The social climate against smoking began to turn in the late 1960s and 1970s. Antismoking sentiment rose, and cigarette advertising on television was banned. The risks of smoking for third parties was noted. Communities and entire states began to legislate against smoking in public places. Higher taxes on cigarette smoking were advocated. Smoking rates in most industrial societies fell, but most impressively in the United States. This sharp decline is not only due to the extensive public discussion devoted to the hazards of smoking but also to the growing sense of social and even moral disapproval of smoking by the larger society. This social disapproval was sometimes seen as a resurgence of moralism. But there is scant evidence that the strong current of disapproval against smoking adds up to moralism.

Moralism and the AIDS Epidemic

As Allan Brandt notes, the battle against venereal diseases in the first decades of the twentieth century and the rise of AIDS more recently give evidence that moralism remains a powerful element in the social construction of society's definition of these diseases. Early in the twentieth century, syphilis was a symbol of a "society characterized by a corrupt sexuality. Venereal disease has typically been used as a symbol of pollution and contamination, [and of] … a decaying social order. Venereal disease makes clear the persistent association of disease with dirt and uncleanness as well" (Brandt, p. 5).

The most serious challenge to modern public health by legal moralism entered with the AIDS epidemic and HIV-related diseases. Because anal sex and frequent sex with multiple partners heightens the risk of transmission of the HIV virus and because intravenous drug use also seriously elevates the risk of infection from contaminated needles, legislation that seeks to regulate these behaviors—which are widely proscribed in many states—is always open to the charge of moralism.

Early in the epidemic in the United States, bathhouses frequented by homosexual patrons became targets of public-health regulations. Many in the gay community charged that the measures were aimed less at fighting the epidemic than at proscribing homosexuality. These advocates argued, quite plausibly, that the regulations would have little impact on the course of the epidemic in San Francisco or New York, the two cities where conflicts primarily arose. This was

because the bathhouses were the site of only a fraction of the proscribed behaviors. Advocates also argued that city officials and state public-health authorities had caved in to political pressures (Bayer, 1991b).

The same charge of moralism and discrimination was also brought when public-health officials attempted to introduce methods of identifying the sexual partners of those who were AIDS victims, or when state medical societies sought legislation to make AIDS and HIV diseases reportable to state health authorities (Bayer, 1991b). (All states require private physicians to report certain communicable diseases to state health officials.) Ronald Bayer, in his book *Private Acts, Social Consequences* (1991b), has provided the best chronicle of the clash between public-health legislation and the civil libertarians defending AIDS victims. As Bayer says, "These two abstractions, liberty and communal welfare, are always in a state of tension in public health policy" (1991b, p. 16).

It is likely, however, that the AIDS epidemic has permanently altered the landscape of public-health policy, and not just in the United States. No longer will it be possible to easily equate public health only with the use of powers to restrict power and liberty to promote the public health or to see the realms of public health and individual liberty as radically distinct. The growing awareness is that a sound public-health policy requires more than restrictions on liberty and property to promote the communal welfare. It also may require the expansion of private liberties and rights for groups suffering social discrimination based on moralism.

PUBLIC POLICY AND BIOETHICS

• • •

There are at least two ways of understanding the relation of public policy to bioethics. The first, focusing on public policy *in* bioethics, involves the public laws (both statutory and case law), policies, regulations, and guidelines that bear on ethical aspects of medical practice and healthcare. These are public in the sense that they emanate from some publicly accountable governmental process, as opposed to private or professional policy; in addition, nonpublic institutions such as hospitals can adopt their own policies to conform to public policy. In this sense, legal requirements to obtain

informed consent for treatment, federal regulations requiring approval of a research protocol by an institution's human subjects committee, and the lack in the United States of any governmental means of ensuring universal access to healthcare for all citizens represent public policy bearing on ethical aspects of medical and research practice.

When the relation of public policy to bioethics is understood in this way, the question arises as to the extent to which bioethics issues have been and should be matters of explicit public policy. Physician–patient relations, for example, may be taken to be a largely private matter to be worked out by physicians and patients outside of the public sphere, as they were to a great extent in the early part of the twentieth century, or to be a matter of professional concern by physicians in professional settings, but not the subject of and regulated by public policy. Alternatively, such issues might be seen, as they increasingly were in the United States in the 1970s and 1980s, as an appropriate concern of public policy. Thus, public policy in bioethics includes what governments choose not to do, as well as what they do, in bioethics.

The second understanding of the relation of public policy to bioethics focuses on public-policy bodies that have been influential in shaping bioethics, public policy on bioethics issues, and healthcare practice. Understood in this way, the subject is the manner and extent to which bodies in the United States, such as the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (hereafter President's Commission) or the National Bioethics Advisory Commission (NBAC), or international bodies, such as the United Nations Educational, Scientific and Cultural Organization (UNESCO) or the World Health Organization (WHO), have shaped bioethics and medicine. Why have the United States and many other countries frequently turned to such bodies in the development of public policy in bioethics? How have such bodies functioned? What has been their impact?

This entry addresses both of these understandings of the relation between public policy and bioethics. A general thesis of this entry is that bioethics and public policy have influenced one another. The field of bioethics has helped shape and has been shaped by both public policy in bioethics and a variety of public policymaking institutions in bioethics.

The Relation between Substantive Public Policy and Bioethics

As bioethics in the United States and elsewhere during the 1970s and 1980s became an area of great public and professional concern, many standard bioethical issues began to be addressed, not just in classrooms or between doctors and patients, but also in explicit public debates and policies. One of the most prominent examples, cardiopulmonary resuscitation (CPR), illustrates a relatively common pattern of this development of public policy on important bioethics issues. First, a new technology was developed; in this case and not atypically, it was a form of life-sustaining treatment. Originally the technology was developed for and applied in a relatively narrow range of cases in which there was clear expected benefit: saving otherwise healthy people who had suffered unexpected cardiac or respiratory arrest. CPR later came to be used in a wider range of cases, including many patients for whom its expected success and benefit were questionable. The reason for the wider use was that the conditions under which CPR was applied precluded taking time to make thoughtful decisions about whether to employ it once a patient was in need of it.

Reports of widely varied practices, including some that were ethically problematic at best and certainly did not represent sound general practice, led many hospitals to develop formal policies concerning resuscitation. In particular, the general interest in "do not resuscitate" (DNR) orders led to scholarly studies of the use of CPR and of DNR orders. Public bodies such as the President's Commission addressed the issue and developed recommendations about institutional policies, and the Joint Commission on Accreditation of Healthcare Institutions required institutions to have a policy regarding DNR orders. In this case, a public-policy response to an identified and significant ethical problem in medical practice led to both a public and a professional policy response.

In other cases, public-policy initiatives have sought to increase the use of a practice generally deemed desirable. For example, the U.S. Patient Self-Determination Act of 1991 was intended to increase the use and effectiveness of advance directives by requiring institutions receiving federal funds both to inform patients at admission of their rights under state law to use advance directives, and to have policies in place for implementing them.

Public policy regarding life-sustaining treatment and the care of the dying reflects as well as any issue the mutual interaction and development of bioethics scholarship and public policy. The Karen Ann Quinlan case first focused public attention in the United States on issues of life-sustaining treatment. In the landmark *Quinlan* ruling in 1976, the New Jersey Supreme Court held that an incompetent patient retained a right to refuse life-sustaining medical care, a right that could be exercised by a surrogate, in this case a parent, acting for the patient. The next fifteen years were filled with intense activity on these issues in both the public-policy and scholarly arenas of bioethics. In addition to books on the topic, many articles appeared in bioethics

journals such as the *Hastings Center Report* and in medical journals such as the *New England Journal of Medicine;* at the same time, state courts around the country were addressing many legal cases concerned with life-sustaining treatment and the care of the dying. Other public-policy bodies issued extensive studies, such as the President's Commission's report *Deciding to Forego Life-Sustaining Treatment* (1983a), and briefer policy statements on the subject came from professional bodies such as the American Medical Association (AMA). The President's Commission's report drew explicitly on a wide range of bioethics scholarly work on life-sustaining treatment decisions, as well as on closely related legal scholarship and healthcare research. Court decisions frequently appealed not only to legal scholarship but also to the growing bioethics literature.

The bioethics literature on life-sustaining treatment issues was influenced by these court cases in two important ways. First, the attention many of these legal cases received served as a relatively direct stimulus for much bioethics commentary and analysis of the arguments made in the opinions. Because there was generally little specific statutory law constraining the judicial rulings, they often appealed in part to explicitly ethical arguments. Second, and at a deeper level, the President's Commission's report and many legal decisions greatly influenced debates on life-sustaining treatment and played a major role in the degree and nature of the consensus that emerged during the 1980s. This was true especially for specific issues such as the moral importance of differences between stopping and not starting life-sustaining treatment and between ordinary and extraordinary treatment, as well as on broader issues such as the nature and importance of the moral values of individual autonomy and well-being in guiding life-sustaining treatment decisions. The issue of forgoing life-sustaining nutrition and hydration is a particularly good illustration. Here, the debate in the bioethics literature began, not coincidentally, at about the same time that nutrition and hydration cases were being brought to a number of courts. Because the bioethics literature and the court decisions are best understood as profoundly interdependent parts of a single debate on which significant consensus was emerging, the bioethics literature and the court decisions were unlikely to veer in sharply conflicting directions on the permissibility of forgoing nutrition and hydration.

From its inception, bioethics has had a micro focus, especially on individual doctor–patient issues, and a macro focus on ethical issues in health policy, especially justice in healthcare. The micro issues were predominant in bioethics during the 1970s and much of the 1980s, and will, no doubt, continue to be important. But as health-policy debates in the United States focus on access to healthcare, containment of healthcare costs, and rationing of healthcare, the macro focus of bioethics is likely to become increasingly prominent. On these macroethical issues in health policy, the profound interaction of bioethics and public policy is even more evident. Unlike many doctor–patient issues, which could to a significant extent be worked out between individual doctors and patients, questions of justice in healthcare can be adequately addressed only at an institutional and policy level. Bioethics scholarship on these questions of justice that hopes to influence public policy and practice must address questions about the design of social, political, and professional institutions and practices. These are public-policy issues at their very core, which means that more profound mutual influences between bioethics and public policy can be expected in the future.

The Role of Public Policymaking Bodies in Bioethics: U.S. Commissions and Efforts

In the United States and throughout much of the rest of the world, public policy bodies have been established in bioethics to study and issue reports on bioethics issues. These public commissions have varied considerably in their nature, roles, and effectiveness.

THE NATIONAL COMMISSION. In 1974 the U.S. Congress established the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter National Commission). Two important factors led to the creation of this first public, national body to shape bioethics thinking and practice in the United States.

First, the character of biomedical research had changed significantly in the preceding three decades. Before World War II, such research was carried out largely in small-scale therapeutic settings in which researchers tended to be well known to and trusted by their patients/subjects and the surrounding community. During and following the war, however, the scale of this research expanded greatly as public expectations about the potential benefits of medical research grew. Biomedical researchers increasingly were distinct from clinicians caring for patients, and the unknown investigator replaced the well-known and trusted clinician.

Second, public concern with research abuses had increased. The shocking abuses of human subjects by Nazi doctors during World War II had earlier drawn public attention to these issues. In 1966 a member of the faculty of Harvard Medical School, Henry K. Beecher, published an article in the *New England Journal of Medicine,* detailing twenty-three instances of published research in which the treatment of human subjects was at best ethically problematic. Around the same time some especially egregious cases of

research abuse received wide public attention, such as the Tuskegee Syphilis Study, in which African-American men infected with syphilis were left untreated in order to study the natural course of the disease.

The National Commission's work has shaped law, federal regulatory oversight, and institutional oversight of research practice. The National Commission consisted of eleven commissioners and a professional staff. The commission held public hearings, sponsored a wide range of studies and scholarly papers, and eventually issued reports on the use of different groups of human subjects—children, prisoners, the mentally infirm, and fetuses—in research. The legislation establishing the National Commission required the secretary of the U.S. Department of Health, Education, and Welfare (forerunner of the Department of Health and Human Services) to implement the National Commission's recommendations or offer a public justification for not doing so. In some cases, the commission's reports led to the virtual elimination of research with particular classes of subjects, such as prisoners, whereas in other cases, they led to the development of special rules for the involvement of particular classes of subjects, such as children. The final report of the National Commission—the *Belmont Report* (1978a)—had a great impact on bioethics because it addressed the moral principles that underlay the various reports on particular aspects of research. Here, the principles of respect for persons, beneficence, and justice were enunciated; these same principles later figured prominently in Tom L. Beauchamp and James F. Childress's *Principles of Biomedical Ethics* (first published in 1979), probably the most widely read and influential scholarly work in bioethics.

The National Commission stressed the moral principle of respect for persons and the implications of this principle: that subjects should be enrolled in research only with their free and informed consent and with their confidentiality properly protected. The work of the National Commission continues to form the ethical basis for the federal government's regulatory oversight of research involving the use of human subjects, carried out by the Office for Human Research Protections within the Department of Health and Human Services (HHS).

THE PRESIDENT'S COMMISSION. When the National Commission concluded its work in 1979, the Congress established the President's Commission with a substantially broader mandate. During the four years of its existence, this commission issued ten book-length reports on a wide variety of topics in bioethics, including the definition of death, the compensation of injured research subjects, genetic screening and counseling, genetic engineering, informed consent in medical treatment, decisions about life-sustaining treatment, access to healthcare, whistle-blowing in research, and protection of research subjects. Like the National Commission, the President's Commission had public commissioners and a full-time professional staff representing a wide variety of academic disciplines.

Because of the diverse nature of the topics addressed by the President's Commission, its reports had different kinds of impacts on bioethics. For example, *Defining Death* (1981) contributed to the adoption of a uniform brain-death standard for death by the great majority of the states; here, the impact was a relatively discrete piece of legislation. On the other hand, the report on informed consent, *Making Health Care Decisions* (1982), had a more diffuse, though no less important, impact in advancing the ideal that physicians and patients share decisions about treatment; here, medical education and the professional ethos for physician–patient relations were affected. *Securing Access to Health Care* (1983b) focused on the ethical problems represented by the more than 20 million Americans who were without health insurance. This report had relatively less immediate impact than many others because massive government expenditures were necessary to solve the problem at a time when the political ideology of the new presidential administration was to reduce, not expand, government social programs. Ten years after it was issued, however, it was clear that this report contributed to the public and political recognition in the United States of the ethical problem of access to healthcare and to understanding the ethical case for government action.

Deciding to Forego Life-Sustaining Treatment (1983a) was almost certainly the commission's most influential report, for several reasons. Following the *Quinlan* decision in 1976, both public and professional attention to this area steadily increased. In addition, new and more widely disseminated life-sustaining medical technology meant that both professionals and the public had had more personal experience with these difficult decisions; individual professionals, healthcare institutions, and the public were uncertain about what was ethically acceptable and desirable practice in this area. Finally, implementation of the commission's recommendations did not require major new government expenditures. The commission's recommendations centered on patients' or their surrogates' rights to weigh the benefits and burdens of any available treatment, including the alternative of no treatment, according to the patient's values, and to accept or refuse treatment. The report criticized and offered alternative language for some distinctions that until then had had an important influence on the bioethics literature and on practice, such as the differences between not starting and stopping a life-sustaining treatment and between ordinary and extraordinary treatment.

The report filled a vacuum: Hospitals, courts, and others sorely needed guidance about ethically acceptable practice. The fact that this report, like the others, was issued by a presidential commission gave its recommendations an unmatched authoritativeness.

NATIONAL BIOETHICS ADVISORY COMMISSION. After a lengthy hiatus in which the United States lacked any national bioethics commission, in 1996 President Bill Clinton established the National Bioethics Advisory Commission (NBAC). Its initial work plan was interrupted by the cloning of the sheep Dolly and the president's request for a report within ninety days on the ethical, social, and legal issues of cloning. This illustrates one role that public commissions sometimes play: responding in a rapid, but measured and reasoned, way to developments in biotechnology that raise serious ethical concerns. The commission recommended that there be a moratorium on any reproductive cloning, largely based on concerns about safety, to allow time for a public debate and a later revisiting of the issue.

