapist–patient relationship. Finally, Freud acknowledged that distortions in the therapist–

patient relationship might result from the therapist unconsciously linking the patient to significant people in the therapist's past ('countertransference') (see *Transference in Psychoanalysis*).

While the reality-based friendly feelings motivated a patient to stay in treatment and engage in therapeutic work, distorted positive and negative transference reactions served as the basis for the therapist's technical interventions. By illustrating these distortions to the patient, previously unconscious conflicts became conscious and such insight lead to patient improvements.

A number of subsequent psychodynamic theorists expanded upon Freud's discussion of the therapeutic relationship. The term 'ego alliance was used by Sterba (1934) to refer to the patient's capacity to work with the therapist in treatment, alternating between experiencing and observing. Subsequently, Greenson (1965) described this capacity as the 'working alliance,' and theorized that it stemmed from the patient's mature ego functioning in conjunction with an identification with the work orientation of the therapist. Zetzel (1956) discussed the patient's attachment to the therapist (labeling it the 'therapeutic alliance'), and postulated that it originated from positive aspects of the mother–child relationship.

Because the analysis of transference became the defining feature of many approaches to psychodynamically-oriented psychotherapy, a relatively large literature has developed on this aspect of the therapist–patient relationship. Esman (1990) has collected a sample of influential papers on transference that illustrate the perspectives of a range of psychoanalytic writers including Freud, Klein, Winnicott, Gill, Kohut, Kernberg, Lacan, and others.

Although there are historical disagreements about whether the positive aspects of the therapist–patient relationship represent patient distortions or realistic appraisals of the treatment situation, the writings of Bordin (1979) served to mark the beginning of consensus on the importance of the reality-based, collaborative therapist–patient relationship (the 'alliance'). This is not to say that other schools of psychotherapy had been silent on the importance of the therapist–patient relationship. In many ways, client-centered psychotherapy, developed by Rogers, can be seen as an approach that relied exclusively on a positive therapist–patient relationship for inducing change (see *Person-centered Psychotherapy*). Unlike the psychodynamic emphasis on reactions of the patient to the therapist, Rogers' (1951) focus was on the therapist's contribution to the relationship. Rogers claimed that if certain 'facilitative conditions' (therapist empathy, genuineness, and unconditional positive regard) were provided to a patient, the patient's natural tendencies for growth and healing would be activated.

The behavioral school of psychotherapy, however, has often been characterized as minimizing the role of the therapist–patient relationship. This school of therapy describes behavior change in terms of principles of learning (i.e., classical or operant conditioning; social learning theory), with no focus on the context in which therapy takes place—i.e., the therapist–patient relationship. Practicing behavior therapists came to realize that this was an oversimplification. Goldfried and Davison (1976), for example, devoted an entire chapter of their book on clinical behavior therapy to the therapist–patient relationship, describing how behavior therapists can use the therapeutic relationship to directly sample aspects of the patient's problematic behavior (see *Behavior Therapy: Psychological Perspectives*). Moreover, a positive relationship was seen as crucial to facilitating favorable patient expectations for change and receptiveness to the behavioral approach, enlisting patient's active cooperation in treatment, and motivating the patient to attempt new behaviors outside of therapy.

Beck's cognitive therapy approach has long acknowledged that the therapist–patient relationship was important to successful outcome, but it was largely considered a 'given,' with only brief explicit attention to the relationship in the original writings on cognitive therapy as a treatment for depression (Beck et al. 1979) (see *Cognitive Therapy*). However, as cognitive therapy expanded its scope to the treatment of other disorders, especially personality disorders, the therapist–patient relationship has come into focus increasingly as a key element of the process of treatment (Newman 1998).

3. *Emphases in Current Theory*

As mentioned, different schools of psychotherapy have largely converged in their agreement that the therapist–patient relationship is of central importance to successful psychotherapy. Even pychodynamic approaches to treatment, which historically have focused attention on patient distortions about the therapist, now highlight the role of the reality-based aspects of the therapist–patient relationship. The consensus about the importance of the therapeutic alliance is evident in a recent edited volume by Safran and Muran (1998) presenting chapters examining the alliance in psychodynamic, cognitive, experiential, strategic, family, and group psychotherapies.

While each approach to psychotherapy tends to stress somewhat different aspects of the therapeutic alliance, Safran and Muran (1998) have identified a number of principles on which there is basic agreement across therapeutic schools regarding what the therapist can do to facilitate a positive alliance. Among others, these include establishing a bond with the patient by conveying warmth, respect, and interest, outlining the tasks and goals of treatment at the beginning of therapy, focusing on realistic goals,

maintaining a clear therapeutic focus, keeping a balance between being active (which helps maintain the treatment focus and the patient's involvement) vs. receptive to patient needs and experiences, and addressing ruptures in the alliances when they occur.

Despite the agreement that has emerged regarding the importance of the alliance, there remains considerable disagreement about how a positive alliance results in more favorable treatment outcome. One view is that the alliance in itself is curative. This perspective proposes that a positive relationship between therapist and patient provides a corrective emotional experience for the patient. Through their relationship with the therapist, the patient emotionally learns over time that other people are not abusive, controlling, manipulative, or otherwise destructive in relationships, as the patient has experienced others to be in the past. Thus, the patient's core expectations or beliefs about people change, and this improves relationships outside of therapy.

The second view on the role of the therapist–patient relationship posits that a good alliance sets the stage for psychotherapy techniques to have their impact. Whether the techniques are cognitive–behavioral, such as homework assignments, or psychodynamic, such as interpretations of interpersonal patterns, the patient's receptivity to such therapist techniques will depend upon the extent to which the patient has a good bond with the therapist and basically agrees with the therapist on the goals and tasks of therapy. In this model, it is neither a good relationship nor good techniques that lead to better outcome, but rather the interaction of the two—a combination of good techniques in the context of a good relationship.

Both of the above models assume that the alliance is a relatively stable aspect of the therapist–patient relationship. A contrasting perspective has been offered that views the alliance as a relatively fluid process with ongoing ruptures occurring frequently during treatment sessions (Safran et al. 1990). It is unclear at this point whether such moment-to-moment fluctuations in the alliance are the norm or whether they occur primarily in the treatments of certain types of patients (e.g., those with severe problems in interpersonal relationships).

4. *Research on the Therapist–Patient Relationship*

Beginning in the 1970's, a variety of studies reported on the development of scales for assessing the alliance and examined its relation to psychotherapy outcome. Several reliable self-report measures and observer ratings scales (applied to tapes of psychotherapy sessions) were constructed. Many of the scales are linked to the theoretical model described by Bordin (1979).

Horvath and Symonds (1991) summarized the emerging literature on the relation of the alliance to psychotherapy outcome. In a meta-analysis of 24 studies, these authors reported that, on average, there was a small to moderate relationship between the quality of the alliance during treatment and eventual treatment outcome. Moreover, the alliance was found to be related to treatment outcome across diverse psychotherapies. The size of the statistical relationship, however, suggests that the alliance is not the only factor, or even a particularly strong factor, in determining psychotherapy outcome. In brief, while the therapist–patient relationship appears critical, there is no reason to suggest that a good therapist–patient relationship is the only curative factor in psychotherapy.

Several studies have examined the common clinical hypotheses that good psychotherapeutic technique has its greatest impact in the context of a positive alliance, i.e., the alliance and technique interact to produce better outcomes. No definitive results, however, have been reported to date, with some studies reporting evidence for an interaction (Gaston et al. 1994), and other studies yielding inconclusive but suggestive findings with small samples (Gaston et al. 1998).

5. *Methodological Issues in Research*

A host of methodological issues need to be considering when conducting research on the relation of the alliance to treatment outcome. Perhaps the most crucial issue relates to whether a positive alliance is actually a causal factor in producing better treatment outcomes. The reverse causal direction needs to be entertained as well: as symptoms improve, patients are more likely to report a positive attitude about the therapist and treatment. Thus, significant correlations between the alliance (measured during treatment) and outcome may be spurious—early improvement in symptom lead to both a positive alliance and good eventual treatment outcome. This potential confound between the alliance and prior improvement was addressed by Gaston et al. (1991), who found large correlations between the alliance and outcome even when prior improvement was controlled; however, because of small sample sizes the findings were not statistically significant. Thus, this important issue of the direction of causality remains to be addressed in future research.

A methodological issue that might limit findings on the relation of the alliance to outcome is the possibility that the alliance may interact with patient dispositional variables in predicting outcome. For example, Horowitz et al. (1984) found that two of four alliance measures interacted significantly with patient pretreatment motivation for psychotherapy in predicting outcome—a good alliance only matters if the patient is also motivated for treatment.

A further consideration is that while most research has examined average levels of alliance over the course

of psychotherapy or sampled alliance at a single session, the patterns in change in the alliance over treatment might be more related to outcome than average levels. This hypothesis was examined by Patton et al. (1997) who speculated that alliance scores would be initially positive, decline somewhat during the difficult working through middle phase of therapy, and then increase again during the termination phase. The results of the study were consistent with the authors hypothesis.

6. *Future Directions*

The almost universal acceptance of the therapeutic alliance as an essential part of psychotherapy points the way to some obvious future directions for scientific study. If a positive therapist–patient relationship is key to successful outcome, can therapists be trained to maximize the quality of the alliance? If not, is this because good therapists are 'born' not 'made'? Resolution of this issue could have profound implications for the training of psychotherapists. If therapists cannot be taught how to establish and maintain a good alliance, perhaps greater effort should be placed on the selection process for training programs in the disciplines (psychology, psychiatry, social work) which conduct psychotherapy. Priority would be given to applicants who have innate interpersonal skills (e.g., empathy) that are associated with positive therapist–patient relationships. If, however, therapists can be trained to maximize the quality of the alliance, such training should become a core element of all training programs, regardless of which treatment modalities are emphasized.

Rather than focusing on the broad question of whether the alliance predicts treatment outcome, future research is likely to continue to explore more refined and specific questions that attempt to unravel the contexts under which a positive alliance is especially important. Larger and more definitive studies, following up on intriguing preliminary findings with smaller samples, can identify the treatment variables and patient dispositional variables that interact with the therapeutic alliance to produce optimal outcome. Research on human relationships, emerging from basic studies in social cognition and interpersonal processes, is likely to provide direction for understanding the nuances of the therapist–patient relationship. Similarly, as intensive empirical examination of the therapist–patient relationship increases our knowledge about the influence of this relationship, we may find applications of these findings to other helping relationships in medicine and elsewhere in society.

P. Crits-Christoph

Thick Description: Methodology

'Thick description' is the term that Geertz (1973) used to describe ethnography in one of the most famous and influential anthropology texts in the second half of

the twentieth century. The phrase was the title of the first essay in the volume of the collected essays, and Geertz explained at the time that he had written it to state his theoretical position as generally as he could. As a result, thick description has come to imply two different things: on the one hand, good ethnography—what all anthropologists have done and do when they write up the results of solid, careful ethnography—and, on the other hand, what Geertz understood to be the intellectual entailments of this particular methodology.

1. As Methodology

Geertz borrowed the phrase 'thick description' from the philosopher Ryle (1949), who used it to contrast two different ways of describing the same piece of behavior. Ryle's example was a boy's twitch and his wink. Both could be described as 'rapidly contracting his right eyelids.' That Ryle called 'thin description.' Thick description was an account of the intentional, communicative, interpretative, meaning of the behavior: why it was done, how it was read, using which social codes. That, Geertz argued, was the object of ethnography: 'a stratified hierarchy of meaningful structures in terms of which twitches, winks, fake-winks, parody, rehearsals of parodies are produced, perceived and interpreted, and without which they would not … in fact exist, no matter what anyone did or didn't do with his eyelids, (1973, p. 7).

Ethnography is the written description of long term participant observation. Professional anthropologists now typically expect that a person doing serious fieldwork (of the sort required for an anthropological dissertation, for example) will spend at least a year living in the 'field,' in the social setting which they have chosen to study. They expect that fieldworkers will speak the dominant language spoken in that setting, and they expect that fieldworkers will learn about that world not only or even primarily by interviewing its members, but by learning how to participate as a member themselves: how to joke, to be in relationship, to be an appropriate person of their type (a woman in her twenties) in this social setting. If you are studying Londoners who practice witchcraft and magic, for example, you learn how to write rituals, to read tarot cards, and to feel the magic running in your blood. If you study Malagasy villagers who plant rice and perform cattle sacrifice, you work in the rice paddies and offer up a cow. Particularly in recent decades, professional anthropologists have decried their pith-helmeted, informant-paying forebears. They are likely to evaluate the student fieldworker by asking whether the student hung back from human contact or really got to know the people he worked among and came to be accepted by them. The point of this emphasis is to make sure that the fieldworker has grasped the realities and the rules of engagement of the world he has come to study. As Stephen Hugh-Jones once remarked, there is little point of having an abstract debate about what it means when the natives say that they 'see' their gods during rituals if you have not participated in those rituals and learned that they involve hallucinogens.

Data that rely on the collector's participation and subsequent recollection can seem hopelessly flawed and subjective to more quantitative researchers. Professional ethnographers use at least three criteria to help them to judge the reliability and validity of the ethnographic report.

First, they look for external corroboration of the ethnography. In part this is provided by pre-publication peer review by experts in the specific area of the world the ethnography concerns. However, the primary responsibility for external corroboration lies with the ethnographer, who is expected to refer to published materials by field subjects (when relevant) and by other ethnographers to support his or her conclusions. At this point in world history, there are few societies remote enough to be completely unknown. Second, they look at the richness of observational detail. Ethnography can be at risk of being dismissed as hearsay or anecdotal. But when the observational detail, reliably reported, is detailed enough, these objections no longer seem plausible. Ethnographic monographs are often weighty and at times tedious for that reason: the ethnographer supports an argument on a foundation of thousands of specific observations about thousands of events.

Third, they look for evidence that the ethnographer knows the ethnographic area well. As in any discipline, the conventions to judge competence are somewhat arbitrary, but still powerful. A year of full-time fieldwork is considered minimal; more years provide more reassurance about the quality of the data. Ethnographies thus present the specific dates and conditions of the fieldwork. To be able to converse in the language is minimal; to command idioms, whether in the spoken language itself or in the metaphorical language of local practice again provides more reassurance. Ethnographies give evidence of language competence and mastery of the local idioms of practice (the sheep trade, the shaman's invocations, the dancers' litany of foot complaints). To be accepted in the target social world well enough to have conversational and observation access to field subjects is also minimal, and so ethnographies typically describe how that access was acquired and maintained; sometimes these accounts are called 'arrival stories.'

There is, however, a hard-to-specify distinction between the competent ethnography and the really good one. Ethnographies do much more than give an account of who did what when. An ethnographer can sit in a courtyard for one full day and describe exactly what he sees, and his observations will fill a monograph; and the monograph will be unreadable and

unintelligible. By contrast, good ethnographies are accounts of a social world that make sense of that world to those who are alien to it. 'What the ethnographer is in fact faced with,' Geertz explained, 'is a multiplicity of complex conceptual structures, many of them superimposed upon or knitted into one another, which are at once strange, irregular, and inexplicit, and which he must contrive somehow first to grasp and then to render' (1973, p. 10). Good ethnography describes what is really important to understand about this world, both to the participants and to its observers; it conveys what people mean when they say, 'you really get it.' When anthropologists use the phrase 'thick description' to refer to the ethnographic method, they mean to imply that the anthropologist does serious, engaged fieldwork; that he really grasps the social process of the world being studied; and that he writes an ethnography so detailed and so observant that it is utterly persuasive.

2. *As an Epistemology*

'If you want to understand what a science is,' Geertz remarks early on in his famous essay, 'you should look in the first instance not at its theories or its findings, and certainly not at what its apologists say about it; you should look at what the practitioners of it do' (1973, p. 5). Ethnographers immerse themselves in another society for long periods of time, and collect far more bits of information than they could ever report or code or convey. Then they write books that attempt to describe the foreignness of that other world in ways that make it comprehensible to their readers.

As a consequence, Geertz argued, ethnographies are by their nature interpretations. They are not hypothesis driven and predictive. This does not mean that they are unconstrained and undisciplined. 'That is like saying that as a perfectly aseptic environment is impossible, one might as well conduct surgery in a sewer' (1973, p. 30). But they are not normal science—normal social science—in the style of psychological experiments and economics theories. The anthropologist, from this perspective, is more like a literary critic who writes about a novel that anyone could in principle read. They may write about the novel in many ways—explain it to those who do not understand, praise, or critique it, argue that other readers have misunderstood it, suggest that it captures certain human experiences that help its readers to see those experiences differently from before, insist that one way of thinking about it is more illuminating than another. But whatever they do, that novel exists as an art form independent of their presence, and their job is to help others to appreciate it more deeply. 'The claim to attention of an ethnographic account does not rest on its author's ability to capture primitive facts in faraway places and carry them home like a mask or a carving, but on the degree to which he is able to clarify what goes on in these places, to reduce the puzzlement—what manner of men are these?—to which unfamiliar acts emerging out of unknown backgrounds naturally arise, (1973, p. 16).

What can be interpreted, however, is only what can be 'read.' The power in the comparison of ethnography and literary criticism lay not only in the reasonableness of the general claim—fieldwork is indeed different from laboratory science—but in the pragmatic usefulness of its central metaphor. Following Paul Ricouer, Geertz not only compared the anthropologist to a literary critic, but described culture and social interaction as a text—the metaphorical 'literature' that the anthropological critic interpreted. More loosely, he described culture as discourse and as language. He argued that culture—'this acted document' (1973, p. 10)—was public because meaning was public. As an ethnographer, a watcher of others, you have no access to people's minds. What you can see is that they communicate, and you can interpret what they communicate, and what you are after is in effect the language or discourse that they are using, not the ideas they have in their mind. Geertz used Wittgenstein's private language argument to support the claim that culture, like language, was a public, social phenomenon, but his primary concern at the time was that you did not need to understand psychological process in order to be a good ethnographer. Understanding the mind was a psychologist's job; understanding culture was the anthropologist's.

And this central metaphor, of culture as a text, gave the ethnographer something specific to do: to identify symbols that somehow represented the particular social process of that group, and to then explain their meaning. In a much quoted definition Geertz stated: 'Believing, with Max Weber, that man is an animal suspended in webs of significance he himself has spun, I take culture to be those webs, and the analysis of it to be therefore not an experimental science in search of law but an interpretive one in search of meaning' (1973, p. 5). Geertz went on to argue that the kinds of things that anthropologists interpret—rituals, myths, cockfights—are themselves interpretations of the society in which they were found, and so the anthropologist is producing second and third order interpretations for a different purpose. 'The culture of a people is an ensemble of texts, themselves ensembles, which the anthropologist strains to read over the shoulders of those to whom they properly belong' (1973, p. 452).

Because (from this perspective) culture is a semiotic system, so that all representation is in effect interdependent, and because the social behaviors that despite everything anthropologists tended to think of as cultural—rituals, stories, songs; the noninstrumental side of life—are also understood as interpretations of their own society, the anthropologist could focus on some practice that on the surface seemed trivial or irrational, and use that practice to understand and reflect upon the nature of the social whole. Geertz did

this most famously in his essay on the Balinese cockfight. The cockfight is a seeming unimportant and irrational piece of Balinese culture in which grown men bet money they cannot afford to watch birds kick each other to death in illegal matches. Geertz suggested that Balinese men were gripped by their cockfights because the matches flung away the restrained, polished social hierarchy that otherwise defined Balinese daily life, and through his discussion, this small social practice became the prism through which you came to understand fundamental features of Balinese society.

In the decade after these two essays were published, Geertz became one of the leading figures of socio-cultural anthropology, if not its dominant presence, and his work precipitated a paradigm shift in the field and influenced other fields as well, most notably history. The new approach was called 'symbolic' anthropology and contrasted both with functionalism (a primarily British approach which sought to understand how all elements of social practice contributed to the effective functioning of that social world) and structuralism (an initially French approach that sought to identify the formal logic underlying cultural representation). David Schneider and the mid-career Marshal (Sahlins were also associated with this new emphasis on the way cultural practices represented social process, and symbolic anthropology tended to be associated with the department of anthropology at the University of Chicago, where Geertz had been before he left for the Institute of Advanced Study at Princeton. Rosaldo's *Knowledge and Passion* (1980), an ethnography which explores the society of the Filipino Ilongot head-hunters through a dominant emotion term, is a good representative of symbolic anthropology.

Now, however, the phrase that is associated with thick description is 'interpretive anthropology.' That phrase tends to mean that the ethnographer values serious (in depth, detailed) fieldwork and understands the ethnography as an attempt to make the foreign world comprehensible to the reader. The phrase also often implies that the anthropologist is self-consciously aware of the literary nature of the ethnographic enterprise: that ethnography is an act of writing, and that successful anthropologists are first and foremost writers. Finally, the phrase often (but not always) implies that this writerly, interpretive act is the primary goal of ethnography, and that anthropology cannot be a hypothesis-testing science, because its methods will not allow it to be so. As a result, the phrase is sometimes used to imply more about what ethnography is not, than about what it is, and the phrase can be used as a battle cry by those who wish to see anthropology associated with the humanities. Those battles however take the phrase beyond the domain that Geertz first mapped out.

Think Tanks

The term 'think tank' originated in the USA during World War II. It was used to describe secure and 'sealed environments' for expert strategists preoccupied with military planning (Day 1993). Subsequently, the term was applied to the RAND Corporation (initially a division of the US Airforce). By the 1960s, the term was entrenched in the lexicon and was being applied to independent research institutes throughout the English-speaking world, including bodies created much earlier in the century. Consequently, social science characterization of think tanks has been shaped by Anglo-American experience.

The proliferation of think tanks has been most pronounced in the USA, where generous foundation and corporate support, as well as government-contract research opportunities has been a boost to their development. Additionally, the constitutional architecture, federal structure, and relatively weak party system provided a conducive environment for think tanks to engage in policy debates and interact with government. At least 1200 think tanks have emerged in the USA since 1945 (Hellebust 1997). The stronger party systems, corporatist modes of decision making, strong, and relatively closed bureaucracies, and sometimes weak philanthropic sectors are often said to have dampened think-tank development in the parliamentary systems of Great Britain, its former dominions of Canada, Australia, and New Zealand, and most of Western Europe. Nevertheless, think tanks were present in these systems throughout the last century, with around 100 based in Britain and smaller numbers elsewhere.

Research institutes and think tanks are relatively autonomous organizations engaged in the research and analysis of contemporary issues independently of government, political parties, and pressure groups. They are relatively autonomous, although they are often in resource-dependent relationships with these organizations, funding may come from government sources, but institutes attempt to maintain their research freedom and usually claim not to be beholden to specific interests. Think tanks attempt to influence or inform policy through intellectual argument and

analysis rather than direct lobbying; they are engaged in the intellectual analysis of policy issues and are concerned with the ideas and concepts that underpin policy, although not all their research and activity need be policy relevant. Think thanks collect, synthesize and create a range of information products, often directed towards a political or bureaucratic audience, but also for the benefit of the media, civil society groups, and the general public. They are concerned with knowledge creation just as much as political communication and the effective application of knowledge.

Think tanks defy exact definition. They vary considerably in size, legal form, policy ambit, longevity, organizational structure, standards of inquiry, and political significance. Not only is there considerable scholarly difference over how to identify these organizations, but also the directors and senior scholars of these organizations often make fine distinctions between 'research institute' and 'think tank.' Such disputes usually revolve around the role of advocacy on the one hand, and organizational capacity for quality policy research on the other, with think tanks deemed to do the former and institutes the latter. Often this distinction is false.

Some organizations claim to adopt a 'scientific' or technical approach to social and economic problems; others are overtly partisan or ideologically motivated. While some institutes are routinely engaged in intellectual brokerage and the marketing of ideas, whether in simplified policy-relevant form or in soundbites for the media, others are more academic. Many institutes are discipline based—economic policy think tanks, foreign policy institutes, social policy units, etc. Specialization is a contemporary phenomenon. There are environmental think tanks, regionally focused operations, and those that reflect the communal interests of ethnic groups. While most display a high level of social-scientific expertise or familiarity with governmental structures and processes, and usually with international politics, there is considerable diversity in style and output of think tanks. The 'ink tank' can be poised against the 'think-and-do tank.' In other words, there are significant differences between think tanks that are scholarly in focus and geared towards publication of books and reports, and think tanks that are more activist and engage in grass-roots activity.

The Western view that a think tank requires independence or autonomy from the state, corporate, or other interests in order to be free-thinking does not accord with experiences in other cultures. In many countries, the line between policy intellectuals and the state is blurred to such an extent that to talk of independence as a defining characteristic of think tanks makes little sense. Many organizations now called think tanks operate within government; this is evident in countries such as the People's Republic of China. Some institutes have been founded or incubated in government and subsequently made independent; it is not unusual to find institutes with political patrons or formal links to political parties. Many of the German foundations, for instance, have been established by political parties or have strong ties to the *Länder*, and some German institutes have grown to such a large size that they rival some of the major American institutes. In other circumstances research institutes are attached to corporations, as is evident in Japan, South Korea, and Taiwan. Notwithstanding funding dependence or political affiliation, high-quality research and analysis along with critical advice is feasible.

Accordingly, financial independence can be construed as developing an endowment or having numerous sponsors and a diverse funding base, so that an organization is not dependent on any one benefactor. Scholarly independence is reliant upon certain practices within an institute: the processes of peer review and a commitment to open inquiry rather than directed research. Legal or administrative independence comes from constitution as a private organization. Administrative and financial independence may be a facade under authoritarian or illiberal regimes where censorship and control prevail. Alternatively, some institutes may exhibit a high degree of research freedom despite being found within the state architecture. Appreciation of the political culture of a nation is essential to interpreting think tank independence and intellectual leverage.

A further problem of definition is that it is often difficult to establish a precise distinction between think tanks and other organizations with similar objectives; for example, operating foundations. Think tanks could also be regarded as more intellectual variants of pressure groups of nongovernmental organizations (NGOs) since many now base their arguments on relatively sophisticated research that is sometimes conducted in-house. Nevertheless, there are important differences: think tanks do not engage in public demonstrations and they tend to address multiple policy areas (notwithstanding specialization) rather than focus on a single issue as do many pressure groups. There are similarities with consultancy firms, financial institutions, or legal offices that provide contract research and analysis, although these organizations engage in a wider range of activity than research; yet many think tanks only survive through their consultancy services and contract research.

Some think tanks have been described as 'universities without students' (Weaver 1989, p. 564); while the relationship between think tanks and universities has been close in most political systems, important differences are usually observed, for example, think tanks are not normally degree-granting institutions. There are a few exceptions, however, notably RAND in the USA and FLACSO in Latin America. In terms of future think-tank development, the blurring of boundaries and the overlap of objectives and activities

between institutes and other organizations in society may mean that these organizations lose organizational distinctiveness.

In the last two decades of the twentieth century, the number of think tanks has proliferated. Countries where think tanks were already present such as the USA, Britain, Sweden, Canada, Japan, Austria, and Germany witnessed further organizational growth. Increased competition in the think-tank industry has often encouraged policy advocacy and the politicization of institutes, most particularly in the USA. The Heritage Foundation is usually cited as the exemplar. Elsewhere, democratic consolidation, economic development, and greater prospects of political stability in Latin America and Asia provided fertile conditions for think-tank development. The demise of the Soviet Union also opened political spaces for policy entrepreneurs. The think-tank model has been exported around the world. The term 'think tank' has been adopted in its English wording, with all its cultural connotations (Krastev 2000). The global think tank boom development has been prompted by foundations, corporations, and other nonstate actors demanding high-quality research, policy analysis, and ideological argumentation on the one hand, but, on the other, by grants and other funding from governments and international organizations seeking to extend policy-analytic capacities, aid civil society development, or promote human capital development.

Beyond the nation-state, there are strong signs of think-tank adaptation and evolution. The activities of international organizations such as the United Nations agencies, the World Bank, the International Monetary Fund, and the World Trade Organization have drawn think tanks into their ambit. The European Community provides yet another institutional forum for think-tank activity with the emergence of EU-wide think tanks disengaged from specific national identities. Furthermore, with the revolution in information and communication technology, the possibilities for policy research disconnected from specific organizational settings has become increasingly feasible and fashionable. It has also made international research exchange and collaboration between think tanks commonplace. Global and regional think-tank networks have become extensive.

In tandem with this extensive organizational growth, scholarly interest has expanded. Where discussion of think tanks was once limited almost exclusively to Anglo-American systems (see *inter alia*, Weaver 1989, Stone 1996, Smith 1991), interest has expanded to other OECD nations. Wider disciplinary interest has resulted from a core of scholars interested in comparative politics (Thunert 2000) and public policy to include international relations and security studies specialists as well as a greater array of anthropologists, economists, and sociologists writing in this field. Current research trends are increasingly focused on think-tank development in the developing world (McGann and Weaver 2000) and post-communist transition countries (Krastev 2000). Think-tank transnationalization is likely to be a field of future research given the impact of globalization and regionalization on institute research agendas and activities.

Analysis of think tanks has diverged into two branches. Those focused on the organizational form such as Weaver (1989), with McGann and Weaver (2000) and James Smith (1991), were interested in explaining why and how think tanks have emerged and why some think tanks are influential. They distinguished independent public-policy institutes from academic research centers, government research units, or lobbyists. They focused on the organizational ingredients of what makes a think tank successful, how think tanks are managed, who funds them, who quotes them, and whom they try to influence. Writers in the second branch analyzed think tanks as a vehicle for broader questions about the policy process and the role of ideas and expertise in decision making. Writers such as Diane Stone (1996), Ivan Krastev (2000), and Martin Thunert (2000) employed network concepts such as 'policy community,' 'advocacy coalitions,' and 'epistemic communities' to explain why ideas matter. It cuts to a central issue in the study of think tanks—policy influence.

Notwithstanding extensive growth, think tanks do not enjoy automatic political access or unhindered bureaucratic routes to decision makers. Think tanks need to have some kind of engagement with government if they are to have policy relevance; however, their desire to preserve intellectual autonomy means that most think tanks try to strike a delicate balance between dependence on government and isolation from it. Conducting policy-relevant research and attempting to broker it to decision makers does not equate with policy influence. This conundrum has been the major methodological problem in the study of think tanks.

Proof of influence is elusive. There is no clear causal nexus between policy research or an idea espoused by an institute, and political decisions and policy change. It is a rare occurrence that a policy outcome can be attributed to one organization, as there are other intermediary forces; political parties, interests, and the media also shape the content and reception of ideas. Furthermore, the cognitive order of politicians and bureaucrats cannot be accessed by 'think-tanks' researchers, and interviewing has its own problems of faded memories and selective recall in establishing the veracity of perceptions of think-tank policy input. This hiatus is compounded in that the political stature of many institutes waxes and wanes over time, and that the criteria by which influence is assessed vary not only across think tanks but within the social sciences in general.

Nevertheless, there are many countries where overstretched bureaucracies and limited capacities for in-

house governmental policy analysis provide the opportunity for think tanks to serve government needs; however, the degree of incorporation and cooption varies from think tank to think tank, and from one country to another. Latin American institutes, particularly the liberal institutes, were often marginal to the political system until the demise of authoritarian regimes. By contrast, a group of elite think tanks in Southeast Asia have enjoyed a much closer relationship with their governments where the trade-off was accommodation with government concerns and controls. A large number of neoliberal or free-market research institutes eschew government funding. The organizational choices made by think tanks about their relationship to centers of power and authority must be understood by reference not only to the ideological disposition or mission of the think tank, but also by acknowledging environmental conditions such as legal and economic constraints of the political culture in which they are located.

Outside the political sphere and state sector, think tanks have cultivated other audiences. Students and academics in colleges and universities regularly use think-tank publications. Foundation officials, business executives, bureaucrats from various international organizations, university researchers, journalists, and, for want of a better term, the 'educated public' are often engaged by think-tank pursuits. Similarly, third-sector intellectuals such as are found among trade unionists, religious spokespeople, NGO leaders, and social-movement activists can be attracted by the intellectual and ideological sustenance to be found in the think-tank community. Furthermore, think tanks provide an organizational link and communication bridge between their different audiences. They connect disparate groups by providing a forum for the exchange of views, by translating academic or scientific research into policy-relevant publications, and by spreading policy lessons internationally.

Third Parties: United States

A third party is any political party in the US political system other than one of the two major parties. The term is applied generically to all such minor parties, regardless of reputation or record. There are many third parties in the USA. In 1996, for example, presidential candidates for the Reform and Libertarian parties appeared on ballots in all 50 states and in the District of Columbia, the Natural Law Party's candidate made it onto 45 ballots, the candidate for the US Taxpayers Party was on 41 ballots, and the Green Party's candidate appeared on 24 ballots. Candidates from 11 other parties were listed on the ballot in at least one state. Moreover, 1996 was not an unusual year. In almost every election many candidates appear on the ballot (Rosenstone et al. 1984, pp. 231–5).

Although there are many political parties in the USA, the US political system is correctly classified as a two-party system. The same two political parties, the Democrats and the Republicans, have held dominant positions since 1860. Third-party candidates win remarkably few elections. In 2000, none of the 100 US senators was elected from a third party, and only one of the 435 members of the US House of Representatives was a member of a third party—Bernard Sanders of Vermont, a socialist elected as an independent. Only two of the 50 state governors were elected as something other than a Republican or a Democrat (Angus King, an independent in Maine, and Jesse Ventura, from the Reform Party in Minnesota), and of the 7,524 state legislators, only 20 were elected from third parties.

The USA has a two-party system for several reasons. The most compelling is the single-member, plurality electoral system used in the vast majority of elections. Under these rules the US House of Representatives, for example, is divided into 435 districts. Each district elects only one representative. The winner in each district is the candidate who receives a plurality of the votes. Third-party candidates almost never succeed under such rules, and a stable two-party system emerges. The generalization that a country with a single-member, plurality electoral system develops a two-party system is called Duverger's Law after the person who first noted it (Duverger 1959).

The two-party system's stability has been reinforced over the years by laws passed by institutions controlled by the major parties that limit the ability of third parties to compete successfully for votes. Ballot access

rules, for example, virtually assure that candidates from the two major parties will appear on them, but often make it very difficult for candidates from other parties to be listed. Indeed, at times during the twentieth century some states employed laws that, in effect, guaranteed the two major parties ballot listings in perpetuity. A 1949 law in Florida, for example, stated that any party that had elected a president since 1900 would automatically qualify for the ballot, something that only the Democrats and Republicans had accomplished. That law was repealed in 1977. Most states now grant ballot access to parties based on their candidate surpassing some threshold percentage of votes in a specified earlier election, typically a gubernatorial election. The other route to gaining ballot access is through a petition drive. Such petitions require the signatures of some specific number of citizens or, in some states, registered voters. The number of required signatures varies by state. The higher the number of signatures required, the greater the obstacle to getting a third-party candidate on the ballot. As Lewis-Beck and Squire (1995) have shown, the difficulty in getting a third-party candidate on the ballot increases with the political stakes in a state. Thus, the states with the greatest number of electoral college votes are those with the most stringent ballot access requirements.

Most American states ban fusion candidacies, another restriction that hampers the ability of third parties to become competitive. Fusion is the process allowing a candidate to appear on the ballot as the nominee of more than one party. In the state of New York, for example, a candidate can be the nominee of more than one party. Thus, a candidate nominated by the Republican Party also can be the nominee of the Conservative Party. Fusion enhances the prospects for third parties by allowing them to associate themselves with popular candidates, and perhaps increase their vote totals over what they would otherwise have gotten. Increased vote totals can matter because they are often the standard used to determine ballot access in the next election. The United States Supreme Court in a 1997 decision, *Timmons vs. Twin Cities Area New Party*, upheld the constitutionality of the state of Minnesota's law prohibiting party fusion.

Finally, campaign finance laws work to the benefit of the two major parties and to the detriment of third parties. In presidential campaigns, for example, the law provides direct financing for the general election campaigns of the Democratic and Republican candidates. Third-party candidates, however, are often in the position of not qualifying for any public financing, or only qualifying after the fact—based on the percentage of votes they receive in the general election. Without the same access to campaign funds as the major parties, third-party candidates find it difficult to make their case to the voters.

There also are informal norms in US politics that work against third parties. Third-party candidates are rarely accorded the same level of news coverage as major-party candidates. Similarly, third-party candidates are often excluded from candidate forums and debates sponsored by civic organizations and the media. Exclusion is usually justified on the basis of the lack of public support for or interest in third parties and their candidates. Such exclusion, however, prevents third parties and their candidates from publicizing their policy positions, keeping them from possibly expanding their meager bases of support.

The first third party was the Anti-Masonic Party, formed in 1827 in response to concerns about the supposed influence of Freemasons on US government. The Anti-Masonic Party lasted only a few years before merging with one of the then major parties, the Whigs, in 1838. During its brief life, the Anti-Masonic Party made one enduring contribution to US politics: they were the first party to hold a national convention, an innovation immediately adopted by the major parties and which they continue to use today.

Third parties became more prevalent on the national political scene during the second half of the nineteenth century. Notable among them were the Greenback Party, the Populist Party, and the Prohibition Party. The Greenback Party existed from 1874 to 1888. It was formed to promote the continued issuance of paper currency (popularly referred to as 'greenbacks') as a means to increase inflation and thereby lighten the debt burden carried by midwestern farmers. Although the party managed to win some seats in the US House of Representatives, support for it declined after a different inflationary scheme, one calling for the free issuance of silver coins, came into vogue.

The push for 'free silver' resulted in the establishment of another third party in the early 1890s. Formally called the People's Party, but more commonly referred to as the Populist Party, this group worked to represent the interests of farmers and the emerging industrial working class. Among the policy positions they espoused in their 1892 platform were free silver, government ownership of the railroads, a graduated income tax, the direct election of US senators, and an eight-hour day for industrial workers. The party enjoyed some success in the 1892 election—their presidential candidate, James Weaver of Iowa, won 22 electoral votes—but that proved to be its high-water mark. By 1896 the Democrats had adopted many of the Populists' positions, and the party ended up supporting the Democrat's presidential candidate, William Jennings Bryan. The Populists ran their own presidential candidates in 1904 and 1908, but ceased to function as a political party after that point in time.

Although many third parties existed during the twentieth century, they were, in most instances, qualitatively different from those in the nineteenth century. As Rosenstone et al. (1984) observed, third parties in the nineteenth century were organized around specific issues and ideologies. The two incarnations of the Prohibition Party, for example, were formed to push a

specific issue, the prohibition of production and consumption of alcohol. In contrast, most twentieth century third parties were centered on particular personalities rather than policies. The three Progressive Parties demonstrate this point. The first Progressive Party was created in 1912 to support Theodore Roosevelt's attempt to recapture the presidency. Also called the Bull Moose Party, this version of the Progressives gave its 1916 nomination to the Republican Party's candidate, and then, in effect, disappeared from the political scene. The Progressive Party re-emerged in 1924, uniting with another third party, the Socialist Party, in support of Robert La Follette's campaign for the White House. The last significant appearance of the Progressive Party label was in 1948, when former Vice-President Henry A. Wallace ran as the party's candidate for president. Although there were some common policy themes across the three major Progressive Parties, there were also significant differences, and there was virtually no organizational continuity. All three efforts were driven by well-known political personalities and after each of them failed to win office, the party, for all intents and purposes, ceased to exist.

The major third-party efforts in the second half of the twentieth century were all personality driven. George Wallace's impressive performance in the 1968 election led to the formation of what is now called the American Independent Party. But without the former Alabama governor on the ballot the party has never again been taken seriously. Of all the third-party efforts in the twentieth century, perhaps only the Reform Party, created primarily through the efforts of 1992 and 1996 presidential candidate Ross Perot, has any chance to become established as a significant political force independent of the personality around which it was first built.

What role do third parties play in US politics? There is little evidence that significant third-party challenges bring more Americans to the polls. In 1948, for example, voters were offered two serious third-party candidates (Governor Strom Thurmond, of the States' Rights Democrat (Dixiecrat) Party, and the Progressive Party's Wallace). Voter turnout that year was almost five percentage points lower than in 1944 when no significant third-party efforts were mounted. Similar patterns held in 1968 and 1980 when important third-party candidates ran, but voter turnout fell compared to the previous election. Only Ross Perot's 1992 campaign was associated with an increase in turnout, an almost five-point gain over 1988. But his presence in the 1996 campaign failed again to increase turnout. In fact, participation declined more than five points.

There are, however, two important contributions third parties make to the US political system. First, they offer voters a way to express dissatisfaction with the two major parties and their candidates. Second, third parties are vehicles for promoting issues and policies that the major parties may ignore. If the issues raised by third parties resonate with the public, the major parties are apt to embrace them. Many of the policies espoused by the Populist Party, for example, proved popular and were commandeered by the major parties. Thus, although the Populist Party disappeared from the political landscape, a number of the ideas it brought to the political debate were later enshrined in law.

Third World

1. Defining the Third World

The Third World has become a convenient catch phrase that refers collectively to the large number of heterogeneous societies, cultures, and civilizations of the non-Western world most of which lie in the tropics, have experienced colonial rule, whose economies are less industrialized or not completely modernized and a majority of whose population has the lowest standards of living or are considered or consider themselves poor relative to those of the First and Second Worlds. The Third World includes all countries of Africa (except South Africa), Asia (except Japan), and Latin America and the Caribbean, and some states and territories of Oceania.

2. The Origin of the Term, and its Varied Meanings

The term 'Third World' (*le Tiers Monde*) is of French origin. It was first used in France in the early 1950s by a number of French writers like Alfred Sauvy (politician, economist, who is credited with coining the term in 1952) and Claude Bourdel, in the context of apparently increasing polarization of the international system into rival blocs. The term conveys a con-

scious echo of the older concept of '*le tiers etat*' that is, 'the third estate' (the common people, the poor and underprivileged) of the prerevolutionary *ancien régime*. Some claim that it was Frantz Fanon, Martiniquan writer and psychiatrist (author of *The Wretched of the Earth* 1963), who first used the term to refer to the poor decolonized societies of Asia, Africa, and Latin America.

The term has been used in several related senses, substituting for or succeeding other terms used by Europeans to refer to non-European peoples and cultures: 'aboriginal,' 'indigenous,' 'savage,' 'barbarous,' 'traditional,' 'native,' 'primitive,' 'tribal,' 'oriental,' 'Arab,' 'Negro,' 'Indian,' 'Mohammedan,' 'pagan,' 'precapitalist,' 'pre-industrial,' 'non-Western,' 'non-White,' 'premodern.' Such terms have been used sometimes with deliberate contempt and condescension, with pejorative connotations, or even racist overtones. These terms have also been adopted by the educated, more privileged urban-dwellers in the Third World itself.

'Third World' has also been employed as a shorthand euphemism for the social condition or plight of the very poor or powerless or underdeveloped society anywhere in the world, including the First and Second Worlds, even though a vast majority of the people fitting the description live in the Third World. In this sense, the phrase 'America's Third World' refers to America's rural and urban poor: the black underclass, native Americans, and rural white Appalachians. In a similar usage, the former Soviet Union was once described by the *Times* of London as having a 'Third World' economy with First World weapons. South Africa is described as a First World society in which the Third World is ever present.

The term 'Third World' has also been extended to the poorer Eastern European countries whose economies were subjected to the needs of and exploited by Northern Europe in the early modern period. In everyday use, the term has thus acquired loose, but frequently negative, social, cultural, political, economic, ideological, and 'racial' meanings, often with a fine disregard for geography. From 1945 to 1989 a capitalist block (First World) led by the United States and a communist one (Second World) led by the Soviet Union fought a cold war which ended with the collapse of the Soviet Union in 1991. In the Cold War context the Third World consisted mostly of newly decolonized, uncommitted countries not aligned diplomatically with either the capitalist world or the communist world. But the two dominant historic models of development, capitalism and socialism, especially the former, continued to broadly shape the rate and direction of change in the Third World.

3. *Third World as an Analytical Concept*

Since World War II and the invention of the term, the conditions of Third World, and the relationship among the First, Second, and Third Worlds, have been the focus of theory, intensive research, and extensive documentation, aimed at understanding the origin and nature of poverty in the Third World, and of policy concerned with strategies for development and poverty alleviation. The leading theories of Third World development include 'modernization theory,' 'dependency theory,' and 'world-system theory.' Some Marxist scholars have rejected the term 'Third World' as a false concept, masking the contradictions of capitalist development in the former colonies. Third World countries often see themselves as old societies 'lagging behind' economically and even politically and thus trying to 'catch up' with the more advanced industrialized countries of the First and Second Worlds.

The rise and spread of capitalism globally were intimately linked to the growth of large powerful oppressive and exploitative European colonial empires, inspired by the prevailing mercantilist philosophy of the early modern period dedicated to the unbridled pursuit of economic power and wealth of states.

Because of its vast natural resources, which were largely untapped, its considerable potential commercial value, and the importance of some areas to White settlement and occupation, the Third World has been for over five centuries a principal focus of European territorial ambition and rivalry. Most of the states and territories of the Third World took their present form in the nineteenth and early twentieth century when large parts of Asia and Africa were colonized by European imperial powers. By the 1880s the world had been carved up among a handful of European industrial powers. By 1914 European economic and political control covered most of the global land surface, claiming nearly the entire non-European world. Japan successfully resisted European colonization, and China was never formally colonized but for the highly lucrative treaty ports along the coasts, e.g. Hong Kong following the Opium Wars of the 1830s. Latin America, conquered, colonized, and settled by the Portuguese and Spanish crowns three centuries before Asian and African colonization, was transformed into independent republics, along with formerly French Haiti in the Caribbean, in early nineteenth century, after long, bloody and bitter nationalist struggles. Likewise, anticolonial protests and revolts, often violent and bloody, led to the decolonization of Asian, African, Caribbean, and Pacific countries in the late 1940s and after. But in both cases political freedom did not end foreign—mostly European—economic control and ownership, or bring about rapid industrialization and better living standards for most of the new states.

The European metropolitan powers made colonies a principal source of raw materials destined for European industries and consumer markets while suppressing the development of manufacturing industries in the colonies to avoid competition as they

provided markets for European manufactured goods. Arguably the affluence of industrial Europe is literally the creation of the Third World.

Colonialism which followed the transatlantic slave trade in Africa, during which an estimated 10 million or more Africans were exported to provide unpaid labor for European plantations and mines of the Americas, did incalculable damage to black Africa, notwithstanding some lasting beneficial by-products: Christianity, schools, hospitals, and the start of modern administration. The colonial borders which were drawn across Africa divided African peoples and cultures, and along with the authoritarian and repressive colonial political tradition are largely responsible for much of the chronic poverty, cultural identity crisis, and political instability of independent African countries. Despite wide differences in local cultures, historical traditions, and responses to colonialism, colonies came to share several common features: political control from Europe; unchecked economic exploitation; and particularly in the black world, the construction and reproduction of a racist social order of which apartheid of South Africa was the most notorious recent example.

One enduring legacy of European colonial empires is a global economic order with an asymmetrical North–South division between a rich industrial North of mostly former imperial powers and poor, less industrialized South of former colonies. The North–South divide is exacerbated by neocolonialist attempts to influence or exercise *de facto* control over the policies of the South through formal and informal alliances and agreements calculated to ensure the perpetuation of the hegemonic economic power of the North.

4. *The UN and the Rise of the Third World*

The United Nations charter endorsed the principle of self-determination and sovereign equality of all nations. After the late 1940s, the large ex-colonies like India, Pakistan, Egypt, and Indonesia, supported by Latin American countries, used the UN as a forum to press for an end to colonialism and rapid development of former colonies. The term 'Third World' received formal endorsement following the Bandung conference of Asian and African states in Indonesia in April 1955, which affirmed the solidarity of the Third World, and prepared for the birth of the nonaligned movement (NAM). At the conference, China declared herself a 'Third World' country. The term was also adopted in the UN classification system to distinguish between the developed and underdeveloped countries.

The conferences of the NAM, the first one held in Belgrade (former Yugoslavia) in 1961, and the founding in June 1964 of the UN Group of 77, at the conclusion of the first UN conference on Trade and Development (UNCTAD), which was convened at the initiative of Third World countries, marked the growth of the Third World as a potent force in world affairs.

With approximately two-thirds of the total UN membership, the 1960s and 1970s witnessed the rapid rise in the power and sense of purpose of the Third World. The G-77 spearheaded the UN call for a New International Economic Order (NIEO) to reform the economic relations between the North and the South and to rectify the inequality evident in the relative access of the rich and poor countries to markets, to supplies, to science and technology, and to credit, which implied a redistribution of wealth in favor of the South. The issue of North–South relations was made the subject of an international commission which met from 1977 to 1979 under the chairmanship of Willy Brandt.

By the 1990s, with the collapse of the Soviet Union and the end of bipolar politics, NAM and the G-77 which have a joint coordinating committee shifted their focus to problems of underdevelopment, the Third World debt burden, trade liberalization, and aid.

The G-77, whose membership increased to 130 with the admission of post-apartheid South Africa, believes that global shared prosperity through North–South cooperation on a fair and equitable basis is the only long-term remedy for Third World poverty and human misery.

5. *Diversity, Division, and Integration*

Depending on the definition and context, different countries or populations will make up the Third World. Accordingly, the 'Third World' may be further divided into those states that have access to rich natural resources, faster growth rates or better development potential and those which do not. While the latter are sometimes described as the 'Fourth World,' that term is probably more frequently used to refer to marginalized indigenous or tribal peoples. Despite internal divisions and differences, Third World countries share some common features as well as problems.

Most of the peoples of the Third World still suffer from hunger, disease, ignorance, lack of shelter, potable water, and opportunities (especially for women) to realize their potential as human beings. Third World countries are faced with crippling external debt burdens, poor social and physical infrastructure, and inadequate technology, making it difficult or impossible to recover from or respond effectively (without massive external help mostly from the First World) to natural disasters and civil conflicts to which many are prone. Because of the chronic and deepening poverty in the midst of burgeoning populations, diminishing natural resources, and increas-

ingly degraded environments, these countries have also become major producers of massive illegal political and economic migrations to the more prosperous industrial capitalist North, and of economic and political refugees and internally-displaced persons within the Third World itself.

6. *The Third World and the Post-Cold War International System*

The 'Third World' as an ideological concept has been undermined by the end of the Cold War, the collapse of Soviet-style communism, and the increasing cooperation between the leading industrial capitalist nations—the G-77—and Russia. Its economic meaning has also been challenged by the fundamental changes in the world economy, brought about by the forces of globalization. The transition of the former Soviet Union and Eastern bloc countries and some Third World nations to pluralist democracy and market economies has made it increasingly difficult to distinguish between some First and Second World countries, and in some cases between Third World and Second World countries.

Given the wide range in the levels of economic development and standards of living within and between Third World countries, placing prosperous Hong Kong and impoverished Haiti, or industrializing Brazil and hunger prone Bangladesh, in the same category is clearly questionable.

Again, by the end of the twentieth century, new economic groupings made up of selected countries of the First, Second, and Third Worlds, some of them regional (e.g., NAFTA), were formed to promote regional prosperity; and others, cross-regional (e.g., Group of 20), emerged to foster dialogue if not unity of action between the rich industrial countries and countries of the emerging markets. The growing convergence of national and transnational economic and political interests has added a new challenge to the usefulness of the Third World as an economic or ideological category.

In the new strategic global environment, the NAM also seems increasingly anachronistic. But the overall objectives of the NAM which include the pursuit of world peace, the elimination of disease, hunger, and ignorance; the conduct of international relations on the basis of respect for and understanding of other cultures, systems, and values; and the elimination of all forms of neo-colonialism and racism, make it still relevant.

Despite the new redefinition/regrouping of economies, and the cross-cutting interests reflecting the progress of globalization, the industrial countries, mostly European—the First and Second Worlds—still have between them most of the world's economic power and military might. Of the estimated global population of six billion, only about 20 percent live in the rich North; the overwhelming majority (80 percent) live in the impoverished South. Yet 86 percent of global output of goods and services is produced and consumed by the developed countries. Key measures of human well-being and survival such as gross-national product per capita (GNP), per capita energy consumption, life expectancy, infant mortality rates, and literacy levels, attest to the unacceptably wide and growing gap between the world's richest and poorest (Third World) countries.

Thirst and Drinking

Drinking is one of the triad of motivated ingestive behaviors used by animals to ingest those substances essential for maintaining metabolism, growth, and

overall bodily integrity. Feeding controls the intake of nutrients (fat, protein, carbohydrates), vitamins, and cofactors; targeted appetites control the intake of specific ions (principally sodium, but also to a lesser extent other essential ions such as calcium) from a variety of sources; while drinking regulates water intake. These behaviors are controlled by complex neural systems that have components distributed throughout the brain, and transform the need to replenish or anticipate deficits, the desire to find suitable goal objects, and knowledge of their whereabouts into appropriate sets of behavioral and visceral motor output (see also *Motivation, Neural Basis of*).

1. Composition and Physiological Regulation of the Body's Fluid Compartments

Understanding how body fluids are compartmentalized and which of their components are maintained within regulated limits is central to understanding how drinking behaviors are initiated.

The body consists of two fluid compartments: a cellular compartment comprising the internal fluid of all cells, and an extracellular compartment comprised of all interstitial fluid and plasma in the blood. In terrestrial mammals the water in the cellular compartment makes up about 65–70 percent of the body's total water. Fluid in the cellular compartment is separated from extracellular fluid (ECF) by the semipermeable membranes that surrounds all cells. This membrane is completely permeable to water, but the transmembrane movement of many other molecules and ions is actively regulated, making the physiology of this membrane critical for water balance.

One of the key features of the cell membrane is its ability of the enzyme Na^+/K^+ ATPase to promote the active transport of sodium ions out of the cellular compartment. This enzyme is a two-subunit transmembrane protein, is a major utilizer of cellular energy, and exchanges 3 Na^+ out of the cell for 2 K^+ in. This process maintains the ECF Na^+ concentration (150 mM) at about tenfold greater than that inside the cell. This concentration gradient is critical for fluid balance and the control of drinking behavior because it determines the rate of water flux across the membrane.

Two variables of the ECF compartment are regulated tightly by physiological and behavioral process: ECF osmolality and volume. Under conditions of isotonicity the net flow of water across the cell membrane is zero. However, any disturbance of this osmotic balance leads to increased transmembrane water flow. The sodium ion is the most important osmolyte in this regard. In terms of thirst and drinking, increasing the osmolality of the ECF compartment is an important parameter that results in cellular dehydration, which is a net loss of water from the cell. In turn, the kidney attempts to excrete the excess sodium from the blood, but this cannot be achieved without incurring an accompanying loss of water from the body.

ECF volume is important for long-term maintenance of blood pressure and efficient cardiovascular function. Unlike cellular dehydration, which involves a net loss of water but not sodium, loss of fluid from the extracellular compartment (hypovolemia) involves loss of water and all of its other components, including sodium. Therefore, in addition to triggering an appetite for water (i.e., thirst), hypovolemia also initiates the specific appetite for sodium (Grossman 1990).

2. Types of Drinking Behavior

Drinking behaviors can be divided usefully into two categories: those that occur in response to a significant disturbance in ECF composition and result in a classic homeostatic response; and those that occur in the absence of such a disturbance, but instead are initiated to prevent the occurrence of such deficits. Each of these types of drinking is associated with distinct neural mechanisms (Grossman 1990, Rolls and Rolls 1982).

2.1 Homeostatic Drinking

The most well-studied aspects of drinking behavior are those initiated in response to significant changes in ECF composition. A large body of work has identified specific types of dipsogenic (i.e., thirst-inducing) sensory signals that are associated with particular disturbances to the composition of the ECF. In humans, the most common form of homeostatic drinking occurs in response to exercise or heat-stress. Pathological causes of homeostatic drinking include severe hemorrhage or conditions associated with severe diarrhea.

2.2 Anticipatory Drinking

Drinking that occurs without a major disturbance to ECF composition requires regulation by regions of the brain concerned with the anticipatory components of motivated behaviors. Two groups of brain regions are particularly concerned with regulating this type of drinking; those involved with controlling arousal state and circadian timing (particularly the circadian clock in the suprachiasmatic nucleus), and those cortical regions concerned with the complex processing of sensory objects and their representation in processes such as reward/aversion, and learning and memory

Figure 1
The relationship between nocturnal water and food intakes in individual laboratory rats allowed either unrestricted (closed circles) or restricted access to food (open circles). Note the strong correlation that is maintained during limited access to food

(Watts 2001). In these circumstances, drinking is often closely associated with feeding behavior, both temporally and in quantity (Fig. 1). Food-associated water intake (either as a component of the food itself or as a separate drinking episode) represents the most common route of water entry into the body for humans living in economically developed countries (see also *Hunger and Eating, Neural Basis of*).

3. *Sensory Signals and their Transduction*

3.1 *Extracellular Fluid Volume*

Physiological mechanisms concerned with maintaining ECF volume are evolutionarily older than those that maintain ECF osmolality. This is because the challenge from water deprivation and increasing ECF osmolality did not pose a physiological threat until the evolution of terrestrial life. Indeed in primitive vertebrates, the physiologically more important actions of two of the hormones most closely associated with the response to dehydration—angiotensin II (ATII) and the vasopressin-related peptides—is vasoconstriction driven by AT1 and V1 receptors, respectively, which leads to a reduction in renal blood flow, and consequently reduced fluid loss from the kidneys. The antidiuretic actions of vasopressin are evolutionarily more recent and are mediated by specific water channel proteins called aquaporins. An elevated insertion rate of these proteins into the basal membrane of convoluted tubule is mediated by vasopressin's interactions with V2 receptors. Although vasopressin has significant effects on water conservation, it has no dipsogenic actions. Decreases in ECF volume are transduced into appropriate motor actions by two sensory mechanisms.

3.1.1 Angiotensin II. Reduced blood flow through the specialized juxtaglomerular apparatus in the kidney stimulates the release of an renin, an enzyme that catalyzes the conversion of angiotensinogen to angiotensin I. Once in the general circulation angiotensin I is converted to ATII by angiotensin-converting enzyme in the lungs. ATII has four major actions associated with thirst and fluid balance. First, it acts on vascular AT1 receptors to constrict blood vessels and maintain blood pressure; second it is dipsogenic; third, it stimulates sodium appetite; and finally, it acts on zona glomerulosa cells in the adrenal cortex to stimulate aldosterone release, which then targets the convoluted tubules in the kidney to potentiate sodium retention. To stimulate drinking, circulating ATII binds to AT1 receptors in the subfornical organ (SFO). This structure is the most sensitive ATII responsive site in the brain and many studies place this structure centrally in a circuit that directly and specifically stimulates water intake (Fitzsimons 1998). The SFO provides neural efferent projections—most of which also contain ATII (Swanson 1987)—to a relatively limited set of brain structures, including parts of the prefrontal cortex, substantia innominata, medial preoptic area, bed nuclei of the stria terminalis (BST), zona incerta, paraventricular hypothalamic nucleus (PVH), supraoptic nucleus, and lateral hypothalamic area (Swanson 1987).

3.1.2 Baroreceptors. Inputs from baroreceptors in the walls of blood vessels on low-pressure (venous) side of the circulation (primarily the superior vena cava) provide important neural information that contributes to the thirst generated by hypovolemia. This is demonstrated by the fact that the thirst generated by hypovolemia is inhibited by a small inflatable balloon placed to maintain the output of the baroreceptors in the wall of the superior vena cava as the animal becomes hypovolemic (Kaufman 1984). The afferent information from these receptors is initially

processed by the nucleus of the solitary tract (NTS) in the hindbrain, before being relayed to those regions of the brain responsible for organizing drinking behavior.

3.2 Extracellular Osmolality

All cells are *osmosensitive* in that they lose water and shrink in proportion to increases in the osmolality of the ECF. However, these increases are only transduced into neural signals by select groups of *osmoreceptive* cells located in the brain and periphery. In terms of thirst and drinking behavior, the most important set is located in the vascular organ of the lamina terminalis (OVLT), a hypothalamic structure located at the rostral end of the third ventricle. Supplementary sets of osmoreceptors may also contribute to the motor responses to dehydration, and are located at other sites in the brain (particularly in the SFO and area postrema) as well as in the periphery (the liver and possibly hepatic portal vein).

A cellular mechanism that accounts for the osmotransduction exhibited by some neurons has recently been described by Bourque and co-workers (Bourque and Oliet 1997). In this scheme, osmoreceptive magnocellular neurons in the supraoptic nucleus possess stretch-inactivated cationic channels that allow increased entry of positive charge as they shrink in response to increasing ECF osmolality (Fig. 2). In turn, these neurons depolarize and generate action potentials in proportion to the change in ECF osmolality (Fig. 2). Interestingly, unlike many other types of sensory receptors, the osmoreceptors associated with drinking apparently do not adapt when exposed to a slowly changing stimulus intensity (Fitzsimons 1963).

3.3 Sensory Processing

The information derived from these sensory receptors that encodes alterations in ECF composition requires initial processing before being integrated into the motor control networks that select the most appropriate motor action. As with many other motivated behaviors, the exact mechanisms involved with this function are not clear. However, a recent insight was recently provided into those regions important for generating human drinking behaviors in response to cellular dehydration by a positron emission tomographic study (Denton et al. 1999a, 1999b). Volunteers were infused intravenously with hypertonic saline and asked to gauge the subsequent intensity of thirst. In turn, those regions in the brain showing increased blood flow were correlated with the hyperosmolemia and the reported intensity of thirst. These studies identified parts of the cortex as well as the cerebellum as being specifically activated by hyperosmolemia.

Figure 2
(A) Top traces show average changes (S.E.M.) of input conductance (filled symbols) recorded from magnocellular neurons (MNC; circles, n = 7) and non-MNCs (squares, n = 8) upon exposure to a hypertonic stimulus. Bottom traces plot the corresponding changes in cell volume (percent of control; open symbols) estimated from 6 MNCs and 5 non-MNCs exposed to an identical stimulus (from Oliet and Bourque 1993; with permission from Annual Reviews Inc.).
(B) Stretch inactivated (SI) cationic channels transduce osmoregulation. Under resting conditions (middle panel) a portion of the SI cationic channels is active and allows the influx of positive charge. Hypotonic stimulation (left) provokes cell swelling and inhibits channel activity, thereby hyperpolarizing the cell. In contrast, hypertonic stimulation (right) causes cell shrinking. Activation of an increased number of channels under this condition augments charge influx and results in membrane depolarization. Traces representing changes in the activity of a single SI channel are shown below (from Bourque and Oliet 1997; with permission from Nature Publishing Group)

4. The Components of Drinking Behavior

4.1 Motor Actions

As animals become dehydrated the sensory mechanisms described above are activated. However, which of these is specifically engaged depends on the nature of the dehydrating stimulus. In the case of water deprivation, which is likely to be the most commonly encountered stimulus by most animals, approximately 70 percent of the drinking behavior can be attributed to the sensory mechanisms associated with cellular dehydration, while the remainder is mediated by the mechanisms triggered by hypovolemia (Rolls and Rolls 1982). On the other hand, the thirst and drinking that follows loss of body fluids resulting from heat stress, for example, leads to isotonic hypovolemia and

consequently ATII and neural baroreceptor sensory mechanisms play critical roles in the subsequent thirst and drinking behavior.

Despite the variety of these sensory mechanisms, there is a strong degree of convergence from the brain regions responsible for organizing drinking behavior onto a well-characterized set of neuroendocrine, autonomic, and behavioral motor mechanisms. These responses should not be considered in isolation and can be usefully categorized as protective, adaptive, or restorative to the body's fluid compartments (Grossman 1990, Watts 2001).

The principal protective responses involve the neuroendocrine and autonomic motor systems (see also *Autonomic Nervous System*; *Neuroendocrinology*). They include the very rapidly initiated release of vasopressin and oxytocin from the posterior pituitary that are activated by neuroendocrine reflexes following dehydration. These hormones help maintain blood pressure, and increase renal water retention and natriuresis. Other protective responses occur after hemorrhage or hypovolemia, and include modifications to autonomic control of cardiovascular function, and the rapid activation of all levels of the hypothalamo-pituitary-adrenal axis.

Both types of dehydration generate a set of adaptive autonomic and behavioral motor responses that target gastrointestinal function to conserve water, although cellular dehydration is more closely associated with actions on the gut. A dry mouth is the sensation that is often identified with thirst. Indeed, one of the earliest theories for the generation of drinking behavior proposed that a dry mouth was the most important sensory trigger (Rolls and Rolls 1982). Although many experiments have now disproved the idea that a dry mouth is the primary instigator of deficit-induced drinking, there is no doubt that it provides important sensory feedback signals that may be important for associating drinking behaviors with particular stimuli that could lead to dehydration. Reduced salivation and a dry mouth may occur as a consequence of reduced blood flow through the salivary glands, as well as reduced parasympathetic activation of salivation in response to increasing plasma osmolality. But a dry mouth also develops as a consequence of, for example, extended talking or eating dry food. Finally, if dehydration is maintained for a significant period decreased gastric motility, and eventually anorexia develop as protective responses to maintain body water by reducing the water investment required by digestion and reducing the inflow of osmolytes into the body (Watts 2001) (see also *Appetite Regulation*).

Finally, restorative mechanisms modify behavior to return water and sodium (in the case of ECV challenges) back into the body. The selection, timing, and magnitude of all these responses ultimately depends on the intensity and kinetics of the stimulus. For example, mild hyperosmolemia will stimulate vasopressin secretion but not anorexia.

4.2 Feedback and Inhibition

The ability to inhibit drinking when sufficient water has been drunk to cover for the deficit is as important a function as behavioral initiation; overhydration can be as much of a problem as dehydration. Two types of mechanism are available for this purpose, although each varies in importance depending on the species: alterations in plasma osmolality, and oropharyngeal and gastric sensory feedback. For alterations in plasma osmolality to be a major factor in inhibiting drinking behavior, they have to occur rapidly. In small animals this does not occur, and drinking is terminated before plasma osmolality has begun to respond to the absorption of water. In this instance oropharyngeal mechanisms activated by the act of drinking are important. In larger species however, the volumes of water imbibed during a drinking episode may be sufficient to lower plasma osmolality rapidly and inhibit drinking (Rolls and Rolls 1982).

Thorndike, Edward Lee (1874–1949)

'Whatever exists at all exists in some amount. To know it thoroughly involves knowing its quantity as well as its quality' (E. L. Thorndike 1918, p. 16). Few careers as diverse as that of Edward Lee Thorndike could be summarized so succinctly. Yet the hallmark of all the work of this extremely prolific psychologist was his abiding faith in the quantifiability of all aspects of human experience. From his first abortive attempts in 1896 to study mind reading through his last publication on shifts of interest with age, he was committed to quantification and, where possible, the controlled experiment. 'Professor Thorndike's major life-purpose was to demonstrate the unrivaled fruitfulness of the scientific method in the solution of social problems and to introduce it in exacting, quantitative forms which had been so productive in the physical fields' (Gates 1949, p. 31).

1. *Life Events*

E. L. Thorndike was born August 31, 1874 in Williamsburg, Massachusetts, the second son of Edward Roberts and Abbie (Ladd) Thorndike. The senior Thorndike was a Methodist minister who served churches in Maine and Massachusetts. The family often spent parts of their summers during E. L. Thorndike's childhood at an evangelical Methodist camp meeting on Martha's Vineyard. Perhaps in part as a reaction to the intensely religious nature of his upbringing, E. L. Thorndike rejected religious practices almost as soon as he left home for study at Wesleyan University. Throughout his life, he maintained a posture that favored science over religion.

After graduating with highest honors from Wesleyan in 1895, Thorndike went to Harvard University to study with William James (see *James, William* (*1842–1910*)). It was under James that he began his psychological studies, first of mind reading (a failure), then of learning (a success). The course of his studies for the next two years took him from William James at Harvard to James McKeen Cattell at Columbia, and from maze learning in chicks to his famous puzzle box studies with cats, in which he traced for the first time the trial-and-error learning process as his hungry subjects attempted to escape from crude cages to reach food. His doctoral dissertation describing these experiments, *Animal Intelligence: An Experimental Study of the Associative Processes in Animals* (1898), is one of the most well-known and influential studies in all of psychology.

Upon completion of his doctorate, Thorndike took a position at Western Reserve University. After one year he gladly accepted an invitation to return to New York City and become a member of the founding faculty at Teachers College in the fall of 1899. Thorndike remained at Teachers College until his retirement in 1940, a period that saw the publication of approximately 450 books, monographs, and papers. Another 70 were published in retirement.

Thorndike married Elizabeth Moulton on August 29, 1900. They had four children who survived infancy. Feeling his own training had been very deficient in mathematics, Thorndike insisted that all his children develop a solid background in mathematics. All of the children earned doctorates in scientific fields, and the second son, Robert L., followed in his father's footsteps so closely that he eventually occupied E. L.'s office at Teachers College.

E. L. Thorndike's work was widely recognized within his own lifetime. He was elected President of the American Psychological Association in 1912, President of the American Association for the Advancement of Science in 1933, and served as Second President of the Psychometric Society in 1936. In 1925 he was awarded the Butler medal in gold by Columbia University. Cattell found him ranked first among American psychologists in a 1921 poll for American Men of Science. Many of Thorndike's friends and colleagues said he was a 'workaholic,' but what he enjoyed more than anything was simply messing around with data. Other than tennis (he built his own court) and golf (he used a putter anywhere within 50 yards of the green), his recreation was analyzing data. Retirement was not a happy time for Thorndike. His health was not good: he had been a heavy smoker and quite overweight much of his adult life, and he suffered from arteriosclerosis. But what troubled him most in his old age was an acute awareness of his own declining cognitive abilities. His mind was no longer capable of the feats of reasoning that had been central to his professional life (R. L. Thorndike, personal communication). He died of a massive cerebral hemorrhage, at his home in Montrose, New York, on August 9, 1949, the day on which plans to celebrate his 75th birthday were to be finalized.

2. *Thorndike's Research and Theory*

As a result of his experiments with learning in cats, E. L. Thorndike formulated a theory of mental associations which he called connectionism. He believed that the central nervous system was the basis of all behavior, that learning and other behavioral modifications took place when connections were formed between neurons, and that there was a continuity

among species and a similar continuity in human development. 'The intellectual evolution of the race consists in the number, delicacy, complexity, permanence, and speed of formation of associations. In man this increase reaches such a point that an apparently new type of mind results, which conceals the continuity of the process' (E. L. Thorndike 1901, p. 65).

It has been suggested that Thorndike was driven to applied work with humans by employment pressures. This may have been true for Robert Yerkes (R. M. Thorndike 1990) but in E. L. Thorndike's case his first interest was humans and he resorted to animal research 'because they wouldn't let him work with children' (R. L. Thorndike, personal communication).

Upon returning to Columbia, Thorndike quickly turned his attention to human problems. He was fascinated by individual differences, trying to measure them, explain them, and use them for prediction. He believed, as did many of his generation, that science could solve all human problems, and he set out to apply scientific method to problems of education. Much of the remainder of his career was spent trying to develop methods to measure individual differences and to use these measurements to make education more efficient and successful.

Thorndike set out immediately to place education on a sound scientific footing. Educational practice of the time, the doctrine of mental discipline, was guided by 'the teachers' faith that mental abilities are so little specialized that improvement in any one of them will help all the rest; manual training is often introduced into schools on the strength of somebody's confidence that skill in movement is intimately connected with efficiency in thinking' (E. L. Thorndike 1903, p. 2).

Curriculum was founded on opinion, not evidence. Based on his transfer of training studies with Woodworth (Thorndike and Woodworth 1901) and similar studies he and his students conducted, he concluded that 'since those who succeed in the study of Latin are better at general discrimination and judgment than those who fail, we conclude that learning Latin vastly improves general discrimination and judgment … It suits the vanity of educational theory to fancy that the changes [that result from study] are wholly due to discipline' (E. L. Thorndike 1903, p. 93).

Thorndike continued his pursuit of quantification and applying scientific method in education with his publication of one of the first books on psychological and educational measurement and statistics in 1904. Here he noted the difficulty of defining interval scales for measuring cognitive activities, advocated the use of norm-referenced measurement as pioneered by Galton, and sounded a strong warning concerning the reliability and validity of measurements.

From the beginning, Thorndike adopted the view that inherited differences in cognitive abilities were important. 'There is no reason to suppose that the brain is less influenced by [immediate ancestry] than the tissues that cause height. … Immediate ancestry is thus the probable cause for original mental nature' (E. L. Thorndike 1903, p. 53). 'The schools always have and always will work to create a caste, to emphasize inequalities. Our care should be that they emphasize inequalities, not of adventitious circumstances, but of intellect, energy, idealism, and achievement' (p. 96). Thorndike was a thoroughgoing intellectual meritocrat, but he opposed discrimination on any other basis.

The rise of behaviorism in the 1920s shifted psychological research away from an interest in 'original nature' for almost 60 years. Many of the findings of modern behavioral genetics and cognitive psychology support positions Thorndike proposed at about the time genes were being rediscovered or the mind was being banished from psychology. For example, he argued that there was an interaction between genotype and environment. Anticipating current thought, he suggested that 'Each nature in some measure selects its own environment, and each nature may get from an environment a different influence' (E. L. Thorndike 1911, p. 48).

In addition to his efforts to make education more efficient and scientifically sound, Thorndike expended considerable effort from 1900 to 1925 in developing measures of what he referred to as intellect. He rejected the notion proposed by Charles Spearman that there was a single mental trait of intelligence, arguing instead that each test must specify what aspects of intellect it was designed to measure (see R. M. Thorndike 1990 for a description of the Spearman–Thorndike debate). Beginning in 1903, and anticipating more popular work by Alfred Binet (see *Binet, Alfred* (*1857–1911*)), Thorndike and his students developed a wide variety of measures of human abilities. The work culminated in the CAVD, a 'test constructed (from 1922 to 1925) as a sample of what a measuring instrument for a mental ability should be' (E. L. Thorndike 1949, p. v). With the CAVD, Thorndike (Thorndike et al. 1927) produced a test that would foreshadow item response theory and the test design methods of the 1990s.

In the 1930s, Thorndike turned his attention to issues of social science and social value. He pioneered the scientific study of environmental quality with his research on urban environments in Your City (1939) and he subjected the domain of values to scientific scrutiny in *Science and Values* (1936). But perhaps Thorndike had his greatest impact during this period through his contributions to lexicography. In the 1930s Thorndike revolutionized the dictionary by placing the design of these reference works on an empirical footing.

For years Thorndike had been collecting data on the relative frequency of words in published English. A list of the most frequently appearing 20,000 words, along with their relative frequencies, was published in 1931. The list was expanded to 30,000 entries in 1944.

Thorndike used word counts to determine which words should appear in his dictionary, and semantic counts (the most common meanings of each word) were used to select the definitions and their order. In addition, Thorndike insisted that each word be defined only in terms of words that would be more familiar than the one being defined. The Thorndike Century Junior Dictionary, published in 1935, was the first dictionary to use these principles and to focus its content on the needs of its most probable users. By 1950, the three Thorndike Century dictionaries dominated the field of dictionaries in education, and every serious competitor was copying his approach. All modern dictionaries follow his pattern.

E. L. Thorndike's influence is so pervasive in modern education and psychology that it is almost impossible to detect. If his contributions to lexicography were not enough, he pioneered the scientific study of education, made major contributions to psychological and educational measurement and testing, and put comparative psychology on a firm experimental footing. There is hardly a specialty in either field, with the possible exception of some clinical areas, that has not been significantly touched by his work or that of his hundreds of students, a list of which would read like a Who's Who of psychology and education in the middle and latter half of the twentieth century, including Abraham Maslow (who rejected his empiricism) and Raymond Cattell (see *Cattell, Raymond Bernard* (*1905–98*)) (who embraced it). A fairly complete list of the publications of E. L. Thorndike is available in Gates (1949); a full biography is given in Joncich (1968).

Time, Anthropology of

Sociocultural constructions of time and time reckoning are now central topics of anthropological inquiry. Many cultures lack an explicit category 'time.' Still, time is everywhere present, in numerous local figurations that may or may not evidence a few universal forms, and thus the anthropological spectrum of research, theories, and contentions is vast (Gell 1992, Munn 1992). I offer here a representative, nonprogrammatic review of the topic that focuses on some of the important concepts, debates, and intriguing new areas of investigation.

1. Universal Time

Certain natural phenomena appear to be universally temporalized in terms of periodicity and, in some but not all cultures, progressive quantification: the human lifecycle and bodily processes (e.g., menstruation), seasonality, celestial patterns, day/night, and so forth. The same is true for the reproduction of social order by generation and various social and kinship groups. All societies regularly coordinate labor, occasionally punctuate the tempo of everyday life with ritual, and envision some type of past, present, and future. Calendrical arrangements of days, weeks, months, and years are also universal—but, again, not everywhere counted. In anthropological theory, time is implicitly understood to be binary. For example, all cultures accommodate conceptual categories and linguistic terms for duration and sequence, which are often said to be the basic forms of time. Leach (1961) proposed that time is a social construction rooted in two basic human experiences: the repetitions of nature, and the irreversibility of life. Many anthropologists contend that all societies possess both incremental/linear/irreversible and episodic/cyclical/repetitive forms of time—which are not necessarily antithetical since time

cycles can return to the 'same logical, not temporal, point' (Howe 1981). While Farriss (1987) claims that any one mode can incorporate the other, Leach proposes that all religions deny the finality of human mortality by subsuming linear time under a cyclical framework. Birth and death become two phases of an eternal sequence. Leach also claimed that time is everywhere a 'sequence of oscillations between polar opposites.' This temporal pendulum is related to basic sociological processes such as reciprocal gift-exchange and marriage. More recently, Gell (1992) argued that all culture-specific patterns of temporality are variations of two cognitive modes: an A-series which orders events according to relative notions of pastness, presentness, and futurity, and a B-series of absolute before/after.