A later report of NBAC addressed a different but related issue—embryonic stem cell research. This was another instance of using a public commission to address an extremely controversial issue in the hopes of achieving a more reasoned debate of the issues and a position that might gain some consensus among parties with widely differing views. One focus of the NBAC report was whether federal funding of this research should be permitted. The commission sought a compromise position by making a distinction in the sources of the stem cells and recommended permitting that funding when the cells were derived from cadaveric tissue or from embryos left over from in vitro fertilization (IVF), but rejected funding of research using cells derived from embryos created for the purposes of research by IVF or by means of somatic cell nuclear transfer. While some found the compromise position appealing, it failed to create any consensus that could guide public policy, in particular on public funding of this research. It was another illustration, along with an earlier fetal tissue study and a failed attempt to establish a national bioethics commission in the late 1980s that foundered on disputes about abortion, of the difficulty of using public commissions to address deeply controversial issues, especially in the United States those that involve the moral status of embryos and fetuses.

As had the earlier U.S. public commissions, NBAC also produced several reports on ethical issues in research, including research with mentally impaired subjects, research in developing countries, and a study of the overall regulatory process of research. This work reflected continuing concern with protecting human subjects in research as well as new concerns such as the potential for exploitation of subjects in the increasingly common research being done in developing countries by investigators from the developed world.

PRESIDENT'S COUNCIL ON BIOETHICS. The charter of NBAC expired in October 2001, and in November 2001 President George W. Bush appointed the President's Council on Bioethics. Through early 2003, the council had produced only one report, *Human Cloning and Human Dignity: An Ethical Inquiry* (2002), which featured special attention to the stem cell research debate. Interestingly, in the case of therapeutic cloning and stem cell research, the council was charged to advise the president on an issue on which he had already taken a formal position, which illustrates the political tensions that these public bodies can sometimes face. There was also considerable controversy about whether the membership of the council was overly slanted in a particular political and ideological direction.

OTHER PUBLIC OR QUASI-PUBLIC BODIES. In the United States, besides the national bioethics commissions, a number of other public or quasi-public bodies have also have entered these frays. Several states, including New Jersey and New York, established bioethics commissions. In addition, many government bodies and commissions with a broader medical or health policy agenda have had one or more bioethicists among their members and have included bioethics issues as a part of their broader concerns. For example, the Task Force on Organ Transplantation of the HHS addressed ethical issues in the procurement and distribution of scarce organs for transplantation, although the ethical issues were not the main focus of its work. The Institute of Medicine within the National Academy of Sciences has done many studies on and issued reports concerning a wide array of bioethics issues as well as broader health and public policy issues that have bioethical components. Furthermore, many other government organizations and studies whose main focus is not ethical issues typically now include some discussion of the ethical aspects of their work.

A striking example of the extent to which bioethics in the United States has become an accepted part of the public realm is the Human Genome Project. This $15 billion, fifteen-year project to map and sequence the complete human genome or genetic code gave the ethical implications of government-sponsored research an unprecedented role. At the time the project was being debated in Congress, there was considerable concern about its ethical, social, and legal ramifications. James Watson, the first director of the National Center for Human Genome Research (now known as the National Human Genome Research Institute) at the National Institutes of Health, committed the center to spending at

least 3 percent of its total budget on research into and public and professional education concerning these legal and bioethical issues, and in fact it has ended up spending more. The genome project's Ethical, Legal and Social Implications (ELSI) Research Program has supported a wide range of studies and projects aimed at the general public as well as the academic, research, and public-policy communities.

A last important manifestation of public-policy bodies in bioethics in the United States has been the formation of grassroots citizen groups in a number of states to address bioethics issues. Such groups have often treated issues of health policy, especially how to set priorities among healthcare services with a view to allocating limited funds in government health insurance programs, such as Medicaid. The widely publicized prioritization of healthcare services in the state Medicaid program in Oregon made use of such citizen groups.

International Activity

The United States is hardly alone in turning to government bodies to address issues of bioethics. Indeed, while the United States had no national government bioethics commissions between 1983 and 1996, countries throughout the world established them during and after this period. Nearly every country in northern and western Europe, as well as a number of eastern European countries, now has a national bioethics commission. Such commissions also exist in a number of countries in the Americas and in Asia and Oceania.

These national bioethics commissions have varied greatly—in their form and membership, in the scope of issues addressed, and in their general effectiveness. For example, the Danish Council of Ethics, established by the Danish Parliament in 1988, has followed a populist model, with largely lay members, and has pursued broad educational efforts. In France, the National Consultative Ethics Committee for Health and Life Sciences has followed a more elite model with scholarly and professional members, high public and professional prestige, and more direct attempts to determine government policy. In Great Britain, government-sponsored groups have addressed ethical policy issues in reports comparable in scope and detail with those of the U.S. commissions. The Nuffield Council on Bioethics in Great Britain has established expert panels that have produced major reports of high quality on a wide range of subjects including genetic screening, use of human tissue, mental disorders and genetics, genetically modified crops, stem cell therapy, research in developing countries, patenting DNA, and behavior genetics.

Although there is no international bioethics commission as such, both the United Nations (U.N.), through two of its agencies, and the Council of Europe have created bodies that have been active in bioethics. UNESCO has an International Bioethics Committee that has addressed many bioethics issues and that developed the Universal Declaration on the Human Genome and Human Rights (1997), following up the earlier general U.N. Universal Declaration of Human Rights. The World Health Organization has been active on such issues as resource allocation and genetics, with special emphasis on developing countries. In 1982 the International Association of Bioethics was formed to foster international interchange among scholars and practitioners in bioethics. Most non-U.S. efforts, however, have been at a national level so that they can reflect a particular society's historical, political, legal, and cultural traditions.

Membership and Authority Issues

The use of governmental bodies to address public policy in bioethics raises political and ethical questions of membership, function, decision-making methods, and the authority of their recommendations. With regard to membership, there has often been an attempt to balance two concerns: first, that members have relevant expertise on the issues the body will address and that the body be representative of the relevant professions and disciplines; second, that members represent their communities in such areas as gender, minority status, and political affiliation. Statutes establishing these bodies often mandate the areas from which members must be drawn.

The membership question is related to the proper function of these bodies and the authority of their recommendations. If these bodies were to provide only the highest-level expertise on the issues of concern, the case for representativeness would be weak, though even then the question of who had expertise in bioethics, and the nature of their expertise, would be more contentious than in most areas of scientific medicine. That has not generally been their sole function, however. They have been viewed as combining such expertise with the role of addressing what public policy should be in a particular area. This latter role is by its very nature a more political role, requiring representation of groups that have a substantial stake or interest in the policy question at issue, both on ethical grounds and because the group's recommendations must be able to be "sold" in the political arena.

The difficulty of using governmental bodies to address deeply divisive ethical and political issues is illustrated in the United States by the task force established to address the use

of fetal tissue in research. Its recommendations to permit limited use of fetal tissue essentially were ignored in the late 1980s by the first Bush administration because the use of fetal tissue was so closely related to the politically contentious issue of abortion. "Right to life" groups feared any use of fetal tissue could increase or appear to condone abortions. The attempt by the U.S. Congress in the late 1980s to establish a biomedical ethics advisory committee to its Biomedical Ethics Board also failed in large part because of political struggles over abortion.

Representativeness in membership is desirable to ensure that concerns and points of view of significant groups are taken account of for pragmatic reasons, so those groups will support instead of block acceptance and implementation of the recommendations, and for ethical reasons, so those most affected by the recommended policies have some input into what the policies will be. At the same time, powerful professional groups, such as physicians, as well as corporate interests, such as pharmaceutical firms, often have a substantial stake in the policy outcomes. When those interest groups have important or dominant roles within bioethics commissions, they can shape and control the debates, the policy alternatives considered, and the recommendations that emerge. Thus, in the membership of public-policy bioethics bodies, as well as in the policy process more broadly, representation for affected groups must be balanced with preventing powerful professional groups from controlling and distorting the policy process.

For several reasons, the authority of the recommendations of these public-policy bioethics bodies is more problematic than those of analogous scientific bodies. First, the nature and even the existence of expertise in ethics generally, and bioethics in particular, is contested to a greater extent than in scientific medicine. Many people believe that ethical claims express attitudes or feelings and cannot be shown in principle, much less in practice, to be true or false in the manner that claims about empirical matters of fact can be. By contrast, a consensus conference on the appropriate treatment of pulmonary hypertension or breast cancer may be controversial and involve ethical or value issues, but it is usually thought that expertise in the medical aspects of these treatment issues is not problematic to the extent that bioethics expertise is.

Second, appeals to authority are widely acknowledged to be out of place in ethical reasoning—it is the strength of the arguments, not who makes them, that should be persuasive. Because public bodies such as the President's Commission or NBAC typically lack any enforcement powers for their recommendations, their impact ultimately should, and does, lie in their ability to persuade others who do have the authority to pass legislation, render court decisions, and make institutional policies, of the wisdom of their recommendations. This has led many such bodies to see their task as articulating and advancing an emerging consensus on the issues addressed. The President's Commission put great efforts into reaching consensus and had only one dissent, from a single commissioner, in all of its reports. Moreover, all such bodies will give some weight to arriving at consensus, and as in the more overtly political process, reaching consensus sometimes requires that ethically problematic but politically necessary compromises be made, especially regarding policy recommendations.

Some would argue that the main purpose of such bodies is to sharply delineate the ethical issues, conflicts, and choices. The President's Council for Bioethics, for example, sees its role as providing a deep exploration and delineation of the issues, but not blurring or sidestepping them in the interests of compromise and consensus. Pragmatic or political compromise, according to this view, should be left to the overtly political process. In this way the ethics body can speak more unequivocally to the ethical issues and not compromise or cut and trim the ethical arguments where it is politically expedient to do so. On the other hand, this approach may make the body less effective than it might otherwise be in influencing policy.

Another issue that has received some attention concerning these public bodies is the methodology they do or should employ in their deliberations and in arriving at policy positions. In their 1988 book, *The Abuse of Casuistry,* Albert R. Jonsen and Stephen E. Toulmin argued that when members of the National Commission addressed concrete cases, they were generally able to arrive at consensus, even when they disagreed strongly on the more general moral principles or theories that underlay their consensus. Jonsen and Toulmin contrasted the experience of the National Commission with what is sometimes called principlism, in which bioethics, and applied or practical ethics more generally, are seen as beginning with moral principles or theories that are applied in a relatively mechanical, deductive fashion to particular cases or policy choices.

Because providing justification for concrete moral judgments involves appeal to moral principles or reasons of often substantial generality, public-policy bodies such as bioethics commissions should, and in fact often do, work back and forth between concrete cases and more general moral principles. The aim should be to develop a position on the particular ethical and policy issue that is backed by the most plausible, coherent reasons. This can often be a great challenge when political pressures to reach a publicly acceptable compromise conflict with the policy backed by the best ethical reasons.

Conclusion

Bioethics issues have come to receive prominent attention in public policy, and bioethics scholarship has strongly influenced public policy in healthcare. At the same time, public policy in the form of legal decisions and public-policy bodies deeply influenced the development of both the field and scholarship of bioethics during the last decades of the twentieth century. As bioethics comes to focus more on broader issues of health policy in coming years, this mutual interaction and influence between public policy and bioethics can only be expected to increase.

R

RACE AND RACISM

• • •

In the biomedical sciences of the United States and in their wider cultural context, ideas about race and gender play a prominent but unacknowledged role. Despite their apparent universality, these concepts vary over time and place. Different beliefs about them and their social consequences are found across cultures past and present. Both are, in fact, cultural constructions, one or another culture's folk theories of human biological variation. The great variability found in racial and gender notions is indicative of their local cultural construction.

Biological and behavioral assertions concerning race are without empirical validity. After decades of research, largely in anthropology, the social and cultural bases of racial conceptions have become clear (American Anthropological Association; American Association of Physical Anthropologists). Race is a folk-culture concept. While many, perhaps most, cultures of the world do not hold racial theories, such theories are important to consider in discussions of biomedicine and biomedical ethics, especially in the United States. Here, we find that admittedly folk ideas of race and ethnicity serve as the formal basis for government practice, policy and research (Office of Management and Budget). Given the demonstrable negative social, psychological, and health results of the perpetuation of the invidious distinctions represented by racial (and gender) conceptions, and the antipathy generated by their stereotypes, the continued use of such identities in biomedical work can be said to represent serious ethical, as well as biomedical research, problems.

Historical Constructions of Race

Race is one of a number of popular cultural conceptions about human variability. The Western concept was developed in its present scientific and related lay versions largely in the nineteenth century (Barkan; Gossett; Naroll and Naroll; Stocking). At its most abstract level, race is an explanation for observed human variation; people differ in appearance because they belong to different races. Behavior is also implicated; people behave differently because they belong to different races. Racism is a set of negative beliefs held by individuals or groups with respect to a population thought to be biologically distinct. Such beliefs about fundamental biological differences came late to the Western world, but not as a result of scientific progress.

The ancients—whether the civilizations of Nubia and Egypt or the later Minoan, Mesopotamian, Greek, and Roman civilizations—held no beliefs about essential human biological or racial differences. There was recognition that people differed in appearance, language, custom, and even ethics (MacIntyre), but such differences were not considered reflections of immutable, biological differences among humans. Nor could there have existed assertions that biology determined behavior, for most of these civilizations were composed of a variety of physical and cultural types in various stages of assimilation to a titular ethnic identity (e.g., Sherwin-White). Were this not the case, the ancient empires could not have expanded their numbers through the recruitment of physically and culturally different peoples, for they would have thought them fundamentally different and nonassimilable.

An important step in the development of the notion of race is to be found in the work of the Swedish botanist and taxonomist Carolus Linnaeus (1707–1778). Linnaeus built upon earlier notions of *species,* distinct groups of living

things that cannot interbreed. Linnaeus proposed a classification comprising six human *groups*; he did not use the term *race.* These human groups were understood as neither pure nor (biologically) stable; they were not represented as distinct species. Such an assertion would have been contradicted at the time by considerable evidence of interbreeding of Europeans and other groups. Such empirical evidence was later ignored in the West.

The French naturalist and founder of invertebrate paleontology George Louis Buffon (1707–1788) introduced the term *race* into the biological literature in 1749. The term then did not refer to distinct human groups with separate origins or biologies (Montagu). Buffon's and Linnaeus's early reflections on human difference regarded such differences, correctly, as representing variations of a single species.

In the eighteenth and nineteenth centuries, English and German philosophy and science began the construction of ideas of fundamental, incommensurate biological differences dividing human groups (Barkan; Boas; Gould). While evolutionist views of monogenesis (a theory of a single origin of all humans) replaced polygenesis (a theory of multiple, separate origins) and creationist views (those based on religious beliefs and not on investigations of the natural world) in Europe, nineteenth-century theories were largely alike in expressing racist sentiments, though the sentiments were not recognized as such. Triumphant nineteenth-century evolutionism fitted well in racist science.

Monogenecists assigned to non-Europeans fates of early separation from a "main" line of Europeans. JeanBaptiste Lamarck (1744–1829) suggested that differences among human groups around the world were to be attributed to the inheritance of acquired characteristics. He implicated the role of the environment in evolutionary change, although he misconstrued the mechanism of biological change.

Non-Europeans, and many eastern and southern Europeans, were believed to have a common origin by many western European scholars, but were seen as less evolved. Some were said to be little different than nonhuman primates (Barkan; Stocking). And some ethnic groups of western Europe created racial alliances. English historians of the nineteenth century repeatedly referred to the "rational and freedom-loving" character of the English as racial traits of the Anglo-Saxon, believed to be a branch of the "German race" (Gossett). As with the Nazi *race science* of the next century, the notion of the German race excluded most people commonly regarded in the United States as belonging to a "white race" (e.g., the French and other circum-Mediterranean people, Celtic ethnics, the Slavic people) as well as people from what are commonly regarded as other "races" in U.S. ideology—Asians, Africans, and Native Americans.

In England, Sir Francis Galton (1822–1911), the father of statistical manipulation, lent both ideas and methods to racial theories. He coined the term *eugenics,* and conceived of this new "science" as a program of "racial" improvement. The idea of group biological improvement was carried to horrendous extremes by Nazi "hygienists." Galton's work on head size and intelligence lent credence to later racist work in the United States as well, such as that of physician Robert Bean of Virginia. His work, in 1906, purportedly showed that parts of the brain were of different sizes in "Whites and Negroes" (in Gould). He also claimed to have found measurable differences in males and females and between higher and lower classes. His interpretations and biased readings, soon disproved (Gould), showed the affinity of the ideas of racism, sexism, and elitism in the United States that are also apparent in English science.