2. *Social Time*

Universal conjectures notwithstanding, most anthropologists focus on local notions of time and subscribe to the Durkheimian thesis that time categories and conventions are 'social representations' that mirror the organization of society. This sociological perspective is best exemplified by Evans-Pritchard's (1939) elegant study of the East African Nuer, which is perhaps the most widely-known anthropological account of a distinctly non-Western style of time. Nuer 'oecological time,' which is cyclical or seasonal, reflects the environmental rhythms of cattle pastoralism. More importantly, Nuer indicate time but they lack an abstract chronological system that is numerical, cumulative, uniformly incremental, and measurable. Beyond the year, Nuer speak about temporal duration, intervals, and sequences with sole reference to 'structural time' or significant genealogical events in the social system—say, the division of a lineage, or the birth of an age set. Since Nuer genealogies are fixed at a depth of five generations, too, the passage of time is contained within a static framework. Similarly, there is considerable debate over whether or not the terminological groupings and repetitions in many kinship systems freeze, reverse, or emphasize the passage of time (Silverman 1997). Here, too, the opposition between cyclical and linear time is a leitmotif of anthropological analysis.

3. *Cultural Time*

The Durkheimian approach to time, enshrined in British social anthropology, anchors temporal conceptions to social organization. An alternative approach to time, represented by the 'interpretivist' tradition of American cultural anthropology, highlights the symbolic dimensions of time. Here, analysis seeks to discern the relationship between general temporal attitudes and the overall emotional emphases and focal symbols of a cultural worldview. Geertz (1973) suggested that the cyclical structure of Balinese kinship, naming, and calendrical systems 'don't tell you what time it is; they tell you what kind of time it is.' In a celebrated passage, Geertz concluded that 'Balinese social life takes place in a motionless present, a vectorless now' in which 'time lacks motion because Balinese social life lacks climax.' Moreover, the Balinese 'immobilization of time' is linked to the 'anonymization of persons.' Ultimately, the formal complexity of Balinese calendars pertains not to social order but to the unique, somewhat aesthetic themes and tones of Balinese culture and personhood. Whereas Evans-Pritchard pioneered the study of how others think about temporality, Geertz has been an inspiration to anthropologists who seek to understand how others experience time.

4. *Political Time*

One key debate in the anthropology of time, then, concerns the locus of analysis—broadly speaking, society vs. culture—and the question of whether or not time configurations can be reduced to a more elemental, causal factor such as human ecology. Another quarrel arises from the materialist division between infrastructure and superstructure. Bloch (1977) criticized Geertz for failing to distinguish between ritual time, which does differ significantly cross-culturally, and universally cognized 'normal' time that organizes practical activities. Hierarchical societies, Bloch continued, tend to elaborate a ceremonial view of timeless time. Consequently, ritual concepts of time are ideologies that sustain everyday productive inequalities. But while Geertz, in this view, may be guilty of foregrounding difference or 'radical temporal alterity,' and thus neglects the politics of time, Bloch himself assumes that people everywhere subscribe to the same 'practical reason,' which remarkably resembles the economic concerns of Western Marxism. Many anthropologists emphasize the lability of time concepts and, more recently, the political manipulation of time. The Northern Thai calendar, which is oriented around a 'fatal quality of time,' enables post hoc explanations of misfortune that exonerate individuals from personal blame (Davis 1976). The Kodi of Indonesia, for whom calendrical knowledge is prestigious, manipulate temporal sequences and durations, question the timing of ceremonial feasts and other public events, and strategically stage disruptions (Hoskins 1993). The Kodi calendar is also a 'debating ground' as traditional forms of time now clash with exoteric calendars associated with the state, Christianity, and modernity. Multiple, or layered, forms of time which are not, moreover, necessarily integrated into a single unifying system are common. One temporal series may regulate markets, while another system organizes lunation. Time is often contextual—

as well as competing and seemingly contradictory. Kabyle precapitalist peasants of Algeria submit to the present but exalt foresight within the temporal horizon of the 'forthcoming.' They also view the future—which capitalist hubris, in this view, seeks to predict—as a void known only to God (Bourdieu 1963). A final note on the politics of time: when competing groups anchor their prestige in a politico-ritual system to ancestral primacy, the mere assertion that a temporal series, or time itself, has a specific beginning point or location is inevitably political since it denies the validity of rival times. This is true for small-scale societies as well as the contemporary USA, which remains embroiled in debate between evolution and creationism.

5. *Ritual Time*

Not only is the differentiation of ritual from mundane time important to many anthropologists, but so is the construction of time within ritual itself. Humans tend, wrote Leach (1961), to conceptualize time as a repeating series of different intervals. Each year is distinctive but they all begin and end with an identical festival. Significant calendric events are everywhere marked by ceremonial antics and attire that are censored from everyday life. These periodic ritual inversions or 'rites of passage' actually create time by introducing intervals in social life. Yet Barnes (1974, pp. 128–9) offered the opposite view for the Kédang of Indonesia: ritual insures precisely that time is not cyclical—that the dead, for example, are irreversibly dead, and that calendric cyclicity is unable to prevail over linear temporality. From a different perspective, Gell (1992, pp. 37–53) recently evoked Lévi-Strauss and argued that the ritual reversal or regression of normal time among the Umeda of Papua New Guinea resolves problems that arise from the imposition of 'cultural' conventions such as temporal classifications onto the 'real' or 'natural' world.

6. *Language of Time*

Unlike spatial deixis, the linguistic study of time remains sparse in anthropology. Yet the famous Sapir–Whorf hypothesis of linguistic relativity was initially popularized through the alleged absence of Hopi verb tenses (now disproved). Still, language shapes our experience of the world, including time. Hence, the Trobriand Islanders of Papua New Guinea are unable to discuss and conceptualize linear, chronological sequences of events (Lee 1950). They have no time line but only temporal points organized as noncausal patterns with 'at most a swelling in value.' Devoid of linguistic temporal connections, Trobriand events are self-contained: 'a series of beings but not becoming.' Related studies of language and time include past vs. future-oriented locutions (e.g., Dundes 1969), orality vs. literacy (Goody 1991), and cognitive 'maps' of spatiotemporal passage (Frake 1985).

7. *Spatial and Bodily Time*

The spatialization of time and the temporality of space are topics of growing anthropological interest (see Munn 1992). Many cultures—e.g., Melanesia and Aboriginal Australia (Silverman 1997)—understand the primordial creation of the universe through a series of ancestral migrations, radiating outwards from an origin place, that simultaneously generated space and time. But other cultures possessing a temporal topology, such as the Iraqw of Tanzania, lack an origin: 'there is no zero point against which to set a regularized chronology' (Thornton 1980, p. 184). Spatiotemporal mythologies occur across lowland South America, where time and space are also embodied. The passage of time in the external world—the flow of a river, the movement of the sun—represents the human lifecycle. Conversely, the temporal unfolding of physiological processes such as sexuality and alimentation are projected onto the local topography (e.g., Hugh-Jones 1979, Chap. 7). The experience of time is thus understood through a bodily schema, specifically, the circulation of substances into and out of the body, and wider cycles of birth and death.

8. *Gendered Time*

The relationship between gender and time is another promising area of anthropological study. The riverine Eastern Iatmul of Papua New Guinea associate water with uterine fertility, death, and the inexorable erosion of land and trees that threatens to regress the cosmos back to the timeless and feminine era that preceded male creation (Silverman 1997). Like the river, female time flows to uncertainty. Male time, often conceptualized as the planting of trees and the establishment of villages, progresses forward against the flow of female temporality. But the arboreal ascendance of masculine structure is illusory. The river and rainy season floods ultimately prevail. All men can do to stem the feminine tide of regressive time is plant trees, build houses, and enact rituals. Weiner (1991) also discusses the gender of time in a Melanesian society, and links temporality to linguistic iconicity and motions through the landscape and body.

9. *The Future and End of Time*

Anthropologists are no longer content merely to bemoan the end of the 'time of the primitive.' Nor do we continue to define non-Western 'Otherness' as an essentially temporal construct, communities who are removed from us in both space and time (Fabian 1983). Instead, anthropologists are increasingly interested in historical conjunctions and contemporary practices that blur the distinctions between local and global times. Through temporal ambiguities, local people exercise creativity and resistance. While all societies allocate time between different activities

(Gross 1984), the spread of global capitalism and wage-labor has imposed on people everywhere computational, monetary, and aggressive notions of temporality such as saving, wasting, and fighting against time. But the future of time, to invoke a common idiom, is not confined to 'time is money.' The millennial turn encouraged many communities to confront the historical dissonances of culture contact by rethinking conventional notions of past, present, and future, cyclical and linear time, tradition and modernity, and the relationship between the biblical apocalypse and ancestral spirits. The millennium was a time to ponder the end of time (Scaglion 2000)—as well as, in the context of Y2K, the opposition between 'virtual time' and 'real time.' Thus the opening decades of this millennium, including its end-of-time scenarios, will doubtless prove to be a propitious era for the anthropological study of time both globally, locally, and in the newest temporal zone: cybertime.

Time, Chronology, and Periodization in History

1. General Remarks on Historical Time

Homo sapiens is the only species on earth equipped to look back on its past consciously. The past, however, is chaotic. Nevertheless, it is the peculiar ability of humankind, as *homo historicus*, to put some kind of order on this chaos, making it understandable. It is this conscious looking back to the past that identifies *homo sapiens* as human.

The most important element in bringing order to the chaos of the past is some concept of time. Time is a human invention rendering chaos intelligible, rather than something that exists in itself. Among the various notions of time, chronology and periodization are the most closely connected with the organization of our past. Without these conceptual inventions, there would be no way of organizing our past as history.

Chronology is a dating system, or a system of reckoning a series of years from a starting point (year), which gives an era a theoretical definition. In this respect, chronology should be distinguished from a calendar, which is defined as a system of fixing the year, month and date.

Periodization is a form of historiological cognition proposed by the human mind for making the past intelligible and meaningful by dividing the collective past into compartments along time.

On the one hand, chronology is different from periodization in that it is used by a group of people for practical purposes, mainly for counting years. Those who try to make sense of history through rendering the past retrospectively intelligible, on the other hand, mostly use periodization. It is of no practical use for counting time.

Chronology, therefore, is in these terms mainly for constructing time, and periodization for dividing time. However, further inquiry reveals the fact that chronology also acts to divide time by creating a starting point for a new era, for example, 'regnal years,' 'Christian chronology,' and 'East Asian era names.' On the other hand, the very act of the periodization of the past effectively constructs a new time by inventing an arbitrary starting point, though these times are not used by people in everyday life, as for example the 'Victorian period' or the 'Middle Ages.'

2. *Four Aspects of Time in History*

Time in history will be considered from the following four viewpoints: the three types of time, the relation between linear time and cyclical time, the relation between what I call the stream of time, and the stack of time, and finally, what governs time.

2.1 *Three Types of Time*

Time will be classified into three categories: natural time, human time, and metaphysical time. Natural time is a reflection of such natural cycles as seasons, human life, etc. Human time is what *homo sapiens* invented to make the remembered past intelligible and comprehensible, and consists of such historical times as chronology and periodization. Metaphysical time is what *homo sapiens* created to make the remembered past meaningful beyond human experience, as has been proposed by philosophers of history.

2.2 *Linear Time and Cyclical Time*

Among Western historians time in history has been discussed in terms of the established dichotomy of linear and cyclical time. There is a consensus among them that a culture based on non-linear time would not be able to construct historical thinking (Needham 1966). This was based on the assumption that the rise of the historical mind is premised on linear time. The assumption is however contradicted by the historiographical accomplishments of East Asia, which led the pre-modern world in both the quality and quantity of historical production, despite the fact that linear conceptions of time were relatively weak in the historical cultures of the region.

Linear time has been almost universal in both the East and the West, despite variation in styles and manners, in the past and present. India has sometimes been described as being without the historical mind, because it was a culture that lacked linear time and lived in cyclical time. However, ancient Indian genealogies inscribed on tombstones and monuments show a richness of linear conceptions of time. Archeological remains discovered in ancient Mesoamerican civilizations also testify to the employment of linear time. The Mosi kingdom in West Africa still conducts the genealogical narrations and historical recitations of the dynasty through the sounding of a drum, and not by means of the spoken or written word.

2.3 *Stream of Time and Stack of Time*

The examination of what constitutes linear time will lead us to a comprehensive understanding of the nature of historical time.

Linear time proceeds from the viewpoint that time is ordered in a straight line like a stream of water in the river. This time is recorded by a sequence of numbers, as is characteristic in the Western (Christian) way of counting years, and it has given us a view of historical time as proceeding in a linear fashion.

Along with this idea, a frame of regnal years, or East Asian era names as a metamorphosis of regnal years has been used widely. This implies a view of time as being stacked like a pile of bricks, rather than flowing like water in the river. This image of time reflects a fundamental stratum of our consciousness, as when we look back into the past, and remember 'my school days,' 'our Tokyo period' or 'between the wars.'

The Western cultures that now dominate the modern world extended their mode of historical thinking based on linear time, and imposed their sense of time as universal. However, recent studies show that linear time is comparatively artificial, while compartmentalized time is in many ways more 'natural' (Sato 1991).

The fact that periodization was so very important in the development of historical studies, therefore, is really a reflection of European circumstances and the primary role that linear time has in that culture. This very rarely happened in the East Asian tradition, where varied combinations of compartmentalized time developed their own historical culture.

It could be said that the idea of a stream of time is rather artificial, and the idea of a stack of time actually constitutes the basic sense of historical time.

2.4 *Time Belongs to the Supreme Nominal Power*

Throughout history human time belonged to the supreme power. Time was made and was controlled by this power.

Historically, the powers that governed human time can be divided into two different types: religious power and political power. Religious powers in the western

hemisphere, in particular Christianity, Judaism, and Islam have controlled time, in broad terms. However, time in the eastern hemisphere has been governed by political power.

In China, time belonged to the emperor. A new dynasty and a new emperor declared the enthronement of a new power by proclaiming a new era name and a new calendar. The Chinese emperor confirmed the establishment of his power by the introduction of his time. In Japan, since the seventh century, time also belonged to the emperor. It was the emperor's duty and prerogative to declare a new era's name, a privilege retained even during military rule. Even the strong Tokugawa shogunate could not deprive the Emperor of this privilege. After World War II, the Christian chronology-based time came into use in East Asia, along with Greenwich Mean Time. However, Japan and Taiwan still employ the era name system officially. North Korea introduced an era name system in 1997, and the new era name was 'Juche' (Autonomy), to commemorate the late Kim Il-Sung. The era started retroactively from his birth in 1921.

The Western time based on Christian chronology and universal time now occupies the role of common time in the world. The introduction of Christian chronology made the practice of a world historiography possible by giving a synchronicity to the history of the world. The time that now governs the world belongs to the supreme world power called 'Globalization.' The expansion of Internet communications necessitates a world common time. A similar situation was found in early modern Europe. Problems arose for merchants in setting contract dates between different countries that used various regnal years and dating systems. As a result merchants were among the first to promote the use of a common Christian chronology strongly.

3. *Chronology*

Chronology can be classified into the three types according to their features: linear chronology, stratified chronology, and cyclical chronology. The major issue of chronology focuses on the question of why, in spite of its defects, the Christian chronology was able to become a common system.

3.1 *Linear Chronology*

Linear chronology is a system of reckoning a series of years in a straight line from a starting point (year) of an era. Jewish chronology, Christian chronology, Islamic chronology, Buddhist chronology, etc. belong to this type of chronology.

Linear chronology consists of two types: one counts the years serially from the starting year towards the future, and the other counts years both backwards and forward from the starting year. The latter idea of reckoning years both to the future and to the past endlessly is only found in Christian chronology.

This idea of a single era system of counting years is found all over the world. In ancient times, Mesopotamian chronology began with the accession of Nabonassar in 747 BC, and Roman chronology reckoned years from the foundation of Rome in 753 BC Jews have counted years from the foundation of the world (*Anno Mundi*) since the third century.

Dionysius Exiguus, an abbot in Rome in 525, first introduced Christian chronology as we know it, on the grounds that years should be noted from the incarnation of Jesus Christ, instead of the era of Diocletian, the persecutor of Christians in ancient Rome. Dionysius calculated the birth of Christ as the 753rd year from the foundation of Rome, and made this year the first year of *Anno Domini* (AD). However, it was not until the eleventh century that this chronology began to circulate widely in Europe.

Islamic chronology (the era of the *Hijra*) was instituted by Caliph 'Umar I in 638 by introducing the system of counting years from the *Hijra*, that is the flight of Mohammed from Mecca to Medina on July 16, 622, the first day of the lunar year. The Islamic chronology is unique among the other linear chronologies in that it is a purely lunar-based chronology, i.e., the year is counted as the cycle of twelve lunar months, not as the revolution of the earth around the sun.

Buddhist chronology is now used in some Southeast Asian countries. In Thailand and Cambodia years are counted from the putative date of the death of the Buddha in 543 BC, while Myanmar employs the date of the introduction of Buddhism in 638 as the first year of their chronology. In India, the government reformed the calendar in 1957 based on the Saka era (starting from 78), and it is now widely used.

At least ten other single-era linear chronologies have been proposed, including the era of the emperor Huang and the era of Confucius in China, and the era of Tangun in Korea.

3.2 *Stratified Chronology*

Stratified chronology is a system of reckoning years by successively piling eras (sets of years) upon one another in sequence, an idea that originated in the regnal year system. The method of counting years by royal succession has been used throughout the world since ancient times, and it was also used widely in Europe even after Christian chronology was circulated in the sixteenth century. The method of dating by regnal years, though troublesome, satisfies the theoretical requirements of specifying years, and this chronology finds its most significant expression in the era name system of East Asia. The era name system derives its origin from the idea of conferring a significant title to a certain series of years, instead of

using simple regnal years. It was first introduced by the emperor Wu of the Han dynasty in China, in 114 BC. The years of his reign were named according to Heavenly good omens as 'Founding the First Era,' 'The First Light,' 'The First Hunting,' etc.

This idea of chronology later rippled out in all directions to the countries on China's periphery. It was employed in Vietnam and Korea by the middle of the sixth century, and by the middle of the seventh century, at the latest, it had reached Japan. These East Asian countries on the Chinese periphery took the idea of the era name system but made little use of the Chinese names themselves. When used in tandem with the Chinese sexagesimal cyclical system, the era name system fulfilled its function as a method of reckoning years in East Asia.

East Asia was chronologically under the exclusive dominance of the era name and sexagesimal cycle systems. The era name system was premised on the very existence of Chinese letters as ideographic characters. Ideographic characters made possible the development of the East Asian philosophy of chronology, i.e., that the counting of years is not an act of assigning an ordinal number to a year, but rather that of giving to a year a meaningful name.

It originates in the *Weltanschauung* inherent in ideographic characters: that Chinese characters by their very nature assign a meaningful name to every aspect of the world and the era name system could be seen as an extension of this. It never crossed the minds of peoples outside East Asia to assign a meaningful name to a set of years.

For more than two thousand years, until the middle of the twentieth century, this era name system was employed in East Asia, to the virtual exclusion of all other modes of reckoning. The Christian era system was brought into East Asia during the latter half of the nineteenth century as part of Western culture. The system took the place of era names in the subsequent century. Japan, Taiwan, and North Korea still employ the era name system officially, though the Christian era system is widely used as well. It tells us that the idea of reckoning years within the context of meaningful names is deeply rooted and alive in the collective consciousness of East Asian people.

3.3 Cyclical Chronology

In addition to the above two types of chronology, cyclical chronologies have long been used all over the world. Well-known examples of these are the chronology by indiction (*indictio*) in early Medieval Europe, and the sexagesimal cycle in East Asia. In this type of chronology, years were given according to their place in the cycle of 15 years (*indictio*), or 60 years (the sexagesimal cycle), the number of the *indictio* or the sexagesimal cycle itself being ignored. They could be called chronologies in the sense that they turned into absolute chronology by giving ordinal numbers to the cycle, in the same way that the Olympic dating system operates. It was also possible to apply such an ordering to the sexagesimal cycle, but it was rarely used in practice. This method may also be called a relative chronology in the sense that it was not used to designate specified years in comparison with an absolute chronology.

The Hindu idea of chronology is cyclical, but it is unique in its philosophy of time in that cosmic cycles of creation and destruction continue indefinitely. In Hinduism, time belongs to the supreme God, and one chronological cycle (*yugas*) is 4,320,000 years.

3.4 The Christian Era System as the Common World Chronology

The twenty-first century begins in 2001, not 2000. The Christian chronology starts from the 1st Anno Domini. The concept of zero was not yet known in the West when the Christian chronology was created in the sixth century. Zero came to Europe around the tenth century, from India, via the Islamic countries. In addition to this defect, it is now believed that there was an error in assigning the year of Jesus's birth, and he was in fact born a few years before the year 1, Anno Domini.

In spite of these imperfections, we live with a Christian chronology that is now so dominant in worldwide usage that there is no possibility of it being replaced with a new or revised method at any time in the foreseeable future. Christian chronology now occupies the role of a common or neutral chronology in the world. This was theoretically brought into effect by introducing the concept of 'BC' and deciding on the first day of January as New Year's Day; and it had been politically determined by the dominance of Western culture since the nineteenth century.

It is important to inquire here why the invention of 'BC' made the Christian era system the universal chronology. It is because it has the great advantage of locating every historical event on a single time base.

Venerable Bede, in his *Historia ecclesiastica gentis Analorum* (731), first proposed the idea as *anno igitur ante incarnationem Dominicam* (in the year, therefore, before the incarnation of the Lord). The expression became widely used after the late sixteenth century in a period known as the dispute over Christian chronology. This dispute arose because of disagreements between scholars concerning the period between the Creation and the birth of Christ, and because of inconsistencies between Christian and non-Christian ancient histories, as for example in the differences between the Chinese records and the Bible. However, since the seventeenth century, the idea of BC has been used widely in Europe.

It should be remembered that BC was first used, not independently, but as an auxiliary chronology to *Anno Mundi*. The secularization of the Christian idea of history was necessary for the exclusive use of BC,

which started in the eighteenth century. An early example of the transformation of the Biblical chronology into a secular chronology can be found in Voltaire's *Essai sur les moeurs et l'esprit des nations* (1756), where the concept of BC became an indispensable part of modern chronology.

As a result of the developments in archaeology and geology in the scientific revolution of early modern Europe, the method of counting serially backwards from the birth of Christ proved extremely useful in dealing with the debate over 'the creation of the world.' It was, perhaps, accidental that BC came into such use, since it was originally conceived in order to describe the years between the Biblical Creation and the birth of Christ. It was beyond the imagination of its founders to think of a time 'before the Creation.'

It is a curious irony that this Christian chronology was so suited to tackle the scientific revolution, and it spread itself beyond the boundaries of Christendom. The invention of BC transformed the Christian era system from being a specifically Christian chronology to being one with a universal potential. It is now widely used in non-Christian countries as the main chronology. For example, China officially introduced the Christian chronology as the common era (*kungyuan*) in 1949, in order to become synchronized with the rest of the world. Joseph Needham proposed the idea of chronological expression avoiding the writing of dates as 'BC' and 'AD' by the use of '−' and '+' respectively in his *Science and Civilization in China*, because, 'such a convention seems also more suitable for civilizations which were never part of Christendom.' In recent years, Jews started to use the notations 'CE' (common era) and 'BCE' (before the common era).

The idea of a common chronology is premised on the notion that all peoples, cultures, and nations have their own 'year,' which allows the common man to create a balanced sense of history, and acquire the possibility of a free and varied sense of time. Because the reckoning of years is not a mere assignment of numbers in order, but the creation of a cognitive framework for experience and memory, it is in itself an advanced intellectual exercise peculiar to the human species. It is also a political, social, and cultural act of human intelligence.

4. Periodization

Periodization has been practiced since ancient times. Well-known examples are the four metallic ages (gold, silver, bronze, and iron) as introduced by Hesiod in the seventh century BC, Daniel's dream of the four kingdoms and its interpretation (Babylonian, Medo-Persian, Macedonian, and Roman monarchies), the Buddhist idea of the threefold periods (the true law, the reflected law, and the end of the law), and Saint Augustine's proposition of six periods (*infantia*, *puericia*, *adulescentia*, *iuventus*, *gravitas*, and *senectus*, the last named corresponding to the period from the Christ to the end of time). Each had a fundamental influence on the pre-modern people in its respective civilization. In the East, it was a matter of primary concern to know when the period of the end of the law started. Similarly, in the West people were eager to know the advent of Doomsday.

An examination of these periodizations shows us that: (a) at a very fundamental historical level people employ compartmentalized time and not linear time for their historical thinking, and (b) characteristically a people acquire their historical *raison d'être* using their past to place their present in history.

This article, however, focuses on the periodization that appeared with the rise of modern historical scholarship in the seventeenth century, and has become a major historiographical asset.

4.1 Two Types of Periodizing Terms

Time has been worked with in two ways, using both continuous time and compartmentalized time.

It is natural and inherent for us to employ compartmentalized time when we look back into the past. In the same way historians in their research invent compartmentalized time in order to give the past a certain unity. Thus compartmentalized time is a natural and indispensable historiographical tool.

Historians have employed compartmentalized time in two fundamentally different ways; one was to use the historically existing compartments, and the other was to invent and retrospectively apply a structure. Dynastic periodizations widely used in the East and the West are typical of the former; however, the latter represented, for example, by Christophus Cellarius, Karl Marx, Fernand Braudel have almost always been created in the West.

4.2 Periodization as a Historiological Tool

Periodization is a form of historical understanding, designed as a historiological tool for making the past understandable, intelligible, and meaningful by dividing it into compartments. It was developed largely in the West in the early modern period under the dominance of Christian chronology. More generally speaking, it was to be found in civilizations where linear chronology played a central role, for example Ibn Khaldun's distinction between the *umran badawi* (rural culture) and the *umran hahari* (urban culture).

Periodization became a key feature of Western historiography, which developed into a cognitive discipline by proposing new perspectives and varied interpretations. This contrasts strongly with the East Asian experience. Even though a rich historiographical culture flourished in East Asia for more than two thousand years as a major field of learning, it did not develop the type of terminologies used by Western

historians, except some periodizations proposed by Japanese historians because East Asian countries used the combination of many different types of periodization in their written history, such as dynasties, era names, sexagesimal cycles, and periods based on changes in the site of the capital. Modern European history, on the other hand, drew on a long and deep-rooted tradition of annals and chronicles, whose style depended solely on a concept of continuous time. The various periodizations were essential for their establishing history. Even now, a list of titles of recent works by Western historians reads like an inventory of variously compartmentalized time.

The Christian era system had been in use in the West long before the birth of historiography in modern Europe, at which time the historians took an interest in compartmentalizing the past in order to analyze history. In one sense, it could be viewed as a declaration of independence by modern historiography from such traditional forms as annals and chronicles.

In the 1700s, the word 'century' came into use, signifying that the modern Western mind needed compartmentalized time for thinking about history. In Western historiography such statements as 'the first half of a century,' 'the first quarter of a century,' or '1930s,' are used quite freely and this is a sign that compartmentalized time has become indispensable for looking back upon the past, which cannot be grasped simply by employing absolute years.

To summarize in simple terms, in the West the idea of a single era count formed the basis of chronology, i.e., the Christian era system. Given this basis historians employed many different kinds of periodization to compartmentalize time to think about history. By contrast, in East Asia only the compartmentalized time could be found in historiography. Their historiographical style was developed on a stratified or stack-shaped chronology and various other types of compartmentalized time. The expansion of modern European historiography, paralleling the global reach of Euro-American military and economic power in the late nineteenth century meant that historians everywhere are now using the technique of using periodization to understand history. '*Pensare la storia e certamente periodizzarla*' (to think history is certainly to periodize, B. Croce) is a view now shared by all world historians.

Later development of periodization to incorporate such concepts as the 'feudal period,' the 'medieval period,' etc., has given rise to the reinterpretation of human history on an international scale. The idea of dividing history into three periods was the first success of the method.

4.3 Universality of the Tripartite Periodization

The universal acceptance of a tripartite periodization: ancient, medieval, and modern has had a fundamental influence on the development of world historiographies.

This threefold periodization was first employed by Georg Hornius, a Dutch historian in his *Arca Noae* (1666), and became widely known later through Christophorus Cellarius, a German historian, in his *Historia nova, hoc est XVI et XVII saeculorum* (1696). With the transmission of modern German historical scholarship it spread across the world two centuries later and has been taken for granted as a global standard since then.

This threefold periodization found universal acceptance for two reasons: (a) the terminologies were almost free from religious connotations and Euro-Christian signs, even though '*medium Aevum*' was originally a theological notion, and (b) it included a universal attitude towards the past by instituting a negative period between the glorious past and the contemporary period.

There is still no agreement in deciding on the exact border years among the ancient, the medieval, and the modern. Professional historians have concentrated later on subdivisions of the three periods. This lack of consensus encouraged disputes among the historians of the world. As a result of this debate and the development of social and economic histories it became apparent that the very idea of border years was out-of-date.

Periodization as a way of historical thinking was developed still further by new proposals for dividing the human past. The most influential of these ideas of periodization were the 'feudal period,' pioneered by Henri Pirenne, and 'historical materialism,' as introduced by Marxist historians. This periodization was discussed in the historical contexts not only of Europe, but also of the non-Western world, especially China, India, and Japan.

After World War II, Fernand Braudel published a new idea of periodization in 1949, by proposing the notion of three different rhythms of history. The *long dureé* (the long duration) became the main concern of postwar historians. This structural periodization spread over the world on the wind of social history, and became the shared perspective of the historians of the world.

5. Visualization of Historical Time, Chronology, and Periodization

History is the science of making our chaotic past intelligible and meaningful through a variety of interpretive and structural techniques; among these, the imposition of a systematic notion of time has proved to be one of the most important. The construction of time lines, royal lines, genealogies, chronicles, annals, and historical tables, which have developed since ancient times, helps to form our historical knowledge and mind. The further necessity

of knowing the synchronicity of the plural lines was the first step towards reaching a historical consciousness. Peoples have proposed a variety of ideas to synchronize the different times of human history.

The synchronizing of historical events that happened in different places and times can be viewed as the singular most distinguished achievement in the historical consciousness of the human mind. This is reflected in the construction of chronological tables or historical tables.

It is necessary here to distinguish chronological tables from annals and chronicles; they have very different purposes. Annals and chronicles attach importance to the content they record; on the other hand, chronological tables stress the date or sequence of historical events.

The chronological table gives us a visualized temporal image of our past, in the same way that a world atlas shows us a visualized spatial image of the world. It has two important functions. One is to give a bird's eye view of the stream of time in history, the other is to make certain of the synchronicity of historical events in various parts of the world.

In East Asia, the use of chronological tables as a reference for comprehending history was first proposed by Sima Qiam (BC135–93) in his *Shiji* (Records of the Historian). They can be viewed as the beginning of a consciousness of historical time. He arranged 'the chronological table of the twelve dukes' by separating lines for the events of each of the twelve states. Reading down the columns, one sees what happened in each state in any given year by using the sexagesimal cycle and regnal years of that state. Reading across the columns, one can see the sequence of historical events for any given state. We could say that he made the table to show us history in both its temporal and spatial contexts.

The development of the chronological table in Europe was effected by choosing Anno Mundi, or Christian chronology, as the key time scale, around which the various historical events were listed.

The historical time-based Christian chronology was already established in Europe by the sixteenth century. However, at that time it was primarily employed in the field of ecclesiastical history. It was not until the eighteenth century that these two chronological methods were unified into Christian chronology. At that time historical events were rewritten in terms of the Christian chronology and thus were synchronized with events in the rest of the world. This synchronicity laid the foundations of a time consciousness capable of giving birth to the modern method of historical thinking. Benjamin Marchall's *Chronological Tables* (1713) is one of the earliest works of this genre. John Blair published *The Chronology and History* (London, 1754), in which he proposed a table of various regnal years in Europe, which was constructed around a time line of years since the birth of Christ. James Bell established the earliest style of modern historical tables in his *A View of Universal History* (London, 1842). Historical tables were disseminated throughout the world through the works of Karl Ploets (1819–81), a German historian.

Since the latter half of the nineteenth century, Christian chronology as the historiographical 'standard time' has spread throughout the non-Christian world. This chronology has been established as the pivotal time by which the world creates and maintains the possibility of a synchronicity of the various local historical times. It is only with this temporal foundation that it is possible to write a history of the world.

Time-geography

The core of the discipline of human geography is often considered to be space. But, as the early navigators found, time is the inevitable correlate of space and it is therefore no surprise that geographers have made continuous contributions to thinking about time as well as space. In the social sciences, such contributions have been notable since at least the 1920s, with the rise of the school of human ecology which understood time and space as inseparable elements of human activity (Thrift 1977). But the major contributions to geographical thinking on time have been made since the 1960s and it is on this latter period that this article is focused.

The study of time has been a notably interdisciplinary field and this means that both geographers and others have worked on the spatial aspects of times, timing, temporal structures, and time consciousness. This article reflects that porosity in that it starts with specifically geographical contributions but then widens the discussion out from narrowly disciplinary considerations to more general geographical contributions.

1. *Specifically Geographical Contributions*

Geographers have made four main contributions to the study of time since the 1960s.

1.1 *Chronogeography*

Chronogeography was an attempt by Parkes and Thrift (1980) to extend the human ecological paradigm. In line with that paradigm, it was stimulated by essentially biological analogies. In particular, a heavy emphasis was put on rhythm. Rhythms were seen as operating at a number of different time–space scales, thereby providing the time–space backbone to different societies. In turn, these rhythms were produced by '*zeitgeber*' of various kinds, sociotemporal 'lighthouses' ranging from the heartbeat and other chronobiological phenomena at one end of the scale to various kinds of economic cycle at the other end, which produced different kinds of timed spaces and different ways of spacing time. Chronogeography was a phenomenon of the 1970s and early 1980s.

1.2 *Time-geography*

In marked contrast, so-called time-geography has made a sustained and lasting contribution to the geographical literature, notwithstanding considerable debates within geography as to the efficacy of certain of its features. Time-geography emerged as a prominent area of geographical work in the late 1960s and early 1970s in Sweden as a result of the work of the remarkably original thinker Torsten Hägerstrand (1982, Carlstein et al. 1978, Pred 1981). It approached the analysis of social interactions by focusing on the time–space paths of their participants, within temporal and spatial structures of interaction, movement, and communications. Time and space are conceived as resources in short supply on which individuals draw to provide 'room' in which they can realize projects. Time and space are facilitating resources in which collateral processes can occur. The use of time and space is constrained in three ways: by the power, wealth, skills, and knowledge of individual participants (capability constraints); by the conditions or circumstances in which people can interact with one another (coupling constraints); and by the power relations that mould people's access to particular spaces and shape the roles in which they do have access (authority constraints). The stress on constraints to the completion of projects provides a series of ways in which the power relations of a society operate by shaping the time–space patterns of human activities. Put another way, social institutions are structures of repetition through which the time–space coherence of societies can be maintained. They do this either by imposing particular projects or time–space routines within a society, or through internalizing certain projects and routines as 'natural' within people's everyday perceptions.

One of the most distinctive elements of time-geography was the unique graphic language that Hägerstrand deployed in order to describe the time–space structures of society. Often likened to a musical score, time–geographic diagrams have clearly been one of the most distinctive contributions made by geographers to the social sciences, since they are both analytic and evocative. Increasingly, as well, it has been realized that Hägerstrand was well ahead of his time in his attention to the nontextual elements of human life which time–geographic diagrams are so well able to conjure up.

Time-geography has been an enormously productive means of showing the time–space structure of situations because of its ability to be both general and concrete. It has been applied widely, both to consider particular problems of the allocation of time and space (most especially in planning) but also more generally, for example to look at problems of technological change or environmental degradation (Carlstein 1982). It has also become the basis of many important social theoretical ruminations.

Yet, like any approach, it is not without its problems. First, even with the benefit of greater computer power, many of its insights are still difficult to operationalize at the scale of a city or region, as opposed to the smaller communities that time-geography seems to fit so well. It is no surprise then that Hägerstrand developed another level of analysis that worked at this larger scale. Second, time-geography is often reticent in discussing struggle within societies, although researchers like Pred (1986) have very successfully addressed this issue using time–geographic approaches. Third, time-geography has been accused of neglecting the symbolic dimension. If this is true it is, in a sense, a philosophical neglect. Hägerstrand has been concerned to show, rather like actor–network theory, that a good deal of what is regarded as symbolic might be more profitably addressed in different ways (see Gren 1994; *Urban Activity Patterns*).

1.3 *Time–space Compression*

The third distinctive geographical contribution to the study of time and geography has been the concept now

known as 'time–space compression,' which is based on the notion of progressive shrinkage in the resources of time and space. From the 1920s onwards, geographers became concerned with what Marx called the 'annihilation of space by time,' as travel times between locations diminished because of new transport and telecommunications technologies. Until the 1980s, this was usually seen as an interesting empirical phenomenon. Then David Harvey (1989) linked 'time–space convergence' to wider processes of spatial extension and intensification within capitalism: the history of capitalism has been characterized by speed-up in the pace of life, while so overcoming barriers that the world seems to collapse in upon us. In other words, ever more intense time–space compression dislocates everyday practices and understandings. Harvey identified postmodernism as the latest form of dislocation and, in line with a political economy approach, was particularly keen to associate it with new post-Fordist production paradigms.

1.4 Nonrepresentational Theory

The last distinctive contribution to the study of time and geography has been nonrepresentational theory (Thrift 1996, 2000). Nonrepresentational theory is concerned with the flow of practices in time, with the 'presentations' produced by acting in the now rather than the *post hoc* reconstructions of the event which are the stuff of much of the social sciences. It draws inspiration from all the approaches so far considered—chronogeography for its interest in the different rhythmical structures of time and space, time-geography for its attention to detail as not just detail, and time–space compression for its attempt to understand certain characteristics of the modern world as integrally bound up with the construction of particular times and spaces—as well as numerous other elements of the social sciences, and especially various theories of practice. Nonrepresentational theory attempts to do two related things: first, to provide an ontology which takes 'mundane' practices seriously and, second, to provide various means of amplifying the creativity of these practices through various performative methods.

2. Geographical Themes in Work on Time

A key area for early work on time was provided by the simple fact of spatial variations in the time-patterns of life, the institutions and practices that were central to different societies' handling of times, and how different societies thought of time. Much of this material was derived from the anthropological literature. One key geographical concern was the identification of environmental or social factors underlying spatial patterns in times. Another was how these spatial patterns were changing as dominant Western patterns of timing diffused around the world. This last concern clearly derived from the 'modernization thesis' of economic and cultural change that dominated the social sciences from the mid-twentieth century (Thompson 1967).

But standard depictions of people of great temporal innocence have not survived close scrutiny, especially once time is conceived more broadly than as the clock time taken for granted in the twentieth-century West. The complexity and variety of traditional and non-Western views of time is now virtually axiomatic. In general, traditional cultures were not caught up in unchanging, nature-based and cyclical ideas of time. They subscribed to complex and sophisticated calendrical arrangements; were able to conceive of a linear time; did not lack a sense of their own past; and were not imprisoned by tenseless languages and a reliance on oral cultural transmission. Rather, the temporal values present in different traditional cultures display an incorrigible diversity (Gell 1992). This diversity is now recognized to be a crucial feature of contemporary societies as well, as can be demonstrated through four main themes.

2.1 Multiple Times and Spaces

Geographers have been among writers highlighting the coexistence of differing time-senses among social or ethnic subgroups within populations, linked to work on similar differences in senses of space and place.