Sir Cyril Burt, dean of twentieth-century educational psychology in England, studied twins during the first half of the twentieth century. He purported to show that twins raised apart had the same IQ. It appears he sought scientific proof for the English folk notion that nature determined human abilities such as intelligence. As a consequence, his views were widely received for decades and influenced the establishment of national examinations. The examinations were used to limit the educational opportunities of millions of young people in Britain. In the 1970s, it was discovered that the late scientist had, in fact, fabricated most of his data. He had also fabricated his long-time research assistants, who supposedly collected most of the data, as well as his coauthors (Gould). The advocates of nature over nurture suffered a heavy blow when this key body of literature was discredited.

In the United States, a multicultural society usually referred to as *multiracial,* Burt's elitist arguments were converted to racist (and sexist) theories by his students, psychologists such as Hans Jurgen Eysenck and Jensen (Gould), as well as others (Fausto-Sterling). Research aimed at showing that African-Americans and other "minorities" were intrinsically less intelligent than the generic "White race." Within each group, moreover, women were said to be less capable than men. Many flaws appear in this sort of research. One of the major problems is the fact that social labels, such as White and Black, were used to make genetic arguments; the arguments were flimsy because they regularly excluded from consideration profound differences in the social and educational experience of the members of the various social categories. This was done in order to arrive at (prejudged) conclusions of inborn racial differences.

A similar idea concerning mental illness was developed in German psychiatry in the mid-1800s. The leader of nineteenth-century German psychiatry, Wilhelm Griesinger, adopted a biological definition of mental disorders. His dictum was that "mind diseases are brain diseases" (Gilman). The idea that mental illness was based in biology and not social environment was actually borrowed from German philosophy, which in turn had taken the idea from popular German culture. Griesinger passed on this popular prejudice in his psychiatric science to a follower, Emile Kraepelin. Kraepelin became the twentieth century's father of biological psychiatry and the creator of a racially based "comparative psychiatry" (Gaines, 1992a; Gilman). This influential figure made the case for the biological basis of major mental diseases such as schizophrenia. His ideas were greatly influential on Nazi and contemporary U.S. biological psychiatry (Barkan; Gaines, 1992c; Gilman).

The Nazi "race science" of the 1930s reverted to nineteenth-century polygenesis to explain differences among racial groups and to assert its group's alleged superiority (Montagu). Some Germans were likewise seen as unfit; they were the disabled, the mentally ill, and the homosexual. In contemporary German society, popular and medical beliefs still express the model of mental illness that considers the mentally ill to be biologically different from "normal" people (Townsend).

As is evident, both English and German cultures exhibit biological theories of human difference. A brief historical look suggests that the ideas of these two cultures are related. In both systems, differences are held to be intrinsic and groups are hierarchically ranked, allegedly in terms of abilities. In the relatively isolated society of England, the Germanic notion of inherent differences and similarities based upon shared "blood" was doubtless introduced by invading Germanic tribes in the fifth century. The idea remained but was applied to internal social differences within England. This focus transformed the theory of difference based upon blood into the English notion of "breeding" that was and is applied to members of the British (which includes the Celtic peoples) social system. It produced Britain's rigid class systems wherein abilities are said to be differentially inherited by those differing in breeding. This conception of inborn qualities then serves to justify the respective social positions of society's members.

The Critique of Scientific Racism

Evolutionists explained the increasing knowledge of human diversity in biological terms (Barkan; Gossett). The allegedly different developmental levels of various societies were said to indicate inferior inborn abilities in the societies' people compared with the usual apex of evolution found in (western) Europe. Eastern Europe, not a direct heir to the Renaissance, has been considered marginal in much of western European thought and totally alien and inferior in Germanic thought. History tells us, however, that Europe was the last of the world's areas to develop the hallmarks of civilization, hallmarks largely borrowed from others who were later alleged to be less evolved than (western) Europeans.

ANTHROPOLOGICAL ARGUMENTS. Racist evolutionist ideas, and many not evolutionist, permeated much of medicine, psychology, biology, and other sciences in Europe and the United States at the beginning of the twentieth century. Among the first to lead a concentrated and protracted attack on scientific racism was Franz Boas (1858–1942). A German immigrant, Boas was the foremost anthropologist of his time and the founder of U.S. anthropology. Among many other things, Boas's research demonstrated the plasticity of the human form and the overlap in measurements (anthropometry) of anatomical features previously asserted to be unique to specific racial groups. These findings flatly contradicted the conceptions of races as stable, unchanging, and distinct physical types. Time has continued to enhance our understanding of the enormous plasticity of human biology, a biology so changeable that it has produced all the variations in the human form found in the world in less than 180,000 years.

Boas himself demonstrated how rapidly biology can change, as well as the nonempirical basis of racial differences, by showing that very different anthropometric readings could be obtained from the children of immigrants to the United States when compared with their parents. The cause was the change in environmental factors, especially nutrition. These measurements indicated, according to the current, specific racial measurement norms, that people in the same family appeared to belong to completely different racial groups (Boas).

Boas also advanced fatal arguments against notions of the relatedness of race to behavior. He showed that so-called races did not exhibit distinct religious, linguistic, or general cultural patterns. People of a variety of races spoke the same language and practiced the same religion. And members of the same race spoke different languages, held different religious beliefs, and otherwise exhibited distinct cultures. Race could not be shown to determine even major forms of human behavior (Boas; Stocking). Many of the positions advanced by Boas remain the most powerful antiracist arguments. It is remarkable that he began his assault on scientific racism before 1910, a time when blatantly racist

statements were common in science and in the White House (see Brandt, 1985).

Evolutionary schemes were soon generally recognized as based on biased conjecture. There were no empirical bases for the evolutionary stages of Karl Marx, Herbert Spencer, Edward Tylor, or any of the other evolutionary theorists. Boas replaced evolutionist theorizing with the study of the historical diffusion of cultural traits. Historical diffusionism based its arguments on empirical evidence from all the branches of anthropology, physical anthropology, linguistics, archaeology, and sociocultural anthropology as well as from history. Such evidence was used to demonstrate that the current cultural (or physical) features or organization of any group were a result of contact and borrowing from other groups it had encountered. Of less influence in cultural change were innovation and creativity. Cultural arrangements, then, had more to do with a particular history of contact than with innate abilities related to alleged evolutionary stages. This understanding replaced a notion of the evolution of a single human general culture with an understanding of particular cultures' histories.

Evolutionists rank people and cultures from low to high, worst to best. Implicit in evolutionist thinking is the idea of progress, the idea that things are changing for the better. Evolution and progress are unrelated in fact and must be kept separate. Evolutionary change is simply descent with modification; there is no implication of improvement or superiority of later social or biological forms over earlier ones.

But evolutionists depicted some groups, such as Africans, as being near the apes because the groups were perceived as different. They were said to resemble nonhuman primates, such as chimpanzees and apes, who were described as having thick lips, curly hair, and dark skin. This representation has persisted despite the fact that nonhuman primates actually have straight hair covering their rather white skin and are totally lacking lips. That is, nonhuman primates exhibit precisely the characteristics claimed by Europeans as indicative of their own racial superiority.

While racism is still common, though less so than earlier in the twentieth century in the United States, evolutionist notions containing the idea of progress persist. A counter to these ideas is one of Boas's most enduring contributions: his articulation of the notion of *cultural relativism,* which is not a theory but a descriptive reaction to wide experience with other cultures. While evolutionists ranked people and cultures, anthropologists after Boas came to see them in relative terms; cultures were not better or worse than one another, they were simply different. One could not judge a culture using values from another; cultures must be evaluated using internal, not external, criteria. Relativism has become a central tenet of anthropology, the science of culture.

Biomedical sciences often evidence not the relativism of Boas but the hierarchical evaluative thinking indicative of evolutionism. An implicit ranking system appeared in medicine and persists in notions of defects afflicting groups of people. Historians of medicine show that this idea was disseminated by medicine's association of specific illness states with specific ethnic groups (called races) and/or genders (Chesler; Gilman; Pernick). This was but one of many techniques for the pathologization of often fictitious differences.

Difference from an implicit standard, that is, Anglo, male, adult (Gaines, 1992a; Gilman), in medical and psychiatric thought has been represented as problematic, dangerous, exceptional, pathological, defective, weak, vulnerable, and/or requiring "special" treatment (Gaines, 1992a; Osborne and Feit). Ultimately, the idea communicated is that culturally defined "others"—in the United States, non-European ethnics, women, and children—are simply, and inherently, "not normal" (Ehrenreich and English; Gilman).

One significant problem with the theories about natural racial groups is the fact that the precise number of them has never been agreed upon. Throughout the last century and a half, enumerations of groups said to constitute races fluctuated from author to author. Indeed, the number of racial groups is still changing. A recent example is the creation, starting in the early 1980s, of a Hispanic race.

The dynamics of the numbers of races should not be surprising given that the boundaries created to distinguish among the various groups have no empirical bases. Such discriminations are everywhere the arbitrary choice of an author (Gould; UNESCO; Stocking). The lack of fixed criteria for differentiation is reflected in the changes over time in racial labels of individuals in modern health statistical records (Hahn), in local and personal history (Domínguez), and in the ever-changing number of races, a number that varies somewhere between one race and three hundred. The correct number is one.

THE HETEROGENEITY OF RACE. Analyses of biogenetic differences of human groups lead to the recognition of a great variety of characteristics, most of which are shared in various proportions. Local configurations of traits (height, color, etc.) produce a huge number of distinguishable groups. On the African continent, there are about one thousand biologically distinguishable groups, as opposed to races

(Hiernaux). Human groups are not divisible into groups that exhibit unique, nonoverlapping physiological characteristics. Differences in biology are always local differences that are characteristic of a local inbreeding population. What is seen as normal human biology also changes from culture to culture (see Kuriyama, in Leslie and Young). Just as the cultural elements exhibited by individuals of ethnic groups vary, so does the biology of members of so-called races.

The central problem for racial classifications is that there exist no intrinsically significant human features. Cultures have selected specific features as worthy of concern and hence as criteria of inclusion or exclusion. The selection of any one trait—such as skin, hair, or eye color, body hair, height, weight, religion, or place of birth—as a criterion of group exclusion or inclusion is, by definition, arbitrary. The selected characteristics represent historical attributions of meaning in local cultural contexts, not the expression of universal human nature or physical characteristics.

Racial Theories in the United States

Most observers in the United States, whether lay or scientific, believe that observation of racial differences and racial antipathy has existed since time immemorial, being an understandable outcome of the encounter of dissimilar social groups. However, this is understandable only in a specific cultural context and is not an accurate rendering of the history of cultural contact.

The deleterious effect of racism on perception and cognition is obvious if the ancestry of U.S. racial groups is examined. Misrepresentations appear in scientific research as well as the popular media. The two—research and media—engage in a kind of cultural conversation that confirms the reality of race. An objective look at the ancestry of members of the major groups in the United States reveals race as a fatal conceptual problem in public health and medical research.

In the United States, most people labeled by self and others as Native Americans are biologically part European; in many cases, they are largely so. Many such individuals also have West African ancestry. Virtually all American "blacks," or African-Americans, are biologically part European. In many if not most cases, more of their ancestors came from Europe than from West Africa. Quite commonly, African-Americans also have Native American ancestry (Blu; Domínguez; Gaines, "Medical/Psychiatric Knowledge," in Gaines, 1992a; Hallowell; Naroll and Naroll; Watts).

All classificatory whites claiming multigenerational descent in the South can be shown to have West African ancestry and, very likely, Native American ancestry (Domínguez; Hallowell; Naroll and Naroll). This is not surprising since most of the colonists who settled in the U.S. South were single males. The relatively few unmarried females were generally of lower status and in long-term bond service. Without Native American and African women, European males in the South could not have had offspring. In the move westward into what was northern Mexico, where the Spanish had settled with Native Americans a century before the English came to the East Coast, one finds again that those "Americans" who went were primarily males from the South and the East. For this reason, the descendants of these early settlers in the West (settlers who were themselves illegal immigrants because this was northern Mexico) are today of mixed ancestry, although this is not publicly known.

Another distortion relates directly to Latinos, Mexicans, and other groups of "Hispanics." Latinos are descendants of western European, Native American, and West African peoples. This mixture is what the term *la raza* means: a "race" born of a mixture of elements. Because many Mexicans are actually Indians or partly so, the difference between Native Americans (many of whom are Spanish-speaking) and Hispanics is often only nationality, a matter of sociolegal definition and not biology. In other instances, Hispanics have no Native American ancestry but do have West African along with their western European ancestry. In many Latino groups (such as those of Venezuela and Puerto Rico), West African ancestry is virtually universal.

Despite the very definition of Latino as people of mixed cultural and biological ancestry, this language group has been homogenized in the scientific literature and, in the 1980s, became a discrete biological group, a "race" (Gaines, "Medical/Psychiatric Knowledge," in Gaines, 1992a; Hahn). In reality, the groups seen as discrete in the United States—white, African-American, Native American, and Latino—are not at all biologically distinct. Indeed, individuals in any of the categories may embody the same mixture of ancestors as do individuals in the others. The difference in the group to which one is assigned depends not on biology but on local context and social history. These groups represent social categories that are unstable and without common biogenetic content.

VARIABLE RACIAL CRITERIA. In considering the referents of the term *race,* no fixed criterion exists even within the United States. Many nonbiological criteria are used to identify races. The term is applied, for example, to people from a region or geographical direction, one usually designated from the perspective of Europe (e.g., Asians/Orientals). Another referent of this cultural term *race* is a specific continental location (e.g., African, [Native] American). A

new basis for a racial group has also emerged quite recently—language. Hispanic, a new racial identity in the United States, may be attributed on the basis only of a surname; here language is biologized.

Putative skin color is commonly used as a marker of race, for example, white, red, black, brown, yellow. This use of color-as-race continues despite the fact that Asians run the gamut in complexion from white to black, as in southern India. The same range of skin color is found among people labeled black or white in the United States. The lack of real color "lines" produces cases of people who are black but look white or the reverse, as well as many other oddities. In such instances, it is social history (i.e., knowledge of ancestry) that produces assignment to an allegedly biological category.

A final criterion of race in the United States is religion. Judaism is employed to demarcate an allegedly biologically distinct group. But it is clear that Jews conform to the local physiological characteristics of the communities in which they reside (e.g., Germany, Poland, Russia, England, Scandinavia, Spain, France). The Jews in the United States represent a (fictional) biological group created by religious intolerance.

If a cultural approach has some predictive value, one can anticipate that the antipathy of U.S. people toward Arabs in the 1980s and 1990s will likely result in the social construction of yet another historically unknown race—Muslims. (The British have used the term *Wogs.*) Some indication of this process may be seen in the descriptions of the 1990s conflict in the former Yugoslavia. The U.S. media described the conflict as between "Muslims, Serbs, and Croats," although the Muslims were themselves either Serbs or Croats whose ancestors converted to Islam.

Because racism clearly influences cognition, perception, and affect (emotion), it could well appear in psychiatric classifications as a specific disorder. Rather than a condition of professional psychiatric concern, racism and its twin, sexism, instead appear as significant implicit elements in psychiatric (mis)diagnosis and (mis)treatment (Adebimpe; Chesler; Good).

The erroneous views of race found in the United States encode several distinct ideas: (1) a fixed number of distinct biological populations, or races, exist in nature; (2) races have distinctive physical, mental, and/or behavioral characteristics; (3) racial characteristics (physical and behavioral) are naturally reproduced over time; and (4) specific group characteristics—physical, mental, and often moral—are hierarchically ranked, that is, some groups are superior to others (Boas; Gould; Stocking; Montagu). These assumptions, however, are not the only extant racial views of human difference.

Cultural Systems of Racial Classification Beyond the United States

Some writers have argued that capitalism, with a need for cheap labor and for justifying expropriation of land and resources, provided the political context and motivation that drove science to create a defensible basis in biology for immoral acts such as slavery and genocide (Rex and Mason). Certainly, Europeans' encounters with Native Americans and imported West Africans affected their constructions of human difference (Gossett). However, it appears more likely that racial views are a form of *ethnobiology,* a cultural classificatory theory about the nature of human variability (Gaines, 1992a), because some racial ideologies predate capitalism. As well, various capitalist countries exhibit distinctive notions of race. Their differing views have resulted in very different treatment of those designated as belonging to different races.

RACE IN EUROPE. Both English and German science and society produced biological constructions of affinity and difference (Gaines, 1992a). Those who are alike share a common "blood" in Germany and "breeding" in England. Those of the same blood constitute a "race." This German belief is a kind of biological essentialism. It is a much more exclusive notion of race than that found in the United States. It is in reality a kind of ancient kinship theory, a theory of a coherent, related descent group (Gaines, 1992a) that later merged with evolutionist ideas. As such, it is much narrower than U.S. notions. In contemporary Germany, the cultural system of group membership based upon descent from a common ancestor continues. It determines social identity as well as citizenship and suitability to hold political office, for non-Germans cannot hold office or become citizens.