Everyday experiences of time are structured by many influences besides the determinants of religion, trade, and industrialization so often emphasized (Thompson 1967). General or specific notions of timing and coordination also arise within households; from structures of preindustrialized work; from communications; from civic administration and law; from recreation and consumption; from disciplinary regimes such as prisons, workhouses, and hospitals; from cartography and navigation; and from the military.

Although most of these arise among relatively specialized temporal communities, it is essential to acknowledge that they coexisted in places, especially in towns, where the institutions of government, church, trade, and industry were most likely to come together, increasingly acting to impose artificial schedules on a population which then began to talk about these schedules as a natural occurrence (Thrift 1996). A geographical focus on time in places, rather than time in particular occupations, can hardly avoid drawing attention to the 'spillovers' of temporal practices within urban populations. In other words, temporal frameworks are only rarely the preserve of a single community of expertise, and everyday temporal orderings are commonly hybrids of several ordering frameworks, each arising from particular subgroups.

The point that any given place or space can take on multiple temporal forms for different social subgroups is rarely more clearly evident than for women. For a long time, women's times were not taken seriously by geographers, who drew on implicitly male social features. Though recent work has begun to remedy the neglect of everyday time practices relating to women, the general area of women's times and spaces cannot be said to be over-researched.

2.2 The Continuing Heterogeneity of Timed Spaces

Historians of time began with ideas of a linear progression from timeless to highly coordinated cultures, through a series of intermediate stages, with 'industrial time consciousness' diffusing through society and across space (Thompson 1967). But it is now clear that spatial differences in sense of time were not being obliterated. Notwithstanding considerable homogenization of industrial production techniques and of temporal frameworks (such as the geographical spread of Greenwich Mean Time) (Thrift 1981, Pawson 1992), there is clear evidence of international and inter-regional differences in temporal frameworks and their interpretations.

In turn, this realization made it possible to revalue time derived from 'natural' cues and to understand that senses of time derived from nature were often associated with impulses to disciplined and unstinting work, and hence attention to saving time. Again, it also became clear that industrial time consciousness was itself a heterogeneous creature, with very different practices instituted in different places.

2.3 Timing in Relation to Travel and Communications

The mobility of people, objects, finance, and information has many effects on time measurement and temporal practices, usually involving not only practical questions of coordination (such as the implementation of regular timetables and calendars for specific purposes), but also new techniques of time-calculation (interest, risk costs, and so on) and new conventions of everyday life. Five topics have been closely researched.

First, new temporal practices are often associated with long-distance trade, including various means for deferred payments and futures trading. Second, temporal precision has been central to knowledge of spatial positions at sea and on land, especially in calculating longitude. Third, the close dependence of administration, as well as business, on efficient handling of information over time and (relatively) rapid communication across space has formed an important theme in historical geographies of European world dominance. The emergence of standard times and time zones and the impact of electronic communications have also received particular attention (Kern 1982). A fourth focus has been on how temporal cues flow from one timed space to others. The obvious instance here is clock time, although even this is taken note of and reacted to differently in different timed spaces. Fifth, time has been studied in relation to tourism, where both the coordinated movement of people and the specific character of the 'tourist experience' itself rest on particular ways of handling, and of representing, time(s).

2.4 Temporal Symbolism as Constitutive of Time-senses

The inherently cultural character of any time-keeping system has become a commonplace observation. Since geography underwent a cultural turn in the 1980s, it is no surprise that the variegated cultural character of time-keeping systems has become a focus of research. This research has followed three main avenues of investigation. First, what counts as a 'task' is very much a matter of cultural values. Industrial geographers have shown how a task varies from place to place in how it is constructed and valued (Stein 1995). Second, there has been work on disputed interpretations of time, demonstrating its heavily symbolic character. Such work includes contemporary and historical studies of strikes during restructurings of industries. Parallel work has considered timings linked to national identities, especially involving disputes over calendars. Third, work considering language as language-in-use necessarily incorporates a temporal perspective.

3. Future Directions of Theory and Research

We end by suggesting some of the themes that might constitute a research agenda for future geographical work on times.

The first of these consists of work on time consciousness as the mediated imposition of a particular set of practices upon a population, which in turn affects the way a population makes accounts of practice. Much here echoes Thompson's (1967) approach, but it is pursued rather differently, with shifts in ideologies of everyday time practice and the consciousness of time indexed through three dimensions: discourses and texts; devices and instruments; and disciplines and routines. Each of these dimensions is strongly geographical. The effectiveness of temporal discourses is limited by the spatially uneven availability of texts and devices and by variations among temporal communities, which in turn shape systems of discipline and meaning that reinforce or undermine particular temporal conceptions and practices.

The second area of work is on instantaneity. Writers like Harvey and Virilio have discussed the supposed

effects of the increasing swiftness of many social practices, but none of this writing stems from any detailed ethnographic research. It all consists of assumptions—usually based in technological determinisms—masquerading as theory. Thus, we know remarkably little about the practices that have sprung up which have refigured the world as 'fast' and which are to be acted out as such. These practices are very diverse, and range all the way from different forms of visualization through different forms of economic practice, including those to do with international finance which have involved the evolving use of different forms of telecommunication stretching over the last 150 years, to different forms of warfare, including Virilio's 'chronopolitics'.

The third area of work consists of temporal policy. Since Kevin Lynch's (1972) *What Time is this Place?* geographers have been interested in practices of temporal planning that they might lay alongside those of spatial planning. Now various experiments in countries like Italy and Germany are starting to give these practices real expression. For example, six Italian cities have passed statutes providing temporal planning in matters such as the staggering of work and school hours so as to smooth traffic peaks. These may be minor interventions, but they begin to show what might be possible.

In conclusion, for a discipline raised on space, geography has had a remarkable amount to say about time. Indeed, recent writings on the importance of time–space as the focus of the discipline (e.g., Massey 1992, May and Thrift 2001) rather than simply space can only reinforce this tendency.

Time Perception Models

Time perception is a distinct area of study with its own psychophysical methods designed for assessing the perceived duration of a temporal interval. There is now an extensive database to guide the development of models of time perception. Most timing models are firmly rooted in an *internal clock*. Internal clock models postulate a timing-specific mechanism which produces perceived temporal values that bear orderly relations to real time. This timing-specific mechanism, or internal clock, is an interval timer, rather than a periodic or oscillatory mechanism. A periodic clock, such as the kind responsible for circadian rhythms, is continuously running and self-sustaining. In contrast, interval clocks need to be initiated with a signal. Once started, the system goes to completion, comes to a rest on its own, and must be restarted.

The first psychophysical models for time perception were proposed at about the same time by Creelman (1962) and Treisman (1963). Creelman (1962) introduced the signal-detection approach, which was continued by Allan and Kristofferson (1974). The most sophisticated signal detection model is Killeen et al.'s (1997) *Pseudo-logistic model* (PLM). The information-processing approach was introduced by Treisman (1963) and continued by many others, including Eisler (1975), Thomas and Cantor (1978), and Zakay and

Block (1994). The most developed of the information-processing models is Gibbon et al.'s (1984) *Scalar timing* (ST), which has been reformulated as a connectionist model by Church and Broadbent (1991). In direct contrast to information-processing models is Killeen and Fetterman's (1988) behavioral theory of timing (BeT).

Because signal-detection models and information-processing models have been applied to both human and nonhuman timing data, we shall focus on such models in this article, presenting ST and PLM as exemplars of these two classes of models. Specific versions of ST and PLM have been derived for a variety of timing tasks, such as time-left, temporal generalization, and *temporal bisection*. We shall examine ST and PLM in their application to temporal bisection.

In the prototypic temporal bisection task (e.g., Allan and Gibbon 1991), the subject is familiarized with a constant pair of referents, one short (S) and the other long (L). On probe trials, a temporal interval t, $S \leqslant t \leqslant L$, is presented, and the subject is required to indicate whether t is more similar to $S(R_S)$ or to $L(R_L)$. Temporal bisection data are summarized as a psychometric function relating the proportion of long responses, $P(R_L)$, to probe duration t. The *bisection point* ($T_{1/2}$) is the value of t at which R_S and R_L occur with equal frequency, $P(R_L) = 0.5$. One interpretation of $T_{1/2}$ is that it is the point of subjective equality (PSE), identifying the perceived value of t that is midway between S and L. Empirically, it has been found that the location of $T_{1/2}$ is influenced by the size of the L-to-S ratio (r) and by the spacing of the probes (see Allan 1998). For $r \leqslant 2$, $T_{1/2}$ is around the geometric mean (GM) of the S and L referents, but moves toward their arithmetic mean (AM) as r increases. For $r > 2$, $T_{1/2}$ for linearly spaced probes is greater than that for logarithmically spaced probes, with the probe spacing effect becoming negligible for $r \leqslant 2$.

1. Scalar Property

Both ST and PLM incorporate *Weber's law* for the duration values used in most psychophysical experiments. According to Weber's law, for a given clock time $t > 0$, the variability in perceived time (σ_t) is *scalar* with mean perceived time (μ_t); that is, there is a constant $\gamma > 0$ such that

$$\frac{\sigma_t}{\mu_t} = \gamma \tag{1}$$

Also, for both models, mean perceived time is a power function of clock time with an exponent close to 1.0, i.e.,

$$\mu_t = t \tag{2}$$

and therefore Eqn. (1) can be rewritten as

$$\frac{\sigma_t}{t} = \gamma \tag{3}$$

The scalar property in Eqn. (3) results in distributions that superpose when the temporal axis is normalized with respect to the mean of the distribution. This superposition in relative time reflects a rescaling in time, a scale-invariant error distribution for perceived time.

2. Scalar Timing

ST has its origins in scalar expectancy theory (Gibbon 1977), and made its appearance as a timing model in Gibbon et al. (1984). The model consists of three, interrelated information processing stages—clock, memory, and decision—which are associated with timing, storage, and responding, respectively. The clock is responsible for transforming clock time into perceived time. It consists of a pacemaker that emits pulses at some mean rate, a switch that is controlled by a timing signal, and an accumulator that sums the pulses. There are two memory registers for the storage of clock information, *working memory* and *reference memory*. Working memory is loaded from the accumulator and serves as an extended buffer for temporal information from the current trial. Reference memory stores critical temporal information from past trials. The comparator determines a response on the basis of a decision rule which involves a comparison of current time stored in working memory with remembered time sampled from reference memory.

According to ST, the decision to respond R_S or R_L in temporal bisection is made by comparing the similarity of the perceived value of t with memories of the two referents, S and L. This comparison is based on a ratio of the similarity of t to S relative to the similarity of t to L. If that ratio is less than some fixed value β, the response is R_L. In his mathematical derivation of the *bisection function*, Gibbon (1981) combined the similarity ratio decision rule with two locations for the scalar variability, perception or memory. In the referent known exactly (RKE) model, he assumed no variability in the memory for the referents and placed the scalar variability in the perception of the probes. In contrast, in the stimulus known exactly (SKE) model, he assumed no variability in the perception of the probes and placed the scalar variability in the memory for the referents. There are two parameters in these models. The noise parameter γ is the coefficient of variation of time. For SKE, γ is the scalar variability in the memory representations of the S and L referents; for RKE, γ is the scalar variability in the perception of t. For both models, β is a response bias parameter. It

follows from the assumptions of the model that the SKE bisection function is approximately

$$P(R_L) = 1-\phi\left[\frac{1-\beta\left(\frac{t}{\sqrt{SL}}\right)^2}{\gamma\sqrt{\gamma^2+2}}\right] \tag{4}$$

and the RKE function is approximately

$$P(R_L) = 1-\phi\left[\sqrt{\frac{SL}{\beta\gamma^2 t^2}}-\frac{1}{\gamma}\right] \tag{5}$$

where ϕ is the cumulative normal distribution function. For both models, $T_{1/2}$ is proportional to the geometric mean (GM) of the S and L referents:

$$T_{1/2} = \sqrt{\frac{SL}{\beta}} = \frac{GM}{\sqrt{\beta}} \tag{6a}$$

and for unbiased responding ($\beta = 1$), $T_{1/2}$ is at the GM of the S and L referents:

$$T_{1/2} = \sqrt{SL} = GM \tag{6b}$$

Equation (6a) provides for variables such as ratio and probe spacing to have their effect on the location of $T_{1/2}$ through β. For example, with a large r and linear probe spacing, $T_{1/2}$ located at the GM would yield more R_L than R_S responses. To balance the frequency of the two response categories, it would be necessary to set $\beta < 1$, moving $T_{1/2}$ towards the AM. With log probe spacing, however, the two response categories would be equal with $\beta = 1$ and $T_{1/2}$ at the GM.

3. Pseudologistic Model

In addition to deriving the bisection function for the similarity ratio rule, Gibbon (1981) also derived the function for the signal detection likelihood ratio rule. For the likelihood rule, the decision to respond R_S or R_L is based on the odds ratio that the perceived value of t is generated by S or L. For this rule, Gibbon (1981) placed the scalar variability in the perception of the probes, resulting in a signal-detection model for temporal bisection. Killeen et al. (1997) simplified the derivation of the bisection function (and the resulting equation) by approximating the normal distribution with the logistic. The pseudologistic bisection function is

$$P(R_L) = \left[1+\exp\left(\frac{C-t}{0.55\gamma t}\right)\right]^{-1} \tag{7}$$

where C is the signal detection criterion. According to PLM, $T_{1/2}$ is the value of t where the S distribution crosses the L distribution. Killeen et al. (1997) showed that $T_{1/2}$ is proportional to the harmonic mean (HM) of S and L; i.e.,

Figure 1
Schematic of the PLM model for $r = 4$ ($L = 8$ and $S = 2$). The logistic density functions [$f(t)$] are for $t = 2$, 4, 6, and 8. The psychometric function [$P(R_L)$] is for C located at $T_{1/2} = (1+k)HM$ and $\gamma = 0.15$.

$$T_{1/2} = (1+k)\frac{2}{\frac{1}{S}+\frac{1}{L}} = (1+k)HM \tag{8}$$

where

$$k = \left(\frac{\gamma\ln\left(\frac{L}{S}\right)}{2}\right) \tag{9}$$

PLM predicts that the L-to-S ratio will affect the location of $T_{1/2}$.

PLM is presented schematically in Fig. 1 for $r = 4$ ($L = 8$ and $S = 2$). The spacing of t is linear, $\gamma = 0.15$, and C is located at $(1+k)HM$. It is clear from Fig. 1 that because of the scalar property a percept located at $C = (1+k)HM$ is more likely to have been generated by L than by S. Killeen et al. (1997) suggested that in order to balance the frequency of the two response categories, C would move toward the AM with increasing r rather than being set at $(1+k)HM$.

4. Pseudologistic Model and the Behavioral Theory of Timing

Killeen et al. (1997) emphasized that PLM is a descriptive rather than a process model in that it resides close to the level of the data and does not

postulate particular underlying processes that generate the data. They do describe, however, how in their view PLM dovetails with BeT.

5. Other Models

Allan and Kristofferson (1974, p. 26) concluded that 'There are few quantitative theories of duration discrimination and few established empirical phenomena to guide theorizing.' Five years later, Allan (1979, p. 340), referring back to Allan and Kristofferson (1974), stated that 'Since that time, there has been a dramatic change. Many articles on the discrimination of brief temporal intervals, and several new quantitative models, have appeared in a period of a few years.' Now in 2000 we have an abundance of quantitative models for time perception. In this short article, I have merely provided the reader with a few gems. To obtain a broader exposure to and appreciation of the current status of quantitative models for time perception, the reader is referred to two special issues of *Behavioural Processes* in 1998 and 1999 edited by Jennifer Higa.

Time Series: Advanced Methods

1. Introduction

Many social phenomena can be described, at least approximately, by a discrete-time dynamical system, which can be expressed as a difference equation,

$$Y_t = F(X_{t-1}) \tag{1}$$

where $\{Y_t\}$ is a sequence of m dimensional observations and X_t is a d' dimensional state vector, with $t = 1, 2, \ldots$ and $1 \leqslant m' \leqslant m$. In many applications, X_t stands for the past values of Y_t. Depending on the functional form $F(\cdot)$, the difference Eqn. 1 can exhibit a variety of dynamical features such as limit cycles, time irreversibility, and periodic changes (Tong 1983, 1990). However, in the real world, stochastic noise is often present and therefore it is more realistic to consider a dynamical system with noise such as:

$$Y_t = F(X_{t-1}, a_t; \theta) \tag{2}$$

where $\{a_t\}$ is often assumed to be a sequence of independent identically distributed (*i.i.d*) (possibly vector valued) random variables and θ is a vector of parameters. For instance, if $Y_t = X_t$ with $m = 1$ and $F(\cdot)$ is a scalar valued function, say, $f215(X_{t-1}; \theta) + a_t$, then (2) takes the form:

$$X_t = f(X_{t-1}; \theta) + a_t \tag{3}$$

which is a non-linear autoregressive process of order one. Clearly Eqn. 3 can be generalized to include more past values of X_t and then we have

$$X_t = f(X_{t-1}, X_{t-2}, \ldots, X_{t-p}; \theta) + a_t \tag{4}$$

which is a general nonlinear autoregressive process of order p. An important special case of Eqn. 4 is when $f(\cdot)$ is linear in the past values of X_t and we have then

$$X_t = \phi_1 X_{t-1} + \cdots + \phi_p X_{t-p} + a_t \tag{5}$$

which is the usual linear autoregressive model of order

p. Depending on $f(\cdot)$ or more generally $F(\cdot)$, the number of nonlinear models is clearly unlimited and the choice of a model is typically dictated by the situation and the ability of the model to describe/predict a social phenomenon.

It is clear that the dynamical system formulations Eqn. 2 and Eqn. 4 can be extended by considering a specification of the variance of the noise term a_t. Thus,

$$X_t = f(X_{t-1}; \theta) + g(X_{t-1}; \theta)a_t \tag{6}$$

where $g(\cdot)$ is positive. Now, X_t is conditionally heteroscedastic. In other words, model Eqn. 6 now consists of both specifications for the mean (the drift) and for the conditional variance (the diffusion). Below we consider some advanced models in time series which have been developed and found to be useful since around 1980. For simplicity, we let $Y_t = X_t$ and a_t be a sequence of *i.i.d.* scalar random variables.

2. Nonlinear Time Series for the Mean

2.1 The Class of Threshold Models

Proposed by Tong in the later 1970s, the threshold models are a natural generalization of the linear autoregression Eqn. 5 by allowing different linear autoregressive specification over different parts of the state space. For example, a two-regime threshold autoregressive model of order p_1 and p_2 may be defined as follows,

$$X_t = \begin{cases} \phi_0^{(1)} + \phi_1^{(1)} X_{t-1} + \cdots + \phi_{p_1}^{(1)} X_{t-p_1} + a_t^{(1)}, & \text{if } X_{t-d} \leqslant c \\ \phi_0^{(2)} + \phi_1^{(2)} X_{t-1} + \cdots + \phi_{p_2}^{(1)} X_{t-p_2} + a_t^{(2)}, & \text{otherwise} \end{cases} \tag{7}$$

where $1 \leqslant d \leqslant \max(p_1, p_2)$, $\{a_t^{(i)}\}$ are two *i.i.d.* noise sequences with mean zero and variance σ_i^2, $i = 1, 2$, $\{a_t^{(1)}\}$ and $\{a_t^{(2)}\}$ are also independent of each other. We call c the threshold parameter and d the delay parameter. Eqn. 7 is called a self-exciting threshold autoregressive (SETAR (2; p_1, p_2)) model. Generalizations to more than two regimes are immediate. Stationarity and ergodicity conditions for Eqn. 7 when $p_1 = p_2 = 1$ and $\phi_0^{(i)} = 0$, $i = 1, 2$ have been obtained while a sufficient condition for the general SETAR (2; p, p) model is available (Tong 1990).

Estimation of Eqn. 7 can be easily done using the conditional least squares method given the parameters p_1, p_2, c, and d. Identification of p_1, p_2, c, and d can be done by the minimum Akaike information criterion (AIC) (Tong 1990). For finite samples the corrected AIC or AICC is recommended (Wong and Li 1998). The computer programme STAR 3 accompanying Tong (1990) provides a comprehensive set of modeling tools for threshold models. Diagnostic checking for model adequacy can be done using residual autocorrelations. The appropriate asymptotic distribution was derived in Li (1992). Tsay (1989) suggested an approach in the detection and modeling of threshold structures which is based on explicitly rearranging the least squares estimating equations using the order statistics of X_t, $t = 1,\ldots, n$, where n is the length of realization. (See Tong 1990 for references.) A similar rearrangement was incorporated in the software STAR 3. Chen and Tsay (1993) considered a functional-coefficient autoregression model which has a very general threshold structure.

An easy-to-use statistic for detecting departure from linearity is the port-manteau test based on squared residual autocorrelations, the residuals being obtained from an appropriate linear autoregressive moving-average model fitted to the data (McLeod and Li 1983). Of course, a general test statistic may not be optimal in terms of power when specific alternative hypotheses are considered. Tong (1990) has described other tests for nonlinearity due to Davies and Petruccelli, Keenan, Tsay and Saikkonen and Luukkonen, Chan and Tong. Petruccelli (1990) considered a comparison for some of these tests.

As a textbook-like example (albeit outside the social sciences), we consider the annual Canadian lynx trapping data in the MacKenzie River for the period 1821–1934. The nonlinearity of the data has been extensively documented by Tong (1990). Threshold nonlinearity was confirmed by applying the likelihood ratio test of Chan and Tong (1990) at the 1 percent level. Following other authors we transform the data by taking common log. We use the AICC as a criterion in selecting the best SETAR (2; p_1, p_2) model. The maximum possible value for p_1 and p_2 is 10, and the maximum possible value for the delay parameter d is 6. It is recommended that possible candidates of the threshold parameter can be chosen from a subset of the order statistics of the data. Following Wong (1998) we use 2.4378, 2.6074, 2.7769, 2.9464, 3.1160, 3.2855, and 3.4550, as potential values of the threshold parameter. The best fitting model using the minimum AICC criterion is the following SETAR (2; 4, 2) model,

$$\begin{aligned} X_t &= 1.0303 + 0.8959X_{t-1} - 0.0313X_{t-2} + 0.0406X_{t-3} \\ &\quad - 0.2001X_{t-4} + a_t^{(1)} \\ &\quad \text{if } X_{t-3} \leqslant 2.9464, \\ X_t &= 1.6092 + 1.3487X_{t-1} - 0.8937X_{t-2} + a_t^{(2)}, \\ &\quad \text{if } X_{t-3} > 2.9464 \end{aligned}$$

where $a_t^{(1)}$ and $a_t^{(2)}$ have estimated variance equal to 0.0164 and 0.0642, respectively. The residual autocorrelation and squared residual autocorrelation show no significant values suggesting that the above model is adequate.

Instead of adrupt jumps between regimes in Eqn. 7 a smooth transition threshold autoregression was proposed by Chan and Tong (1986). Teräsvirta (1994)

considered some further work in this direction. Continuous time threshold model was considered by Tong and Yeung (1991) with applications to water pollution data. Brockwell (1994) and others considered further work in the continuous time. Multivariate (mainly bivariate) threshold models were included in the seminal work of Tong in the 1980s and further developed by Tsay (1998). The relation between chaos and nonlinear time series is also treated in some detail in Tong (1990).

2.2 The Class of Bilinear Time Series Models

Bilinear models featured for a while in the early days of nonlinear time series modeling. In its simplest form, a single term bilinear model is given by

$$X_t = \beta X_{t-k} a_{t-l} + a_t \tag{8}$$

where $k, l \geqslant 1$. Note that Eqn. 8 is linear in $X_{t-k}(a_{t-l})$ given $a_{t-1}(X_{t-k})$.

Granger and Andersen (1978) provided the first comprehensive introduction to these models. By deriving the second order autocovariances of Eqn. 8, they demonstrated that if $l < k$ then the time series cannot be distinguished from an uncorrelated noise process. The general bilinear autoregressive moving average model of order (p, q, P, Q) has the form

$$X_t = \sum_{j=1}^{p} \alpha_j X_{t-j} + \sum_{i=0}^{q} b_i a_{t-1} + \sum_{k=1}^{P} \sum_{l=1}^{Q} \beta_{kl} X_{t-k} a_{t-l}. \tag{9}$$

Granger and Andersen (1978, p. 31) denoted this by BARM (p, q, P, Q) and Subba Rao (1981) denoted this by $BL(p, q, P, Q)$. Subba Rao (1981) and Subba Rao and Gabr (1984) gave a general theory for model (9). Further results on causality and stationarity were given by Liu and Brockwell (1988). Identification (in the sense of estimation) of model (9) is in general difficult because of the enormous number of possibilities.

3. Models with Conditional Heteroscedasticity

One very popular class of such models is the autoregressive conditional heteroscedastic (ARCH) models of Engle (1982). The ARCH model of order one (ARCH(1)) is given by

$$X_t = \sqrt{h_t} a_t \tag{10}$$

and $\sqrt{h_t} = g(X_{t-1}; \theta) = (\alpha_0 + \alpha_1 X_{t-1}^2)^{\frac{1}{2}}$. Here $\alpha_0 > 0$, $\alpha_1 \geqslant 0$ and a_t is again *i.i.d.* with mean zero and unit variance. It can be shown that X_t is covariance stationary if $0 \leqslant \alpha_1 < 1$. The unconditional variance of (6) is then $\alpha_0/(1-\alpha_1)$. The fourth moment of (6) exists if $\alpha_1^2 < \frac{1}{3}$. It is then greater than 3. For $r > 1$, the

Figure 1
Sample autocorrelations of R_t

ARCH(r) model is defined by including more past values of X_t^2 so that $h_t \equiv E(X_t^2 \,|\, \text{past information}) = \alpha_0 + \alpha_1 X_{t-1}^2 + \cdots + \alpha_r X_{t-r}^2 (\alpha_0 > 0, \alpha_i \geqslant 0 \quad \text{for} \quad i > 0)$. Again, X_t is covariance stationary if $\alpha_1 + \alpha_2 + \cdots + \alpha_r < 1$. It can be shown that the autocorrelation function of X_t^2 behaves like that of an AR(r) process. Milhøj (1985) derived the condition for the existence of the $2m$-th moments of X_t. Estimation of model 10 can easily be done by assuming a_t to be standard normal so that X_t is conditionally normal with mean zero and variance h_t. The conditional log likelihood l is then given by

$$l = \sum_{t=1}^{n} l_t = \sum_{t=1}^{n} -\tfrac{1}{2} \log h_t - \frac{1}{2} \frac{X_t^2}{h_t}. \tag{11}$$

Maximum likelihood (ML) estimation can be performed using Newton–Raphson or a method that does not require explicit derivatives. Assuming finite 4-th moments, Weiss (1986) showed that the ML estimates are consistent and asymptotically normally disturbed. Many commercial statistical softwares such as the SAS now provide capabilities for ARCH modeling.

Diagnostic checking of the fit of ARCH models using standardized squared residual autocorrelations was considered in Li and Mak (1994). A fast method of detecting ARCH is by means of the portmanteau test of McLeod and Li (1983) using residuals from an autoregressive moving average model. As an illustration, we consider the daily closing price of the Hong Kong Hang Seng Index in the year 1980. The data are transformed by taking natural logarithm and differenced once to achieve stationarity. The transformed data R_t are called the returns of the index. There are 245 observations. The sample autocorrelations of R_t in Fig. 1 show basically no noticeable dependence struc-

Figure 2
Sample autocorrelations of R_t^2

ture in R_t itself. However, the sample autocorrelations of R_t^2 in Fig. 2 show a very strong dependence structure for R_t^2 suggesting the presence of an ARCH structure. Based on the partial autocorrelations of R_t^2 we consider an ARCH model of order 7 for R_t. Using the method of maximum likelihood we have the following result:

$$R_t = \sqrt{h_t} a_t$$

with

$$h_t = 0.00012 + 0.03997 R_{t-1}^2 + 0.13506 R_{t-2}^2 + 0.12798 R_{t-3}^2 + 0.15475 R_{t-6}^2 + 0.28445 R_{t-7}^2.$$

As reported in Li and Mak (1994) the sample autocorrelations of R_t^2 standardized by h_t show no further significant values and the above ARCH model is thus considered adequate.

Bollerslev (1986) generalized the ARCH(r) model to the GARCH(r, s) model, where

$$X_t = \sqrt{h_t} a_t$$

and

$$h_t = \alpha_0 + \sum_{i=1}^{r} \alpha_i X_{t-i}^2 + \sum_{i=1}^{s} \beta_i h_{t-i} \tag{12}$$

with $\alpha_0 > 0$, $\alpha_i \geqslant 0$, $\beta_i \geqslant 0$.

The condition for covariance stationarity is $\sum_{i=1}^{r} \alpha_i + \sum_{i=1}^{s} \beta_i < 1$. Estimation of model 12 is similar to that of the ARCH models and exogeneous variables can be easily included. The second order moment properties of X_t^2 are like those of an ARMA(p, s) where $p = \max(r, s)$. The GARCH models have been very popular in the modeling of volatility in the finance literature. Bollerslev et al. (1992, 1994) provided two extensive reviews of the GARCH literature. Gourieroux (1997) and Bera and Higgins (1995) gave a more advanced coverage including multivariate ARCH models. The work edited by Engle (1995) has included many of the important contributions to the ARCH literature.

4. *Models with Long Memory*

Many stationary dynamical systems under model 4 in fact lead to $\{X_t\}$ which are short memory in the sense that the moduli of the autocovariances $C(k) = \mathrm{cov}(X_t, X_{t-k})$, $k = 1, 2, \ldots$ sum to a finite value. However, in some applications it is possible that $\sum_{k=0}^{\infty} |C(k)| = \infty$. A time series with this property is said to have the long memory property. One approach to modeling the long memory property is by means of fractional differencing. Suppose that B is the backshift operator, $BX_t = X_{t-1}$. Then a long memory dynamical system can be constructed by considering the process satisfying (Granger and Joyeux 1980),

$$(1-B)^d X_t = a_t \tag{13}$$

where d is a non-integer and

$$(1-B)^d = \sum_{k=0}^{\infty} \binom{d}{k} (-1)^k B^k.$$

The process is stationary and invertible if $-1/2 < d < 1/2$ and possesses the long memory property if $0 \leqslant d < 1/2$. The fractionally integrated autoregressive moving average (FARIMA) process of order (p, d, q) satisfies (Hosking (1981), and Granger and Joyeux (1980),

$$\phi(B)(1-B)^d X_t = \theta(B) a_t \tag{14}$$

where

$$\phi(B) = 1 - \phi_1 B \cdots - \phi_p B^p,\ \theta(B) = 1 - \theta_1 B \cdots - \theta_q B^q$$

and d is as in Eqn. 13. It is further assumed that ϕ(B) and θ(B) have all roots outside the unit circle, which implies that X_t is stationary and invertible. Hosking (1981) showed that the autcovariances $C(k)$ of X_t are of the order $|k|^{2d-1}$ so that unlike ARMA process, $C(k)$ decays hyperbolically rather than exponentially. The spectral density $f(\lambda)$ of the process can be written in the form

$$f(\lambda) = \frac{\sigma_a^2}{2\pi} |1 - e^{i\lambda}|^{-2d} \cdot \frac{|\theta(e^{i\lambda})|^2}{|\phi(e^{i\lambda})|^2}, \tag{15}$$

where σ_a^2 is the variance of a_t. Beran (1994) contained a detailed exposition of the subject while Brockwell and Davis (1991) gave a good introduction including least squares and maximum likelihood estimation.

5. *Second Generation Models*

Tong (1990) suggested that many of the aforementioned models can be combined to form new nonlinear models. He called these second generation

models. For example, Tong (1990) suggested the possibility of a threshold AR model with ARCH. His idea was applied to real data by Li and Lam (1995). Li and Li (1996) extended this further to the double threshold ARCH or DTARCH models. These models allow for a threshold structure in both the conditional mean and the conditional variance. Clearly the number of possibilities is unlimited and one can consider models like double threshold long memory models with GARCH.

6. Discrete Valued Time Series

In many applications, the time series under consideration may be integer valued or may possess a discrete marginal distribution. An obvious approach to generate discrete random variables is by means of a possibly higher order Markov chain. Such is the approach of Raftery (1985) and Pegram (1980). A more elegant approach is that of McKenzie (1986) which is based on the method of thinning. Böckenholt (1999) considered a mixed integer-valued autoregressive Poisson regression with an application to category purchase data. Discrete-valued time series may also be generated using a conditional generalized linear model as in Zeger and Qaqish (1988). Li (1991) considered the goodness of fit problem for this approach. The recent work of MacDonald and Zucchini (1997) gave a valuable and timely survey of this vast area.

7. Conclusion

There is certainly a myriad of non-linear models to consider when one decides to leave the restriction of the linear domain. What models to consider clearly depends on the goal and nature of the investigation. In many cases, flexibility in describing a variety of features such as time irreversibility, limit cycles, and autocorrelation structure is an important criterion. The availability of handy softwares is another important factor as illustrated by the examples considered. In many cases, automatic model selection criteria such as AIC and BIC, appropriately used, help to reduce the number of choices to a manageable few and so do model checking methods. The final test of a model in time series, in many applications is, of course, its ability to predict the future accurately.

Time Series: ARIMA Methods

1. Objectives of Time Series Analysis

Data in business, economics, engineering, environment, medicine, and other fields of scientific investigations are often collected in regular time intervals. Such data are called time series. Examples are hourly temperature readings, daily stock prices, weekly traffic volume, monthly money supply, quarterly GNP (gross national product), annual growth rates, etc. Time series data tend to exhibit patterns such as trends, seasonal fluctuations, irregular cycles, and occasional shifts in level or variability. The data are, therefore, dynamically or serially correlated.

In practice, the main objectives of analyzing time series are: (a) to ascertain and extrapolate the dynamic pattern in the data for forecasting future observations, (b) to assess the effect of exogenous interventions known to have occurred at given time points, and (c) to detect unknown and unsuspected interventions. For example, one may use the available weekly sales of frozen orange juice over the last three years to forecast the sales for the next six weeks and to assess the impact of a major promotion campaign initiated four weeks ago. As another example, an air pollution data analyst may discover a sudden drop in the time series of monthly ambient carbon monoxide concentration level and find out that the drop can be attributed to an unsuspected change in the measuring instrument. We here sketch some useful methods for achieving these objectives.

2. Stochastic Structure of Time Series Observations

Let $\ldots, t-1, t, t+1, \ldots$ denote equally spaced time points and y_t the observation at time t. The probability model generating the series $\{y_t\}$ is called a *stochastic process*, and the observed time series data are then a realization of the process. It is important to note a key distinction between time series observations and observations generated from designed experiments. For time series, there is usually one and only one realization at a given time point t, while because experiments can be repeated, there can be many realizations under the 'same' experimental conditions. Thus, statistical inference on time series depends critically on the nature of the serial dependence of the stochastic process under study.

3. Stationary vs. Nonstationary Processes

When the joint probability distribution of any k observations $y_{t+1}, \ldots, y_{t+k}$ from a stochastic process remains the same for different values of t, the process is said to be 'stationary.' In practice, this means that there is a state of equilibrium in which the overall behavior of the time series stays roughly the same over time. When this condition does not hold, the series is said to be nonstationary. The theory of stationary processes has been well developed and plays an important role in time series analysis. Although many of the time series encountered in practice exhibit a nonstationary behavior, it is frequently the case that a suitable transformation such as differencing the data will render them stationary so that the theory of stationary processes can be applied.

Figure 1
Monthly interest rates of 90-day Treasury bills, 1985–93

Figure 2
Month to month changes of the interest rates

To illustrate, Fig. 1 shows the time series of monthly interest rates of 90-day Treasury bills from January 1985 to December 1993, and Fig. 2 the series of month to month changes of the rates (first differences). The interest rate series exhibits a drifting or wandering behavior without a stable level. On the other hand, the series of the first differences seems to fluctuate about a fixed mean level with constant variance over the observational period. This example shows that a drifting nonstationary series can be transformed into a stationary one by the differencing operation. In fact, financial time series such as stock prices, prices of derivatives, and exchange rates often behave in this manner.

4. *Linear Dynamic Models*

The serial dependence in the time series $\{y_t\}$ can often be adequately approximated by a linear model of the form

$$y_t = c + \pi_1 y_{t-1} + \pi_2 y_{t-2} + \ldots + \pi_j y_{t-j} + \ldots + a_t \quad (1)$$

where c is a constant, $\pi_1, \pi_2, \ldots$ are parameters relating y_t linearly to its past values, and a_t is the innovation or shock hitting the system at time t. It is commonly assumed that $\{a_t\}$ is a series of identically and independently distributed normal random variables with zero mean and common variance σ^2. The linear dynamic model in Eqn. (1) can also be expressed in the alternative form

$$y_t = c^* + a_t + \psi_1 a_{t-1} + \psi_2 a_{t-2} \ldots + \psi_j a_{t-j} + \ldots \quad (2)$$

where c^* is a constant, and the two parameter sets $(\pi_1, \pi_2, \ldots)$ and $(\psi_1, \psi_2, \ldots)$ are functionally related. In Eqn. (2) ψ_j measures the effect of the shock a_{t-j} hitting the system j periods ago on the observation y_t. The ψ_j's are called impulse responses or the memory of the system. The two representations in Eqns. (1) and (2), although equivalent, highlight two distinctive features of the linear system.

For forecasting future observations at a given time origin T, let us consider first the next observation y_{T+1}. By putting $t = T+1$ in Eqn. (1), it is easy to show that the best (minimum mean squared error) predictor of y_{T+1} is a linear combination of the available observations $(y_T, y_{T-1}, \ldots)$, $\hat{y}_{T+1} = c + \pi_1 y_T + \pi_2 y_{T-1} + \ldots$, and the associated forecast error is simply $y_{T+1} - \hat{y}_{T+1} = a_{T+1}$ having variance σ^2. It is straightforward to deduce from Eqn. (1) best predictors of observations y_{T+l}, $\ell = 2, 3, \ldots$ periods ahead as linear functions of $(y_T, y_{T-1}, \ldots)$ and their associated forecast errors as linear combinations of future shocks $(a_{T+1}, \ldots, a_{T+\ell})$.

5. *ARMA and ARIMA Models*

In reality, the model in Eqns. (1) or (2) is not known and has to be built from available data. Since y_t can in principle relate to its remote past, or to the remote past of a_t, for parsimony it is useful to make the π's or ψ's functions of a small set of parameters which can then be accurately estimated from the data. A class of such models originally proposed by Yule and Slutsky in the 1920s is the (mixed) autoregressive moving average (ARMA) models of orders (P, Q),

$$y_t - \phi_1 y_{t-1} - \ldots - \phi_P y_{t-P} = c + a_t - \theta_1 a_{t-1} - \ldots - \theta_Q a_{t-Q} \quad (3)$$

This class of models has been found useful to represent a variety of stationary, nonstationary, and seasonal time series in diverse scientific fields. By straightforward substitutions, one can readily deduce the π's and ψ's in Eqns. (1) and (2) as functions of the finite parameter set $(\phi_1, \ldots, \phi_P; \theta_1, \ldots, \theta_Q)$ in Eqn. (3).