The same system of social classification is found in Alsace, the culturally Germanic northeastern province of France. The biological German system exists alongside a very different, French cultural system that determines ethnic identity by other means. It accords in-group identity to those sharing French civilization and culture. Membership is primarily based on language, not appearance or place of birth (Gaines, 1992a). The term *race* in France thus refers to people who share a particular language and civilization. Both can be acquired, but the latter only by means of the former. Anyone can become French; being French is a linguistic existential state, not a biological one as in the case of the German system.

The so-called racist groups of France may be seen as *culturalists*; their targets are not races but culturally distinct groups, such as unassimilated Muslims. French-speaking sub-Saharan Africans are not targets of the French racism.

North Africans have been historically white even though their complexions run the gamut from black to pale. The conflicts in France thus cannot be based upon race, though they are reported as such in the U.S. media where cultural differences are always interpreted as "racial differences."

RACE IN JAPAN AND SOUTH AFRICA. In Japan, a modern, industrial, and scientific society, a conception of human races exists that differs from that of the United States. Japanese sciences hold, and offer evidence to support, that the Japanese are a race distinct from Koreans, Chinese, the indigenous Ainu people, and the outcast Eta group (DeVos and Wagatsuma). In contrast, U.S. science and society hold that all these people from the East constitute a single biological race, along with South Asians, Indonesians, Filipinos, and others. These people do not evidence a common language, culture, or physical appearance, so the U.S. cultural system converts a geographical designation of people, borrowed from Europe, into an "Asian race."

In South Africa, there exists yet another system that classifies "racial groups." There, before the official collapse of apartheid, a sociolegal system was in place that distinguished four groups: Black, White, Asian, and Coloured. All people with ancestry in more than one of the first three groups were categorized as Coloured. Chinese were Asian, but Japanese were White. Each group historically has had different rights and privileges (see Schwartz, in Gaines, 1992a). All have equal status, at least legally, in the new South Africa.

In the United States, unlike South Africa, science and society ignore mixed ancestry and label individuals as wholly belonging to the least prestigious group of his or her parents, that is, to one exclusive category or another. In medical research, epidemiological studies, and clinical practice, people of mixed ancestry—that is, most Americans—are treated as if they had no ancestry except (West) African, Native American, Asian, or European. Designations are assumed to refer to homogeneous, distinct biological groups. If "admixture" is noted, researchers tend to ignore European ancestry and focus on genetic "vulnerabilities" deriving only from the subject's putative "minority" ancestry (Duster; Gaines, 1985; Wailoo).

In the United States, virtually all people called black or African-American, a term coined by anthropologist Melville Herskovits, would be classified in South Africa as Coloured because of their mixed ancestry (West African, western European, Native American). Indeed, all U.S. residents who claim long lines of U.S. antecedents would be likewise classified because they too have mixed ancestry. The same would hold true for most Native Americans and Latinos. Ironically then, the major U.S. racial groups, those with major antipathies and conflicts enduring over centuries based on their racial differences, all would be classified in South Africa as belonging to the same racial group—Coloured.

Race as a Key Variable in Biomedical Research and Practice

The ideas of race enumerated above underlie almost all medical and psychiatric research in the United States that pertains to group differences other than age or sex (Gaines, 1992a; Hahn; Robbins and Regier; Osborne and Feit). Remarkably, these beliefs concerning the existence or homogeneity of human populations called "races" have not the slightest scientific (or logical) basis; no empirical evidence has ever existed for the differentiation of humanity into broad racial groups (Gould; Montagu; UNESCO, 1969). In reality, thousands of biologically distinct human groups exist (Hiernaux, 1970; Montagu; Naroll and Naroll; Watts).

Assertions of the biological bases of differences among races are used to justify caste systems; that is, the results of oppression, discrimination, and poverty are commonly used to justify further discrimination and prejudice (Boas; DeVos and Wagatsuma; Naroll and Naroll; Thomas and Sillen). As is shown below, medical research, theory, and practice often play this same role in U.S. society and thereby serve as "scientific" justification for the persistence of popular conceptions of racial difference and of racism (Brandt, 1985; Gilman; Duster).

Racial groups are mental constructs. As mental constructs they cannot evidence medical conditions. Yet "one of the most common methodological blunders in scientific studies of the significance of racial differences in the United States is the tacit acceptance of this phantasmic notion of race as the basis for establishing research samples" (Harris, 1968, p. 264). Given this, it can be noted that a folk medicine, or *ethnomedicine,* is largely a creation of cultural beliefs. Its practices serve to reinforce and even justify those beliefs. Such is precisely the nature of medical research on group differences in the United States. This supportive role may be seen in research on afflictions said to appear only in certain populations.

THE MYTH OF RACE-SPECIFIC DISEASES. In biology or psychology, research science is used to reach conclusions that are in fact a priori assumptions; "prejudice not … documentation dictates conclusions" (Gould, p. 80). In today's medical and scientific community, expressed ideas concerning ethnic and gender inferiority are largely implicit.

They are replaced in the medical literature by vague assertions such as vulnerability, susceptibility, tendency, increased risk, and difference. One aspect of this discourse that constructs and maintains racial difference concerns "race-specific diseases." Since it is believed that races are distinct groups with their own biologies, it stands to reason that they would exhibit particular diseases. Sickle-cell anemia is a case in point.

At the beginning of the twentieth century, sickle-cell anemia was found originally through laboratory analysis of the blood of five patients—two European-Americans, two *mulattos* (in the parlance of the time, persons of mixed European and West African ancestry, but very largely the former), and one Negro (who doubtless was also part European). The findings were reported in the medical literature, however, as a condition found only in Negroes (Wailoo). In fact, this condition has existed in most world populations including the Mediterranean, Middle Eastern, Indian, Filipino, and South American. Instructively, the condition is not found among people in eastern, southern, or central Africa. Rather, it is found largely in West Africa, the ancestral area of most people in the Americas with African ancestry. Clearly, the condition is not a "racial disease" but rather a characteristic of some local populations.

Tay-Sachs disease is said to be a Jewish disease. In fact, it is a disorder found in a specific local population of the eastern Mediterranean from which some Jews, as well as Arabs, came. Jews not from this area, and not descended from people who were, have no risk of developing the disorder. The same is true of the so-called Portuguese disease, a degenerative, fatal neurological disease said to afflict Portuguese people. The afflicted are in reality descended from a single person (one Joseph) who carried the gene causing the disease. It is purely by chance that the antecedent person was Portuguese. Unrelated Portuguese are not at risk for developing the disease. In Tay-Sachs and the Portuguese diseases, specific sites of affliction are generalized to all in the racial category of the afflicted. "Local biologies" (Gaines, 1992a) are ignored in favor of "racial" ones.

The medical assertion that certain diseases are peculiar to specific races is without merit. The fiction is maintained through a number of techniques. Findings in a single person of a racial group are regularly generalized to all members of that putative group (Brandt, 1978; Wailoo); a part is made to stand for a whole. For example, a clinical finding that Indians in Britain required lower therapeutic levels of certain psychotropic medications became the basis for research comparing "Asians" and "Caucasians" (Lin et al., 1990; Lin et al., 1986; Mendoza et al.).

Tendencies discerned in research are commonly reinterpreted to suggest significant differences in research on hypertensive medications; "diuretics are best for 'blacks' and beta-blockers for 'whites.'" Since members in neither group have common ancestry in the United States, such stereotypes can limit diagnosis of problems to groups "known" to be afflicted; others are then overlooked, misdiagnosed, or considered to be exceptions. As such, they do not challenge the stereotype, though logically such exceptions should call into question the very notion of racial distinctiveness.

Despite the absence of any scientific basis, the idea of race represents the basic population variable, aside from age and sex, on which inquiries focus and in terms of which results are interpreted and recommendations made. The huge body of literature on race-specific problems and racial comparisons are actually of unknown scientific value, though they represent a rich corpus for cultural study.

As long as medical science continues in its archaic racial folk beliefs, its claims to objective, acultural, and disinterested status in the health field are seriously compromised. Because these and gender beliefs are purely popular, modern medical sciences appear as cultural medicines, ethnomedicines, albeit professional ones (Gaines, 1992c; Hahn and Gaines). The validity of racial conceptions has been challenged and its use compromised. The continued use of racial conceptions in biomedical research and practice looms as a central conceptual and methodological problem in the biomedical sciences.

CONSEQUENCES OF RACIAL BELIEFS. Common to intentional and unintentional discriminatory motivations is the unstated theory that ancestry in nonwhite groups "taints" the individual, not only determining identity but also causing disease. This is the implicit pathologization of perceived "difference" typical in research on high blood pressure and diabetes as well as a variety of other conditions (Cowie et al.; Harris, 1991; Jones and Rice). Affliction is attributed to the fact that the individuals are "minority," by which is meant biologically different and therefore "defective."

Considering the study of diabetes in African-Americans more closely, it is found that while no risk factors and very few cases of diabetes exist in West Africa, individuals classified as African-Americans are still commonly said to be at "high risk" for developing the disease because of their "racial or ethnic ancestry." The presence of diabetes in these populations has other probable causes that are normally overlooked in research. They are (1) the European genetic background of the African-Americans; (2) poverty and related poor nutrition caused by discrimination; and (3) the high animal-fat content of the dominant northern European diet.

Racial thinking leads researchers to ignore oppression, racism, and discrimination—all of which can implicate the researchers themselves—as well as other cultural and biological factors. Research is confined to allegedly biological problems existing as defects within the afflicted. The real biogenetic makeup of individuals goes unanalyzed while their social identity is blamed for their illness.

Research on the treatments of choice and treatment recommendations in U.S. biomedicine demonstrates that medical and psychiatric diagnoses and therapeutic choices are often made on the basis of patients' social identity, be it race, class, or gender rather than objective need (Brandt, 1985; Ehrenreich and English; Gilman; Good; Lindenbaum and Lock; Osborne and Feit). Historically, this includes the differential use of anesthesia; the poor didn't need it but the wealthy did, as they were more delicate! (Pernick).

The form of intervention in psychiatry, pharmacotherapy, and psychotherapy is today heavily dependent on racial and/or sexual stereotypes rather than on empirical psychiatric signs or symptoms (Katz; Gaines, 1982, 1992a, 1992c; Littlewood). Blacks and Hispanics are often seen as belonging to that group of patients termed *psychologically unsophisticated* or *not psychologically minded* (e.g., Leff; MacKinnon and Michels; Sudack). Psychopharmacotherapy is seen as more "appropriate" for such patients than forms of "talk" therapy.

It should be recalled that U.S. psychiatry in the nineteenth century "found" that psychiatric disorders afflicted black slaves who otherwise "unaccountably" ran away from their masters. This is a historical version of a biological psychiatry and posits that all conditions are biological and will ultimately yield to somatic interventions. Environment, in this view, can be discounted or its consideration delayed until suspected "biological components" can be studied.

In medical research, behavior is also related to race. Medical researchers often choose research topics that implicate behaviors judged as immoral or incautious when dealing with minority populations, for example, number of sex partners, unwed mothers, and drug addiction (Gaines, 1985; Osborne and Feit). In this way, medical research also becomes moral research and supports blame-the-victim thinking.

In the psychiatric literature, neo-evolutionist racial theories lurk behind some assertions. Certain groups, such as the English, are said to be more evolved and psychologically normal (see Leff). In this view, somatization is allegedly less evolved and is characteristic of less developed "traditional" or "primitive" societies. The position inserts a cultural view of emotion and thought into a not-too-implicit neo-evolutionist scheme.

In the West, emotions are believed to be natural, universal, and distinct from cognition. But anthropological research has shown that specific emotions are not universal nor are they naturally distinct from cognitive or bodily states and functions (see Good et al., Lutz, Obeyesekere, Schieffelin, in Kleinman and Good). While highly valued in a very few cultures, psychologization of distress is not "natural," but rather a learned, shared, and transmitted cultural approach (Kleinman). Psychologization is not found in many areas of Europe itself, for example, the Mediterranean and eastern Europe (Gaines, 1992c; Gaines and Farmer; see Good et al. in Kleinman and Good), or in China, Japan, or India (Kleinman and Good; Leslie and Young).

Research on racial differences provides the scientific bases for the maintenance of popular and scientific racial ideology in the United States. This ideology clearly leads to differential evaluation of social actors in medical and nonmedical contexts. As such, biomedical practices can be said to contribute to the social problems caused by racism. These problems include unequal access and poor medical outcomes (Good). The use of racial categories in biomedical research and practice, then, may be seen to breach the medical profession's own primary ethical injunction "to do no harm."

GENES, RACE, AND VIOLENCE. Biomedicine conceives of its domain as the discovery and manipulation of nature (see Gordon, in Lock and Gordon). Its wider culture perceives nature as something to be dominated and controlled (Pike). Ideas of nature, as well as those of difference and inferiority that are encoded in racial and gender identities, greatly affect practice and research in U.S. biomedical sciences. Classes of people believed to be closer to nature are seen as requiring control and guidance, even domination. Such people—among them women, children, non-Anglo or non-Germanic European ethnics (e.g., French, Italian, Spanish, Celtic, and Slavic people), Africans and their descendants, Native Americans, Hispanics, Pacific Islanders—are, in the United States, rather widely believed to be emotional, and therefore dangerous, unpredictable, and wild. Comments about "natural abilities" (intuitive, musical, irrational, fierce, shrewd) or characteristics of particular groups indicate their closeness to nature; they, like animals, are thought to be dominated by instinct and irrationality, not by "reason," a European cultural and masculine virtue (Chesler; Fausto-Sterling; Kleinman and Good; Pike).

The imputation of wildness, impulsiveness, and irrationality is doubtless a culturally constituted defensive projection of aggression that actually exists in the dominant group (Gilman; Pike). It is used to justify control, domination, and even extermination, as with Africans and Native

Americans in the United States and non-German ethnics and the disabled in World War II Germany.

A similar logic appears in contemporary U.S. society. Urban violence, born of repression, discrimination, violence, and poverty, is recast as "genetic predispositions to violence or criminality" in individuals and the groups to which they are ascribed, especially after periods of civil unrest. However, rather obvious examples of genetic predispositions toward criminality and violence in the dominant group are regularly ignored as are centuries of clear provocations of African-Americans.

If researchers were indeed interested in a dispassionate evaluation of genetic components of violence and criminality, it would be appropriate to study people descended from generations of individuals all of whom have committed crimes of a serious nature. In the United States, such a population would be the many immigrants from Russia or Germany, as well as their offspring. Another group of subjects would be the descendants of slave traders and owners. Mass murderers and serial killers in the United States and Europe are virtually always white; their relatives would be suitable subjects of biological research on white criminality. These data might suggest some genetic basis for the inheritance of violent tendencies, if one were to think in racial terms. But researchers on violence and its causes regularly ignore such evidence. It appears that violence and criminality are possible genetic predispositions only when they appear in individuals belonging to specific low-status racial groups.

RACE AND CLINICAL STUDIES. That racial groups are considered unequally in U.S. biomedical science and society is clearly demonstrated by the infamous and tragic Tuskegee syphilis study. In 1932, the U.S. Public Health Service (PHS) began a prospective study of syphilis infection among four hundred rural Alabamans who were black male sharecroppers. The researchers asserted that the study could be a "natural experiment" because it was assumed (for racist reasons) that "such people" were all infected and would not seek treatment for their condition (Brandt, 1978). For these reasons, the PHS argued that it could observe the natural history of syphilis infection in these black men. As it happened, the subjects, who had been unknowingly selected, began to seek treatment almost immediately.

Rather than provide healthcare, the PHS initiated a vast conspiracy to prevent the subjects from receiving care from any source. It conspired with local and state health officials, clinics and hospitals, and the U.S. Army, in which some of the men had enlisted, to prevent disclosure to the subjects of their diagnosis and to prevent treatment of their affliction.

Despite the fact that the natural experimental premise was invalidated in short order, this horrendous project continued over four decades until 1972, when public outcries finally stopped it. Until that time, however, the study was often reported in the medical literature without raising ethical concerns about informed consent, the sometimes fatal use of these human subjects, or the conspiracy to prevent them from receiving efficacious treatments (Brandt, 1978, 1985).

Aside from specific research projects that indicate differential concern for specific groups in the United States, "minorities" in day-to-day medical settings are often underdiagnosed for problems that could be treated (e.g., heart disease) and overdiagnosed for others. For example, blacks are regularly misdiagnosed with schizophrenia. These misdiagnoses lead to confinement and inappropriate pharmacological regimens. Loss of freedom and improper use of powerful psychotropic medications may themselves lead to chronicity in the illnesses that are left untreated, illnesses that led the patient to the attention of health professionals in the first place (see Adebimpe; Mukherjee et al.; Bell and Mehta; Good). This is one means by which medicine creates chronicity of particular disorders as well as increases in the reported incidence of these disorders in a specific population. The circular logic is completed by the subsequent tendency to diagnose in an individual a disorder that is reported as "common" in members of his or her racial or ethnic group.

It is important for a full understanding of the role of racial classifications in the biomedical field to see it as part of a cultural system. This allows for the recognition of both the clearly concerned altruistic practitioners and researchers and the profoundly troubling aspects of racial thought in biomedical practices. In this view, the problems of racial thinking may be seen to arise frequently from the use of popular racial notions by force of tradition—tradition in the Weberian sense, wherein it is one source of authority for human action (Weber). The use of racial categories is thus not necessarily racist.

Conclusions

The U.S. version of human biology is a folk biology that assumes that social categories—"races"—are reflections of nature rather than culture. As a result, biomedical work, as well as public healthcare, is conducted and interpreted in these terms. In clinical practice in U.S. medicine, every patient record begins with three basic bits of information thought to be of critical importance: age, race, and gender (e.g., "A thirty-seven-year-old black female presented with

…"). This is a significant part of the discourse of medicine that reconfirms the cultural conceptions that race, age, and sex are natural and empirical realities that make a difference.

Specific forms of communalism, such as racism and sexism, are intrinsic to U.S. society. As a result, they are fundamentally part of its medical institutions, because U.S. medicine is a reflection of the culture that created it. Culturally specific prejudice makes U.S. biomedicine an expression of a particular culture and its history. That culture has held and still expresses empirically problematic and ultimately unethical conceptualizations of human variation. However, neither contemporary medicine nor society remains monocultural; different ethnic and gender voices are being heard advocating what may be seen as more cultural and therefore humane and equal medical-research concerns and treatment. In many scientific fields, the lessons learned from the Nazi atrocities—as well as the inclusion of Jews, African-Americans, and women into collegial relations—has helped to reduce scientific racism and sexism since the 1950s (Barkan). Trends of pluralism begun then continue and expand.

Modern biomedical thought in the United States appears to lag in its understanding of the bases of human differences. The basis is culture, not biology. Even though racial terms are now often exchanged for ethnic ones, the problems persist in biomedicine and related sciences. Ethnicity has a cultural referent, and race has a putatively biological one. The two terms are incommensurate and cannot be used interchangeably.

Intentionally or unintentionally, biomedicine conserves, employs, and disseminates racial and gender-biased conceptions in its theory and practice. Such actions may be seen to derive both from habit and from nefarious intent. Comparisons are at the heart of science. U.S. science, along with U.S. popular society, has always thought that comparisons of black versus white or other races are the more or less "natural" ones to make in a "multiracial" society. Some others yet seek to show one group's superiority over others.

Biomedical enterprises will surely be subject to increasing ethical and practical criticism in the future "both from without and within its cultural tradition by those it fails to serve and those it serves to fail" (Gaines, 1992c). The growing understanding of the cultural biases of the professional medicines (and sciences) of the world suggests that medicines, like their particular medical ethics, reflect local cultural realities. A pluralistic medicine is needed in a multicultural country such as the United States. In such a country, a single medical voice may easily lead to, if not generate, bioethical conflicts. A medicine without cultural understandings, unreflective of its own cultural foundations, is inadequate, and an inadequate medicine cannot be of great help in a multicultural society.

REHABILITATION MEDICINE

• • •

Rehabilitation medicine encompasses medical, psychosocial, and vocational interventions provided to persons who have experienced some type of functional impairment. Individuals receiving rehabilitation services may have been born with a disabling condition, such as cerebral palsy, spina bifida, muscular dystrophy, or mental retardation; or they may have acquired disability from stroke, spinal cord injury, polio, amputation, cardiovascular disease, acquired immune deficiency syndrome (AIDS), or traumatic brain injury. They may receive rehabilitation treatments at a traditional acute-care hospital, at a hospital specializing in rehabilitation, or at a post-acute facility, sometimes called a *transitional* or *independent living* facility. Increasingly, individuals receive rehabilitation services in their homes through home health agencies or visiting nurses (DeLisa).

Consumers of rehabilitation medicine, especially if their disabilities are acquired rather than congenital, invariably experience intense feelings of anger, rage, helplessness, and worthlessness (Gunther, 1971). Ethical problems arise from the way disability disrupts one's capacity to make autonomous choices and decisions and to develop and sustain meaningful social relationships. The transformation of a self that experiences profound alienation resulting from a disability to a self that can productively engage the world is the ultimate challenge of rehabilitation and prompts many of its ethical considerations.

Certain aspects of contemporary rehabilitation medicine derive from treatment strategies, dating back to the 1920s, for managing job-related injuries. A series of developments associated with World War II, however, shaped rehabilitation medicine as it is known today. Widespread use of penicillin resulted in the survival of seriously injured soldiers. The resultant crowding of nursing homes and chronic-care facilities created an imperative to return wartime casualties either to the front or to meaningful civilian life. President Franklin Roosevelt, himself no stranger to rehabilitation, wrote to Secretary of War Henry Stimson in

1944 that "No overseas casualty [shall] be discharged from the armed forces until he [*sic*] has received the maximum benefit of hospitalization and convalescent facilities, which must include physical and psychological rehabilitation, vocational guidance, prevocational training and resocialization." Toward the war's end, financier Bernard Baruch and physicians who included Howard Rusk and Henry Kessler established Veterans Administration hospitals that would translate the war experience of rehabilitation into civilian life. Their vision evolved into the comprehensive multidisciplinary approach of rehabilitation that is known today (Berkowitz).

Admission to a rehabilitation facility, typically a few weeks or months after acute hospitalization, anticipates that the individual is medically stable and not at serious risk of a life-threatening episode. Most important, patients admitted to rehabilitation facilities are deemed to have sufficient capacity and "rehabilitation potential" to engage in various therapeutic programs aimed at restoring as much functional ability as possible (Purtilo, 1992). Absence of rehabilitation potential may result in the individual's admission to a long-term-care facility.

Contemporary rehabilitation interventions focus on reducing the disabling effects of physical impairments (e.g., poor motor control, loss of sensorimotor skills, muscle weakness, loss of sensation, paralysis, loss of bowel and bladder control); cognitive impairments (e.g., poor concentration, memory, attention, insight, information processing, problem solving); or behavioral impairments (e.g., emotional disorganization, poor emotional expression, inability to engage in goal-directed behavior, poor interpersonal skills). Because the patient's impairments often appear in combinations or clusters, rehabilitation medicine involves an array of specialized therapies and services to assist patients in overcoming their often multiple functional limitations (Keith).

In acute rehabilitation hospitals, treatments are typically provided by a specially designated team of professionals that, depending on the nature and extent of the patient's impairments, may include a physiatrist (a physician who specializes in physical medicine and rehabilitation), a rehabilitation nurse, a physical therapist, an occupational therapist, a specialist in communicative disorders, a recreational therapist, a psychologist, a social-service specialist, a spiritual adviser, an orthotistprosthetist, a vocational rehabilitation counselor, and perhaps a rehabilitation engineer (Lyth). Length of stay for rehabilitation patients varies according to medical need and the extent of health insurance. Stroke patients commonly spend two to six weeks in acute rehabilitation (Parfenchuck et al.); persons with serious brain injury may spend one to four months (Cope and Hall); and persons with spinal cord injury may spend three to five months (Apple).

Bioethical Issues

Because the scope of rehabilitation medicine is so broad, and because other entries will focus on bioethical aspects of disability that either follow from or are independent of an individual's formal stay in an in-patient rehabilitation facility, this entry will discuss certain bioethical aspects of rehabilitation medicine as they derive from the provider-patient relationship. Examining how rehabilitation relationships form and evolve illuminates how bioethical ideals such as autonomy, nonmaleficence, beneficence, and justice occur in the context of treating persons with serious disability. The provider-patient models whose bioethical ramifications will be discussed below are the contractual, paternal, educational, and empowering models.

THE CONTRACTUAL MODEL. The contractual model usually refers to the clinician and the patient developing a mutual understanding and accord on the nature of and need for treatment, its probable benefits and risks, and so forth. Informed consent is central in such discussions; the provider of services assumes certain contractual responsibilities to inform and secure consent to treat the patient, while the patient's consent implies an agreement to the conditions of treatment, including reasonable compliance with the treatment program, remunerating the provider, and so on (Caplan et al.).

The rehabilitation patient's engagement in treatment is not passive, as it would be in an acute, surgical scenario. Active and eventually self-directed, it focuses on learning and performing a variety of functional tasks, such as walking, dressing, toileting, and bathing. Nevertheless, the contractual model in acute rehabilitation is immediately qualified by the fact that many rehabilitation patients have sustained organic impairments that substantially interfere with their cognitive ability to make autonomous decisions. Some patients may not be able to concentrate on, understand, evaluate, or process information well enough to make choices and decisions congruent with their welfare. Or the patient may be psychologically devastated by the onset of disability and unwilling to participate in therapy. Certain rehabilitation patients may experience serious cognitive disorganization accompanied by frightened, anxious feelings and regression to childlike levels of behavior, especially with respect to managing their feelings and impulses (Rosenthal).

Although rehabilitation is defined as elective treatment, many patients do not elect it at all. The onset of a disability like stroke, spinal cord injury, or brain injury can be so

abrupt and severe that many rehabilitation patients begin to comprehend the nature and extent of their disability only *after* they have been medically stabilized and referred to the rehabilitation environment. There the patient, confronted with the functional challenges that the disability has imposed, may begin to try to make sense out of what has happened and to deal with the fact that some of his or her life expectations may have to be modified. To the extent that patients are cognitively or psychologically unable to manage these situations, their capacity to make autonomous choices is problematic (Purtilo, 1988). Furthermore, the individual who is discharged directly from an acute hospital to a rehabilitation facility, and only then begins to realize his or her circumstances, has not voluntarily assumed the promissory role that is implicit in the contractual model. To view such a patient's subsequent resistance to or noncompliance with the rehabilitation effort as a violation of a contractual agreement overlooks the fact that the patient may never have reflected on or consented to rehabilitation in the first place.

In sum, the contractual model's presumption of an autonomous self who can voluntarily and insightfully contemplate, assume, and fulfill a variety of promises and obligations is hardly congruent with the reality of the acute rehabilitation environment for many patients. From what has been implied above, a more probable model of care, at least in the early stages of recovery from a neurological event, is the one that will be examined next: the paternalistic model.

THE PATERNALISTIC MODEL. Paternalism has been defined as "the interference with a person's liberty of action justified by reasons referring exclusively to the welfare, good, happiness, needs, interests or values of the person being coerced" (Dworkin, p. 65). Once the prevailing model in provider-patient relationships, paternalism has since 1970 come under increasing fire, both from the patient-rights' movement and in the literature of bioethics. Compelling legal justifications for paternalism now condone overriding a patient's decision only when the decision would pose serious harm to the patient or to identifiable others (Jonsen et al.). In acute rehabilitation, justified paternalism is usually predicated on the patient's impaired cognition or psychological disorganization. As Arthur Caplan observed, "If it is true that time is essential in allowing patients to accommodate to the reality of severe impairment, then this would seem … at least for some patients in some settings, to allow for the presence of paternalistic medical care" (1988, p. 315).

Paternalism in acute rehabilitation frequently appears when patients resist complying with their therapeutic program. Patients may object to the time at which they must rise in the morning to begin therapy, the nature and intensity of their therapies, their diet, the kinds of medications they require, the aesthetics of their hospital room, the personalities of other patients in their room, the date of discharge, or the discharge site. Alternatively, some rehabilitation patients will insist on engaging in activities that pose harm to them, such as trying to walk unassisted despite poor balance or muscle weakness.

Paternalistic interventions in certain instances—such as refusing to comply with a clinically depressed, suicidal patient's request for privacy—are easily justified. Paternalism cannot serve as the preferred provider-patient relationship, however, for at least three reasons. First, justifying a paternalistic intervention in rehabilitation on the basis of a patient's cognitive or psychological impairment requires an objective determination of that impairment. If the rehabilitation patient exhibits profoundly impaired memory, extreme confusion, or very poor judgment, he or she has a doubtful claim to self-determination. Yet providers may disagree on which of the patient's decisions are sufficiently problematic to justify a paternalistic decision. Richard Wanlass and his colleagues showed that rehabilitation clinicians do not consistently or reliably apply the labels "mild," "moderate," and "severe" to cognitively impaired patients; Vivian Auerbach and John Banja found that considerable discrepancy exists among physicians, mental-health professionals, and lawyers in distinguishing competent from incompetent decisions made by persons with traumatic brain injury; and Bruce Caplan noted a marked disparity between patient and provider ratings of the patient's mood. In cases of considerable professional disagreement about a patient's "competence" to make decisions or the severity of a patient's cognitive impairment or mood disorder, it is not possible to justify overriding the patient's decision *on those bases.*

A second reason for rejecting a thoroughgoing paternalism in rehabilitation is that providers with paternalistic attitudes risk misinterpreting resistance to therapy as "noncompliant" or "unmanageable." Whatever their therapeutic value, such attitudes and behaviors may indicate the provider's need to be in control (McKnight). When patients resist the provider's ministrations, the provider may become angry or exhibit behaviors destructive to the therapeutic relationship (Gunther, 1987). What may appear to be noncompliant patient behaviors may in fact be the patient's attempt to assert himself or herself, an attempt that perhaps ought to be applauded as an expression of the patient's striving for independence rather than discouraged as inappropriate behavior.

A third reason for rejecting paternalism is that it ultimately runs counter to the rehabilitation ideal of independence. If the goal of rehabilitation is to help the person's movement toward functional independence, then patients

ought to begin learning how to assume control of their lives in the rehabilitation environment. Consequently, the rehabilitationist who excludes the patient's input or interest in defining goals and making decisions is stifling the very behavior and attitude he or she is supposed to be cultivating. Indeed, because a profound change in one's bodily image and functional capacity can so seriously affect one's self-image and identity, the ultimate goal of rehabilitation may well be to bring patients to accept themselves as persons with disability and empower them with the necessary will and information to engage the world on somewhat new terms (Banja).

THE EDUCATIONAL MODEL. Empowerment depends in part on various kinds of information the patient will need to function as autonomously as possible. Newly disabled persons require information on and training in managing their activities of daily living (e.g., bathing, grooming, feeding, toileting, and so on); they may also need to learn about creative recreational opportunities, financial planning, social skills training, problem solving, accessing community resources, sexual enjoyment, using community transportation, assertiveness, and perhaps vocational planning or training. Patients should also learn about their rights as rehabilitation consumers before and after rehabilitation discharge: that they have the right to request reasonable changes in the personnel of their teams; that disclosures of otherwise confidential information may occur, for example, to family members or third-party payers; how rehabilitation termination is decided and what evidence is used to determine the nature and length of the rehabilitation; and how they are protected by legislation, such as the Americans with Disabilities Act (Caplan et al.).

Providing this information responds to the same ethical principles requiring that information be imparted to an individual about to undergo surgery. In the latter case, information is treatment-specific, while in the former, the information addresses a host of functional issues. But whereas consent to surgical procedures pertains only to the intervention at issue, consent to rehabilitation reflects a disabled person's willingness to manage his or her life. If no effort is made to stimulate the rehabilitation patient's will to use that information or to be autonomous, then the rehabilitation effort may ultimately fail. Rehabilitation providers not only must convey important information but also must seek to deepen the patient's appreciation of its value and encourage the patient to use it.

THE EMPOWERMENT MODEL. Able-bodied persons frequently confess to being uncomfortable around and having negative feelings toward individuals with disability. Persons with disability are therefore often isolated, deprived, discriminated against, and generally assigned to dependent roles. Ironically, even public programs presumed to assist persons with disability toward autonomy and independence sometimes foster dependency (McKnight). Persons who receive services from such programs frequently complain of feeling dehumanized, subservient, devalued, and ostracized. Studies of the psychodynamic aspects of relationships among program personnel and clients suggest that program staff may develop a narcissistic feeling of authority from these relationships that is threatened by their clients' acting independently (Mullins). Consequently, it is not surprising that such programs may be perceived by clients as unhealthy.