To illustrate, consider first the case $(P = 0, Q = 1)$ so that $y_t = c + a_t - \theta_1 a_{t-1}$, which is the first-order moving average model. This model says that when the shock a_t hits the system at time t it will affect not only the observation y_t but also the next observation y_{t+1} (since $y_{t+1} = c + a_{t+1} - \theta_1 a_t$). Thus, the effect of the shock a_t will last over the two periods t and $t+1$ and

dissipate afterward. This short memory stationary model has been found useful to represent time series of various financial returns.

Consider next the case ($P = 1, Q = 0$) so that the model is $y_t = c + \phi_1 y_{t-1} + a_t$, which is the first-order autoregressive model frequently discussed in the economics literature. This model is stationary when $|\phi_1| < 1$. It can be expressed in the alternative memory form $y_t = c^* + a_t + \phi_1 a_{t-1} + \phi_1^2 a_{t-2} + \mathrm{L}$ showing that the effect or memory of the shock a_t will persist over many periods but will gradually dissipate when the model is stationary. In this case, the l-step ahead forecast will converge to the mean level of the series as the horizon l increases. For ($c = 0, \phi_1 = 1$), this model is a nonstationary 'random walk' widely believed to be appropriate for stock prices in an 'efficient market.'

As a final illustration, for ($c = 0, P = Q = 1, \phi_1 = 1$) we have the model $y_t - y_{t-1} = a_t - \theta_1 a_{t-1}$. For this model, the left-hand side is the first difference of y_t implying that the series $\{y_t\}$ is nonstationary but the first difference series is stationary and follows the first-order moving average model. At the time origin T, the l-step ahead predictor is, for all $\ell \geqslant 1$, $\hat{y}_{T+\ell} = (1-\theta_1)y_T + \theta_1(1-\theta_1)y_{T-1} + \theta_1^2(1-\theta_1)y_{T-2} + \ldots$, which is an exponentially weighted average of current and past observations. Predictors of this kind which give more weight to recent information and less and less weight to information from the remote past seem intuitively appealing because time series data, especially in business and economics, tend to exhibit nonstationary behavior over time. As a result, the 'exponential smoothing' forecast discussed here has been the most widely applied forecasting technique in practice. It will be seen later that the Treasury bills data shown in Fig. 1 can be adequately represented by this model.

To sharpen the distinction between stationary and nonstationary models, we can express the ARMA (P, Q) models in Eqn. (3) alternatively as

$$\begin{aligned}\nabla^d y_t - \varphi_1 \nabla^d y_{t-1} - \ldots - \varphi_p \nabla^d y_{t-p} \\ = c + a_t - \theta_1 a_{t-1} - \ldots - \theta_q a_{t-q}\end{aligned} \tag{4}$$

where $d = 0, 1, 2, \ldots$, $\nabla^d y_t$ is the dth difference of y_t (i.e. $\nabla^d y_t = y_t$ if $d = 0$, $\nabla^d y_t = y_t - y_{t-1}$ if $d = 1$, $\nabla^d y_t = y_t - 2y_{t-1} + y_{t-2}$ if $d = 2$, etc.), $P = p + d$, $Q = q$, the two parameter sets ($\phi_1, \ldots, \phi_P$) and ($\varphi_1, \ldots, \varphi_p$) are functionally related, and we shall assume that the ARMA model for $\nabla^d y_t$ is stationary. This is saying that the time series $\{y_t\}$ is such that its dth difference $\nabla^d y_t$ is stationary and follows a mixed autoregressive moving average model. For $d = 0$, y_t itself is stationary; and for $d > 0$, y_t is nonstationary. The models in Eqn. (4) are called autoregressive integrated moving average (ARIMA) models of orders (p, d, q) for the time series y_t. Here d signifies the order of differencing to make the transformed series stationary, p is the number of lagged values of $\nabla^d y_t$, and q is the number of lagged terms of a_t in the model.

It should be noted that for the ARIMA models in Eqn. (4), the nonstationarity of the series y_t is solely accounted for by the difference operation $\nabla^d y_t$. While this is not the only kind of nonstationarity in the ARMA models in Eqn. (3), we shall, however, focus primarily on this class of models.

6. *Model Building*

To build an ARMA or ARIMA model for the data at hand, Box and Jenkins (1976) have proposed an iterative approach consisting of (a) tentative model specification, (b) efficient estimation, and (c) diagnostic checking. This approach has been widely adopted and in fact has revolutionized the use of time series models for forecasting in practice.

In the tentative specification phase, the goal is to employ computationally simple techniques to narrow down the range of parsimonious models worthy of more detailed further study. Techniques such as the sample autocorrelation function (SACF) and sample partial autocorrelation function (SPACF) have been widely used. The SACF can help determine the order of differencing needed to make the transformed series stationary and pin down the order of a moving average model for stationary series. The SPACF, on the other hand, is useful to help decide the order of a stationary autoregressive model. The more recently proposed sample extended autocorrelation function (SEACF, see Tsay and Tiao (1984)) makes it possible to specify directly the orders of an ARMA (P, Q) model, stationary or nonstationary, and hence simplifies the procedure for model specification. In this case, the question of stationarity will be answered at the estimation stage.

Once a model is tentatively entertained, the parameters can then be efficiently estimated by the method of maximum likelihood. In addition to standard tests on the statistical significance of parameter estimates, unit root tests may provide a useful tool here to help determine the order of nonstationarity in the series if needed. Finally, residuals calculated from the fitted model are then subject to various diagnostic checks to determine the overall adequacy of the entertained model and to search for directions of improvement. Of particular importance are procedures to detect the existence of autocorrelations in the residuals, outliers and structural changes such as level shifts, variance changes, and nonlinearities.

To illustrate this model building approach, we consider the monthly interest rate data introduced earlier. Table 1 shows the SACF of the series y_t, the SACF and SPACF of the differenced series ∇y_t, and the SACF of the residuals $\hat{a}_t$ for lags 1–12.

In each of the four panels in Table 1, the first row gives the sample correlation values and the second their associated estimated standard errors. We now discuss tentative model specification. First, the per-

Estimation results for the interest rate data

	$\hat{\phi}_1$	$\hat{c}$	$\hat{\theta}_1$	$\hat{\sigma}$
Model (5)			−0.597 (0.077)	0.198
Model (6)	0.993 (0.017)	−0.002 (0.107)	−0.592 (0.078)	0.196

sistently high values of the SACF of y_t over long lags suggest that the series is nonstationary, leading to considering the first difference of the series. Second, the SACF of ∇y_t has only one large value at lag 1, and this 'cutting off' property strongly indicates that a simple first-order moving average model would be adequate for the differenced series. On the other hand, the pattern of the SPACF of ∇y_t, showing two large values at lag 1 and lag 3, would suggest a more complex model. Consequently we are led to consider the ARIMA (0, 1, 1) model

$$\nabla y_t = a_t - \theta_1 a_{t-1} \tag{5}$$

The above mode of model specification, while widely adopted in practice, has several drawbacks. First, judgment of whether to difference the data based on 'persistently high values of SACF' can often be difficult in practice. Second, for $d \geqslant 2$, at least three cycles of SACF and SPACF are needed before a model can be determined. Third, both SACF and SPACF are not designed to help specify stationary mixed ARMA (P, Q) models. The SEACF procedure is designed to address these difficulties. Table 2 gives the simplified SEACF for the interest rate data. In this two-way table, the rows correspond to the AR orders P and the columns the MA orders Q. An entry 'X' signifies that the sample estimate is over twice its estimated standard error in magnitude and a '0' otherwise. The goal is to search for a triangle of 0's just like the one shown in Table 2, and the coordinates of the vertex give the AR and MA orders. In our case, we have clear indication of an ARMA (1, 1) model.

$$y_t - \phi_1 y_{t-1} = c + a_t - \theta_1 a_{t-1} \tag{6}$$

which reduces to the model in Eqn. (5) when $\phi_1 = 1$ and $c = 0$. The estimation results for both models in Eqns. (5) and (6) are summarized in Table 3. The values in parentheses are the associated estimated standard errors of the estimates. The results $\hat{\phi}_1 \cong 1$ and $\hat{c} \cong 0$ clearly show that the fitted models Eqns. (5) and (6) are essentially identical. Thus, instead of making the decision to difference the data series at the tentative model specification stage, the same result can be obtained at the estimation phase which seems more appealing. To provide a partial check of the adequacy of the model, the bottom panel of Table 1 shows the

SACF of the residuals $\hat{a}_t$'s from the model in Eqn. (5). All the sample autocorrelations are very small, indicating no dynamic pattern left in the residuals. Some additional residual diagnostics including the Box–Ljung statistic and an iterative outlier test have also been performed without revealing any serious model inadequacy. The fitted model can then be used to predict future observations if desired.

7. Seasonal ARIMA Models

Business, economic, and atmospheric time series data often exhibit a strong, but not necessarily deterministic, seasonal behavior. It seems natural to think that the seasonal pattern arises simply because observations at the same time point of the year are dynamically related across the years. For monthly data, this means that observations 12, 24,… periods apart are correlated. Just as the class of ARIMA (p, d, q) models represent the dependence of observations in successive periods (months), we may construct similar models to account for dynamic dependence of observations in the same month of successive years. As an illustration, corresponding to the regular ARIMA (0, 1, 1) model in Eqn. (5), we may consider a seasonal model of the form $\nabla_{12} y_t = e_t - \Theta_{12} e_{t-12}$, where $\nabla_{12} y_t = y_t - y_{t-12}$ is the seasonal difference and e_t is the noise term. To account for both seasonal dependence as well as month to month dependence, we may make e_t to follow the ARIMA (0, 1, 1) model $\nabla e_t = a_t - \theta_1 a_{t-1}$. Together, we have that

$$\nabla\nabla_{12} y_t = a_t - \theta_1 a_{t-1} - \Theta_{12}(a_{t-12} - \theta_1 a_{t-13}) \qquad (7)$$

where $\nabla\nabla_{12} y_t = y_t - y_{t-1} - (y_{t-12} - y_{t-13})$ is the double, regular and seasonal, difference of y_t. This 'doubly' exponential smoothing model, proposed by Box and Jenkins and motivated by their analysis of airline passenger data, has been widely used to present a variety of seasonal time series in practice. It is known as the 'airline model.' Similar extensions are readily obtainable for other ARIMA models.

8. Intervention Analysis and Outlier Detection

Time series observations are often subject to the influence of special events, or interventions, that occurred at known time points. Examples are the outbreak of armed conflicts, natural disasters, changes in fiscal policy, and major sales promotions. It has been found useful to employ linear dynamic models of the form

$$Y_t - \delta_1 Y_{t-1} - \ldots - \delta_r Y_{t-r} = \omega_0 x_t - \ldots - \omega_s x_{t-s} \qquad (8)$$

where x_t is an indicator (dummy) variable for an intervention and Y_t represents its dynamic impact on the time series observations. This class of models can accommodate a very wide variety of dynamic patterns including isolated large values, level shifts, trend, oscillations, and cycles. We can write the model of the observations as the sum of the intervention component Y_t and a noise component N_t, $y_t = Y_t + N_t$, where N_t follows an ARMA model of the form in Eqn. (3). The parameters in the intervention and the noise components can then be jointly estimated to quantify the effects of these two components.

When the time of occurrence of interventions is not known or the interventions themselves are unsuspected, we have the problem of detecting unusual events or 'outliers' in time series. Estimation procedures developed for interventions can be readily adapted to become iterative procedures for outlier detection, and these methods, especially those for detecting isolated large values and level shifts, have been commonly adopted as part of diagnostic checking.

9. Time Series with Heterogeneous Variances

The ARMA model in Eqn. (3) supposes that the variance σ^2 of the innovation a_t stays constant over time. In reality, this variance homogeneity assumption is often violated, especially in highly disaggregated financial data such as hourly stock returns or exchange rates where clusters of high volatility tend to occur. Several models have been developed to describe this kind of phenomenon. Denoting σ_t^2 as the variance of a_t, one may employ a random step-change model in which there is a nonzero probability λ that σ_t^2 may change at any given point of time. Alternatively, one may relate σ_t^2 to past values of a_t^2 and itself. In particular, the model

$$\sigma_t^2 = \alpha_0 + \alpha_1 a_{t-1}^2 + \beta_1 \sigma_{t-1}^2 \qquad (9)$$

which is called the generalized autoregressive conditional heteroscedastic (GARCH) model of orders (1, 1) has been extensively used in the analysis of financial time series. Now writing $a_t^2 = \sigma_t^2 + u_t$, the above model can be alternatively expressed as

$$a_t^2 = \alpha_0 + (\alpha_1 + \beta_1) a_{t-1}^2 + u_t - \beta_1 u_{t-1} \qquad (10)$$

It can be readily shown that the u_t's have zero mean and common variance, and are uncorrelated. Thus the model in Eqn. (10) has exactly the same autocovariance structure as an ARMA (1, 1) model in a_t^2. The above correspondence is readily extended to higher order models. Thus the GARCH models can be viewed as an interesting extension of the ARMA structure to the squared innovations a_t^2's.

10. Nonlinear Time Series Models

There is an extensive literature on nonlinear time series models where y_t is related to its past values more generally by a nonlinear function. Such models are

necessarily more complex, but they can represent phenomena such as time irreversibility and limit cycles that cannot be adequately described by linear models. For example, it is well known that the dynamic behavior of economic indicators such as the GNP or the unemployment rate during a recession is quite different from that when the economy is expanding. To describe this kind of nonhomogeneous behavior, one may employ a piecewise linear model for different regimes of economic activity. To illustrate, let y_t represent the quarterly change in GNP. We may postulate a model such that

$$y_t = \begin{cases} c^{(1)} + \phi^{(1)} y_{t-1} + a_t^{(1)}, & \text{if} \quad y_{t-1} < 0 \text{ and } y_{t-2} < 0 \\ c^{(2)} + \phi^{(2)} y_{t-1} + a_t^{(2)}, & \text{if} \quad \text{otherwise} \end{cases} \tag{11}$$

where $c^{(1)} \neq c^{(2)}$, $\phi^{(1)} \neq \phi^{(2)}$, and $a_t^{(1)}$ and $a_t^{(2)}$ have unequal variances. In Eqn. (11) the regime ($y_{t-1} < 0$ and $y_{t-2} < 0$) represents a period of economic decline, and the model says that the dynamic behavior of y_t is different for the two regimes. This model is a special case of a class, known as the threshold autoregressive models, which have been used for time series data in atmospheric sciences, economics, and other scientific fields.

11. Further Reading

The reader interested in a deeper understanding of the basic concepts and methods of time series analysis may consult the books by Box et al. (1994), Brockwell and Davis (1996), Shumway and Stoffer (2000), and Wei (1990), and the book edited by Pena et al. (2001) which also contains several chapters on multivariate ARMA models. For further details on the GARCH models and the general topic of heterogeneous variances and volatility clustering in economic time series, see Hamilton (1994). Nonlinear time series models are discussed in Priestley (1988) and Tong (1990). Finally, for multivariate extension of linear time series models, the reader may study the books by Lutkepohl (1993), Reinsel (1993) and Reinsel and Velu (1998).

Time Series: Co-integration

1. Introduction

Co-integration deals with the common behavior of a multivariate time series. It often happens in practice that each individual component of a multivariate time series may be nonstationary, but certain linear combinations of these components are stationary. Co-integration studies the effects of these combinations and the relationships among the components.

A survey on recent developments in unit root test and nonstationary time series is covered by Dickey (see *Time Series: Nonstationary Distributions and Unit Roots*). As far as co-integration is concerned, a large number of texts have been written on the subject since the publication of the seminal paper by Engle and Granger (1987). For example, the book by Johansen (1995) provides one of the most complete coverage on

the statistical theory of co-integrated time series. A succinct survey of some of the results presented in this book is given in the review article by Johansen (1996). Other references about statistical inference for co-integrated systems include Stock and Watson (1988), Phillips (1991), Park (1992), Reinsel and Ahn (1992), and Chan and Tsay (1996). In the econometric front, several monographs and special collections of papers have also been devoted to this subject see, for example, Banerjee et al. (1993), Engle and Granger (1987), Maddala and Kim (1998), and special issues of *Oxford Bulletin of Economics and Statistics* (1990 and 1992), and *Journal of Policy Modeling* (1993).

The notion of co-integration usually is discussed with topics such as nonstationarity, unit roots, and common trends. Two excellent surveying articles on trends and co-integration are Stock (1994) and Watson (1994). Given the large number of papers written on this subject, it seems prudent to limit this article to a few fundamental concepts of co-integration. By adopting such an approach, this article aims at providing a useful tutorial in co-integration for social scientists.

From a statistical perspective, the idea of co-integration stems from the notion of transformations. When the underlying data exhibit certain nonstationary behavior, one usually introduces a transformation to render the data to stationarity. For example, the Box–Cox power transformation is often applied when nonconstant mean or nonconstant variance behaviors are detected. In a time series context, Box and Tiao (1977) discuss the idea of applying canonical correlation transformations on a multivariate time series to identify stationary components.

In economics, it is often the case that although individual components of a multivariate time series $\boldsymbol{X}_t = (X_{t1},\ldots, X_{tk})'$ appear to be nonstationary, the overall behavior of $\boldsymbol{X}_t$ may be modeled by a stationary process when an appropriate transformation is applied to $\boldsymbol{X}_t$. Thus, the idea of co-integration deals with the common behavior of a multiple time series. It stems from the fact that certain linear transformations of $\boldsymbol{X}_t$ may be stationary. Engle and Granger (1987) formulate the idea of co-integration and present statistical procedures to test for co-integration for a multiple time series.

2. Definitions and Examples

To begin, first note that nonstationarity arises when a stationary process is aggregated. For example, consider the process $\boldsymbol{X}_t = \sum_{i=1}^{t} Z_i$ where Z_i is an uncorrelated sequence of random variables with mean zero and variance σ^2, usually known as a white noise sequence and is denoted by $Z_t \sim WN(0, \sigma^2)$. The $\boldsymbol{X}_t$ has variance $t\sigma^2$ so that $\boldsymbol{X}_t$ is nonstationary. In this case, $\boldsymbol{X}_t$ is an example of an integrated order 1, $I(1)$, process and it is the cumulated sum of Z_t, that gives rise to the nonstationarity. Specifically, the notion of integration for a multivariate time series $\boldsymbol{X}_t$ is defined as follows:

(a) The process

$$\boldsymbol{X}_t = \sum_{i=0}^{\infty} \Psi_i \boldsymbol{Z}_{t-i}$$

is said to be integrated of order zero,

$$I(0), \text{ if } \sum_{i=0}^{\infty} \Psi_i \neq 0.$$

Having defined the notion of $I(0)$, we can now define the notion of $I(1)$ as follows. Herein, we define $B\boldsymbol{X}_t = \boldsymbol{X}_{t-1}$.

(b) A k-dimensional $\{\boldsymbol{X}_t\}$ is said to integrated of order *1*, $I(1)$, if

$$\boldsymbol{\Delta X}_t = (I-B)\boldsymbol{X}_t = \boldsymbol{X}_t - \boldsymbol{X}_{t-1} \text{ is } I(0) \tag{1}$$

To understand the real effect of co-integration on a multivariate time series, consider the following three-dimensional example.

Let

$$X_{t1} = \sum_{i=1}^{t} Z_{i1} + Z_{t2},\ X_{t2} = \frac{1}{2}\sum_{i=1}^{t} Z_{i1} + Z_{t3},\ X_{t3} = Z_{t3} \tag{2}$$

where $(Z_{t1}, Z_{t2}, Z_{t3})' \sim WN(\mathbf{0}, I_3)$, and I_3 denotes the identity matrix of order 3.

Clearly, $\boldsymbol{X}_t = (X_{t1}, X_{t2}, X_{t3})'$ is nonstationary since the first two components consist of the common term $\sum_{i=1}^{t} Z_{i1}$, the so-called common trend or the common nonstationary component of $\boldsymbol{X}_t$. On the other hand

$$\begin{aligned}\boldsymbol{\Delta X}_t &= (I-B)\boldsymbol{X}_t = \boldsymbol{X}_t - \boldsymbol{X}_{t-1} \\ &= (Z_{t1} + Z_{t2} - Z_{t-1,\,2},\ \tfrac{1}{2}Z_{t1} \\ &\qquad + Z_{t2} - Z_{t-1,\,2}, Z_{t3} - Z_{t-1,\,3})'\end{aligned} \tag{3}$$

is stationary. It can easily be checked that $\boldsymbol{\Delta X}_t$ is $I(0)$, hence $\boldsymbol{X}_t$ is $I(1)$. Furthermore

$$\begin{aligned}X_{t1} - 2X_{t2} &= \sum_{i=1}^{t} Z_{i1} + Z_{t2} - \sum_{i=1}^{t} Z_{i1} - 2Z_{t3} \\ &= Z_{t2} - 2Z_{t3}\end{aligned} \tag{4}$$

which is stationary as it is expressed as a finite sum of two uncorrelated white noise sequences. Although $\boldsymbol{X}_t$ is nonstationary, $\beta'\boldsymbol{X}_t$, where $\beta = (1, -2, 0)'$ is stationary and we say that $\boldsymbol{X}_t$ is co-integrated with co-integrating vector $\beta = (1, -2, 0)'$. The part $\sum_{i=1}^{t} Z_{i1}$ is called a common stochastic trend of the process $\boldsymbol{X}_t$. In this example, stationarity is attained by either differencing or by taking linear combinations.

As an application of this example, suppose X_{t1} represents the wholesale price index for a specific country, X_{t2} represents a trade-weighted foreign price index, and X_{t3} represents the exchange rates between these two countries, all measured in logarithmic scale. Preceding equations indicate that the two indices are driven by the same stochastic common trend $\sum_{i=1}^{t} Z_{i1}$. The equation

$$X_{t1} - 2X_{t2} - X_{t3} = Z_{t2} - 3Z_{t3} \tag{5}$$

represents a stationary equilibrium relationship between the two indices and the exchange rate with $(1, -2, -1)'$ being an co-integrating vector. This is an example of the so-called purchasing power parity (further details can be found in Johansen 1996). With this example as the background, we can define co-integration precisely.

(c) Let $\{\boldsymbol{X}_t\}$ be an $I(1)$ process. If there exists $\beta \neq 0$ such that $\beta'\boldsymbol{X}_t$ is stationary by a suitable choice of $\beta'\boldsymbol{X}_0$, then $\boldsymbol{X}_t$ is called co-integrated and β is called the co-integrating vector. The number of linearly independent co-integrating vectors is called the co-integrating rank and the space spanned by the co-integrating vectors is called the co-integrating space.

Let $\boldsymbol{X}_t$ be $I(1)$ and let A be a matrix of full rank. Then $A\boldsymbol{X}_t$ is also $I(1)$. Further if β is the co-integrating vector, then $(A^{-1})'\ \beta$ is the corresponding co-integrating vector of $A\boldsymbol{X}_t$. Consequently, the notion of $I(1)$ is invariant under any nonsingular linear transformation.

3. *Error Correction and Granger's Representation Theorem*

Consider a k-dimensional vector autoaggressive (VAR(p)) model $\boldsymbol{X}_t$ which satisfies the equation

$$\boldsymbol{X}_t = \Phi_1 \boldsymbol{X}_{t-1} + \cdots + \Phi_p \boldsymbol{X}_{t-p} + \boldsymbol{Z}_t \tag{6}$$

where $\{\boldsymbol{Z}_t\} \sim WN(\boldsymbol{0}, I_k)$, a k-dimensional white noise process. It is well known that (see, for example, Lütkepohl 1993, p.11), a sufficient condition for $\boldsymbol{X}_t$ to be stationary is that the solutions of the characteristic polynomial to Eqn. (6) have to lie outside that unit circle (no unit roots allowed), i.e.,

$$\det(I - \Phi_1\zeta - \cdots - \Phi_p\zeta^p) \neq 0 \text{ for all } |\zeta| \leqslant 1 \tag{7}$$

Now, define $\Phi(\zeta) = I - \Phi_1\zeta - \cdots - \Phi_p\zeta^p$, $\Phi = -\Phi(1)$, and $\Gamma = -d\Phi(\zeta)/d\zeta|_{\zeta=1} + \Phi$. Then

$$\begin{aligned}
\Phi &= -\Phi(1) = \Phi_1 + \cdots + \Phi_p - I \\
\Gamma &= -\frac{d\Phi(\zeta)}{d\zeta}\Big|_{\zeta=1} + \Phi \\
&= \Phi_1 + 2\Phi_2\zeta\,|_{\zeta=1} + \cdots + p\Phi_p\zeta^{p-1}|_{\zeta=1} + \Phi \\
&= \Phi_1 + 2\Phi_2 + \cdots + p\Phi_p + \Phi_1 + \cdots + \Phi_p - I \\
&= 2\Phi_1 + 3\Phi_2 + \cdots + (p+1)\Phi_p - I'
\end{aligned} \tag{8}$$

With these definitions, we first state a well-known condition under which a stationary VAR(p) process is $I(0)$.

If $\boldsymbol{X}_t$ is a stationary VAR (p) process such that det $(\Phi(\zeta)) \neq 0$ for all $|\zeta| < 1$, then $\boldsymbol{X}_t$ can be given an initial distribution such that it becomes $I(0)$ if and only if Φ is full rank. In this case, there is no unit root for $\boldsymbol{X}_t$ (stationary) and

$$\boldsymbol{X}_t = \sum_{i=0}^{\infty} \Psi_i \boldsymbol{Z}_{t-i} \tag{9}$$

where $\Psi(\zeta) = \sum_{i=0}^{\infty} \Psi_i \zeta^i = (\Phi(\zeta))^{-1}$converges for $|\zeta| < 1 + \delta$ for some $\delta > 0$.

Since $\Phi = \Phi_1 + \cdots + \Phi_p - I$, the full rank condition of Φ in this statement holds if and only if det Φ = det $(\Phi(1)) \neq 0$. In other words, the full rank condition of Φ simply means that det $(\Phi(\zeta)) \neq 0$ for $\zeta = 1$. When this matrix is of reduced rank, then we have a co-integrated system.

Let α be any $k \times r$ matrix of rank r $(r < k)$. Define $\alpha_\perp$ to be $a\ k \times (k-r)$ matrix which is full rank such that $\alpha'\alpha_\perp = 0$. Now assume the following condition holds for $\boldsymbol{X}_t$: $\det(\Phi(\zeta)) \neq 0$ for all $|\zeta| < 1$, i.e., the process $\boldsymbol{X}_t$ is nonstationary since it can have unit roots. Under this assumption, we have the Granger's representation theorem.

3.1 *Granger's Representation Theorem*

Let $\boldsymbol{X}_t$ be a VAR(p) and $\det(\Phi(\zeta)) \neq 0$ for all $|\zeta| < 1$, i.e., unit roots are allowed so that the process $\boldsymbol{X}_t$ can be nonstationary. Then $\boldsymbol{X}_t$ is $I(1)$ if and only if

$$\Phi = \alpha\beta' \tag{10}$$

where α and β are $(k \times r)$ matrices which are of full rank r $(r < k)$, and $\alpha_\perp'\Gamma\beta_\perp$ is of full rank. In this case, $\Delta\boldsymbol{X}_t$ and $\beta'\boldsymbol{X}_t$ can be given initial distributions so that they become $I(0)$. Furthermore, under these circumstances, $\boldsymbol{X}_t$ can be expressed as

$$\boldsymbol{X}_t = \beta_\perp(\alpha_\perp'\Gamma\beta_\perp)^{-1}\alpha_\perp' \sum_{i=1}^{t} \boldsymbol{Z}_i + \Psi(B)\boldsymbol{Z}_t \tag{11}$$

and

$$\Delta\boldsymbol{X}_t = \alpha\beta'\boldsymbol{X}_{t-1} + \sum_{i=1}^{p-1} \Gamma_i \Delta\boldsymbol{X}_{t-i} + \boldsymbol{Z}_t \tag{12}$$

where

$$\Gamma_i = -(\Phi_{i+1} + \cdots + \Phi_p),\ i = 1, \ldots, p-1 \tag{13}$$

Note that Eqn (12) in this theorem is the error correction form expressed in terms of $\Delta\boldsymbol{X}_t$. This theorem can best be interpreted in terms of a specific VAR(2) example

$$\Delta\boldsymbol{X}_t = \begin{pmatrix} -\alpha_1 & 2\alpha_1 \\ 0 & 0 \end{pmatrix} \boldsymbol{X}_{t-1} + \boldsymbol{Z}_t = A\boldsymbol{X}_{t-1} + \boldsymbol{Z}_t \tag{14}$$

In other words

$$X_t = (I+A)X_{t-1} + Z_t = \Phi_1 X_{t-1} + Z_t \tag{15}$$

where

$$\Phi_1 = (I+A) = \begin{pmatrix} 1-\alpha_1 & 2\alpha_1 \\ 0 & 1 \end{pmatrix} \tag{16}$$

Observe that

$$\begin{aligned} \Phi(\zeta) &= I - \Phi_1\zeta = I - (I+A)\zeta \\ &= \begin{pmatrix} 1-\zeta+\alpha_1\zeta-2\alpha_1\zeta \\ 0 \qquad 1-\zeta \end{pmatrix} \\ &= \begin{pmatrix} \alpha_1 & -2\alpha_1 \\ 0 & 0 \end{pmatrix} + (1-\zeta)\begin{pmatrix} 1-\alpha_1 & 2\alpha_1 \\ 0 & 1 \end{pmatrix} \end{aligned} \tag{17}$$

with

$$\Phi = \Phi(1) = \begin{pmatrix} \alpha_1 & -2\alpha_1 \\ 0 & 0 \end{pmatrix} \tag{18}$$

and

$$\det(\Phi(\zeta)) = (1-\zeta)(1+\alpha_1\zeta-\zeta) \tag{19}$$

This characteristic polynomial has roots $\zeta = 1$ and $\zeta = (1-\alpha_1)^{-1}$, if $\alpha_1 \neq 1$. Therefore, for $0 < \alpha_1 < 1$, $\det \Phi(\zeta) = 0$ for $\zeta = 1$ and $\zeta = \frac{1}{1-\alpha_1}$ and as a result, $\det\Phi(\zeta) = 0$ for $|\zeta| \geqslant 1$. Clearly, Φ has reduced rank $(=1)$ and $\Phi = \alpha\beta'$, where $\alpha = (\alpha_1, 0)'$, $\beta = (1,-2)'$, $\alpha_\perp = (0, 1)'$ and $\beta_\perp = (2, 1)'$. Hence

$$\alpha_\perp'\Gamma\beta_\perp = (0, 1)(2\Phi_1 - I)\begin{pmatrix} 2 \\ 1 \end{pmatrix} = 1 \tag{20}$$

By letting $X_0 = \mathbf{0}$, the condition of the Granger's representation theorem is satisfied and X_t is, therefore, $I(1)$. In this case

$$\begin{aligned} X_t &= \begin{pmatrix} X_{t1} \\ X_{t2} \end{pmatrix} \\ &= \begin{pmatrix} 2\sum_{i=1}^{t} Z_{i2} + \sum_{i=0}^{\infty}(1-\alpha_1)^i(Z_{t-i,1} - Z_{t-i,2}) \\ \sum_{i=1}^{t} Z_{i2} \end{pmatrix} \\ &= \begin{pmatrix} 0 & 2 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} \sum_{i=1}^{t} Z_{i1} \\ \sum_{i=2}^{t} Z_{i2} \end{pmatrix} + \sum_{i=0}^{\infty}\Psi_i Z_{t-1} \end{aligned} \tag{21}$$

where

$$\Psi_i = \begin{pmatrix} (1-\alpha_1)^i & -2(1-\alpha_1)^i \\ 0 & 0 \end{pmatrix}, \; i = 0, 1, \ldots \tag{22}$$

that is,

$$X_t = \beta_\perp\alpha_\perp'\sum_{i=1}^{t} Z_i + \sum_{i=0}^{\infty}\Psi_i Z_{t-i} \tag{23}$$

Note that the quantity $\alpha_\perp'\sum_{i=1}^{t} Z_i$ of Eqn (23) constitutes the common trend. Substituting the definition of $\alpha_\perp = (0, 1)'$ into this expression, the common trend equals to $\sum_{i=1}^{t} Z_{i2}$. Furthermore

$$\begin{aligned} \Delta X_t &= \begin{pmatrix} -\alpha_1 & 2\alpha_1 \\ 0 & 0 \end{pmatrix} X_{t-1} + Z_t \\ &= \begin{pmatrix} \alpha_1 \\ 0 \end{pmatrix}(1,-2)X_{t-1} + Z_t \\ &= \alpha\beta' X_{t-1} + Z_t \end{aligned} \tag{24}$$

In this case, the co-integrating vector is $\beta = (1,-2)'$ and $\Gamma_i = 0$ in the Granger's representation theorem.

4. *Statistical Inference for Co-integrated Systems*

Recall that from the Granger's representation theorem, given that X_t is $I(1)$, the error correction form is

$$\Delta X_t = \Phi X_{t-1} + \sum_{i=1}^{p-1}\Gamma_i\Delta X_{t-i} + Z_t \tag{25}$$

where $\Phi = \alpha\beta'$ is of rank $r(r < k)$ with α, β being $(k \times r)$ matrices. Let $Z_t \sim \mathrm{N}(\mathbf{0}, \sum_Z)$ so that X_t becomes a Gaussian time series. We now show how to construct estimators and tests for co-integrated systems by the following steps. Let the length of the underlying series be T.

(a) Regress ΔX_t on ΔX_{t-i}, $i = 1,\ldots, p-1$ and form the residuals R_{0t}.

(b) Regress X_{t-1} on ΔX_{t-i}, $i = 1,\ldots, p-1$ and form the residual R_{1t}.

(c) Calculate the sums

$$S_{ij} = \frac{1}{T}\sum_{t=1}^{T} R_{it}R_{jt}', \quad i, j = 0, 1 \tag{26}$$

Under the hypothesis H_r: $\Phi = \alpha\beta'$ with rank $(\Phi) = r$, the maximum likelihood estimate for β is given by

$$\hat{\beta} = (\hat{v}_1,\ldots, \hat{v}_r) \tag{27}$$

where each $\hat{v}_i$ is a $k \times 1$ vector obtained by solving the following 'eigenvalues' and 'eigenvectors' problem:

$$|\lambda S_{11} - S_{10} S_{00}^{-1} S_{01}| = 0 \tag{28}$$

for

$$1 > \hat{\lambda}_1 > \cdots > \hat{\lambda}_p > 0 \tag{29}$$

with

$$(\hat{\lambda}_i S_{11} - S_{10} S_{00}^{-1} S_{01}) \hat{v}_i = 0 \tag{30}$$

In this case, the maximum likelihood function becomes

$$L_{\max}^{-2/T} \propto |S_{00}| \Pi_{i=1}^{r} (1 - \hat{\lambda}_i)$$

and an estimator for α is given by $\hat{\alpha} = S_{01}\hat{\beta}$.

Note that by the definition of canonical correlation, $\hat{\lambda}_i$, represents the squared canonical correlation between $\Delta \boldsymbol{X}_t$ and $\boldsymbol{X}_{t-1}$ after adjusting for the effects of $\Delta \boldsymbol{X}_{t-1}, \ldots, \Delta \boldsymbol{X}_{t-p}$. A number of remarks follow from this theorem.

(a) If $r = 0$, $\Delta \boldsymbol{X}_t$ is $I(0)$ but $\boldsymbol{X}_{t-1}$ is $I(1)$ so that we expect that $\Delta \boldsymbol{X}_t$ and $\boldsymbol{\Delta X}_{t-1}$ are 'uncorrelated.' Proof of this fact can be found in Chan and Wei (1988). This result means that all $\hat{\lambda}_i$ should be very small.

(b) If $r = k$, $\Delta \boldsymbol{X}_t$ and $\boldsymbol{\Delta X}_{t-1}$ are both $I(0)$. In this case, we expect significant relationship among them. As a result, the estimates of β are coming from those that correlate most with the stationary process $\boldsymbol{\Delta X}_t$ after adjusting for the effects of $\boldsymbol{\Delta X}_{t-1}, \ldots, \boldsymbol{\Delta X}_{t-p}$.

(c) For r in between, we choose $\hat{\beta}$ by taking the most correlated components in the canonical correlation sense.

After estimating $\hat{\beta}$ as above, we can estimate α by means of $\hat{\alpha} = S_{01}\hat{\beta}$. Turning to testing for the hypothesis of H_r, i.e., there are at most r co-integrating relationships, consider the likelihood ratio statistic as follows

$$Q_r = -2\log Q(H_r|H_k) = -T \sum_{i=r+1}^{k} \log(1 - \hat{\lambda}_i) \tag{31}$$

We reject H_r in favor of H_{r+1} if Q_r is too big. The interpretation for constructing such a statistic can be argued as follows. When H_r is true, there are supposed to be r co-integrating relationships which should be captured by $\hat{\lambda}_1, \ldots, \hat{\lambda}_r$. As a consequence, $\hat{\lambda}_i$ for $i = r+1, \ldots, k$ should then be relatively small. If, on the contrary, they are observed to be too big for any given series, Q_r becomes huge and there is strong evidence of rejecting H_r in favor of H_{r+1}. With this interpretation, the next step is how to compare Q_r with known distributions. In a standard multivariate context, we expect to compare Q_r with some form of a chi-squared distribution. Unfortunately, due to the nonstationarity of $\boldsymbol{X}_t$, standard asymptotic is no longer available. Instead, we need to consider the following.

Let $\boldsymbol{X}_t$ be a VAR(p) with r co-integrating relations. Then

$$\begin{aligned} Q_r &= -2\log(Q(H_r|H_k)) \\ &= -T \sum_{i=r+1}^{k} \log(1 - \hat{\lambda}_i) \\ &\xrightarrow{\mathscr{L}} \xi \end{aligned} \tag{32}$$

where

$$\xi = \text{trace} \left\{ \int_0^1 \mathrm{d}B(s)(B(s))' \left[\int_0^1 B(s)\, B'(s)\mathrm{d}s \right]^{-1} \int_0^1 B(s)(\mathrm{d}B(s))' \right\} \tag{33}$$

with $B(s)$ being the $(k-r)$ dimensional standard Brownian motion, and $\xrightarrow{\mathscr{L}}$ designates convergence in distribution of the test statistics Q_r to that of ξ as the length of the time series $T \to \infty$.

Notice that the limiting distribution depends only on the number $(k-r)$, which is the number of common trends in the underlying series $\boldsymbol{X}_t$. Tabulations of special cases of ξ can be found in a number of places, including Banerjee et al. (1993), Johansen (1995), Tanaka (1996), Maddala and Kim (1998), and Lütkepohl (1993).

5. *Summary*

As indicated in the introduction, co-integration has been an actively pursued area of research, particularly among econometricians. Owing to its simple idea, it is reasonable to expect that the concept of co-integration will be more significant in other areas of social sciences. Recently, the concept of co-integration has found applications in many areas in finance. For example, Hiraki et al. (1996) use co-integration and common trend to explain the term structure of offshore interest rates and, more recently, Lee et al. (1999) use the idea of co-integration to determine the intrinsic value of the Dow Jones industrial index. Another area that is under rigorous development is combining long-memory phenomena together with co-integration, the so-called fractional co-integration (see, for example, Lien and Tse 1999). It is hoped that this survey offers a focused and practical introduction to co-integration.