According to the empowerment model, which is moored in principles of social justice, the goal of rehabilitation is to facilitate the rehabilitation consumer's access to social goods. Necessary elements of this access involve social attitudes and measures that aim at equalizing opportunity. Because persons with disability face limitations on normal functioning, justice theorists like Norman Daniels (1985) argue that a society ought to assume certain duties to make up for the fact that an unequal distribution of disabilities among citizens unfairly handicaps the disabled person's attempts to satisfy his or her life needs. Legislation such as the Americans with Disabilities Act, which calls for reforms in hiring practices, barrier-free architecture, handicapped-accessible public transportation, and the implementation of communication devices in business operations for employees who are speech- or hearing-impaired, is highly responsive to the goal of empowerment.

The robust sense of autonomy explicit in the empowerment model transcends clinical objectives that stop at restoring functional ability. In seeking to enhance the individual's power to control his or her life, the empowerment model aims at liberating the individual's self by respecting and advocating the individual's right to his or her choices, preferences, and decisions. From a therapeutic standpoint, therefore, the provider may have to honor the patient's preferences even if they contradict the therapist's, allow the patient to take reasonable decision-making risks, and be prepared to assist when the patient fails. Most important, the therapist must provide the patient with the tools necessary to seize, maintain, and enjoy control of his or her life.

Because many rehabilitation patients are depressed and despondent over the onset of their disability, various empowering models or strategies have been formulated by mental-health professionals (O'Hara and Harrell). A key ethical challenge for the therapist is determining when patients are reasonably ready or "competent" to gainsay

therapeutic recommendations, or when patients can "reasonably" assume the risks inherent in the enjoyment of their moral and constitutional liberties and freedoms (Purtilo, 1988).

Meeting this kind of challenge requires an acute sensitivity on the therapist's part in judging when certain types of paternalistic interventions are warranted versus when patients may assume control and responsibility. While the empowerment model may not object to vesting decision-making authority in the provider at the beginning of rehabilitation, in ideal cases that power is increasingly channeled to the consumer as rehabilitation discharge nears. The goal is for patients to realize their right to engage the world on their terms and to enjoy the self-esteem and dignity of risk that derives from doing so (O'Hara and Harrell).

Familial and Social Obligations

Families play a critical role during the rehabilitation process, not only supporting their loved ones but also learning how to accommodate their needs after rehabilitation discharge. The nature and extent of familial duty that occurs by virtue of a member's becoming disabled is nevertheless problematic. Overwhelmed by the financial and personal toll that caring for someone with serious disability poses, families may feel that the burdens imposed on them by the individual's care needs are unreasonable. If the family defaults, does an individual's misfortune in sustaining a disability impose special obligations on society? The extent to which the disabled person's family assumes the responsibilities of care depends on the family's love, sense of values, and willingness to sacrifice, rather than on legal or constitutional mandates (Callahan). If both family and society repudiate a duty to care for the person with disability, then the rehabilitation itself is jeopardized.

The future of allocating rehabilitation services requires a moral consensus about what disability within human life means and whether and to what extent society has a duty to accommodate the needs of persons with disability. Because such a consensus about disability does not yet exist in contemporary American society, rehabilitation medicine is available largely on the basis of the ability to pay (Brody). Shrinking financial resources may preclude the provision of rehabilitation resources to those who desperately need but cannot afford them. Although condoning such a situation in an egalitarian society seems ethically repugnant (Purtilo, 1992), a marked reluctance, if not downright hostility, exists toward imposing social obligations—such as increased tax revenues—to improve care for persons with disabilities. In the face of moral arguments that the burdens resulting from disability should be lightened by spreading them as widely and equitably as possible, libertarians counter that because "I am not my brother's keeper," others' disability and its rehabilitation are not their concern (Will).

To the extent, however, that able-bodied persons accept the idea of valid social roles for persons with disabilities, social stigmas that have interfered with the latter's participation in mainstream American life may diminish. The implementation of the Americans with Disabilities Act may facilitate this change in attitude because it insists that greater opportunities be made available for persons with disability to enter the economic mainstream of American life. Furthermore, demographic projections indicate an astonishing rate of growth among elderly persons in the United States, many of whom will require rehabilitation services at some point in their lives. To the extent that they can influence the political will, access to rehabilitation resources may expand rather than shrink through legislative enactments.

If moral arguments are not sufficient to justify the allocation of rehabilitation services, certain purely material considerations might compel an examination of the merits of rehabilitation medicine. Extensive research indicates that the social costs of disability without rehabilitation are staggering (Brooks; Davidoff et al.). Reimbursement for rehabilitation services might be straightforward and noncontroversial, then, simply because of its cost-effectiveness.

Appeals to self-interest may also sustain an interest in rehabilitation's merit. As medical technology and improved lifestyle choices result in increased longevity, the need for rehabilitation services will doubtless increase. To the extent that living longer increases the probability of a disabling neurological or musculoskeletal impairment, Americans might seek to protect their own access to rehabilitation services by advocating an entitlement to such access for everyone else.

In any case, rehabilitation's objective of securing independence for its consumers fits admirably into an egalitarian culture's sociopolitical aspirations. Independence for persons with disability is the same thing as independence for the able-bodied: the ability to enjoy life as a chooser of ends and to participate in a just and democratic society. Much to its credit, and perhaps more than any other medical specialty, the ethos of rehabilitation medicine embodies these cherished ideals of individual freedom and liberty.

REPRODUCTIVE TECHNOLOGIES

I. INTRODUCTION

The development of effective and imaginative approaches to the management of human infertility has focused public attention on the techniques themselves and on their ethical and legal implications. Although differing widely in their complexity, these methods have one characteristic in common: the separation of human reproduction from the act of coitus. An understanding of these reproductive technologies is essential to an overall consideration of the ethical issues surrounding them.

Artificial Insemination

Artificial insemination involves the mechanical placement of spermatozoa into the female reproductive tract. Inseminations are separated into two broad categories: those using the semen of the husband or designated partner (AIH) and those employing semen of a third party, or donor insemination (DI). Because the ethical and moral issues surrounding AIH and DI take on different dimensions, each will be considered separately.

AIH constitutes effective treatment when, for whatever reason, the male partner is unable to ejaculate within the vagina. Some males are unable to ejaculate during coitus but can ejaculate through masturbation or the use of vibratory stimuli. Certain anatomical abnormalities result in faulty semen placement. Hypospadias, a penile abnormality in which the opening of the urethra is located a distance from the tip of the glans penis, causes the ejaculate to be deposited at the periphery of the vagina even when the penis is well within. Retrograde ejaculation is a condition usually caused by a complication of prostatic surgery resulting in the formation of a channel that causes the ejaculate to be directed away from the penis and retrograded into the bladder. After ejaculation, semen for artificial insemination can be recovered from the bladder by catheterization.

Normal vaginal intercourse may be precluded by congenital or acquired vaginal abnormalities. In rare cases, the vagina is constricted as the result of in utero exposure to the hormone diethylstilbestrol (DES) or possibly by past trauma. Psychological problems in the male or female or both may interfere with normal coital exchange.

In recent years, AIH has been recommended when the semen displays deficiencies in numbers of sperm or their ability to move. Laboratory techniques have been developed to separate and concentrate the most active spermatozoa. These are then introduced into the uterine cavity, closer to the site of fertilization. Intrauterine insemination has been successful in cases of male infertility and in couples with unexplained infertility (Guzick et al.).

TECHNIQUES OF OBTAINING SEMEN. Semen for use in artificial insemination is usually obtained by masturbation. An alternate possibility is intercourse using a plastic condom. Coitus interruptus is not recommended, as the first portion of the ejaculate, which contains the majority of active, motile spermatozoa, is sometimes lost. In cases of obstruction of the vas deferens, which serves as the conduit for spermatozoa, spermatozoa can be obtained surgically from the epididymis, the storage depot for spermatozoa. Specimens so retrieved have been used successfully for in vitro fertilization.

TIMING OF THE INSEMINATION. Placement of spermatozoa should be timed to coincide with the twelve hours immediately preceding ovulation. Approximately twenty-four hours before ovulation, increased levels of luteinizing hormone can be detected in the urine, using a color indicator to predict ovulation. The day-to-day development of the egg-containing ovarian follicle can be monitored with pelvic ultrasound. To enhance the accuracy of ovulation timing still further while causing the release of additional eggs for fertilization, the use of human gonadotropins to induce ovulation has become increasingly popular.

INSEMINATION AND SEX SELECTION. Insemination has also been used with limited success for sex selection. Laboratory methods have been suggested to separate the X-chromosome-bearing (female-producing) from the Y-chromosome-bearing (male-producing) spermatozoa. Success rates in the production of male offspring in the 80

percent range are claimed (van Kooij and van Oost). Such techniques are useful in animal husbandry but do not yield a consistently satisfactory success rate in humans. Sex selection would be useful to avoid a sex-linked genetic disease. Sex preselection based solely on preference for a boy or a girl has much wider social implications.

DONOR INSEMINATION. Donor insemination was mentioned as a method of treating infertility in the nineteenth century. As DI has become more widely used, the legal climate has become more favorable and the status of the offspring much less uncertain. With this has come awareness of the importance of careful counseling and the use of appropriate permission forms. There has not yet been a case in U.S. law in which the anonymous sperm donor has been assigned parental responsibility.

The clinical indications for donor insemination are related mainly to deficiencies in the semen. The most clear-cut cases are those in which the male partner suffers from azoospermia (absence of spermatozoa). Indications have been extended to include those in whom some spermatozoa are present but the quality of the specimen is poor. Known hereditary disorders in the male partner, such as Huntington's disease, Tay-Sachs disease, or hemophilia, are also indications for DI.

In vitro fertilization (IVF) has widened the possibility of conception with severely deficient semen. Donor insemination is sometimes used in IVF when there is failure of fertilization using the male partner's specimen.

EVALUATION OF THE COUPLE FOR DONOR INSEMINATION. A couple considering donor insemination should be thoroughly counseled. If either partner has reservations, it is wise to accept these at face value and encourage consideration of other options, including adoption. The man's fertility should be thoroughly evaluated, and efforts made to correct any abnormalities. The woman also should be thoroughly evaluated for factors that might contribute to infertility. Both partners are usually required to review and sign a detailed informed-consent form.

SELECTION AND SCREENING OF DONORS. Unless he expresses willingness to be identified, the donor is anonymous. Occasionally there is a request that a close relative (usually a brother or even a father) be used. In such cases, the couple should be encouraged to consider carefully the potential for future familial conflicts. Analysis of donor semen should meet the normal standards for fertility (ASRM, 2002). The donor should be in excellent health and be screened for any family history of genetic disorders. Serologic tests for syphilis and serum hepatitis B antigen are obtained initially and after six months. The genitalia are cultured for gonorrhea and chlamydia. An initial screening for the AIDS virus antibodies is performed and repeated after six months because the antibody test for AIDS may not turn positive until several months after infection. Most centers now use frozen semen exclusively. If a donor is providing repeated specimens, periodic reevaluation of his health status is essential. Clinics should maintain records of pregnancies and set a limit on the number of pregnancies any one donor may produce. To decrease the possibility of consanguinity (procreation between close relatives, such as siblings or first cousins) in a given population, an arbitrary limit of ten or fewer pregnancies is recommended.

It is important to maintain confidential donor records, including all of the information on the screening procedures, so that it is available in the future in case it is needed for medical reasons.

TECHNIQUE OF INSEMINATION. The standard insemination involves placing the specimen, thawed if it has been frozen, into the cervical canal by means of a small, flexible tube (cannula). As the vaginal speculum is removed, the remainder of the specimen is placed in the vagina, at the outer cervical canal. The patient remains supine for twenty minutes or so. The specimen may be held in place with a cervical cap, which is removed four to six hours after insemination. For intrauterine insemination, a plastic cannula is passed through the opening of the cervix into the uterine cavity, where the concentrated, pretreated (i.e., washed) spermatozoa are deposited.

CRYOPRESERVATION OF SEMEN. Since the first successful insemination with freeze-stored semen in 1953, this technique has had a significant impact on clinical practice. In the 1970s, formal semen banks were established, largely to address the needs for long-term preservation of the specimens of men who had undergone vasectomy. Semen also is preserved prior to chemotherapy or radiation, which might result in sterility. Although there is no formal reporting system, information accumulated over the years has failed to uncover an increased incidence of genetic defects among the offspring resulting from insemination with cryopreserved semen.

The response of spermatozoa to cryopreservation is unpredictable and varies on an individual basis. Some specimens freeze well and others do not. The pregnancy rate is lower overall with frozen semen. The only reliable way to determine whether a specimen is suitable for cryopreservation is to cryopreserve it, thaw it, and evaluate the impact of the procedure on the quality of sperm motility. Specimens are usually stored in individual straws or small vials so that

fractions may be thawed while the remainder is preserved for future use. The Ethics Committee of the American Society for Reproductive Medicine (formerly the American Fertility Society, AFS) has determined that cryopreservation of human semen is ethically and medically acceptable (ASRM, 2002). Most programs use only cryopreserved semen for donor insemination.

In Vitro Fertilization

In vitro fertilization and embryo transfer (IVF-ET) is increasingly common in infertility practice. Initially used exclusively in women with damaged fallopian tubes, the indications for IVF-ET have been extended to include male factor infertility and cases in which no cause for the infertility can be uncovered. Much as artificial insemination separates procreation from the coital act, in vitro fertilization separates fertilization from the normal maternal environment, allowing the initial phases of development to occur outside the reproductive tract, followed by transfer of the embryo into the uterus. The first successful in vitro fertilization was carried out in a normally ovulating woman whose tubes had been surgically removed. A single egg (ovum, oocyte) was obtained by aspiration at the time of laparoscopy. The procedure required general anesthesia and involved placing a telescope through the umbilicus for visualization of the pelvic structures. The oocyte was fertilized in vitro and transferred to the uterus after two days.

In later developments, the ovaries were stimulated with human urinary gonadotropins to induce development of several follicles, each containing an ovum, in a given cycle. This approach is now standard. Follicular development is followed by means of blood estrogen levels, and the size of the growing follicles is measured by ultrasound. When the follicles are judged ready for ovulation, a second hormone, human chorionic gonadotropin, is administered to induce ovulation. This causes further development of the follicles and the maturing of oocytes within them. The oocytes complete their first division in a process referred to as meiosis, releasing half their complement of chromosomes in a small, round structure, the first polar body. The maternal chromosomes are now ready for the second meiotic division, which occurs after the ovum has been penetrated by the spermatozoa. Within two to three hours of the expected time of ovulation, the oocytes are aspirated from their follicles.

In the early phases of IVF development, this was carried out with the aid of the laparoscope. The oocytes were obtained by needle aspiration. Today, ova are obtained by ultrasound-guided transvaginal aspiration. This procedure can be done without general anesthesia, and the overall approach to in vitro fertilization is greatly simplified.

Another major clinical problem in the early phases of IVF development was that occasionally a patient would ovulate before the oocytes could be obtained, and the cycle would have to be canceled. Analogues of the gonadotropin-releasing hormone are now used to prevent this. These analogues are capable of blocking the release of the patient's pituitary gonadotropins, and the ovaries can be brought under the complete control of exogenously administered hormones. The number of follicles that develop varies from patient to patient, and even in the same patient from one cycle to the next. By and large, the aim is to obtain as many oocytes as possible in a given treatment cycle, especially if the couple has selected cryopreservation as a possible option.

IVF treatment is both physically and emotionally demanding. Several visits for hormone determinations and ultrasound are required. Ovum recovery, although relatively safe, is not without complications. Rarely ovarian infection occurs, which can further compromise the fertility status of the patient. This point is particularly pertinent when oocytes are being obtained for donation.

A freshly ejaculated semen specimen is obtained for insemination. The ova are placed in individual containers and mixed with spermatozoa that have been prepared by separating them from the semen and incubating them in a solution designed to enhance their fertilizability. The inseminated ova are cultured for approximately twenty-four hours and then inspected for evidence of fertilization.

Much has been learned about human fertilization through in vitro fertilization. When it is removed from the woman's body, the ovum is surrounded by layers of small, loosely packed cells, the cumulus oophorus. An inner layer of more densely arranged cells, the corona radiata, immediately surrounds the oocyte. These cells interface with the zona pellucida, a translucent protein shell that immediately surrounds the egg. Penetration past these barriers is accomplished through a sequence of interactions between spermatozoa and the ovum and its layers (Kopf and Gerton). When the spermatozoon reaches the zona pellucida, a series of chemical communications occurs. These condition the spermatozoon so that it can penetrate through the zona pellucida. Once past the zona, the spermatozoon attaches to the egg membrane and is then incorporated into the egg cytoplasm, the tail along with the head. The head is then transformed into a pronucleus. The second polar body is released and the nucleus of the egg is transformed into a pronucleus. The pronuclei then join and the chromosomes are intermingled in preparation for the first cell division. Twenty-four hours after insemination, there are two pronuclei and two polar bodies. This constitutes evidence that the penetration has been successful and fertilization is in process. After three days, the embryo has developed to the eight-

to sixteen-cell stage and is ready for transfer into the uterus. Transfer is sometimes delayed until day five or six to allow growth to the blastocyst stage.

EMBRYO TRANSFER. The dividing embryos are incorporated into the end of a catheter that is then passed through the cervical opening into the uterine cavity, where they are discharged. The pregnancy rate is progressively improved if more than one embryo is transferred. If more than three are transferred, there is a greatly increased possibility of multiple pregnancy. Twins are not usually a problem, but triplets or more greatly increase the possibility of fetal loss. Therefore, in many IVF programs no more than two fertilized oocytes are transferred in women under age thirty-five and three in the older group. The availability of cryopreservation has made such decisions easier.

Moral Status of the Embryo

The issue of when meaningful human life begins is pivotal in any discussion of IVF. The fertilization process is a complex series of events. The spermatozoon must be exposed to the environment of the female reproductive tract for a period of time before it acquires the ability to penetrate the layers surrounding the recently ovulated oocyte. This process, referred to as *capacitation,* takes between one and two hours in the human. It is reproduced in vitro in the fluids used for sperm preparation. The series of events involving penetration through the zona pellucida requires complex chemical communication between sperm and egg. After the spermatozoon has penetrated into the cytoplasm, completion of fertilization, although increasingly probable, is not assured.

The events that follow, including the formation and subsequent fusion of the pronuclei, occupy more than twenty-four hours. In the natural sequence of events, the conceptus remains in the fallopian tube for approximately three days. At the eight-to-sixteen-cell stage, it is transported into the uterus. There it develops into a fluid-filled structure, the blastocyst, that attaches to the uterine lining, or endometrium, on the sixth to seventh day after fertilization. The blastocyst is incorporated into the endometrium and invades blood vessels. Development occurs rapidly thereafter, but it is not until the fourteenth day that it develops unique characteristics. This coincides with the formation of the primitive streak, a linear region that can be identified on the early embryonic disk; it signals the beginning of the development of a distinct category of cells. Until this point, there is the potential for division into identical twins. Each of the individual cells in the early conceptus has the potential to develop into a complete adult. On or about day five or six, specialized cells, the trophoblasts, are formed. They provide the point of attachment for the placenta and are essential to the nourishment of the growing embryo. The Ethics Committee of the American Society for Reproductive Medicine applies the term *pre-embryo* to the conceptus through the first two weeks of gestation (AFS). It takes the position that the moral status of the pre-embryo is different from that of either the unfertilized eggs and spermatozoa or the later stages in embryonic development.

Cryopreservation of Pre-embryos

Techniques for freeze-preserving pre-embryos have contributed to the success of human in vitro fertilization and embryo transfer. The incidence of multiple pregnancy, which increases dramatically if more than two to three pre-embryos are transferred, can be reduced with the availability of cryopreservation. Pre-embryos not transferred during the treatment cycle can be used in subsequent spontaneous ovulation cycles. When pregnancy occurs in the initial treatment cycle and pre-embryos have been cryopreserved, a number of future options must be considered. These issues should be reviewed and decisions made before the pre-embryos are frozen. Patients whose response to stimulation clearly indicates that more than three oocytes will be recovered should consider the freezing option well in advance of ovum recovery. Those who for whatever reason, including deeply felt moral reservations, choose not to cryopreserve may wish to have sperm added to no more than three oocytes and have all of the fertilized specimens transferred. Remaining ova can be disposed of in their unfertilized state. Another alternative short of cryopreservation is to fertilize all available ova and select only the best of the resulting pre-embryos, as determined by their appearance and rate of cell division, for replacement, discarding the remainder.

The standard consent form should contain a detailed description of the possibilities to consider if a decision is made to cryopreserve human pre-embryos. As far as is known, cryopreservation of human pre-embryos is not associated with adverse fetal effects. Generally it is agreed that the pre-embryos will be frozen and stored for use in subsequent cycles. Unforeseen situations can occur, such as failure of equipment, although backup freezer systems and liquid-nitrogen holding facilities are usually available in the event of such an occurrence.

In most major centers, the disposition of unused frozen pre-embryos is reviewed in advance of cryopreservation. Handling of these pre-embryos is subject to the couple's joint disposition. They agree that if one partner is unwilling or unable to assume responsibility for the fertilized eggs, the responsibility reverts to the other partner. If that person is

not willing or able to assume ownership, the hospital or clinic usually reserves the right to dispose of the pre-embryos in accordance with policies in existence at the time.

Micromanipulation of Oocytes and Embryos In Vitro

Instruments have been developed to allow manipulation of gametes and pre-embryos under magnification. These techniques of micromanipulation have been used extensively in laboratory mammals. More recently they have been applied to human eggs, spermatozoa, and pre-embryos. When the oocyte is not penetrated by spermatozoa that are otherwise apparently normal, micromanipulation can be used to insert a spermatozoon mechanically through the zona pellucida directly into the oocyte itself, a technique known as intracytoplasmic sperm insertion (ICSI). In males with a congenitally obstructed vas deferens, sperm may be recovered directly from the epididymis and used for ICSI. Pregnancies that would otherwise be impossible can occur as a result of these procedures. Because abnormalities in the semen and vas obstruction may be associated with genetic risk factors, these should be considered before proceeding with ICSI (Dohle et al.).

Micromanipulation has been extended to pre-embryos. It has been suggested that the second polar body, the cell that is released from the ovum at the time it is penetrated by the spermatozoon, be removed for chromosome analysis in an effort to determine whether the embryo is genetically normal. This approach could be used in couples at risk of genetic abnormalities and would avoid the onus of a decision to terminate the pregnancy later on. Individual cells have been removed from the embryo for analysis without apparent harm (Tarin and Handyside). Other possibilities may eventually emerge, including the removal and storage of individual cells as clones of the embryo that is transferred. Some of these approaches have not yet attained clinical practicality, but they raise moral, ethical, and legal issues that it would be wise to address now.

Gamete Intrafallopian Tube Transfer

The procedure referred to as gamete intrafallopian tube transfer (GIFT) involves the transfer of freshly recovered ova and conditioned spermatozoa into the fallopian tubes. Thus, fertilization actually occurs in vivo. GIFT is not applicable to all infertility patients. Those with damaged or absent fallopian tubes are obviously not candidates. GIFT has been recommended for couples with unexplained infertility and women with extratubal disease, such as pelvic adhesions or endometriosis. Although fertilization occurs within the fallopian tube, GIFT is certainly assisted reproductive technology and is clearly separated from the coital act. When more than four ova are recovered at the time of a GIFT procedure, one or more are usually fertilized in vitro and cryopreserved for transfer in subsequent cycles. Transfer of the ova and spermatozoa into the fallopian tubes is usually carried out by means of laparoscopy. The success rate following GIFT is now surpassed by that of in vitro fertilization (SART/ASRM). In most centers, GIFT is now largely supplanted by IVF.

Surrogate Gestational Mothers

Human in vitro fertilization has opened the possibility that the resulting pre-embryos can be transferred to a woman other than the woman providing the oocytes. The second woman, referred to variously as a surrogate carrier, a womb mother, a placental mother, or a surrogate gestational mother, provides the gestational but not the genetic component of that pregnancy. Usually arrangements are made for the couple whose egg and sperm produced the embryo to adopt the newborn.

In another type of surrogacy, a husband's spermatozoa are used to inseminate a woman other than his wife. This surrogate mother carries the gestation to term. Agreement is reached before the procedure is carried out that the contracting couple will have custody of the resulting child.

In everyday infertility practice, there are circumstances that seem to justify these procedures. Consider a woman who was born without a uterus but with normal, functioning ovaries. Her husband is normally fertile. The patient's sister had a tubal sterilization after three pregnancies and is healthy in every way. The patient's sister's husband is entirely in agreement with the patient's sister's desire to act as a gestational surrogate mother. Oocytes are obtained from the patient, they are fertilized with her husband's spermatozoa, and the pre-embryos are transferred to her sister's uterus. In this situation we are virtually 100 percent confident that the pregnancy resulted from the procedure and is not an accidental result of coitus between the surrogate and her husband. The offspring is the genetic product of the husband and wife and has no direct genetic relationship to the patient's sister.

Other cases involve the use of a surrogate mother who contributes 50 percent of the chromosomal makeup of the offspring; this represents a more complex situation. The birth mother, who clearly is genetically related to the offspring, will be giving up her newborn child (hers in terms of both birth process and genetics). Indications for the use of

a surrogate gestational mother include any condition in which there are functioning ovaries but an absent or nonfunctioning uterus. The uterus may be congenitally absent or may have been removed because of disease; it may be nonfunctional as a result of in utero DES exposure. A surrogate carrier may also be considered if pregnancy is ill-advised for reasons of maternal health. Another issue concerns responsibility for the child in the event that the child is abnormal or damaged as a result of premature birth or birth trauma. There are also issues of the health status and behavior of the surrogate gestational mother during pregnancy. One must consider the impact of drugs or alcohol and the possibility of transmission of diseases. Finally, there is the matter of payment to the surrogate gestational mother. The possibility for exploitation certainly exists.

Oocyte Donation

The clinical indications for the use of donor ova usually are rather straightforward. They include premature menopause and the inability of the wife to produce genetically normal oocytes. On the surface, the ethical issues surrounding the use of donor oocytes should be no different from those involved in the use of donor semen. They are compounded, however, by the risks involved in obtaining oocytes compared with obtaining a semen specimen. For example, ovarian infection could occur following ovum retrieval, which could result in permanent sterility (Tureck et al.). In addition to the cost of the procedures, which is usually borne by the couple requiring the oocytes, there is also the question of payment to the donor for her time, pain, and suffering.

In contrast to spermatozoa, oocytes are difficult to cryopreserve; hence, menstrual cycle coordination between the recipient and the donor is required. Alternatively, donor oocytes may be fertilized with the husband's sperm, and the pre-embryos cryopreserved for future transfer. Sources of donor oocytes include the excess eggs from patients undergoing IVF, oocytes obtained incidental to an operative procedure such as a sterilization, or a specific donation by a relative or close friend. Increasingly, the source of the eggs is a paid "volunteer" (ASRM Ethics Committee). The availability of this technology allows pregnancy in women who are well past the ordinary childbearing age (Sauer, Paulson, and Lobo).

In an effort to improve oocyte quality, cytoplasmic transfer between human oocytes, that is, ooplasm donation, has been attempted. The procedure involves aspirating cytoplasm, the portion of the egg surrounding but not including the nucleus, from a donor egg and injecting it into a recipient egg. Recipient oocytes were deemed to be of poor quality or were recovered from women in their late reproductive years or who previously had a failed IVF cycle. Not unlike some of the early approaches to IVF, the procedure was carried out with minimal basic research background, although in limited studies the technique was found not to impair successful fertilization and cell division in the mouse. Unfortunately, children born as a result of this technique have now exhibited traces of mitochondrial DNA from the donor egg. This foreign cytoplasmic DNA may result in untoward consequences in the future and, defects that are transmitted might be heritable and therefore could be observed in the next generation. Until and unless the safety and efficiency of this approach is established in suitable animal models, this effort to rejuvenate deficient oocytes must be approached with extreme caution.

Conclusion

The techniques employed in what is known as the *new assisted reproductive technologies* are varied and challenging. They range in complexity from seemingly straightforward artificial insemination to micromanipulation of ova, spermatozoa, and pre-embryos—and perhaps, in the future, to treatment of genetic disease by gene insertion in vitro. Just as the techniques vary, so do the ethical issues surrounding them. In no other field is there a greater opportunity for interaction among the physician-scientist, ethicist, moral theologian, social scientist, and legal scholar.

II. SEX SELECTION

Sex selection or sex selection techniques usually refer to methods that can be used to help ensure that children are of a specific sex.

Traditional and Scientific Techniques

INFANTICIDE. The simplest, most effective and most morally problematic form of sex selection is infanticide. Before the development of modern techniques the only way to determine the sex of offspring was to kill infants of the undesired sex after birth. This method has been practiced in many areas and at many times in human history.

While some people argue that infanticide can be morally acceptable (Tooley), such support is usually in cases where the individual would have a life that was not worth living. It is implausible to suppose that sex alone could ever be a condition that makes a life not worth living. Therefore even if we accept that there can be justified instances of infanticide we are not committed to permitting infanticide for the purposes of selecting sex.

PRENATAL DIAGNOSIS AND ABORTION. The first genetic testing technologies emerged in the 1950s. They provided the possibility of determining the sex of the fetus in utero (Bubeck).

The development of ultrasound during the 1970s further opened up the possibilities for determining the sex of offspring. It enabled parents to determine the sex of their child in utero and then abort the fetus if it was not of the desired sex. This practice is prevalent in India, China and other countries where a high value is placed upon the first child being male.

PREIMPLANTATION GENETIC DIAGNOSIS AND EMBRYO SELECTION. Preimplantation Genetic Diagnosis (PGD) was developed primarily so that embryos could be tested for genetic abnormalities before implantation. While the intention was to provide a technique for avoiding genetic diseases, it can also be used for determining the sex of the embryo. While PGD does not involve aborting a fetus growing in utero, it can involve discarding unwanted embryos. Some legislative bodies draw a distinction between techniques that are requested for medical as opposed to nonmedical reasons (see The Ethics Committee of the American Society of Reproductive Medicine). The implication is that a technique may be acceptable for a medical reason (PGD for avoiding genetic disease) but unacceptable for nonmedical reasons (PGD for determining the sex of the child). PGD is, next to infanticide, the most effective method of sex selection with an effectiveness of nearly 100 percent.

SPERM SORTING. Rather than determining the sex of a child after it has become an embryo or fetus, sperm sorting techniques attempt to ensure that sperm is sorted by whether

they are X chromosome bearing (female) or Y chromosome bearing (male). If this is done successfully then the sperm can be used in artificial insemination or in vitro fertilization (IVF) to help ensure that any resulting child will be of the desired sex.

Sperm swim up or swim through techniques have been in development for some time but have not proved to be effective. More recently greater success rates have been achieved using flow cytometry. Recent figures on the effectiveness of this technique rate have evaluated it as 88 percent effective for determining X chromosome bearing sperm and 73 percent effective for determining Y chromosome bearing sperm. (Microsort.com)

Successful sperm sorting techniques have a number of advantages over other sex selection methods. They are less expensive in that, instead of invasive and potentially harmful techniques such as ultrasound and abortion or PGD and IVF, they involve relatively noninvasive Assisted Insemination. For those who believe that there is something morally significant about aborting a fetus or discarding unwanted embryos, sperm sorting is morally less problematic than PGD or selective abortion.

While these techniques are not likely to become very cheap in the foreseeable future they are already at a cost that could be born by most parents wanting to access this service. For those needing selection services in order to prevent a genetic disease that is carried by the X or Y chromosome, the techniques provide an attractive alternative to other forms of treatment.

Motives for Determining the Sex of the Child

There are a number of reasons why people might want to determine the sex of their child. These reasons range widely in the ethical difficulties that they present.

SOCIAL VERSUS MEDICAL REASONS. At the least problematic end of the spectrum is the intention to determine the sex of offspring so as to avoid the transmission of sex-linked disease. Sperm sorting for this reason is, arguably, morally unproblematic. PGD might also be justifiably used for this reason. Even ultrasound followed by abortion has a morally strong case to support it. However the greatest demand for these technologies comes from those who want to determine the sex of a child for so-called *social reasons.*

SOCIAL REASONS. Social reasons are reasons for wanting sex selection that do not aim at avoiding disease. John Robertson (2001) thinks that there are two different types of social reason, which, together, constitute the most significant demand for sex selection services. First, there are those who want a child of a particular sex because they already have a number of children of one sex or because they are only having two children and have a preference for one of each sex. A second group is those who have a strong preference for their first child being of a particular sex. The first scenario is often referred to as a *family balancing* reason and is often viewed as less morally problematic than valuing male children more highly.

Ethical Issues Raised by These Technologies

It is vital that the ethical issues raised by sex selection techniques are carefully considered because they are, essentially, techniques that select for particular genes.