Time Series: Cycles

Time series data in economics and other fields of social science often exhibit cyclical behavior. For example, aggregate retail sales are high in November and December and follow a seasonal cycle; voter registrations are high before each presidential election and follow an election cycle; and aggregate macroeconomic activity falls into recession every six to eight years and follows a business cycle. In spite of this cyclicality, these series are not perfectly predictable, and the cycles are not strictly periodic. That is, each cycle is unique. Quite generally, it is useful to think of time series as realizations of stochastic processes, and this raises the question of how to represent cyclicality in stochastic processes. The major descriptive tool for this is the 'spectral density function' (or 'spectrum'), which is the subject of this article.

1. *Cycles in a Typical Time Series*

Figure 1 shows a time series plot of new housing authorizations ('building permits') issued by communities in the USA, monthly, from 1960 through 1999. This plot has characteristics that are typical of many economic time series. First, the plot shows a clear seasonal pattern: permits are low in the late fall and early winter, and rise markedly in the spring and summer. This seasonal pattern is persistent throughout the sample period, but does not repeat itself exactly year-after-year. In addition to a seasonal pattern, there is a slow moving change in the level of the series associated with the business cycle. For example, local minima of the series are evident in 1967, the mid-1970s, the early 1980s, and in 1990, which correspond to periods of macroeconomic slowdown or recession in the US economy.

How can the cyclical variability in the series be represented? One approach is to use a periodic function like a sine or cosine function. But this is inadequate in at least two ways. First, a deterministic periodic function doesn't capture the randomness in the series. Second, since several different periodicities (seasonal, business cycle) are evident in the plot, several periodic functions will be required. The next section presents a representation of a stochastic process that has these ingredients.

Figure 1
Building permits in the USA

2. *Representing Cyclical Behavior in Time Series: The Spectrum*

2.1 *Spectral Representation of a Covariance Stationary Process*

Consider a sequence of scalar random variables $\{Y_t\}$ where $t = 0, \pm 1, \pm 2, \ldots$, and $E(Y_t) = \mu$, $Cov(Y_t Y_{t-k}) = \lambda_k$. That is, assume that Y_t is observed at regular intervals, like a week, a month, a year, etc. Assume that the first and second moments of the process do not depend on time, that is μ and λ_k are time invariant. To simplify notation, assume that $\mu = 0$.

To motivate the spectral representation of Y_t, it is useful to begin with a very special and simple stochastic process:

$$Y_t = \alpha \cos(\omega t) + \delta \sin(\omega t) \tag{1}$$

where α and δ are random variables with $E(\alpha) = E(\delta) = 0$; $E(\alpha\delta) = 0$; and $E(\alpha^2) = E(\delta^2) = \sigma^2$. While simple, this process has three attractive characteristics. First, it is periodic: since $\cos(a + 2\pi) = \cos(a)$ and $\sin(a + 2\pi) = \sin(a)$, then $Y_{t+j2\pi/\omega} = Y_t$ for $|j| = 1, 2, \ldots$. So Y_t repeats itself with a period of $2\pi/\omega$. Second, the random components α and δ give Y a random amplitude (value of at its peak) and a random phase (value at $t = 0$). Thus, two realizations of Y will have different amplitudes and different timing of their peaks and troughs. Finally, the process is covariance stationary with $E(Y_t) = 0$ and $\lambda_k = \sigma^2 \cos(\omega k)$.

Adding together several components like Eqn. 1 produces a more interesting stochastic process:

$$Y_t = \sum_{j=1}^{n} [\alpha_j \cos(\omega_j t) + \delta_j \sin(\omega_j t)] \tag{2}$$

with $E(\alpha_j) = E(\delta_j) = 0$, for all j; $E(\alpha_j \delta_k) = 0$, for all j, k; $E(\alpha_j \alpha_k) = E(\delta_j \delta_k) = 0$, for $j \neq k$; and $E(\alpha_j^2) = E(\delta_j^2) = \sigma_j^2$. For this process, Y_t is the sum of n different uncorrelated components, each corresponding to a different frequency, and each with its own variance. (The variance of $\alpha_j \cos(\omega_j t) + \delta_j \sin(\omega_j t)$ is σ_j^2.) A calculation shows $E(Y_t) = 0$, $\lambda_k = \sum_{j=1}^{n} \sigma_j^2 \cos(\omega_j k)$, and the variance of Y_t is given by $var\,(Y_t) = \sum_{j=1}^{n} \sigma_j^2$.

So far, this has all been special. That is, two very special processes have been constructed. However, a fundamental result (Cramér 1942, Kolmorgorov 1940) shows that a generalization of this decomposition can be used to represent any covariance stationary process. The result, known as the 'Spectral Representation Theorem,' says that if Y_t is covariance stationary, then it can be represented as

$$Y_t = \int_0^{\pi} \cos(\omega t)\, d\alpha(\omega) + \int_0^{\pi} \sin(\omega t)\, d\delta(\omega)$$

where $d\alpha(\omega)$ and $d\delta(\omega)$ are zero mean random variables that are mutually uncorrelated, uncorrelated across frequency, and have variances that depend on frequency. Like the special example shown in Eqn. 2, this general representation decomposes Y_t into a set of strictly periodic components—each uncorrelated with the others, and each with its own variance. For example, processes with important seasonal components will have large values of the components corresponding to the seasonal frequency, processes for series with strong 'business cycle' components will have large variances at business cycle frequencies, etc.

Sometimes the spectral representation is written using complex numbers as:

$$Y_t = \int_{-\pi}^{\pi} e^{i\omega t} d\gamma(\omega) \tag{3}$$

where $d\gamma(\omega) = (1/\sqrt{2})[d\alpha(\omega) - i d\delta(\omega)]$ for $\omega \geqslant 0$ and $d\gamma(\omega) = d\gamma(-\omega)$ for $\omega < 0$. This representation simplifies notation for some calculations.

The spectral representation Eqn. 3 is a generalization of Eqn. 2 where the 'increments' $d\gamma(\omega)$ have orthogonality properties like those of α_j and δ_j. The variance of each component is frequency specific (like σ_j^2), and is summarized by a density function $S(\omega)$. Specifically, the variance of $d\gamma(\omega)$ is $E(d\gamma(\omega)\overline{d\gamma(\omega)}) = S(\omega)d\omega$. (The use of a density function to summarize the variance of $d\gamma(\omega)$ is not completely general and rules out processes with deterministic (or perfectly predictable) components. The references listed in the last section provide this more general result.)

You may wonder why the spectral representation doesn't use frequencies larger than π. The answer is that these are not needed to describe a process measured at discrete intervals. This discreteness means that periodic components associated with frequencies larger than π will look just like components associated with frequencies less than π. For example, a component with frequency 2π will have period of 1 and, because the series is measured only once every period, this component will appear to be constant—it will look just like (be 'aliased' with) a component that has a frequency of $\omega = 0$.

2.2 Relationship Between the Spectral Density and the Autocovariances

There is a one-to-one relationship between the spectral density function and the autocovariances of the process. The autocovariances follow directly from the spectral representation:

$$\begin{aligned}\lambda_k = E(Y_t Y_{t-k}) &= E(Y_t \bar{Y}_{t-k}) \\ &= E\left[\int e^{i\omega t}\, d\gamma(\omega) \int e^{-i\omega(t-k)}\, \overline{d\gamma(\omega)}\right] \\ &= \int e^{i\omega k} S(\omega)\, d\omega. \end{aligned} \tag{4}$$

The spectrum can be determining by inverting this relation:

$$S(\omega) = (2\pi)^{-1} \sum_{j=-\infty}^{\infty} \lambda_j e^{-i\omega j} \tag{5}$$

(To verify that Eqn. 5 is the inverse of Eqn. 4, use

$$\int_{-\pi}^{\pi} e^{i\omega k} d\omega = \left\{ \begin{array}{lll} 2\pi & \text{for} & k = 0 \\ 0 & \text{for} & k \neq 0 \end{array} \right\} \tag{6}$$

so that $(2\pi)^{-1}\{\int_{-\pi}^{\pi} \sum_{j=-\infty}^{\infty} \lambda_j e^{-i\omega(j-k)} d\omega\} = \lambda_k$.)

A simpler formula for the spectrum is

$$S(\omega) = (2\pi)^{-1}[\lambda_0 + 2\sum_{j=1}^{\infty} \lambda_j \cos(j\omega)]. \tag{7}$$

which follows from Eqn. 5, since $\lambda_j = Cov(Y_t Y_{t-j}) = Cov(Y_{t+j} Y_t) = \lambda_{-j}$.

2.3 A Summary of the Properties of the Spectrum

Summarizing the results presented in Sect. 2.2., the spectrum (or spectral density function) has 4 important properties.

(a) $S(\omega)d\omega$ can be interpreted as the variance of the cyclical component of Y corresponding to the frequency ω. The period of this component is $2\pi/\omega$.

(b) $S(\omega) \geqslant 0$. This follows, because $S(\omega)$ is a variance function.

(c) $S(\omega) = S(-\omega)$. This follows from the definition of $\gamma(\omega)$ in the spectral representation Eqn. 3, or from Eqn. 7, since $\cos(a) = \cos(-a)$. Because of this symmetry, plots of the spectrum are presented $0 \leqslant \omega \leqslant \pi$.

(d) $Var(Y) = \int_{-\pi}^{\pi} S(\omega)\, d\omega$.

2.4 The Spectrum of Building Permits

The time series plot of building permits (Fig. 1) shows that most of the variability in the series comes from two sources: seasonal variation over the year and business-cycle variability. This is evident in the estimated spectrum for the series, shown in Fig. 2. Most of the mass in the spectrum is concentrated around the seven peaks evident in the plot. (These peaks are sufficiently large that spectrum is plotted on a log scale.) The first peak occurs at frequency $\omega = 0.07$ corresponding to a period of 90 months. This represents the business cycle variability in the series. The other peaks occur at frequencies $2\pi/12$, $4\pi/12$, $6\pi/12$, $8\pi/12$, and π. These are peaks for the seasonal frequencies: the first corresponds to a period of 12 months, and the others are the seasonal 'harmonics' 6, 4, 3, and 2 months.

Spectrum of building permits

3. *Spectral Properties of Moving Average Filters*

3.1 *Some General Results*

Often, one time series (Y) is converted into another time series (X) through a moving average function such as:

$$X_t = \sum_{j=-r}^{s} c_j Y_{t-j}$$

For example, X_t might be the first difference of Y_t, i.e., $X_t = Y_t - Y_{t-1}$, or an annual moving average $X_t = \frac{1}{12}\sum_{j=0}^{11} Y_{t-j}$, or one of the more complicated moving averages that approximate official seasonal adjustment procedures (see *Time Series: Seasonal Adjustment*).

Let the 'lag' operator L shift time series back by one period (so that $LY_t = Y_{t-1}$, $L^2 Y_t = L(LY_t) = Y_{t-2}$, $L^{-1}Y_t = Y_{t+1}$, etc.), then this moving average can be represented as:

$$X_t = c(L)Y_t$$

where,

$$c(L) = c_{-r}L^{-r} + \cdots + c_{-1}L^{-1} + c_0 L^0 + c_1 L + \cdots + c_s L^s$$

The operator $c(L)$ is sometimes called a 'linear filter.'

How does $c(L)$ change the spectral properties of Y? If the spectral representation of Y_t is written as:

$$Y_t = \int_{-\pi}^{\pi} \mathrm{e}^{i\omega t}\, \mathrm{d}\gamma(\omega)$$

then X_t can be written as,

$$\begin{aligned} X_t &= \sum_{j=-r}^{s} c_j Y_{t-j} \\ &= \sum_{j=-r}^{s} c_j \int_{-\pi}^{\pi} \mathrm{e}^{i\omega(t-j)}\, \mathrm{d}\gamma(\omega) \\ &= \int_{-\pi}^{\pi} \mathrm{e}^{i\omega t} \left(\sum_{j=-r}^{s} c_j e^{-i\omega j} \right) \mathrm{d}\gamma(\omega) \\ &= \int_{-\pi}^{\pi} \mathrm{e}^{i\omega t} c(\mathrm{e}^{-i\omega})\, \mathrm{d}\gamma(\omega) \\ &= \int_{-\pi}^{\pi} \mathrm{e}^{i\omega \left(t - \frac{\rho(\omega)}{\omega} \right)} g(\omega)\, \mathrm{d}\gamma(\omega) \end{aligned} \tag{8}$$

where the last line uses the polar form of $c(\mathrm{e}^{-i\omega})$: $c(\mathrm{e}^{-i\omega}) = g(\omega)\mathrm{e}^{-i\rho(\omega)}$ where

$$g(\omega) = |\, c(\mathrm{e}^{i\omega})\, | \tag{9}$$

and

$$\rho(\omega) = \tan^{-1}\left[\frac{-\mathrm{Im}[c(\mathrm{e}^{-i\omega})]}{\mathrm{Re}[c(\mathrm{e}^{-i\omega})]}\right] \tag{10}$$

This representation for X_t shows that the filter $c(L)$ 'amplifies' each component of Y_t by the factor $g(\omega)$ and shifts it back in time by $\rho(\omega)/\omega$ time units.

The function $g(\omega)$ is called the filter *gain* (or sometimes the 'amplitude gain.' The function $\rho(\omega)$ is called the filter 'phase' and $g(\omega)^2 = [c(\mathrm{e}^{-i\omega})c(\mathrm{e}^{i\omega})]$ is called the 'power transfer function' of the filter.

3.2 Three Examples

3.2.1 Example one: lag filter. Suppose that $c(L) = L^2$. Then $c(\mathrm{e}^{-i\omega}) = \mathrm{e}^{-2i\omega}$,

$$g(\omega) = |c(\mathrm{e}^{i\omega})| = 1$$

and

$$\rho(\omega) = \tan^{-1}\left[\frac{\sin 2\omega}{\cos 2\omega}\right] = 2\omega$$

Thus, this filter does not alter the amplitude of any of the components, $g(\omega) = 1$, but shifts each component back in time by $\rho(\omega)/\omega = 2$ time periods.

3.2.2 Example two: first difference filter. Suppose that $c(L) = (1-L)$ so that X_t is the first difference of Y_t. Then $c(\mathrm{e}^{-i\omega}) = 1-\mathrm{e}^{-i\omega}$,

$$g(\omega) = (-\mathrm{e}^{-i\omega}+2-\mathrm{e}^{i\omega})^{\frac{1}{2}} = \sqrt{2(1-\cos(\omega))}$$

and

$$\rho(\omega) = \tan^{-1}\left[\frac{\sin(\omega)}{1-\cos(\omega)}\right]$$

Thus, both the gain and phase are frequency specific. For example, $g(0) = 0$ so that the first difference filter eliminates the lowest frequency component of the series (the level of the series is 'differenced out'), and $g(\pi) = \sqrt{2}$ so that the high frequency components are amplified (X_t is 'choppier' than Y_t).

3.2.3 Example three: census X-12 seasonal adjustment Filter. The official monthly seasonal adjustment procedure in the USA and several other countries (Census X-12) can be well approximated by a linear filter $c(L) = \sum_{j=-84}^{84} c_{|j|}L^j$ where the coefficients c_i are given in Wallis (1974). Since the filter is symmetric, $c_j = c_{-j}$, $c(\mathrm{e}^{i\omega})$ is real and so $\rho(\omega) = 0$. The function $g(\omega)$ is plotted in Fig. 3. The gain is nearly unity except near the seasonal frequencies, and so the filter can be interpreted as producing a new series that leaves the non-seasonal components unaltered, but eliminates the seasonal components. For a detailed discussion of seasonal adjustment procedures see *Time Series: Seasonal Adjustment*.

3.3 Band-pass Filters

The seasonal adjustment filter has the desirable properties of (essentially) zeroing out certain frequency components (the 'seasonal') and leaving the other components (the non-seasonals) unaltered. Filters with this characteristic are called 'band-pass filters,' since they 'pass' components associated with certain frequencies.

Band-pass filters for prespecified frequencies are easy to construct. For example, suppose that you want a filter with no phase shift that passes components between $0 \leqslant \omega \leqslant \underline{\omega}$. That is, you want to construct a filter, say $c(L)$ with gain $|g(\omega)| = 1$ for $0 \leqslant \omega \leqslant \underline{\omega}$ and $|g(\omega)| = 0$ for $\underline{\omega} < \omega \leqslant \pi$. (Assume that the corresponding negative frequencies are also passed.) Choosing a symmetric filter, $c_j = c_{-j}$, will make the phase 0 for all ω. In this case, $c(\mathrm{e}^{i\omega})$ is a real number, and so the gain is given by:

$$g(\omega) = \sum_{j=-\infty}^{\infty} c_{|j|}\mathrm{e}^{-i\omega j}$$

Now, using Eqn. 6, it is straightforward to verify the identity

$$\begin{aligned} c_j &= (2\pi)^{-1}\int_{-\pi}^{\pi} \mathrm{e}^{-i\omega j} \sum_{j=-\infty}^{\infty} c_j \mathrm{e}^{-i\omega j}\,\mathrm{d}\omega \\ &= (2\pi)^{-1}\int_{-\pi}^{\pi} \mathrm{e}^{i\omega j} c(\mathrm{e}^{i\omega})\,\mathrm{d}\omega \end{aligned}$$

Replacing $c(\mathrm{e}^{i\omega}) = g(\omega)$ with the target value of the gain for the band-pass filter and carrying out the integration yields

$$c_j = (2\pi)^{-1}\frac{1}{ij}\,\mathrm{e}^{i\omega j}\Big|_{-\underline{\omega}}^{\underline{\omega}} = \left\{\begin{array}{ll} \dfrac{1}{j\pi}\sin(\underline{\omega} j) & \text{for} \quad j \neq 0 \\ \underline{\omega}/\pi & \text{for} \quad j = 0 \end{array}\right\}$$

The resulting filter $c(L)$ passes all components with frequencies between $0 \leqslant \omega \leqslant \underline{\omega}$. This means that the filter $1-c(L)$ passes everything except these frequencies. The filter $c(L)$ is called a low-pass filter (it passes low frequencies), and $1-c(L)$ is called a high-pass filter (it passes the high frequencies). Combinations of high- and low-pass filters can be used to construct band-pass filters for any set of frequencies. For example, a filter that passes components with frequencies between ω_1 to ω_2 (with $\omega_2 \geqslant \omega_1$) can be

Figure 3
Gain of linear approximation to monthly × 12 seasonal adjustment filter

constructed as the difference of the low-pass filter for ω_2 and the low-pass filter for ω_1.

One practical problem with exact band-pass filters is that the coefficients c_j die out very slowly (at the rate $1/j$). This introduces important 'endpoint' problems when applying these filters to finite realizations of data, say $\{Y_t\}_{t=1}^{T}$. One approach is simply to truncate the filter at some point, for example to use $c_k(L) = \sum_{j=-k}^{k} c_j L^j$ and apply this filter to $\{Y_t\}_{t=k+1}^{T-k}$. An alternative procedure is to construct a minimum mean square error estimate of the infeasible band-pass values:

$$X_t = c(L)Y_t = \sum_{i=-\infty}^{\infty} c_i Y_{t-i},$$

as

$$E(X_t \mid \{Y_j\}_{j=1}^{T}) = \sum_{i=-\infty}^{\infty} c_i E(Y_{t-i} \mid \{Y_j\}_{j=1}^{T})$$

This can be accomplished by using backcasts and forecasts for the missing pre-sample and post-samples values of Y_t. The relative merits of these two approaches for band-pass filters is discussed in Baxter and King (1999), Geweke (1978) and Dagum (1980) discuss this problem in the context of seasonal adjustment.

4. *Spectra of Commonly Used Stochastic Processes*

Suppose that Y has spectrum $S_Y(\omega)$ and $X_t = c(L)Y_t$. What is the spectrum of X? As was shown in Eqn. 8, the frequency components of X are the frequency components of Y scaled by the factor $g(\omega)e^{-i\rho(\omega)}$, where $g(\omega)$ is the gain and $\rho(\omega)$ is the phase of $c(L)$. This means that spectra of X and Y are related by:

$$S_X(\omega) = g(\omega)^2 S_Y(\omega) = |\, c(e^{-i\omega})\,|^2 S_Y(\omega)$$

which follows from $|e^{-i\rho(\omega)}| = 1$ and the definition of $g(\omega)$.

Now, suppose that ε_t is a 'white noise' process, defined by the properties $E(\varepsilon_t) = 0$, $\lambda_0 = \sigma^2$, and $\lambda_k = 0$ for $k \neq 0$. The spectrum of ε is then easily calculated from Eqn. 7:

$$S_\varepsilon(\omega) = (2\pi)^{-1}\sigma^2$$

So, the spectrum of white noise is constant. (Which is why the process is called 'white' noise.)

Now suppose that $Y_t = c(L)\varepsilon_t$. Then:

$$S_Y(\omega) = |c(e^{-i\omega})|^2 S_\varepsilon(\omega) = |c(e^{-i\omega})|^2 (2\pi)^{-1}\sigma^2$$

This result can be used to determine the spectrum of any stationary ARMA process (see *Time Series:*

ARIMA Methods) for a detailed discussion of these models). If Y_t follows an ARMA process, then it can be represented as:

$$\phi(L)Y_t = \theta(L)\varepsilon_t$$

The autoregressive operator, $\phi(L)$ can be inverted to yield $Y_t = c(L)\varepsilon_t$ with $c(L) = \phi(L)^{-1}\theta(L)$. This means that:

$$S_y(\omega) = |c(\mathrm{e}^{-i\omega})|^2(2\pi)^{-1}\sigma^2 = \frac{2(\pi)^{-1}\sigma^2|\theta(\mathrm{e}^{-i\omega})|^2}{|\phi(\mathrm{e}^{-i\omega})|^2} \qquad (11)$$

As an example, consider the AR(1) model:

$$Y_t = \phi Y_{t-1} + \varepsilon_t$$

equivalently written as,

$$(1-\phi L)Y_t = \varepsilon_t.$$

Applying Eqn. 11 yields

$$S_Y(\omega) = \frac{\sigma^2}{2\pi}\frac{1}{|1-\phi\mathrm{e}^{-i\omega}|^2} = \frac{\sigma^2}{2\pi}\frac{1}{(1+\phi^2-2\phi\cos(\omega))}$$

This spectrum is equal to $\sigma^2[2\pi(1+\phi^2-2\phi\cos(\omega))]^{-1}$ at $\omega = 0$. When $0 < \phi < 1$, it falls steadily as ω increases from 0 to π. This means that, relative to white noise, the low frequency components of the AR(1) are more important than the high frequency components. Thus, realizations of the series appear smoother than white noise.

5. *Spectral Estimation*

There are two general approaches to estimating spectra. Perhaps the simplest is to estimate an ARMA model for the series (as explained in *Time Series: ARIMA Methods*) and then compute the implied spectrum for this estimated model. Asymptotic approximations can then be used for statistical inference. Since the estimators of the ARMA parameters are asymptotically normally distributed and the spectrum is a smooth function of these parameters (see Eqn. 11), the estimated spectrum at any point ω will be asymptotically normal with a variance that can be computed using the δ-method (a mean-value expansion).

An interesting extension of this procedure is discussed in Berk (1974). He shows that, quite generally, a suitably long autoregression can be specified and the spectrum estimated using the estimated AR coefficients. The precise definition of 'suitably long' depends on the size of the available sample, with more terms included in larger samples. These 'autoregressive spectral estimators' are shown by Berk to be consistent and approximately normally distributed in large samples.

An alternative set of estimators are based on nonparametric methods. These estimators can be motivated by Eqn. 7 which shows the spectrum as a weighted sum of the autocovariances. This suggests an estimator of the form:

$$S(\omega) = (2\pi)^{-1}\sum_{k=-l_T}^{l_T} w_T(k)\hat{\lambda}_k$$

where $\hat{\lambda}_k$ is an estimator of λ_k, l_T are truncation values that depend on the sample size T, and $w_T(k)$ is a weight function that also depends on T. These estimators can be studied using nonparametric methods (see *Nonparametric Statistics: Asymptotics*).

A closely related set of nonparametric estimators are based on the 'periodogram'. The periodgram provides a frequency decomposition of the sample variance of a partial realization of the process, say $\{Y_t\}_{t=1}^T$. The periodgram is computed at frequencies $\omega_j = 2\pi j/T$, $j = 1, 2,\ldots, T/2$ (assuming T is even), and the value of the periodgram at frequency ω_j is:

$$p_j = \frac{2}{T}\left|\sum_{t=1}^{T}(y_t-\bar{y})\mathrm{e}^{-i\omega_j t}\right|^2$$

The periodgram has three interesting asymptotic sampling properties: (a) $E(p_j)/4\pi \to \mathrm{S}_Y(\omega_j)$; (b) $var(p_j/2\pi) \to \mathrm{S}_Y(\omega_j)^2$; and (c) $cov(p_j, p_k) = 0$ for $j \neq k$. Property (a) shows that a scaled version of the periodgram provides an asymptotically unbiased estimator of the spectrum, but since the variance doesn't approach zero (property (b)), the estimator is not consistent. The third property shows that averaging a set of periodgram ordinates around a given frequency reduces the variance of the estimator, although (from property (a)) it may introduce bias. By carefully selecting the averaging weights, consistent estimators with good finite sample mean square error properties can be constructed.

Some recent advances for nonparametric spectral estimators are developed in Andrews (1991).

Time Series: Economic Forecasting

Time-series forecasts are used in a wide range of economic activities, including setting monetary and fiscal policies, state and local budgeting, financial management, and financial engineering. Key elements of economic forecasting include selecting the forecasting model(s) appropriate for the problem at hand, assessing and communicating the uncertainty associated with a forecast, and guarding against model instability.

1. *Time Series Models for Economic Forecasting*

Broadly speaking, statistical approaches to economic forecasting fall into two categories: time-series methods and structural economic models. Time-series methods use economic theory mainly as a guide to variable selection, and rely on past patterns in the data to predict the future. In contrast, structural economic models take as a starting point formal economic theory and attempt to translate this theory into empirical relations, with parameter values either suggested by theory or estimated using historical data. In practice, time-series models tend to be small with at most a handful of variables, while structural models tend to be large, simultaneous equation systems which sometimes incorporate hundreds of variables (see *Economic Panel Data*; *Simultaneous Equation Estimation: Overview*). Time-series models typically forecast the variable(s) of interest by implicitly extrapolating past policies into the future, while structural models, because they rely on economic theory, can evaluate hypothetical policy changes. In this light, perhaps it is not surprising that time-series models typically produce forecasts as good as, or better than, far more complicated structural models. Still, it was an intellectual watershed when several studies in the 1970s (reviewed in Granger and Newbold 1986) showed that simple univariate time-series models could outforecast the large structural models of the day, a result which continues to be true (see McNees 1990). This good forecasting performance, plus the relatively low cost of developing and maintaining time-series forecasting models, makes time-series modeling an attractive way to produce baseline economic forecasts.

At a general level, time-series forecasting models can be written,

$$y_{t+h} = g(X_t, \theta) + \varepsilon_{t+h} \tag{1}$$

where y_t denotes the variable or variables to be forecast, t denotes the date at which the forecast is made, h is the forecast horizon, X_t denotes the variables used at date t to make the forecast, θ is a vector of parameters of the function g, and ε_{t+h} denotes the forecast error. The variables in X_t usually include current and lagged values of y_t. It is useful to define the forecast error in (1) such that it has conditional mean zero, that is, $E(\varepsilon_{t+h}|X_t) = 0$. Thus, given the predictor variables X_t, under mean-squared error loss the optimal forecast of y_{t+h} is its conditional mean, $g(X_t, \theta)$. Of course, this forecast is infeasible because in practice neither g nor θ are known. The task of the time-series forecaster therefore is to select the predictors X_t, to approximate g, and to estimate θ in such a way that the resulting forecasts are reliable and have mean-squared forecast errors as close as possible to that of the optimal infeasible forecast.

Time-series models are usefully separated into univariate and multivariate models. In univariate models, X_t consists solely of current and past values of y_t. In multivariate models, this is augmented by data on other time series observed at date t. The next subsections provide a brief survey of some leading time-series models used in economic forecasting. For simplicity attention is restricted to one-step ahead forecasts ($h = 1$). Here, the focus is on forecasting in a stationary environment; the issue of nonstationarity in the form of structural breaks or time varying parameters is returned to below.

1.1 *Univariate Models*

Univariate models can be either linear, so that g is linear in X_t, or nonlinear. All linear time-series models

can be interpreted as devices for modeling the covariance structure of the data. If $\{y_t\}$, $t = 1, \ldots, T$ has a Gaussian distribution and if this distribution is stationary (does not depend on time), then the optimal forecast is a linear combination of past values of the data with constant weights. Different linear time-series models provide different parametric approximations to this optimal linear combination.

The leading linear models are autoregressive models, autoregressive–integrated moving-average (ARIMA) models, and unobserved components models.

An autoregressive model of order p (AR(p)) is written,

$$y_{t+1} = \mu + \alpha_1 y_t + \cdots + \alpha_p y_{t-p+1} + \varepsilon_{t+1} = \mu + \alpha(L) y_t + \varepsilon_{t+1},$$

where $(\mu, \alpha_1, \ldots, \alpha_p)$ are unknown parameters, L is the lag operator, and $\alpha(L)$ is a lag polynomial. If y_t is observed at all dates, $t = 1, \ldots, T$, these parameters are readily estimated by ordinary least squares.

ARIMA models extend autoregressive models to include a moving-average term in the error, which has the effect of inducing long lags in the forecast when it is written as a function of current and past values of y_t. These are discussed in *Time Series: ARIMA Methods*.

In an unobserved components model, y_t is represented as the sum of two or more different stochastic components. These components are then modeled, and the combined model provides a parametric approximation to the autocovariances; see Harvey (1989) for a detailed modern treatment. The unobserved components framework can provide a useful framework for extracting cyclical components of economic time-series and for seasonal adjustment (see *Time Series: Seasonal Adjustment*).

If $\{y_t\}$ is not Gaussian, in general the optimal forecast will not be linear, which suggests the use of forecasts based on nonlinear time-series models. Parametric nonlinear time-series models posit a functional form g, and take this as known up to the finite-dimensional parameter vector θ. Two leading examples of parametric nonlinear time-series models, currently popular for economic forecasting, are threshold autoregressive models and Markov switching models. Both are similar in the sense that they posit two (or more) regimes. In the threshold autoregression, switches between the regimes occur based on past values of the observed data; in Markov switching models, the switches occur based on an unobserved or latent variable.

The threshold autoregressive family of models can be written

$$y_{t+1} = d_t \alpha(\mathrm{L}) y_t + (1 - d_t) \beta(\mathrm{L}) y_t + \varepsilon_{t+1} \qquad (2)$$

where the mean is suppressed, $\alpha(\mathrm{L})$ and $\beta(\mathrm{L})$ are lag polynomials, and d_t is a nonlinear function of past data that switches between the 'regimes' $\alpha(\mathrm{L})$ and $\beta(\mathrm{L})$. Variations of Eqn. (2) interact d_t with only some autoregressive coefficients, the intercept, and/or the error variance. Various functions are available for d_t, either a sharp indicator function (the threshold autoregressive model) or a smooth function (smooth transition autoregression). For example, setting $d_t = (1 + \exp[\gamma_0 + \gamma'_1 \zeta_t])^{-1}$, yields the logistic smooth transition autoregression (LSTAR) model, where ζ_t denotes current or past data, say, ζ_t might equal y_{t-k} for some k. See Granger and Teräsvirta (1993) for additional details. For an application of threshold autoregressions (and other models) to forecasting US unemployment, see Montgomery et al. (1998).

The Markov switching models are conceptually similar, except that the regime switch depends on an unobserved series. In the context of Eqn. (2), d_t is modeled as unobserved and following a two-state Markov process; see Hamilton (1994).

An alternative approach is to treat g itself as unknown, which leads to nonparametric methods. These include nearest neighbor, kernel, and artificial neural network models for the conditional expectation. In practice these nonparametric approaches to economic forecasting have met with success which is mixed at best. There are several possible reasons for this, including that there are insufficiently many observations in typical economic data sets to support the use of these data-intensive methods.

1.2 Multivariate Models

In multivariate time-series models, X_t includes multiple time-series that can usefully contribute to forecasting y_{t+1}. The choice of these series is typically guided by both empirical experience and by economic theory, for example, the theory of the term structure of interest rates suggests that the spread between long and short term interest rates might be a useful predictor of future inflation.

The multivariate extension of the univariate autoregression is the vector autoregression (VAR), in which a vector of time-series variables, Y_{t+1}, is represented as a linear function of $Y_t, \ldots, Y_{t-p+1}$, perhaps with deterministic terms (an intercept or trends). An interesting possibility arises in VARs that is not present in univariate autoregressions, specifically, it might be that the time-series are cointegrated (that is, the individual series are nonstationary in the sense that they are integrated, but linear combinations of the series are integrated or order zero); see *Time Series: Co-integration* and Watson (1994).

Multivariate time-series models involve a large number of unknown parameters, a problem which is greatly exacerbated when nonlinearities are introduced. Conceptually, the extension of univariate nonlinear models to the multivariate setting is straightforward. In practice, however, because of the relatively

small number of time-series observations available to economic forecasters, it is unclear how best to implement nonlinear multivariate models and there are currently no definite conclusions in this area.

1.3 Models for Forecasting Higher Moments

The foregoing categorization of forecasting models has focused on prediction of conditional means. In some economic applications, especially in financial economics, interest is also in forecasting conditional higher moments. The most developed tools in this area are models of conditional variances. Two families of such models are autoregressive conditional heteroskedasticity (ARCH) models (Engle 1982; see Bollerslev et al. 1994) and stochastic volatility models. Both approaches provide parametric models for the volatility of the series, which can then be forecasted given parameters estimated from historical data.

2. When Do Time-series Forecasts Fail?

Regrettably, only by luck will economic forecasts be 'right': there are inevitable sources of uncertainty that make perfectly accurate predictions of the future impossible.

2.1 Shock, Model, and Estimation Uncertainty

Sources of uncertainty that comprise the error term ε_{t+h} in (1) ('shock uncertainty') consist of unknowable future events, random measurement error in the series being forecast, and unforeseeable data revisions. Additional forecast uncertainty arises from model approximation error (that is, error in the choice of g) and from error in the estimation of the model parameters θ.

Sensible use of economic forecasts requires that this forecast uncertainty be accurately communicated. Prediction intervals can be computed either directly based on historically estimated parameters and residuals, or by simulation for more complicated nonlinear models. Ideally these prediction intervals should incorporate parameter estimation uncertainty. There are several ways to do this, but a natural one is to construct forecast error distributions using a simulated out of sample prediction methodology. In this approach, the model is estimated using data through some date, say t', then a forecast is made for the next period ($t'+h$, for h-step ahead forecasts). The model is then reestimated using data through date $t'+1$, and the forecast is made for $t'+h+1$. This is repeated until a series of simulated out of sample forecast errors is constructed, which in turn can be used to construct prediction intervals around the point forecast of interest.

2.2 Overfitting

Overfitting poses a particular threat in economic forecasting given the impossibility of creating new data sets through experiments and given the relatively short number of observations on many economic time-series. Overfitting can be addressed in part by relying on automatic methods for pruning a model. Leading such methods are model selection using information criteria such as the Akaike or Bayes information criteria (see *Model Testing and Selection, Theory of*). Alternatives include Bayes or Empirical Bayes estimation. Combining forecasts by taking averages or weighted averages can also be interpreted as a method for addressing the overfitting that arises in model selection.

2.3 Difficulties Modeling Trends

An important characteristic of economic data is that many economic time-series contain considerable persistence, sometimes resembling a trend. Starting with the seminal work of Nelson and Plosser (1982), there has been considerable debate about whether these trends are best modeled as deterministic or stochastic (that is, arising from unit autoregressive roots), see Stock (1994). If a forecasting model incorrectly incorporates deterministic trends, but the series is highly persistent, spuriously large weight can be placed on an estimated trend component and out-of-sample forecasts can suffer. Such considerations lead to the use of methods that explicitly address the possibilities of stochastic trends, an example being preliminarily testing for a unit root in a univariate time-series and constructing a univariate model in levels or in differences depending on the outcome of the pretest.

2.4 Model Instability

Clements and Hendry (1999) argue that many major failures of economic forecasts arise because of structural breaks to which conventional forecasting models fail to adapt. In some cases, model instability can arise because of slow changes in parameter values, perhaps arising from evolution in underlying technologies in the economy. In other, more dramatic cases, model instability appears as a sudden break, such as a change in monetary policy or the collapse of an exchange rate regime.

Whether structural change is gradual or abrupt, it is critical to monitor forecast performance and to test for model instability. Various statistical methods are available for detecting structural change; these typically involve testing for evidence of instability either in estimated coefficients or in simulated forecast errors. In practice, these methods need to be augmented by expert judgment that draws on information not incorporated in the model, such as knowledge of

particularly severe weather (which could lead to a structural break being spuriously detected) or of a known change in a policy regime (so a break might be imposed even if it is not detected statistically). Unfortunately, expert judgment can be wrong, and knowing when to intervene in an economic forecast is a rather murky art.

3. Which Methods Work Best?

It is perhaps overly ambitious to hope for a simple prescription that provides a good forecasting method for all economic time-series. Nonetheless, a number of studies have attempted to provide some general guidance on this question. Two general lessons emerge: among univariate models, simple linear models often forecast as well or better than more complicated nonlinear models; and the gains from moving from univariate to multivariate models are often (but not always) small.

This is illustrated by forecasts of the rate of price inflation over six months in the United States, as measured by the percentage rate of inflation of the Consumer Price Index (this example is taken from Stock and Watson's (1999) comparison of linear and nonlinear forecasting models for 215 US macroeconomic time-series). Simulated out of sample six-month-ahead forecasts over the period March 1971 to June 1996 (the full sample begins January 1959) produce a root mean-square forecast error (RMSFE) of 2.44 percentage points (at an annual rate) for a univariate AR(4) fit recursively to the annualized rate of inflation. If the autoregressive lag length is selected recursively using the Bayes information criterion and a recursive unit root protest is used to determine whether the AR is fit to the rate of inflation or the change in the rate, the RMSFE drops to 2.05. Forecasts based on artificial neural networks and LSTAR models have RMSFEs exceeding 2.15 and in some cases exceeding 2.5, depending on the specification. A VAR which adds the unemployment rate and short-term interest rate (recursive Bayes information criterion lag selection) produces a RMSFE of 2.31. For these models, then, introducing nonlinearity or adding these other predictors does not improve upon a simple autoregression with a unit root pretest and data-dependent lag length selection.

The future of economic forecasting promises the development of new, computer-intensive methods and the real-time availability of very large data sets with complex patterns of historical dependence. These developments could prove invaluable for advancing economic forecasting, and the lessons from the past four decades of economic forecasting might not extend to these new datasets. Yet those lessons do underscore the importance of having a simple and reliable benchmark forecast against which alternative forecasts can be assessed.

Time Series: General

A *time series* is a stretch of values on the same scale indexed by a time-like parameter. The basic data and parameters are functions.

Time series take on a dazzling variety of shapes and forms, indeed there are as many time series as there are functions of real numbers. Some common examples of time series forms are provided in Fig. 1. One notes periods, trends, wandering and integer-values. The time series such as those in the figure may be

Figure 1
Some different types of time series

contemporaneous and a goal may be to understand the interrelationships.

Concepts and fields related to time series include: logitudinal data, growth curves, repeated measures, econometric models, multivariate analysis, signal processing, and systems analysis.

The field, time series analysis, consists of the techniques which when applied to time series lead to

improved knowledge. The purposes include summary, decision, description, prediction.

The field has a theoretical side and an applied side. The former is part of the theory of stochastic processes (e.g., representations, prediction, information, limit theorems) while applications often involve extensions of techniques of 'ordinary' statistics, for example, regression, analysis of variance, multivariate analysis, sampling. The field is renowned for jargon and acronyms—white noise, cepstrum, ARMA, ARCH (see Granger 1982).

1. Importance

'... but time and chance happeneth to them all' (*Ecclesiastes*).

Time series ideas appear basic to virtually all activities. Time series are used by nature and humans alike for communication, description, and visualization. Because *time* is a physical concept, parameters and other characteristics is mathematical models for time series can have real-world interpretations. This is of great assistance in the analysis and synthesis of time series.

Time series are basic to scientific investigations. There are: circadian rhythms, seasonal behaviors, trends, changes, and evolving behavior to be studied and understood. Basic questions of scientific concern are formulated in terms of time series concepts—Predicted value? Leading? Lagging? Causal connection? Description? Association? Autocorrelation? Signal? Seasonal effect? New phenomenon? Control? Periodic? Changing? Trending? Hidden period? Cycles?

Because of the tremendous variety of possibilities, substantial simplifications are needed in many time series analyses. These may include assumptions of stationarity, mixing or asymptotic independence, normality, linearity. Luckily such assumptions often appear plausible in practice.

The subject of time series analysis would be important if for no other reason than that it provides means of examining the basic assumption of statistical independence invariably made in ordinary statistics. One of the first commonly used procedures for this problem was the Durbin–Watson test (Durbin and Watson 1950). The autocovariance and spectrum functions, see below, are now often used in this context.

2. History

Contemporary time series analysis has substantial beginnings in both the physical and social sciences. Basic concepts have appeared in each subject and made their way to the other with consequent transfer of technology. Historical researchers important in the development of the field include: Lauritzen (1981), Hooker (1901), Einstein (1914), Wiener (1949), Yule (1927), Fisher (1929), Tukey (1984), Whittle (1951), Bartlett (1966). Books particularly influential in the social sciences include Moore (1914) and Davis (1941). Nowadays many early analyses appear naive. For example, Beveridge in 1920 listed some 19 periods for a wheat price index running from 1500 to 1869 (Beveridge 1922). It is hard to imagine the presence of so much regular behavior in such a series. When statistical uncertainty is estimated using latter-day techniques most of these periods appear insignificant; see the periodogram with 95 percent error bounds in Fig. 2. Many historical references are included in Wold (1965).

Figure 2
The dashed lines provide 95 percent bounds about a central curve

Historians of science have made some surprising discoveries concerning early work with time series. An example is presented in Tufte (1983). He shows a time series plot from the tenth or eleventh century AD. This graph is speculated to provide movements of the planets and sun. It is remarkable for its cartesian type character. More generally Tufte remarks, following a study of newspapers and magazines, that 'The time-series plot is the most frequently used form of graphic design.' Casual observation certainly supports Tufte's study.

Important problems that were addressed in the twentieth century include: seasonal adjustment, leading and lagging indicators, and index numbers. Paradigms that were developed include:

$$\text{series} = \text{signal} + \text{noise}$$

$$\text{series} = \text{trend} + \text{seasonal} + \text{noise}$$

$$\text{series} = \text{sum of cosines} + \text{noise}$$

$$\text{series} = \text{regression function} + \text{noise}$$

These conceptualizations have been used for forecasting, seasonal adjustment and description amongst other things. There are surprises, for example, ordinary least squares is surprisingly efficient in the time series case (see Grenander and Rosenblatt 1957). Other books from the 1950s and 1960s that proved important are Blackman and Tukey (1959), Granger and Hatanaka (1964), Box and Jenkins (1970). Important papers from the era include: Akaike (1965), Hannan (1963) and Parzen (1961).

An important development that began in the 1950s and continues today is the use of recursive computation in the state space model; see Kalman (1963), Harvey (1990), Shumway and Stoffer (2000), and Durbin and Koopman (2001).

3. Basics

3.1 Concepts

There are a number of concepts that recur in time series work. Already defined is the *time series*, a stretch of values on the same scale indexed by a time parameter. The time parameter may range over the positive and negative integers or all real numbers or subsets of these. *Time series data* refer to a segment of a time series. A time series is said to have a *trend* when there is a slowly evolving change. It has a *seasonal* component when some cyclic movement of period one year is present. (The *period* of a cyclic phenomenon is the amount of time for it to repeat itself. Its *frequency* is the reciprocal of the period.)

There is an algebra of mathematical operations that either nature or an analyst may apply to a time series $\{X(t)\}$ to produce another series $\{Y(t)\}$. Foremost is the *filter*, or *linear time invariant operation* or *system*. In the case of discrete equispaced time this may be represented as

$$Y(t) = \sum_u a(u)X(t-u)$$

$t, u = 0, \pm 1, \ldots$ An example is the running mean used to smooth a series. The functions $X(.)$, $Y(.)$ may be vector-valued and $a(.)$ may be matrix-valued. In the vector-valued case feedback may be present. The sequence $\{a(u)\}$ is called the *impulse response function*. The operation has the surprising property of taking a series of period P into a series of the same period P. The filter is called *realizable* when $a(u) = 0$ for $u < 0$. Such filters appear in causal systems and when the goal is prediction.

The above ideas concern both deterministic and random series. The latter prove to be important in developing solutions to important problems. Specifically it often proves useful to view the subject of time series as part of the general theory of stochastic processes, that is, indexed families of random variables. One writes $\{Y(t, \omega),\ t \text{ in } V\}$, with ω a random variable and V a set of times. Time series data are then viewed as a segment, $\{Y(t, \omega_0),\ t = 0, \ldots, \mathrm{T}-1\}$ of the realization labeled by ω_0, the obtained value of ω. Stochastic time series $\{Y(t),\ t = 0, \pm 1, \pm 2, \ldots\}$ sometimes are conveniently described by *finite dimensional distributions* such as

$$\text{Prob}\{Y(t) \leqslant y\} \quad \text{and} \quad \text{Prob}\{Y(t_1) \leqslant y_1, Y(t_2) \leqslant y_2\}$$

This is particularly the case for time series values with joint normal distributions.

Time series may also be usefully described or generated by stochastic models involving the independent identically distributed random variables of ordinary statistics.

Stochastic models may be distinguished as parametric or nonparametric. Basic parameters of the nonparametric approach include: moments, joint probability and density functions, mean functions, autocovariance and crosscovariance functions, power spectra.

One basic assumption of time series analysis is that of *stationarity*. Here the choice of time origin does not affect the statistical properties of the process. For example, the mean level of a stationary series is constant. Basic to time series analysis is handling temporal dependence. To this end one can define the *crosscovariance function* of the series X and Y at lag u as the covariance of the values $X(t+u)$ and $Y(t)$. In the stationary case this function does not depend on t. In an early paper, Hooker (1901) computed an estimate of this quantity. Another useful parameter is the *power spectrum*, a display of the intensity or variability of the phenomenon vs. period or frequency. It may be defined as the Fourier transform of the autocovariance function. The power spectrum proves useful in displaying the serial dependence present, in discovering periodic phenomena and in diagnosing possible models for a series.

In the parametric case there are the *autoregressive moving average* (ARMA) series. These are regression-type models expressing the value $Y(t)$ as a linear function of a finite number of past values $Y(t-1)$, $Y(t-2)$, ... of the series and the values $\varepsilon(t), \varepsilon(t-1), \ldots$ of a sequence of independent identically distributed random variables. ARMAs have proved particularly useful in problems of forecasting.

Contemporary models for time series are often based upon the idea of *state*. This may be defined as the smallest entity summarizing the past history of the process. There are two parts to the state space model. First, a state equation that describes how the value of the state evolves in time. This equation may contain a purely random element. Second there is an equation indicating how the available measurements at that time t come from the state value at that time. It too may involve a purely random element. The concept of

the state of a system has been basic to physics for many years in classical dynamics and quantum mechanics. The idea was seized upon by control engineers, for example, Kalman (1963) in the late 1950s. The econometricians realized its usefulness in the early 1980s (see Harvey 1990).

A number of specific probability models have been studied in depth, including the Gaussian, the ARMA, the bilinear (Granger 1978), various other nonlinear (Tong 1990), long and short memory, ARMAX, ARCH (Einstein 1914), hidden Markov (MacDonald and Zucchini 1997), random walk, stochastic differential equations (Guttorp 1995, Prakasa Rao 1999), and the periodically stationary.

A list of journals where these processes are often discussed is included at the end of this article.

3.2 Problems

There are scientific problems and there are associated statistical problems that arise. Methods have been devised for handling many of these. The scientific problems include: smoothing, prediction, association, index numbers, feedback, and control. Specific statistical problems arise directly. Among these are including explanatories in a model, estimation of parameters such as hidden frequencies, uncertainty computation, goodness of fit, and testing.

Special difficulties arise. These include: missing values, censoring, measurement error, irregular sampling, feedback, outliers, shocks, signal-generated noise, trading days, festivals, changing seasonal pattern, aliasing, data observed in two series at different time points.

Particularly important are the problems of association and prediction. The former asks the questions of whether two series are somehow related and what is the strength of any association. Measures of association include: the cross-correlation and the coherence functions. The prediction problem concerns the forecasting of future values. There are useful mathematical formulations of this problem but because of unpredictable human intervention there are situations where guesswork seems just as good.

Theoretical tools employed to address the problems of time series analysis include: mathematical models, asymptotic methods, functional analysis, and transforms.

4. Methods

4.1 Descriptive

Descriptive methods are particularly useful for exploratory and summary purposes. They involve graphs and other displays, simple statistics such as means, medians and percentiles, and the techniques of exploratory data analysis (Tukey 1977).

The most common method of describing a time series is by presenting a graph, see Fig. 1. Such graphs are basic for communication and assessing a situation. There are different types. Cleveland (1985) mentions the connected, symbol, connected-symbol and vertical-line displays in particular. Figure 1 presents connected graphs.

Descriptive values derived from time series data include extremes, turning points, level crossings and the periodogram (see Fig. 2 for an example of the latter). Descriptive methods typically involve generating displays using manipulations of time series data via operations such as differencing, smoothing and narrow band filtering.

A display with a long history (Laplace 1825, Wold 1965) is the Buys–Ballot table. Among other things it is useful for studying the presence and character of a phenomenon of period P such as a circadian rhythm. One creates a matrix with entry $Y((i-1)P+j)$ in row i, column $j = 1, \ldots, P$ and then, for example, one computes column averages. These values provide an estimate of the effect of period P. The graphs of the individual rows may be stacked beneath each other in a display. This is useful for discerning slowly evolving behavior.

Descriptive methods may be time-side (as when a running mean is computed), frequency-side (as when a periodogram is computed) or hybrid (as when a sliding window periodogram analysis is employed).

4.2 Parameter Estimation

The way to a solution of many time series problems is via the setting down of a stochastic model. Parameters are constants of unknown values included in the model. They are important because substantial advantages arise when one works within the context of a model. These advantages include: estimated standard errors, efficiency, and communication of results. Often parameter estimates are important because they are fed into later procedures, for example, formulas for forecasting.

General methods of estimating parameters include: method of moments, least squares and maximum likelihood. An important time series case is that of harmonic regression. It was developed in Fisher (1929) and Whittle (1951).

There are parametric and nonparametric approaches to estimation. The parametric has the advantage that if the model is correct, then the estimated coefficients have considerably smaller standard errors.

4.3 Uncertainty Estimation

Estimates without some indication of their uncertainty are not particularly useful in practice. There are a variety of methods used in time series analysis to develop uncertainty measures. If maximum likelihood estimation has been used there are classic (asymptotic)

formulas. The delta-method or method of linearization is useful if the quantity of interest can be recognized to be a smooth function of other quantities whose variability can be estimated directly. Methods of splitting the data into segments, such as the jackknife, can have time series variants. A method currently enjoying considerable investigation is the bootstrap (Davison and Hinkley 1997). The assumptions made in validating these methods are typically that the series involved is stationary and mixing.

4.4 Seasonal Adjustment

Seasonal adjustment may be defined as the attempted removal of obscuring unobservable annual components. There are many methods of seasonal adjustment (National Bureau of Economic Research 1976), including state space approaches (Hannan 1963).

The power spectrum provides one means of assessing the effects of various suggested adjustment procedures.

4.5 System Identification

System identification refers to the problem of obtaining a description or model of a system on the basis of a stretch of input to and the corresponding output from a system of interest. The system may be assumed to be linear time invariant as defined above.

In designed experiments the input may be a series of pulses, a sinusoid or white noise. In a natural experiment the input is not under the control of the investigator and this leads to complications in the interpretation of the results. System identification relates to the issue of causality. In some systems one can turn the input off and on and things are clearer.

4.6 Computing

Important computer packages for time series analysis include: Splus, Matlab, Mathematica, SAS, SPSS, TSP, STAMP. Some surprising algorithms have been found: the fast Fourier transform (FFT), fast algorithms from computational geometry, Monte Carlo methods, and the Kalman–Bucy filter. Amazingly a variant of the latter was employed by Thiele in 1880 Lauritzen 1981), while the FFT was known to Gauss in the early 1800s (Heideman et al. 1984).

5. Current Theory and Research

Much of what is being developed in current theory and research is driven by what goes on in practice in time series analyses. What is involved in a time series analysis? The elements include: the question, the experiment, the data, plotting the data, the model, model validation, and model use. The importance of recognizing and assessing the basic assumptions is fundamental.

The approach adopted in practice often depends on how much data are available. In the case that there are a lot of data even procedures that are in some sense inefficient are often used effectively. A change from the past is that contemporary analysis often results from the appearance of very large fine data sets. The amount of data can seem limitless as, for example, in the case of records of computer tasks. There are many hot research topics. One can mention: exploratory data analysis techniques for very large data sets, so-called improved estimates, testing (association? cycle present?), goodness of fit diagnostics. There are the classical and Bayesian approaches, the parametric, semi-parametric, and nonparametric analyses, the problem of dimension estimation and that of re-expression of variables.

Current efforts include research into: bootstrap variants, long-memory processes, long-tailed distributions, nonGaussian processes, unit roots, nonlinearities, better approximations to distributions, demonstrations of efficiency, self-similar processes, scaling relationships, irregularly observed data, doubly stochastic processes as in hidden Markov, cointegration, disaggregation, cyclic stationarity, wavelets, and particularly inference for stochastic differential equations.

Today's time series data values may be general linear model type (Fahrmein and Tutz 1994), for example, ordinal, state-valued, counts, proportions, angles, ranks. They may be vectors. They may be functions. The time label t may be location in space or even a function. The series may be vector-valued. The data may have been collected in an experimental design.

There are some surprises: the necessity of tapering and prewhitening to reduce bias, the occurrence of aliasing, the high efficiency of ordinary least squares estimates in the correlated case, and the approximate independence of empirical Fourier transform values at different frequencies (Brillinger 1975).

6. Future Directions

It seems clear that time series research will continue on all the existing topics as the assumptions on which any existing problem solution has been based appear inadequate. Further, it can be anticipated that more researchers from nontraditional areas will become interested in the area of time series as they realize that the data they have collected, or will be collecting, are correlated in time.

Researchers can be expected to be even more concerned with the topics of nonlinearity, conditional

heteroscedasticity, inverse problems, long memory, long tails, uncertainty estimation, inclusion of explanatories, new analytic models, and properties of the estimates when the model is not true. The motivation for the latter is that time series with unusual structure seem to appear steadily. An example is the data being collected automatically via the World Wide Web. Researchers can be anticipated to be seeking extensions of existing time series methods to processes with more general definitions of the time label—spatial, spatial-temporal, functional, angular. At the same time they will work on processes whose values are more general, even abstract.

More efficient, more robust, and more applicable solutions will be found for existing problems. Techniques will be developed for dealing with special difficulties such as missing data, nonstationarity, outliers. Better approximations to the distributions of time series based statistics will be developed.

Many have stressed the advantages of linear system identification via white noise input. Wiener (1958) stressed the benefits of using Gaussian white noise input. This idea has not been fully developed. Indeed data sets obtained with this input will continually yield to novel analytic methods as they make their appearance.

The principal journals in which newly developed statistical methods for time series are presented and studied include: *Journal of Time Series Analysis*, *Annals of Statistics*, *Stochastic Processes and their Applications*, *Journal of the American Statistical Association*, *Econometrica*, *IEEE Transactions in Signal Processing*.

Time Series: Nonstationary Distributions and Unit Roots

1. Introduction

A stationary time series is one whose mean and variance are constant and the covariance between observations depends only on their separation in time. From a statistics point of view the distinction between stationary and nonstationary series is important because of its implications about the distributions of estimators. From an economics point of view, the distinction is important because certain economic theories imply nonstationarity and can be tested by looking for it in the data. There are questions about the impact of unanticipated shocks to an economic system. Do they produce permanent or transitory shifts in economic variables? This too boils down to a stationarity question. Diebold and Nerlove (1990) provide a long list of references in this area.

2. The Role of Nonstationary Processes and Unit Roots

When data are taken over time, a natural way to forecast future observations is to model the current observation Y_t as a linear combination of previous observations Y_{t-j}. Deviations from some deterministic function, such as a long run mean μ, are often the basis for prediction. Such a prediction is written as

$$\hat{Y}_t - \mu = \alpha_1(Y_{t-1}-\mu) + \alpha_2(Y_{t-2}-\mu) + \ldots + \alpha_p(Y_{t-p}-\mu)$$

For the usual *autoregressive model of order p*

$$Y_t - \mu = \alpha_1(Y_{t-1}-\mu) + \alpha_2(Y_{t-2}-\mu) + \ldots + \alpha_p(Y_{t-p}-\mu) + e_t$$

this predictor is the conditional expected value of Y_t given the past. Here e_t is *white noise*, that is, a sequence of i.i.d. $(0,\sigma^2)$ variates. One must estimate the α_i and μ parameters as well as the number p of lags to use. Early work by Mann and Wald (1943) established the asymptotic normality of parameters estimated by least squares regression of Y_t on $Y_{t-1},\ldots,Y_{t-p}$ for *covariance stationary* time series. A series is covariance stationary if it has a constant mean and the covariance between Y_t and Y_{t+h} is a function only of $|h|$ denoted by $\gamma(h)$ and called the autocovariance function. For an autoregressive series as defined above, covariance stationarity is ensured if the roots of the characteristic equation

$$1 - \alpha_1 m - \alpha_2 m^2 - \ldots - \alpha_p m^p = 0$$

are all greater than 1 in magnitude. In that case the covariance $\gamma(h)$ is bounded by some constant multiple of $(1/|m_{\min}|)^{|h|}$ where $m_{\min}$ is the root of the characteristic equation with minimum (closest to 1) magnitude.

For example if $p = 2$ lags, with $Y_{99} = 150$ and $Y_{100} = 120$, then using

$$(\mu,\alpha_1,\alpha_2) = (100, 0.9, -0.2)$$

the one-step-ahead forecast is $\hat{Y}_{101} = 108$ computed as

$$100 + 0.9(120-100) - 0.2(150-100) = 0.3(100) + 0.9(120) - 0.2(150)$$

while $(\mu,\alpha_1,\alpha_2) = (\mu, 1.2, -0.2)$ gives the forecast

$$\hat{Y}_{101} = \mu + 1.2(120-\mu) - 0.2(150-\mu) = 1.2(120) - 0.2(150) = 114$$

regardless of the value of μ. The characteristic equations factor as $(1-0.4m)(1-0.5m) = 0$ in the first and $(1-0.2m)(1-m) = 0$ in the second case. The *unit root* $m = 1$ in the second case is the reason that the forecast does not involve μ. A unit root series is nonstationary, having no tendency for mean reversion.

The bounding of the autocovariance by an exponentially decaying function in the stationary case makes the data sequence close enough to an uncorrelated sequence so that standard results like asymptotic normality of regression estimates will hold. While convenient from a statistical theory point of view, the exponentially decreasing covariance seems inconsistent with many observed data sets. Furthermore, exponential decay of the correlations implies that forecasts h steps into the future will approach the series mean at a rate bounded by $(1/|m_{\min}|)^{|h|}$.

Such quick reversion to the mean may at times seem unrealistic.

As a motivating example, suppose the price of a stock were represented as

$$Y_t - \mu = \alpha(Y_{t-1} - \mu) + e_t$$

an autoregressive process of order $p = 1$. The deviation of the current price from the historic mean should hold no information about future prices. If it did, the pattern would be known to intelligent market participants who would in turn bid the price up or down in such a way as to nullify the effect of the information. What does this say about α? It eliminates $|\alpha| < 1$, for then the prediction of Y_{t+h}, $\mu + \alpha^h(Y_t - \mu)$ would move toward the historic mean thus implying useful information in the knowledge of $Y_t - \mu$. Assuming that such knowledge is not informative suggests $\alpha = 1$, a testable hypothesis.

For $|\alpha| < 1$, the series can be represented as a convergent infinite sum

$$Y_t - \mu = \sum_{j=0}^{\infty} \alpha^j e_{t-j}$$

in which the effect of the unanticipated 'shocks' e_{t-j} in the distant past is negligible. However, for $\alpha = 1$ the recursive model becomes $Y_t = Y_{t-1} + e_t$, a simple *random walk* in which the mean μ has no apparent role and the only thing moving the stock price is the unanticipated (white noise) shock e_t. When $\alpha = 1$, Y_t becomes $Y_t = Y_1 + e_2 + e_3 + \ldots + e_t$ and the shocks e_t have a permanent effect. Each Y_t is Y_1 plus a sum of es so the deviation of Y_t from the average will not involve Y_1 nor will the residuals from any regression that includes an intercept. The assumptions on Y_1 will be irrelevant for any statistics computable from a regression with an intercept column.

In a more general context, whenever the characteristic equation has a unit root, the term μ drops out of the model, the forecasts do not revert to a historic mean, the forecast error variance grows without bound, and the distribution of the least squares regression estimates are not all normal even in the limit. Just as the reported Dow Jones average is usually followed by its difference, the 'up or down points' on the evening news, series with unit roots are often differenced prior to analysis in order to produce stationary series with nice statistical properties. The nonstationary series

$$Y_t - \mu = 1.2(Y_{t-1} - \mu) - 0.2(Y_{t-2} - \mu) + e_t$$

with a bit of algebra, is re-expressed as

$$Y_t - Y_{t-1} = 0.2(Y_{t-1} - Y_{t-2}) + e_t$$

This is a stationary autoregressive process in the differenced series $Y_t - Y_{t-1}$. The parameter 0.2 can be estimated by regressing the difference on its lag. In general

$$Y_t - \mu = \alpha_1(Y_{t-1} - \mu) + \alpha_2(Y_{t-2} - \mu) + e_t \text{ becomes}$$
$$Y_t - Y_{t-1} = -(1 - \alpha_1 - \alpha_2)(Y_{t-1} - \mu) - \alpha_2(Y_{t-1} - Y_{t-2}) + e_t$$

The coefficient of the lag level term $(Y_{t-1} - \mu)$ is seen to be the negative of the characteristic polynomial $1 - \alpha_1 m - \alpha_2 m^2$ at $m = 1$. This coefficient is 0 if and only if there is a unit root and is negative if the series is stationary.

The expression above gives a general method for testing the hypothesis of a unit root in autoregressions. Regress $Y_t - Y_{t-1}$ on $Y_{t-1}$and enough lags of $Y_t - Y_{t-1}$ to reproduce the autoregressive order of the series, then test to see if the coefficient of Y_{t-1} is 0. Of course to do that, one must have at hand the null distribution of the estimated coefficient and/or its t statistic. The work of Mann and Wald does not apply to a nonstationary series and in fact, the limit distributions are not normal. This does *not* imply that the regression t statistic is an inappropriate test. It does imply that a new distribution will need to be tabulated for it.

3. *Distributions for Unit Root Tests*

Starting very simply, assume $Y_t = \alpha Y_{t-1} + e_t$ or equivalently $Y_t - Y_{t-1} = (\alpha - 1)Y_{t-1} + e_t$ and $\alpha = 1$ is to be tested. If $\alpha = 1$, the regression of $Y_t - Y_{t-1}$on Y_{t-1} for $t = 2,3,\ldots,n$ gives regression coefficient

$$\sum_{t=2}^{n} Y_{t-1} e_t \Big/ \sum_{t=2}^{n} Y_{t-1}^2$$

(because $Y_t - Y_{t-1} = e_t$). Dickey and Fuller (1979) show that this statistic converges to 0 at rate $1/n$. The *normalized bias* statistic

$$n(\hat{\alpha} - 1) = \frac{1}{n\sigma^2} \sum_{t=2}^{n} Y_{t-1} e_t \Big/ \frac{1}{n^2\sigma^2} \sum_{t=2}^{n} Y_{t-1}^2$$

is of order 1. For stationary series $\sqrt{n}(\hat{\alpha} - \alpha)$ is the $O_p(1)$ normalization. Here the numerator and denominator quadratic forms have each been normalized to be $O_p(1)$. Dickey and Fuller derive a representation for the denominator using its eigenvalues. The limit is an infinite weighted sum of squared $N(0,1)$ variables. They derive the joint representation for the numerator and denominator in terms of these $N(0,1)$ variables and a method for simulating from the limit distribution. Empirical

Table 1
Limit-critical values for unit root tests (τ, τ_μ, τ_τ) compared to normal

Regress $Y_t - Y_{t-1}$ on	1 percent critical value	5 percent critical value
Y_{t-1} plus lagged differences	-2.58	-1.95
1, Y_{t-1} plus lagged differences	-3.42	-2.86
1, t Y_{t-1} plus lagged differences	-3.96	-3.41
(normal values)	-2.326	-1.645

percentiles appear in Fuller (1996). Matching of the large n and limit percentiles provides a check on the theory and computer simulations.

An alternative approach to the distribution of this statistic was suggested by White (1958, 1959) and shown in detail by Chan and Wei (1987) and by Phillips and his students in a series of papers; see for example Phillips and Perron (1988). This mathematically elegant approach expresses the limit distribution of the normalized bias statistic $n(\hat{\alpha}-1)$ in terms of a Weiner process $W(t)$ as

$$\frac{1}{2}(W^2(1)-1)/\int_0^1 W^2(t)dt$$

Billingsley (1968) gives the general theory for this type of convergence. The denominator and numerator are both random variables and the limit distribution is the same regardless of whether a quadratic form decomposition or Weiner Process representation is written, so the tables from Fuller (1996) are used either way.

The associated studentized statistic, called τ rather than t by Dickey and Fuller to emphasize its nonstandard distribution, converges to

$$\frac{1}{2}(W^2(1)-1)/\sqrt{\int_0^1 W^2(t)dt}$$

in the Weiner process representation and has a similar quadratic form representation. An exceptionally nice feature of τ is that its limit distribution under the null hypothesis is the same for higher order autoregressive processes.

4. *Beyond Autoregression*

For purely autoregressive processes, it has been seen that regression of the first difference on the lagged level and enough lagged differences gives a unit root test. The test on the lagged level term in the presence of lagged differences has become known as the augmented Dickey–Fuller test or ADF. Said and Dickey (1985) show that in mixed models (ARIMA models involving both lags of Y_t and e_t) direct nonlinear estimation of the parameters results in test statistics having the same limiting distributions as discussed above. Said and Dickey (1984) show that if one ignores the true mixed structure and simply fits a long enough autoregression, the asymptotics again give the previously discussed τ test. This has been quite reassuring for practitioners who often just use autoregressive representations at this stage of analysis. Hall (1994) studied methods for determining the correct number of lagged differences to include based on the data. Overfitting then testing to omit unnecessary lagged differences appeared to be a good way to prepare a model for unit root testing. With that in mind, a nice feature of unit root models in the ADF form is that the limit distribution of the regression t tests for the lagged difference terms have the usual standard limiting normal distributions, as in Mann and Wald (1943).

For higher order mixed models, Phillips and Perron (1988) regress the difference on the lagged level as though a lag one model is appropriate. They then adjust the test statistics based on the autocorrelation function of the differenced series which, of course, must be estimated. Decisions on how to estimate these autocorrelations and how many of them to use in the adjusting process must be made, just as a decision on how many lagged differences to use must be made in the ADF test. The method uses the same critical values as ADF. All methods are justified by asymptotics. The finite sample power and adherence to the claimed significance level will differ. Schwert (1989) provides a comparison.

5. *Models with Deterministic Parts*

In a usual regression problem, under the null hypothesis the t test for a regression coefficient has a t distribution in a properly specified model regardless of what other terms are in the model. Unfortunately the same is not true of τ in unit root testing. For example, a lag 1 model with a trend and autocorrelation might be posed as

$$(Y_t-\beta_0-\beta_1 t) = \alpha(Y_{t-1}-\beta_0-\beta_1(t-1))+e_t$$

or equivalently in two parts as $Y_t = \beta_0+\beta_1 t+Z_t$ where $Z_t = \alpha Z_{t-1}+e_t$. Now if $|\alpha| < 1$ we have stationary errors around a trend, or *trend stationarity* as it is

known in the econometric literature. On the other hand if $\alpha = 1$ our model becomes

$$Y_t = Y_{t-1} + \beta_1 + e_t$$

known as a random walk with drift β_1. In order to estimate the model well under both the null and alternative hypotheses, one regresses $Y_t - Y_{t-1}$ on Y_{t-1}, 1, and t, then tests the coefficient of Y_{t-1} using its studentized statistic τ_t. Even if the process is a simple random walk, this test has neither a limit normal distribution nor the limit obtained when regressing $Y_t - Y_{t-1}$ on just Y_{t-1}. The limit distributions for both normalized bias and studentized statistics change when an intercept and/or trend are added to the regression.

The 1 percent and 5 percent critical values from the limit distribution of the studentized test statistic for cases in which one regresses the first difference on a lagged level and lagged differences (τ) are given in Table 1, along with the corresponding critical values when an intercept (τ_μ) or both an intercept and time (τ_τ) are included. These are tabulated under the unit root null hypothesis. The familiar normal distribution critical values are also shown for comparison.

Clearly the naive use of normal or t critical values in this time series setting will result in far too many spurious declarations of stationarity, even in extremely large samples. From the table it is seen that the problem worsens with the fitting of deterministic mean and trend components. Models containing 1 (and t) are invariant to nonzero means (and deterministic trends) in the data. That is, the calculated test statistics used in rows 2 and 3 will remain exactly the same if an arbitrary constant is added to the data, while that in the third row will be unchanged by the addition of an arbitrary linear trend. In discussing trends, it is important to recall that under the $\alpha = 1$ null hypothesis, a trend is induced by a nonzero β_1 in the model $Y_t = Y_{t-1} + \beta_1 + e_t$.

6. Beyond Regression

In an attempt to increase the power of unit root tests, several alternative estimation methods have been tried. Dickey et al. (1984) introduce a symmetric estimator which combines the regression of Y_t on past Ys with a regression of Y_t on future Ys. Fuller (1996) discusses this and a weighted symmetric estimator. Elliott et al. (1996) base a test statistic on the following clever idea. Pick a point in the alternative that depends on n, say $\alpha = 1 - 0.7/n$. Now find the point optimal test of $\alpha = 1$ vs. the simple alternative $\alpha = 1 - .7/n$. Counting on the continuity of the power curve, that test should give good power over a range of alternative points near that for which it is point optimal.

The estimator that maximizes the stationary normal likelihood function performs slightly better than least squares in the stationary case. Looking at this likelihood function as simply an objective function to be maximized, Gonzalez-Farias (1992) and Gonzalez-Farias and Dickey (1999) compute its maximum for a unit root process defining what she calls the *unconditional maximum likelihood* estimator. She gets representations for it including cases with intercepts and trends in the model. In a comparison study by Pantula et al. (1994) this estimator and Fuller's weighted symmetric estimator have very similar behavior and seem to be the best performers of the tests mentioned here. All tests described in this section require new tables of critical values which the corresponding authors provide.

7. Related Topics

Unit roots can arise in multivariate time series, that is, in cases where a vector of observations is recorded at each time point. In such cases, there may be some linear combinations of the vectors that form stationary time series and other linear combinations that are nonstationary. These results appear under the name 'co-integration analysis' and 'reduced rank regression.' Another recent area of research is 'trend breaks.' There might be one mean during the first period of data collection and a second one later. How do unit root tests perform if the break is undiscovered? Can we discover the break point? Is it possible that series we thought were nonstationary are in fact stationary around two or three different means? Seasonal unit roots and methods of decomposing them are also currently popular topics.

Time Series Quasi-experiment

Campbell and Stanley (1963), Campbell (1963) recommend the time series quasi-experiment for assessing the causal effect of a discrete intervention on a time series. In the simplest case of this design, a discrete intervention breaks a time series into pre- and post-intervention segments of N_{pre} and N_{post} observations. For pre- and post-intervention means μ_{pre} and μ_{post}, analysis of the quasi-experiment tests the null hypothesis

$$H_0\colon \omega = 0 \text{ where } \omega = \mu_{post} - \mu_{pre} \qquad (1)$$

Rejecting H_0, H_A attributes ω to the intervention. The validity of H_A can be challenged on the two grounds that Cook and Campbell (1979) call 'threats to internal validity' and 'threats to statistical conclusion validity.' Whereas the threats to internal validity apply to quasi-experiments generally, the threats to statistical conclusion validity, which arise because the time series observations are sampled sequentially, distinguish this design from other quasi-experiments. Whereas the threats to internal validity are controlled by design, a statistical model must control the threats to statistical conclusion validity.

1. Internal Validity

Although in principle, all eight of the threats to internal validity discussed by Campbell and Stanley (1963) apply to the time series quasi-experiment, four threats are inherently plausible. The threats of history and maturation are plausible due to the design's relatively long time frame and to the nature of long time series. The threats of instrumentation and regression are plausible due to the nature of planned interventions; for unplanned interventions, a special case that Campbell (1969) calls the 'natural experiment,' neither threat is plausible.

Hennigan et al. (1982) use the time series in Fig. 1 to document an increase in property crime following the introduction of commercial television. In 34 'early' and 34 'late' cities, television broadcasting begins in 1950 and 1954, respectively. If the two time series are considered separately, history is a plausible threat to the internal validity of both effects. The 'late' effect may be due to an economic recession that began in 1955, for example, and the 'early' effect may be an artifact of the Korean War mobilization. As husbands were called away to military service and wives joined the workforce, homes were left undefended against property criminals. Although history is a plausible threat to the internal validity of each effect, however, it is implausible for the joint effect.

The other three common threats to internal validity are less robust to standard designs. Fig. 2 shows monthly burglaries for Tucson before, during, and after an intervention (McCleary et al. 1982). Prior to 1979, burglaries were investigated by uniformed police officers. When this task was taken over by detectives, burglaries dropped abruptly. Two years later, when the task was transferred back to uniformed officers, burglaries returned abruptly to pre-1979 levels. While the on-off component of this design rules out the threat of history, the other threats are still plausible. In fact, this effect is entirely explained by differences in the way detectives and uniformed officers keep records; it is an instrumentation artifact.

Because interventions often affect the way in which a target phenomenon is measured, instrumentation is always a plausible threat to the evaluation of planned interventions. Regression threats are also associated with planned interventions but for different reasons. Following a 1955 traffic 'crackdown' in Connecticut, for example, highway fatalities dropped significantly. Examining a long time series, however, Campbell and Ross (1968) show that the reduction was largely due to an uncontrolled regression threat. The 'crackdown' was implemented in 1955 because traffic fatalities in

Figure 1

Figure 2
Monthly burglaries for Tucson, 1975–1981. Source: McCleary et al. (1982)

that year were abnormally high; regression to the mean was virtually guaranteed.

Unlike history and instrumentation, which are controlled by design, a statistical model controls regression. The opportunistic timing of the intervention biases the estimates of the pre- and post-intervention means, μ_{pre} and μ_{post}. As N_{pre} and N_{post}, grow longer, this bias approaches zero and, accordingly, authorities on the statistical model recommend $N_{pre} + N_{post} > 50$ (McCleary and Hay 1980, McDowall et al. 1980).

Like regression, the statistical model controls maturation. Because secular trend or stochastic drift generates this threat, and because these properties are found in most long social science time series, maturation is plausible in virtually all time series quasi-experiments.

Fig. 3 shows a weekly productivity series from the Hawthorne experiment. From 1927 to 1932, researchers manipulated daily rest breaks and, though not conducting a formal analysis, claimed that rest breaks had a large, positive impact on productivity. However, formal analyses of these data challenge the original finding. Regressing step functions coded for three 'punishments' regimes, Franke and Kaule (1978) demonstrate that the productivity increases were motivated by fear.

The fundamental problem with this interpretation, as well as with the original interpretation, is that the productivity time series exhibits a systematic trend throughout its history. To the extent that the bank wiring room machine operators were becoming more productive over time, maturation is a plausible threat to the internal validity of both interpretations.

To illustrate the problem, the punishment effects estimated by Franke and Kaule are plotted against the

Figure 3
Weekly productivity measures for five machine operators in the first bank wiring room (Hawthorne) experiment. Estimated step function effects are plotted against the series. Source: Franke and Kaul (1978)

productivity series in Fig. 3. The effects are collinear with the natural trend of this series. Reanalysis of these data with a difference equation model controlling for trend finds a modest but significant effect for rest breaks and no effect for punishment (McCleary 2000).

2. *Statistical Conclusion Validity*

Reliance on a sophisticated statistical model distinguishes the time series quasi-experiment from other quasi-experimental designs. Although times series designs appear in the social science literature as early as the nineteenth century, without a statistical model, the design offered little advantage over a simpler, more economical pre-post design. In the year 2000, the most widely used statistical model for the time series quasi-experiment was the *A*utoRegressive *I*ntegrated *M*oving *A*verage (ARIMA) model (Box and Jenkins 1970, McCleary and Hay 1980. A statistically adequate ARIMA model controls the maturation threat to internal validity and all relevant threats to statistical conclusion validity.

The seven threats to statistical conclusion validity discussed by Cook and Campbell (1979, pp. 42–4) refer to misstatements of the Type I and Type II error rates. A Type I error occurs whenever a true H_0 is rejected; at the nominal 0.95 confidence level, the Type I error rate is $\alpha = 0.05$. A Type II error occurs whenever a false H_0 is accepted; at the nominal 0.80 power level, the Type II error rate is $\beta = 0.2$. Threats to statistical conclusion validity distort the nominal values of α and β resulting in false inferences about the hypothetical impact of an intervention; that the intervention had a significant impact in the Type I case, or that the intervention had no impact in the Type II case.

The Type II threats to statistical conclusion validity are relatively straightforward in explication and control. Not withstanding the magnitude of an impact—small effects are difficult to detect in even the best circumstances—the statistical power of the time series quasi-experiment is a function of series length, balance, and model adequacy. Because estimation algorithms rely on large sample properties, analyses of short time series will often fail to achieve the nominal level of statistical power. Given a long time series, say $N \geqslant 50$ observations, statistical power is at its maximum when $N_{pre} = N_{post}$. Given a long time series and a balanced design, however, statistical power assumes a statistically adequate model; i.e., a model that adequately decomposes the series into a stochastic component that is unrelated to the intervention and into a component that is related to the intervention.

The Type I threats to statistical conclusion validity, which have received greater attention in the literature, are associated with common stochastic time series properties, particularly trend or drift and autocorrelation. And since the time series model controls these properties, all Type I threats are a function of a model property called statistical adequacy.

Virtually all of the models used to analyze time series quasi-experiments are based on the *A*uto-Regressive *I*ntegrated *M*oving *A*verage (ARIMA) model (Box and Jenkins 1970, McCleary and Hay 1980. The general ARIMA model can be written as,

$$\varphi(B)\nabla Y_t = \theta(B)a_t + \omega(B)I_t \qquad (2)$$

where Y_t, a_t, and I_t are, respectively, the tth observations of a time series, an independently, identically distributed (*iid*) Normal error series, and a step function defined such that $I_t = 0$ t N_{pre} and $I_t = 1$ thereafter; where $\varphi(B)$ and $\theta(B)$ are polynomial lag operators; where $\omega(B)I_t$ is a transfer function of I_t; and where ∇ is a differencing operator. When the inter-

vention has had no impact on the series, H_0 is true so $\omega = 0$ and the ARIMA model reduces to

$$\varphi(B)Y_t = \theta(B)a_t \tag{3}$$

This simpler form reveals the statistical rationale for the three operators.

The threat to statistical conclusion validity posed by the most common nonstationary properties of time series, trend or drift is illustrated in the productivity series (Fig. 3). In a trending series, any arbitrary intervention biases the estimates of μ_{pre} and μ_{post} and, thus, the test of H_0. Assuming a homogeneous nonstationary time series, however, the differencing operator, ∇, transforms the nonstationary Y_t to a stationary form. If Z_t denotes the differenced time series,

$$Z_t = \nabla Y_t = Y_t - Y_{t-1} \tag{4}$$

Then Z_t retains the fundamental characteristics of the original time series, at least with respect to the hypothetical impact of the intervention, but is flat or trendless.

Although differencing controls the threats to statistical conclusion validity posed by trend or drift, Z_t is not necessarily *iid*. On the contrary, successive values of the differenced time series will ordinarily be highly correlated and autocorrelation poses a separate threat to statistical conclusion validity. Contrary to popular belief, unlike trend or drift, autocorrelation cannot be seen in most time series. Nevertheless, the autocorrelation threats are potent and plausible in most time series quasi-experiments.

In the ARIMA model, the threats due to autocorrelation are controlled by the polynomial lag operators, φ(B) and θ(B). If the parameters of φ(B) and θ(B) are restricted a range of values where the operators have algebraic inverses, the model can be solved for the *iid* error term.

$$a_t = \theta(B)^{-1}\,\varphi(B)Z_t \tag{5}$$

Because the *iid* time series satisfies the assumptions of an ANOVA model, μ_{pre} and μ_{post} can be estimated with conventional maximum likelihood methods.

Although the ARIMA model controls all threats to statistical conclusion validity in principle, in practice the ARIMA model must satisfy two criteria. First, the inverted model must yield an *iid* time series; this criterion has been called statistical adequacy. Second, among all statistically adequate ARIMA models, the final model must have the minimum residual variance. The first criterion pertains to Type I threats and can be tested empirically. Given that there are many statistically adequate models for most time series, the second criterion has no firm empirical sign. If the final ARIMA model does not have a minimum residual variance, statistical power will be less than optimal and a Type II threat will be plausible. This suggests the need for conducting formal analyses of statistical power whenever H_0 cannot be rejected.

3. *External Validity*

Although components of the ARIMA model were available as early as 1920 (e.g., Slutzky 1927, Yule 1927), practical applications of the model required computing resources that were unavailable before 1970. In an appendix to *Time Series Analysis: Forecasting and Control*, Box and Jenkins (1970) described a general algorithm for building ARIMA models from time series. Implementations of the algorithm became available shortly after 1970. Modern time series software packages, which are included in virtually all-commercial statistical analysis systems, use the original Box and Jenkins (1970) modeling algorithm.

As software became more widely available, after 1980 applications of the time series quasi-experiment began to accumulate. In evaluation research, effect estimates of replicated social programs often-supported discrepant substantive inferences about the program's effectiveness. The literature evaluating the effectiveness of gun-control legislation is typical in that the published estimates include both positive, negative, and null effect estimates (Reiss and Roth 1993, pp. 255–87). Whereas a small proportion of randomly distributed null effects can be ignored, a broader range of quasi-experimental effect estimates suggests that the inter-replication variance is more important than the general effect itself.

This raises questions of external validity which, following Cook and Campbell (1979, p. 71) concern 'generalizing across types of persons, settings, and times.' The external validity of several time series quasi-experiments can be analyzed in either of two ways. First, the set of k time series can be defined as vector time series, $\mathbf{Y}_t$:

$$\mathbf{Y}_t' = \{Y_{1,t}, Y_{2,t}, \ldots, Y_{k,t}\} \tag{6}$$

The vector $\mathbf{Y}_t'$ can then be analyzed as a vector *ARIMA* process (e.g., McGaw and McCleary 1985). Second, variance in the set of k reported effect estimates,

$$\omega' = \{\omega_1, \omega_2, \ldots, \omega_k\} \tag{7}$$

can be decomposed into components associated with threats to external validity. Since the second approach is a special, restricted case of fitting the set of k related quasi-experiments into a vector ARIMA model; the first approach is preferred. In practice, unfortunately, few time series satisfy the rigid assumptions required for a vector ARIMA model.

Though less general, the second approach is more practical and flexible in most situations. The statistical

models used to analyze the set of k related effect estimates, which were originally developed in meta-analysis or research synthesis, decompose the effect variance into components that can be attributed to setting (place, historical period, etc.), properties of the intervention (resources devoted to the intervention, mode of implementation, etc.), methodology (time series properties, dependencies, etc.), and other potential threats to external validity. McDowall et al. (1992) demonstrate this method for combining effect estimates from evaluations of gun control laws; McCleary (2000) uses a similar model for combining effect estimates from the Hawthorne experiment plotted in Fig. 3.

4. Future Directions

At this point in its development, solutions to the questions of internal validity have been proposed, tested, and accepted. Although solutions to the questions of external validity are still too novel to enjoy the same level of consensus, it appears that the currently available solutions will become more widely used in the near future. The unresolved problems relate to statistical conclusion validity. The problems of missing data and short time series (e.g., $N < 30$ observations) pose a particular need.

Time Series: Seasonal Adjustment

Time series data are often subject to various adjustments among which seasonal adjustment is one of the most common. Seasonal adjustment means the removal of seasonal variations from the original series. Seasonality represents the composite effect of climatic and institutional events which repeat more or less regularly every year. One main reason for seasonal adjustment is the standardization of socioeconomic series because seasonality affects them with different timing and intensity. Hence, the seasonally adjusted data reflect variations due only to the remaining components, trend, cycle, and irregulars. The infor-

mation given by seasonally adjusted series plays a crucial role in the analysis of current economic conditions and provides the basis for decision making and forecasting, being of major importance around cyclical turning points. This article discusses the main characteristics of seasonal variations, common statistical seasonal models and several seasonal adjustment methods with emphasis on those widely applied by statistical agencies.

1. *The Main Characteristics of Seasonality*

The impact of seasonality in socioeconomic activities has long been recognized. Seasonal variations in agriculture, the low level of winter construction and high pre-Christmas retail sales are all well known. The four major causes of seasonality are the weather, the composition of our calendar, timing decisions, and expectations. These causes are mainly exogenous to economic systems but human intervention can modify their extent and nature. Thus, seasonal variations in the automobile industry are affected by manufacturers' decisions regarding the extent of model changeover each year; seasonality in the money supply and related series can be controlled by central banks' decisions on the interest rate. Another characteristic of seasonal variations is that although they repeat annually with certain regularity, they may evolve. Many causes can produce an evolving seasonality, for example, changes in technology alter the importance of climatic factors; customs and habits are affected by different distributions of income and thus, can modify the seasonal demand pattern for certain goods. For most time series, moving seasonality is more the rule than the exception. Depending on the main causes of the seasonal variations, these can change slowly or rapidly, in a deterministic or a stochastic manner or a mixture of both. A third important feature of seasonality is the feasibility of its identification even if it is a latent (non-directly observable) variable. The identification and estimation of seasonality, however, is not done independently of the other components affecting the series under study. Traditionally, three other components have been distinguished, namely; the trend, the cycle, and the irregulars. The trend reflects long term movements lasting many years. It is generally associated with structural causes, for example, institutional events, demographic and technological changes, new ways of organization. The cycle, usually referred to as business cycle, is a quasiperiodic oscillation characterized by periods of expansion and contraction. It lasts from 3–5 years on the average. In much analytical work, the trend and the cycle are combined because, for series covering a short period of time, the long-term trend cannot be estimated adequately. Finally, the irregulars represent unforeseeable movements related to events of all kinds. In general, the irregular component has a stable random appearance but, in some cases, it may include extreme variations or outliers with well identifiable causes, for example, floods, severe winters, strikes.

The seasonal variations can be distinguished from the trend by their oscillatory character, from the business cycle by having annual periodicity and from the irregulars by being systematic.

For series characterized by flows such as sales, production, other variations associated with the composition of the calendar have also been recognized. Of these, the most important are the 'trading-day' variations which represent the 'within-month effects' due to the number of times that each day of the week

Figure 1

Figure 2
Seasonal component—Canadian unemployed women over 25

Figure 3
Trend cycle—Canadian unemployed women over 25

occurs in a calendar month; and moving holidays effects, such as those due to Easter which can fall in consecutive months or quarters depending on the year. These variations attributed to the calendar are usually treated as seasonal in character and removed together with the other seasonal variations when producing a seasonally adjusted series.

For illustrative purposes, Fig. 1 shows the pattern of an observed time series (Canadian Unemployed Women, 25 years old and over, from 1979 to 1997) which is affected strongly by both seasonality and the business cycle, but their effects cannot be inferred by simply looking at the graph. The various components estimated with the X11ARIMA method are shown in Figs. 2–4. Figure 2 exhibits the seasonal variations that are characterized by two peaks and two troughs. A large peak is observed in August and a secondary one in March whereas the maximum trough corresponds to the month of December followed closely by another in June. Furthermore, it is apparent that seasonality evolves with increasing amplitude. The effects of the trend-cycle are shown in Fig. 3 with two large jumps in 1981–82 and 1990–91 which are recession years. The irregulars exhibited in Fig. 4 are generally small except for a few cases where extreme values are present. Finally, the seasonally adjusted

Figure 4
Irregular component—Canadian unemployed women over 25

Figure 5
Seasonally adjusted series—Canadian unemployed women over 25

data are shown in Fig. 5 clearly indicating that the impact of seasonality has been removed from the original series. The seasonally adjusted series contains the effects of the trend-cycle and those of the irregular component and, therefore, it is less smooth than the trend-cycle shown in Fig. 3.

2. *Seasonal Models*

The most often discussed seasonal models can be classified as deterministic or stochastic according to the assumptions made concerning the time evolution of the seasonal pattern.

The simplest and often studied seasonal model assumes that the generating process of seasonality can be represented by strictly periodic functions of time of annual periodicity. The problem is to estimate s seasonal coefficients (s being the seasonal periodicity, e.g., 12 for monthly series, 4 for quarterly series) subject to the seasonal constraint that they sum to zero.

This regression seasonal model can be written as

$$Y_t = S_t + \varepsilon_t, \quad t = 1,\ldots, T;$$

$$S_t = \sum_{j=1}^{s} \gamma_j d_{jt} \quad \text{subject to} \quad \sum_{j=1}^{s} \gamma_j = 0 \tag{1}$$

where the d_j's are dummy variables taking a value of unity in season j and a value of zero otherwise; $\{\varepsilon_t\} \sim \mathrm{WN}(0, \sigma_\varepsilon^2)$ is a white noise process with zero mean, homoscedastic, and nonautocorrelated. The seasonal parameters γ_j's can be interpreted as the expectation of Y_t in each season and represent the seasonal effects of the series under question. Since the parameters are constant, the seasonal pattern repeats exactly over the years, that is,

$$S_t = S_{t-s}, \quad \text{for all } t > s \tag{2}$$

Eqn. (1), often included in econometric models, assumes that the effects of the seasonal variations are deterministic because they can be predicted with no error. However, for most economic and social time series, seasonality is not deterministic but changes gradually in a stochastic manner. One representation of stochastic seasonality is to assume in regression Eqn. (1) that the γ_j's are random variables instead of constant. Hence, the relationship, Eqn. (2), becomes

$$S_t = S_{t-s} + \omega_t, \quad \text{for all } t > s \tag{3}$$

where $\{\omega\} \sim \mathrm{WN}(0, \sigma_\omega^2)$ and $\mathrm{E}(\omega_t \varepsilon_t) = 0$, for all t. The stochastic seasonal balance constraint is here given by $\sum_{j=0}^{s-1} S_{t-j} = \omega_t$ with expected value equal to zero.

Eqn. (3) assumes seasonality to be generated by a nonstationary stochastic process. In fact, it is a random walk process and can be made stationary by seasonal differencing $\nabla_s = (1 - B^s)$ where B denotes the backward shift operator. In reduced form, the corresponding regression model is a linear combination of white noise processes of maximum lag s. Since $(1 - B^s) = (1 - B)(1 + B + \ldots + B^{s-1})$, model-based seasonal adjustment methods attribute only $S(B) = \sum_{j=0}^{s-1} B^j$ to the seasonal component leaving $(1 - B)$ as part of a nonstationary trend. Thus, the corresponding seasonal stochastic model can be written as

$$S(B) S_t = \omega_t, \tag{4}$$

Eqn. (4) represents a seasonality that evolves in an erratic manner and it is often included in seasonal adjustment methods based on structural model decomposition (see, e.g., Harvey 1981, Kitagawa and Gersch 1984). This seasonal behavior is seldom found in observed time series where seasonality evolves smoothly through time. To represent this latter, Hillmer and Tiao (1982) introduced a major modification

$$S(B) S_t = \eta_s(B) b_t \tag{5}$$

where the left-hand side of Eqn. (5) follows an invertible moving average process of maximum order $s-1$, denoted by MA($s-1$). Eqn. (5) is discussed extensively in Bell and Hillmer (1984) and can be generalized easily by replacing the MA part with stationary invertible autoregressive moving average (ARMA) processes of the Box and Jenkins (1970) type. Depending on the order of the ARMA process a large variety of evolving stochastic seasonal variations can be modeled.

Other seasonal models used in regression methods where the components are assumed to be local polynomials of time, are based on a smoothness criterion. For example, given $Y_t = S_t + \varepsilon_t$, $t = 1, \ldots, T$, restrictions are imposed on S_t, such that, $\sum_t (S_t - S_{t-s})^2$ and $\sum_t [S(B) S_t]^2$ be small. The solution is given by minimizing a weighted linear combination of both criteria as follows

$$\sum_{t=1}^{T} (Y_t - S_t)^2 + \alpha \sum_{t=1}^{T} (S_t - S_{t-s})^2 + \beta \sum_{t=1}^{T} [S(B) S_t]^2 \tag{6}$$

where the ill-posed problem of choosing the α and β parameters was solved by Akaike (1980) using a Bayesian model.

Finally, mixed seasonal models with deterministic and stochastic effects are given in Pierce (1978).

3. Seasonal Adjustment Methods

The seasonal adjustment methods developed so far are based on univariate time series decomposition models with no causal explanation for any of the components involved. It is difficult to classify existing methods into mutually exclusive categories. However, it is possible to group the majority of seasonal adjustment methods into two main classes, one based on moving average techniques and the other on explicit models with a small number of parameters for each component.

3.1 Moving Average Methods

The best known and most often applied seasonal adjustment methods are based on moving averages or time-invariant smoothing linear filters applied sequentially by adding (and subtracting) one observation at a time. These methods assume that the time series components change through time in a stochastic manner. Given a time series Y_t, $t = 1, \ldots, T$, for t far removed from both ends, say $m + 1 \leqslant t \leqslant T - m$ the seasonally adjusted value Y_t^a is obtained by application of a symmetric moving average (linear smoothing filter) $h_m(B)$

$$Y_t^a = h_m(B) Y_t = \sum_{j=-m}^{m} h_{m,j} Y_{t-j}, \tag{7}$$

where the weights $h_{m,j}$ are symmetric, that is, $h_{m,j} = h_{m,-j}$ and the length of the filter is $2m + 1$. For current

and recent data ($T-m < t \leqslant T$) a symmetric filter cannot be applied and, therefore, truncated asymmetric filters are used. For example, for the last available observation Y_T, the seasonally adjusted value is given by

$$Y_T^a = h_0(B)Y_T = \sum_{j=0}^{m} h_{0,j} Y_{T-j}. \tag{8}$$

The asymmetric filters are time varying in the sense that different filters are applied for the $m+1$ first and last observations. The end estimates are revised as new observations are added because of: (a) the new innovations and (b) the differences between the asymmetric and symmetric filters. The estimates given by symmetric filters are called 'final.'

The development of electronic computers contributed to major improvements in seasonal adjustment methods based on moving averages and facilitated their massive application.

In 1954, Julius Shiskin of the US Bureau of the Census developed software, called Method I, based mainly on the works of Macaulay (1931) already applied by the US Federal Reserve Board for seasonal adjustment. Census Method I was followed by Census Method II and 11 more experimental versions (X1, X2,…, X11). The best known and widely applied is the X11 variant (Shiskin et al. 1967). This method, however, produces poor seasonally adjusted estimates for the most recent observations that are of crucial importance to assess the direction of the short-term trend and the identification of a cyclical turning point in the economy. Dagum (1978) developed the X11ARIMA method to correct for this serious limitation.

The X11ARIMA method consists of: (a) modeling the original series with an autoregressive integrated moving average (ARIMA) model of the Box and Jenkins (1970) type, (b) extending the observed series with 1–3 years of extrapolated values from an ARIMA model that fits and extrapolates the data well according to well-defined acceptance criteria, and (c) estimating each component with moving averages that are symmetric for middle observations and asymmetric for both end years. The latter are obtained from the convolution of the smoothing linear filters of Census Method II- X11 variant and those of the ARIMA model extrapolations.

For flow series, deterministic components such as trading-day variations and Easter holiday effects are estimated with dummy variable regression models and removed from the series, so that only the remainder is subject to steps (a) to (c) above. This sequential procedure is followed by the X11ARIMA/88 and X11ARIMA/2000 computer packages developed at Statistics Canada which are today the most widely applied by statistical agencies for the seasonal adjustment of official statistics. Another recent software called X12ARIMA developed by Findley et al. (1998) of the US Bureau of the Census offers a RegARIMA option that enables the estimation of the deterministic components simultaneously with the ARIMA model for extrapolation. It also includes an option for analysis of revisions to most recent estimates and spectral techniques to assess the goodness of the seasonal adjustment.

All the moving average methods here discussed are *nonlinear* and consequently, the seasonally adjusted total of an aggregated series is not equal to the sum of the seasonally adjusted series that enter into the aggregation. The main causes of nonlinearity result from the use of: (a) a multiplicative decomposition model for the unobserved components, (b) the automatic procedure for the identification and replacement of extreme values, (c) the ARIMA model extrapolations, and (d) the automatic selection of moving averages for the estimation of the trend-cycle and seasonality.

The properties of the combined linear filters applied to estimate the various components were originally studied by Young (1968) for a standard option. Later, Dagum et al. (1990) studied the properties for all the symmetric and asymmetric linear filters of Census X11 as well as those of the X11ARIMA. Although these methods lack explicit models for the unobserved components, Cleveland and Tiao (1976) and Burridge and Wallis (1984) have found ARIMA models which can approximate well some of the linear filters used for the trend-cycle and seasonal components.

3.2 Model-based Seasonal Adjustment Methods

The best known among the model-based methods are: (a) the *regression* methods with globally or locally deterministic models for each component and, (b) stochastic-model-based methods that use ARIMA models.

3.2.1 Regression methods. Seasonal adjustment by regression methods is based on the assumption that the systematic components of a time series can be approximated closely by simple function of times over the *entire* span of the series. In general, two types of functions of time are considered. One is a polynomial of fairly low degree to represent the trend component; the other, linear combinations of sinusoidal functions with different periodicity and fixed amplitude and phase, to represent the cycle and seasonality. To overcome the major limitation of using global deterministic representations for the trend-cycle and seasonality, regression methods were extended to incorporate stochastic representations of the components by means of local polynomials (spline functions) for successive short segments of the series and introduc-

ing changing seasonal amplitudes. The estimated values were still significantly affected at the beginning and end of the series by the choice of the functions for each component. A major breakthrough on this direction was made by Akaike (1980) who introduced prior constraints to the degree of smoothness of the trend-cycle and seasonality and solved the problem by a Bayesian modeling. Another important contribution is a regression method with locally deterministic models estimated by the loess (locally weighted regression) smoother, developed by Cleveland et al. (1990).

3.2.2 Stochastic-model-based methods. Stochastic-model-based methods were mainly developed during the 1980s following two different approaches. One is known as seasonal adjustment by signal extraction (Burman 1980) or as ARIMA-model-based seasonal adjustment (Hillmer and Tiao 1982), and the other referred to as structural model decomposition method (see, e.g., Harvey 1981). The major difference between these two approaches is that in the latter simple Gaussian ARIMA models are directly specified for each unobserved component whereas in the former an overall Gaussian ARIMA model is obtained from observable data and by imposing certain restrictions, models for each component are derived.

Since the components are unknown, to obtain a unique decomposition from the overall ARIMA model fitted to the observed series, Hillmer and Tiao (1982) proposed a canonical decomposition which has the properties, among others, of maximizing the variance of the white noise component and minimizing the variance of the stochastic seasonal model.

ARIMA models are very sensitive to outliers and cannot handle deterministic components such as trading-day variations and moving holidays that can be present in flow series. Therefore, further developments were made by combining dummy variables regression models with ARIMA errors to deal with these cases. In this regard, Gomez and Maravall (1996) developed software for seasonal adjustment using ARIMA models with exogenous regressors.

On the other hand, the structural model decomposition method starts directly with an observation equation (sometimes called measurement equation) consisting of the unobserved components, trend-cycle, seasonality, and irregulars (trading-day variations and moving holidays effects can also be included if present). Simple ARIMA or stochastic trigonometric models are assumed for each component. The structural model is cast in a state-space form and often estimated with Kalman filtering and smoothing. Koopman et al. (1998) developed software for structural model seasonal adjustment, which includes several types of models for each component. Model-based seasonal adjustment methods are seldom used by statistical agencies. The main reason for this is the fact that the models are very restrictive and, thus appropriate only for a limited class of series, particularly, highly aggregated data. Furthermore, they have not yet proved to be superior to official moving average methods concerning the two most important conditions for seasonal adjustment, namely, stability of the estimates and lack of residual seasonality in the seasonally adjusted data.

4. Conclusion

Seasonal adjustment plays a significant role in the analysis of current social and economic conditions, particularly in determining the stages of the business cycle at which the economy stands. Such knowledge provides the bases for decision making to control the level of economic activity and it is of major importance around turning points.

The fact that seasonality and the other time series components change through time leads to major modifications of the traditional methods based on moving averages and to the development of new ones mainly based on ARIMA models.

During the 1990s, major financial, economic, and ecological changes of a global character have introduced more variability in time series and, consequently, in their seasonally adjusted values, making it very difficult to determine the direction of the short-term trend for an earlier detection of a turning point. As a consequence, producers and users of seasonally adjusted data have centered their attention on the need for further smoothing. In this regard, new research in seasonal adjustment has been oriented toward a better estimation of the trend-cycle for current economic analysis, including parametric and non-parametric approaches as well as linear and nonlinear smoothers. The presence of many outlying observations have also stimulated research on nonlinear and non-Gaussian models for seasonal adjustment.

For information on trend-cycle estimation the reader may refer to Kenny and Durbin (1982), Maravall (1993), Dagum (1996), Dagum and Luati (2000), and references given therein. More information on seasonal adjustment theory and practice can be found in Hylleberg (1992) and Zellner (1978, 1983).

Time–Space in Geography

Geographers have always regarded space and time as fundamental attributes of reality. However, significant variations have existed in the meaning associated with these concepts. The independence of space and time, where each concept provides a separate frame of reference for positioning objects and events, is seen in both regional studies and in attempts to cast geography as a purely spatial science. In contrast, the merger of time and space into the singular notion of time–space has for many researchers become the ideal in concept if not in practice.

1. *Absolute vs. Relative Views of Time and Space*

Immanuel Kant (1724–1804), less noted for instruction in physical geography at the University of Königsberg than for his broader theory of knowledge, was instrumental in laying a philosophical basis for treating time and space as *a priori* separate from each other, with absolute dimensions validated through human experience. In contrast to Kant's view, the inseparability of space and time is embraced in the concept of time–space as a single definable dimension of reality, where one cannot have space without time, and vice versa. This perspective, one of the foundations of relativity theory, conceives time–space in relationship to the movement of material objects and to events. Conceptually, the coincidence of time and space is easy to grasp—any object or event embraces simultaneously positions in time and in space (e.g., tossing a ball and observing its flight).

From an operational and measurement perspective, researchers often return to the Kantian view, treating the separation of time and space as a practical necessity. Geographers have attempted to work around this difficulty in two principal ways. First, explanatory and descriptive models (e.g., Walter Christaller's central place theory) may be used to consider the human settlement system at different points in time as a means of detecting historical changes in the spatial character of the landscape. Second, researchers may abstract the time dimension of change into periods or stages, sometimes in arbitrary correspondence to the processes being investigated. An example of the later is use of census data, where changes might be assessed over a 10-year period,

such as population growth within a region between 1990 and 2000. In contrast, frequently researchers also define periods of time or stages according to the dominance of certain social circumstances (for instance, the baby-boom period) or of prevailing technologies, such as the automobile era.

2. *From Spatial to Time–Spatial Perspectives*

Attempts in the 1950s and 1960s to recast geography from a descriptive to a predictive science offer a clear demarcation in the progression of thinking about time–space in geography. In the traditional paradigm of regional descriptive geography, time and space were treated as separate even though attention was given to documenting landscape conditions at different points in time. Theoretical quantitative geography emerged to counter the descriptive focus of this tradition, but many researchers, nonetheless, retained the separation of time from space in what was termed the exceptionalism of the spatial paradigm. This was most pronounced in the advocacy of Schaefer (1953) and Bunge (1962) for whom geography was a theoretical science in search of spatial morphological laws. The merger of geography's theoretical thrust with practical issues of society, however, necessitated a predictive perspective.

Interest in prediction resulted in a shift of emphasis from the depiction and explanation of geographical patterns to that of process identification to understanding the dynamics of regional economies and the nature of human spatial behavior. Thus, from a fundamental focus on pure spatial form, attention turned to the movements of objects and to the passage of events through space and time. Models to simulate urban growth and other phenomena as processes of spatial diffusion (see *Diffusion: Geographical Aspects*) (represent explicit attempts to mesh the time and space dimensions in geographical research. Significant statements advancing time–space perspectives are found in Hägerstrand's (1973) conceptualizations of spatial diffusion and time-geography, Janelle's (1969) formulation of time–space convergence, and Harvey's (1990) notion of time–space compression.

At the behavioral level, Hägerstrand's time-geography model of society stands out in its attempt to capture the movement and activity participation of people through graphic representation of their simultaneous and sequential space and time locations. The concept of an individual's time–space path portrays the continuity of human existence as a line that occupies space and time simultaneously and continuously, relative to a person's activities in space through the temporal cycles of the day or a lifetime. The inherent Euclidean nature of this space is a consequence of treating time and space as homogeneous media for movement, broken up in response to social constraints that determine who has access to specific spaces at given times and under what circumstances.

3. *Time–Space Convergence and Human Extensibility*

Time–space convergence is a measure of change in the effort required to overcome distance. Generally, it is defined as the average rate of decline in travel time between two places over time. For example, owing to innovations that span the eras of stagecoach travel to automobiles on limited-access highways, Boston and New York have approached each other at an average annual rate of 22 min per year between the years 1800 and 2000. The parallel concept of time–space divergence provides for the tangible measurement of increases in separation between places that result from traffic congestion and failure to maintain infrastructure. Implicit in the convergence/divergence viewpoint is the recognition that physical points (places on the earth) are in relative motion with respect to one another whenever functional measures (such as travel time and cost) are used as the distance metric. Because levels of investment in transportation and communication technologies are not uniform, some places converge much more rapidly with the remainder of the settlement system than others. Some places, bypassed by modern space-adjusting technologies, will diverge, and others will converge and diverge selectively relative to various parts of the urban system. Variations in the set of rates that define convergence among all possible pairs of places create a nonhomogeneous time–space that is relative and dependent on the inferred movement of places with respect to one another. In this time–space, places are seen to compete in their quest to gain relative accessibility over other places, thereby gaining advantages for attracting economic and other opportunities.

Time–space convergence is analogous to the physical concept of velocity and purports to assess the earth-shrinking impact of technological investments to overcoming distance. As a time-rate changes over time, it fits in the domain of metaconcepts. It is not a velocity of sensation; rather it is a process identifiable and abstracted only through measurement. The structure of the resulting space, the frame of reference for human activities, is constantly in flux and is not describable in terms of Euclidean geometry. Even though this abstraction of reality may not be recognized intuitively, the time–space convergence/divergence process embraces explicit recognition of its social origins as the result of deliberative innovation through investment decisions. It is this human behavioral response to time–space convergence that reshapes the space of human geography. Yet, Forer (1974) demonstrates reciprocity in this process, whereby the existing spatial structure of society also

influences emergent patterns of investment to encourage time–space convergence.

As a complement to time–space convergence, Janelle (1973) advanced a reciprocal concept of human extensibility. Developed more fully by Adams (1995), this refers to the ability of an individual or agency to extend their influence and presence over space and through time to distant locations via media and other means of influence over human resources. Human extensibility parallels the construct of time–space distanciation as advanced in Giddens's (1984) structuration theory. Together, these concepts pose questions regarding the closure or spatial boundedness of human societies and systems. They also bring forward issues concerning the differential abilities of individuals, firms, nations, and other forms of human agency to reach beyond their physical locations to shape possibilities for human livelihood elsewhere. Such discrepancies lead Harvey (1990) to advance yet another conception of time–space, one rooted in the historical materialism of the political economy.

4. *Time–Space Compression*

Harvey advances the notion of time–space compression and provides a compelling rationale for imbuing time–space with social content and experiential meaning. This is brought about by attempts within Capitalism to extract as much surplus value per unit of time as possible. Though annihilation of space through time is analogous to time–space convergence, the broad implications of compression may be less amenable to direct measurement. Use of the term compression captures the general speeding up of all kinds of events that intensify the turnover of capital and that implode on human existence as substantive levels of stress. Furthermore, in Harvey's interpretation, the transcendence of global capital over local domains thrives on shortened time horizons and on the ability to eradicate distance as an inhibitor to exchange and dominance. The ability of capital to shift resources to different places easily, and often with impunity to the disruption of life at the local scale, suggests that time-space compression may denigrate the importance of place in human society. It is in the inherent mobility and speed of such possible actions that time–space compression challenges any attempts to define the time–space nature of society too rigidly.

5. *Time–Space, Dynamic Cartographic Visualization, and the Humanist Challenge*

One of the issues that hinders broad application of time–space perspectives in the social and behavioral sciences is the difficulty inherent in representing the underlying complexity in the human organization of space through time. This is both an issue regarding the nature of the tools at the disposal of researchers and of how questions in empirical research are linked within alternative theoretical frameworks. The integration of space-time analyses and modeling within the frameworks of dynamic mapping, cartographic visualization, and Geographic Information Systems (see *Dynamic Mapping in Geography*; *Geographic Information Systems: Critical Approaches*) holds promise that research tools finally are catching up with needs of social and behavioral scientists for assessing alternative theoretical constructs. The transfer of these technologies to the interactive realm of the Internet offers the potential for incorporating simultaneous representation of processes through space and time. Both real-time and simulated processes are possible. Driving the interest in such developments are the needs for planners, policy makers, and scholars to understand the dynamic time–space transformations that are occurring among places and regions as a consequence of continuing advances in information and communication technologies. However, these transformations pose fundamental challenges to how social and behavioral scientists interpret the meaning of place in everyday life and to how they integrate these interpretations within theoretical and decision-making frameworks (see *Place in Geography*; *Space and Social Theory in Geography*).

Do the meanings of space and the meanings of time mean anything aside from their relationship to one another as time–space? The theoretical grounding of answers to this question rest, in part, on the ability of researchers to use the emerging tools of analytical representation in their descriptions and analyses. At the same time, answers rest fundamentally on being able to recognize humanist qualities in the nature of time–space (e.g., temporality and spatiality, as discussed in Kellerman (1989)). The humanization of time–space acknowledges its relativity to different value systems, recognizes its manifold possible metrics, and is able to relate these to human thought processes and experiences. Casting time–space in this manner draws on past formulations and opens the realm of possible investigations to include analytical time–space prediction as well as research formulations grounded in the approaches of critical science and postmodernism.

Time-use and Gender

Men and women have to make decisions on how to use their time, as a day has only 24 hours, or rather time is limited. Activities men and women make decisions about can be divided into paid work, domestic work and childcare, personal obligations, and leisure. Time has become an increasingly scarce good; newspapers and other media abound with stories suggesting that time pressure is becoming a real epidemic. The article discusses how time use is measured and the patterns of time use of men and women and provides explanations of gender differences.

1. The Measurement of Time-use

To understand time use of men and women, it can be categorized in several ways. If one is interested in paid work and leisure, a distinction is made between work vs. nonwork activities. With respect to the division of labor between husbands and wives, the most frequently used division is between paid work, domestic work and childcare. It is evident what is meant by paid work, and most authors use more or less the same description. However, household labor can be defined in a variety of ways. Naturally, cooking and cleaning are domestic tasks, but it isn't clear how to classify activities that are part leisure and part work, such as vegetable gardening, gourmet cooking, or playing with the children. Leisure is a broad category, including indoor activities like reading books and watching television, outdoor activities like sporting, but also social contacts and going out for dinner. Personal obligations often form a kind of residual category, including activities like sleeping and eating at home.

The most accurate and reliable way to measure the time use of people is the time diary method (Andorka 1987, Juster and Stafford 1991, Harvey 1993). In this approach, respondents are asked to keep records of what they were doing at all times for a day or more. In some studies the main activity is noted in fixed interval units (e.g., in quarters of an hour) while in others intervals are left free (i.e., starting and finishing times are indicated). The period of time when the diary is kept also differs. In some cases respondents are only required to keep a diary for a single day, while in others they are asked to do so for a whole week. The time diary method prevents respondents from exaggerating the durations of their favorite activities while neglecting the time devoted to day-to-day concerns and trivialities. Thus, the actual subject being studied is not overstated, which sometimes happens when specialized questionnaires are used. A serious limitation of time diaries is the difficulty in dealing with more than one activity performed simultaneously (Warner 1986). For example, people may cook dinner while supervising children, or sew while watching television. Another method to measure patterns of time use is asking direct questions that require men and women to estimate their usual time spent on a list of activities. In order to help the respondent, in these questionnaires often domestic work is distinguished into some clear categories like cooking, cleaning, doing the laundry, and shopping. Those few studies that compare time-diary to direct-question data find that direct questions typically produce higher time estimations than time-diary questions (Juster and Stafford 1991), especially for activities that occur frequently (Marini and Shelton 1993). Both husband and wife overestimate their time devoted to domestic duties.

2. Time-use Patterns

There has been a traditional gender division of time consuming activities within western societies: women used to do most of the household work and childcare, whereas men worked for pay the whole day and were responsible for providing family income. This has changed substantially in recent decades. In the western world, women's paid work has increased vastly. Now a majority of women in many nations are employed for pay, something that would have been hard to imagine just after the Second World War. Despite the overall increase in levels of women's employment large differences exist between countries in the northern continents. Nordic countries, such as Sweden and Denmark, have had higher levels of female labor force participation than other western countries for a long time. The Anglo-Saxon countries, such as the USA and the UK were runners up, while in Italy, Spain and Greece still less than half of the active female population has a paid job. For Eastern Europe, the picture is different. The communist ideology, established after the Second World War in Eastern Europe with the exception of Russia, forced many women to enter the labor market. In the 1960s already three quarters of the women had a paid job. Despite the

overall increase in the level of women's employment there are considerable differences between countries in the number of hours per week that women work for pay. While part-time work is common in Sweden, Denmark, and the Netherlands, employed women in Italy, Greece, Spain, and Portugal almost all work full-time. About 80 percent of US employed women work full-time. In Eastern Europe part-time work simply did not exist before the political turnover. After 1989 full-time work is still the rule in the former socialist countries (van der Lippe and Fodor 1998).

The growth in paid work of women is linked to the often noted decline in domestic work on the part of women in western countries (Gershuny and Robinson 1988, Gershuny 1992). Compared to this large change in women's time use in the west in general, there has been hardly any change in men's time use. Although there has been a small increase in men's domestic work, these changes are trivial compared to the increase in women's employment and the reduction in their household work. The more equal division of domestic work between husbands and wives nowadays is less a result of an increase in men's domestic work and more because of the reduced time women spend on household duties. When men perform domestic tasks, they disproportionately do what are often considered more 'pleasant' tasks (e.g., childcare and cooking rather than cleaning the toilet).

The amount of leisure time differs not so much between the sexes as between those in paid and domestic work. Between the 1960s and the 1990s for both sexes leisure time accounted for between 20 to 30 percent of weekly time (Robinson 1991). Men do rather more outdoor activities such as sport, whereas women spend more time on social contacts. Some authors argue that the workweek in most industrialized countries has been reduced and therefore the amount of free time has increased (Robinson 1991, Gershuny 1993). However, others point to a reduction of leisure and household time as more women are employed and working hours increase for some men (Schor 1998a). According to Schor 'the quality of European life is threatened as relatively short working hours, relaxed daily life and appreciation for the "finer things" are giving way in a number of countries to longer hours of work, a faster pace of life, and American style consumption' (Schor 1998b, p. 7). In two-earner families both partners are exposed to the greed associated with the jobs in which they work, and thus both will bring the restrictions imposed by their work situation to the time allocation in the household.

3. *Explanations for the Different Use of Time by Gender*

A rich body of literature is available on men and women's allocation of time (Szalai 1966, Robinson 1977, Gershuny 1993, Shelton and John 1996). Many study men's and women's division of paid and domestic work (Coverman 1985, Huber and Spitze 1983, Presser 1994) and some of these studies compare several countries.

3.1 *The Individual Level*