Because couples or individuals, typically, request these techniques, the historical worries about eugenics have tended not to be raised in this context. However in contexts where there is a widely held view about the relative worth of a specific sex whether sex selection is a form of eugenics is much less clear. It is because of considerations such as these that Mary Anne Warren coined the term *Gendercide* for the systematic way in which female embryos, fetuses and children are killed and neglected in some parts of the world.

PROCREATIVE AUTONOMY. The main argument for open access to sex selection services is the interest that individuals have in exercising their reproductive autonomy. One key advocate of extending reproductive autonomy to sex selection is Robertson (1994) who borrows from English philosopher and economist John Stuart Mill's (1806–1873) harm principle. Mill theorized that the only reason a society has for restricting the liberty of individuals is if the exercise of that liberty would result in physical harm to others. A key freedom in western democracies is the liberty to make choices about procreation. The level of harm that is required for us to interfere with procreative autonomy is ordinarily very high. Even if there were some harms to others that result from the use of sex selection technologies, they would not be as serious as the harm that would be required to constrain this important liberty. Therefore we should not restrict access to sex selection services.

A second important defense of autonomy comes from German philosopher Immanuel Kant (1724–1804). He argued that persons must always be treated as ends in themselves and never as a means only. There are a number of reasons upon which Kant based his opinion but very significant among them is the status of human beings as project

pursuers. It is the ability of persons to pursue projects that bestows value upon these projects. The wish to have children is an important component of the life projects of many people. Not only do people wish to have children they can also desire that those children be of a specific sex. Thus blocking access to sex selection services is a severe limitation upon the interests of individuals who want a child of a specific sex.

Restricting access to sex selection technologies may frustrate more than just the desire to have a child of specific sex. Robertson (2001) argues that in cases where the sex of a child will be the deciding factor in whether that child is born, selection techniques are necessary for parents to exercise their reproductive autonomy.

RESPECTING CHILDREN AS PERSONS. While Kantian considerations about how we should treat persons can count in favor of sex selection technologies, the same considerations can also be used to argue against them. When parents wish to use sex selection services they do so because they have a preference about what kind of child they want to have. If they use a sex selection technology and have a child the child's sex has been determined to satisfy an end of the parents and the child has been used as an instrument to bring about this end.

There are a number of responses to this argument. A child is either male or female and all sex selection does is to remove the randomness from the natural process. Children are born a specific sex and removing the randomness from this process does not violate them. A possible counter to this argument is to insist that children have the right to an *open future* (Feinberg). An open future means that a child has the right to its own liberties or conceptions of the good that are not intentionally limited by decisions and preferences of others. In the context of sex selection this would derive to the right to have one's sex determined by a random process. In other words, while most of us know that our sex resulted from no human action, persons whose sex has been selected will know that they are a specific gender because of a parental preference.

A second response is to think carefully about what the Kantian theory demands. Kant requires us to treat persons as ends in themselves and never as a means only. In actuality, it would be impossible to never use other persons as a means because it implies that employing the assistance of another to achieve any end negates the personhood of that other. Kantian theory directs us to only use persons for our own ends when this does not violate their status as persons. So while it may be that parents who use sex selection techniques are using their children as a means it is not obvious that this in consistent with respecting their children as persons. Furthermore it is not clear that "wanting to have a child of a specific sex" for your own reasons is any different from *wanting to have a child* for your own reasons.

SEX-RATIO IMBALANCES. A major objection to the widespread introduction of sex selection is that it might result in a significant imbalance of male to female sex ratios. A preference about the value of having male children or a male first child could result in many more male babies being born.

In the Western world there is little reason to be concerned about sex ratio imbalances. Research in the United States and the United Kingdom on the preferences of those requesting sex selection services indicates that there was a slight preference for girls over boys (Lui and Rose). A majority of people wishing to access these services in the West do so for family balancing reasons.

However there are good reasons for worrying about sex ratio balance in parts of the world where male children are more highly valued.

IMPLICATIONS OF SEX SELECTION FOR COUNTRIES OR CULTURES WHERE SONS ARE VALUED MORE HIGHLY. In some parts of the world there is a significant imbalance in the sex ratios. By comparing the sex ratio of North America and Europe to that of Asia and North Africa there are more than 50 million fewer women in China than there should be. When the sub-Saharan ratio is used (where beliefs about the relative importance of women are more similar to Europe and America) there are 44 million in China, 37 million in India and over 100 million world-wide fewer women than there should be (Sen).

The differences in sex ratios are not due solely to sex selection; they are also a result of factors such as poor diet, limited access to healthcare and other environmental factors.

There is every reason to suppose that the introduction of new sex selection services will increase this imbalance. In 1993 ultrasound machines constituted 20 percent of the total Indian market in medical technology (Miller). Sperm sorting technologies could potentially become readily affordable and they are likely to result in an increase in the number of male babies born.

A society having a balanced sex ratio can be considered to be a public good. It is an indicator that there is equity between the sexes in terms of access to healthcare, education, nutrition and wealth. Barbara Miller has suggested that in India sex ratio imbalances correlate with high levels of intersocietal warfare, the frequency of violence, and violence towards women.

THE IMPLICATIONS FOR WOMEN OF A BAN ON SEX SELECTION. While there is a likelihood that better access to sex selection services in India and China will increase the selection of male offspring, it is important to bear in mind the implications of banning access to these technologies. Without access to pre-conception methods of sex selection women may be forced or coerced into aborting fetuses if they are female. There is also the likelihood that some female neonates will be neglected when that child might have been preconception selected as male. The arguments are counterbalanced to some extent by the fact that the increased use of these technologies might make it easier for these practices to continue and will do little to rectify the value system which makes them possible.

IS THE MOTIVATION SEXIST? OR ARE SOME REASONS MORALLY ACCEPTABLE? On one level it is hard to deny that sex selection is sexist because it is a practice that involves acting on a preference to have a child of a determinate sex. This implies that having a child of a particular sex is in some way better, according to the person with that preference. If a person did not believe that having a child of a specific sex would be better, they would have no reason for wanting a child of a specific sex.

The problem with this analysis is that it implies that any preference that has sex as a distinguishing feature is sexist. This is absurd because it implies that a heterosexual woman who has a preference for cohabitating with a man is sexist. Sexism is the making of morally relevant discriminations on the basis of morally irrelevant features. On this view if parents want to have a female child because they already have a male child and will only have two children, their preference is not sexist; the preference is not based upon believing that there is anything inherently more valuable about male children.

While there are some reasons for wanting to select the sex of a child that are sexist and therefore morally unacceptable, whether society should stop people from acting upon these reasons is another question.

Some justifications people give for their actions are so immoral that we might consider them *illegitimate* reasons—or reasons that are immoral to the extent that a liberal democracy does not need to respect their legitimacy. Profoundly sexist beliefs fall into the class of reasons that we might consider to be illegitimate.

However if a couple wishes to select the sex of their child for sexist reasons it is unclear whether allowing them access to sex selection services will make things any worse or perpetuate sexism. Failing to allow the couple access to these services may not do anything to change their beliefs about the relative worth of male and female children.

GROWING TECHNOLOGIZATION OF REPRODUCTION. Sex selection technologies are part of the growing trend towards the technologization of reproduction. Reproduction used to occur only naturally and within the context of a family unit. Care and concern in parenting has always been the province of traditional family units and technologization of reproduction might be a threat to this important human institution.

While the values that surround nurturing our children are of great value and ought not be placed at risk, it is unfair to single out sex selection technologies. If the growing technologization of reproduction is a serious problem then the response ought to be to place restrictions on all new reproductive technologies.

That there is a broad spectrum of technologization of reproductive services must be considered. At one end are the relatively low-tech practices of artificial insemination and at the other technologies such as PGD. Sex selection by sperm sorting is closer to the low-tech end of the spectrum and therefore does not have the same potential to technologize reproduction as do technologies like PGD.

INAPPROPRIATE USE OF MEDICAL TECHNOLOGY. Sex selection for social reasons is not a healthcare need. We can plausibly think of infertility as constituting a healthcare need because it is a deviation from a capacity that people of childbearing age usually have. But the capacity to determine sex is over and above normal human capacity. Sex selection is more like cosmetic surgery or other services that can be provided by physicians. Given that there are morally problematic reasons for wanting these services, reproductive specialists need to consider whether this is an appropriate use of their resources and expertise (see Dresser). The concern regarding the appropriate use of medical resources can be partially addressed if sex selection services are privately funded and do not result in any person not receiving treatment for a medical condition. However the issue of whether sex selection services are something that the medical profession ought to be using its knowledge and skill to provide is more difficult to resolve.

THE WELFARE OF THE SEX SELECTED CHILD. A major objection to sex selection technologies is that they may result in harm to children. There are a number of ways in which harm may result.

First, if a sex selection technique is used and fails, the child that results may be neglected or be psychologically

harmed by the knowledge that he or she is not the sex that the parents wanted. This consideration can be also be used as an argument for sex selection technologies. If a child will be harmed if he or she is not of the desired sex, then it is better to ensure that the parents have a child of the sex that they want.

Second, if parents have strong views about the way in which children of a certain sex ought to be raised, a child of the undesired sex may be born into an overly restrictive environment.

Third, sex selection techniques can carry risks to the child that may result. At this point in time there is no evidence to suggest that there are harms to children born after sperm sorting interventions. PGD may carry some risks to resulting children. When PGD is used to predict disease the benefit may offset the risk of the technique, but when it is used in selecting sex, determining the value of the benefit in relation to the risk is more problematic.

Sex selection techniques present a broad range of ethical issues. Many objections can be turned into arguments for sex selection. However, some reasons for wanting sex selection are undoubtedly unethical. Moreover, the consequences of sex selection may justify regulation, if not prohibition.

III. FERTILITY DRUGS

The diagnosis and treatment of infertility in humans is a complex matter. The trend has been to regard infertility as a problem that a couple faces, not an issue that rests with the man or the woman alone. Infertility is generally defined as the inability to achieve a pregnancy after one year of unprotected intercourse (Office of Technology and Assessment). There are a number of approaches to the treatment of infertility, one of which is the use of fertility drugs. Some aspects of these drugs, however, are ethically troublesome or controversial.

The causes of infertility in men are much less understood than the causes in women. Historically, the inability to become pregnant and have a healthy child has been viewed

TABLE 1

Summary of Drugs Used to Stimulate Ovulation

Drug Name	Use	Side Effects
Clomiphene citrate	Mildest drug used to induce ovulation	Headaches, blurred vision Hot flashes Enlarged ovaries Abdominal discomfort Rarely, ovarian hyperstimulation syndrome Dry, thick cervical mucus Luteal phase defect Slightly increased risk of miscarriage Increased risk of multiple births Increased ovarian cancer risk?
Pituitary gonadotropins (FSH and LH)	Strongest drugs used to induce ovulation	Redness/swelling at injection site Mood swings, depression Enlarged ovaries Abdominal distention/pain Ovarian hyperstimulation syndrome (may be severe) Increased risk of ectopic pregnancy Increased risk of miscarriage Increased risk of prematurity Increased risk of multiple births Increased ovarian cancer risk?
Human chorionic gonadotropin (hCG)	Spurs release of oocytes	False positive pregnancy test if given late in cycle
Gonadotropin-releasing hormone (GnRH)	Induces ovulation in cases of certain hormone deficiencies	Redness, swelling at catheter site Headaches, nausea Slight risk of ovarian hyperstimulation syndrome Slight risk of multiple births
GnRH analogs	Disrupts normal cycling to allow greater control over ovarian stimulation	Hot flashes Vaginal dryness, painful intercourse Insomnia, mood swings Bone loss (with lengthy use)

as a woman's problem, and initial attempts to treat infertility were (and often still are) aimed at the woman—even in the absence of the most basic assessments of the presence of viable sperm in the man. In a 1998 report, the American Society for Reproductive Medicine, the main professional association for infertility specialists in the United States, stated that: "Prior to embarking on a course of induction of ovulation with exogenous gonadotropins (originating outside of the ovaries or testes), other fertility factors should be defined and treated as required. Screening tests for these factors should include at least one semen analysis and a hysterosalpingogram (radiography of the uterus and oviducts using a contrast medium) or laparoscopy and hysteroscopy" (p. 2).

Given that one of the earliest and most basic elements in the initiation of a pregnancy is the formation of an embryo as a result of fertilization of an oocyte (egg) in a woman, infertility problems are often traced to ovulatory problems—that is, any biological or structural impairments in the ability to ovulate or release one or more oocytes during the menstrual cycle. Implantation, the process of attachment of the early embryo to the uterine wall, is also a crucial step in the development of a pregnancy, but implantation problems

are not well understood, and thus not treated with drug therapy.

There are a number of reasons why a clinician might want to provoke increased ovulatory activity in the female (at her request), including: (1) to increase the likelihood that fertilization will take place naturally, or *in vivo* (in the body of the woman), as a result of usual intercourse or artificial insemination; and (2) to aspirate (remove by suction) oocytes from the woman for donation to another infertile woman, for research, or for attempts to create embryos via *in vitro* fertilization (IVF) for donation, research, or transfer back to the uterus for possible implantation, pregnancy, and birth (National Advisory Board on Ethics in Reproduction).

A Brief History of Fertility Drug Development

Drug therapy to treat infertility in women started in the 1930s, when the relationship between the normal menstrual cycle and ovarian and pituitary function began to be understood. It was discovered that "the pituitary gonadotropin follicle stimulating hormone (FSH) and luteinizing hormone (LH) stimulate follicle growth in the ovary producing estrogen, and this influenced endometrial growth in the uterus" (Leibowitz and Hoffman, p. 203). This led to scientific efforts to obtain gonadotropin extracts. Serum from pregnant mares was the source of the first manufactured gonadotropin (PMG, or pregnant mare gonadotropin), an approach that was eventually abandoned because of the threat of allergic response in humans injected with animal protein (Lunenfeld). Human menopausal gonadotropins (HMGs) were developed in the 1950s using extracts from postmenopausal women.

Since the 1960s, a series of drugs have been discovered, synthesized, and developed to promote or provoke ovulatory activity in women. These drugs are generally labeled *fertility drugs,* and the basic types are reviewed in Table 1. Fertility drugs for men are those that promote and enhance ejaculatory activity (e.g., Viagra), although there are no drug remedies for oligospermia (low sperm count) and azoospermia (no sperm in the semen). More recently, for women, naturally occurring agents to stimulate fertility are being replaced by synthetic agents that are highly purified and designed to reduce side effects.

Economic Considerations

There are economic considerations involved in the use of fertility drugs because, in most U.S. states, patients must pay for these drugs themselves (in the absence of third party reimbursement). In fact, it has often been suggested that cost influences the choice of infertility treatment. Drug therapy alone may cost as much as 3,000, which is still considerably cheaper than cycles of *in vitro* fertilization, which, as of 2002, costs between $8,000 and $10,000 per cycle (Jain et. al.). In addition, there are global economic issues that influence the delivery of this care. Drugs to treat infertility have historically been considerably cheaper in Mexico, for example, and individuals or couples may travel outside of the United States to have their prescriptions filled at a lower cost (Kutteh).

Risks and Ethical Issues

There are two distinct steps in drug regimens to stimulate ovulation. The first step is to promote the actual development of oocytes within the ovarian follicles. The second is to administer drugs that provoke the release of oocytes for purposes of retrieval or natural transit through the fallopian tube. The hazards associated with drug use for this purpose include: (1) the likelihood that a large number of follicles may form and rupture at once, which increases the chances that a number of oocytes may be fertilized, resulting in a multiple birth; and (2) the likelihood that ovulation in large numbers will increase the chances of an ectopic pregnancy (a pregnancy that takes place outside of the uterus, often in the fallopian tube). Ectopic pregnancies are life threatening and considered an adverse event in pregnancy management or infertility treatment. Even in a controlled situation, ovarian stimulation entails both known and theoretical risks.

Ovarian hyperstimulation syndrome (OHSS) is a potential complication of ovarian stimulation with exogenous gonadotropins. OHSS can be classified as mild, moderate, or severe (ASRM, 1998). The pathophysiology of this syndrome is not well understood, but it seems to be caused by "increased capillary permeability, which allows major fluid shifts from the intravascular compartment to the extravascular space within the follicle and ovary" (Gianaroli et al., p. 175). Physical symptoms that OHSS might be occurring include: a weight gain of one to two pounds or more daily after human chorionic gonadotropin (hGC) has been administered, severe abdominal pain, nausea, vomiting, or diarrhea (Leibowitz and Hoffman, p. 208). In addition, a concentration of red blood cells can lead to thromboembolic events, electrolyte imbalance, oliguria (low production of urine), shock, or death in 1 percent of women (Miller and Hoffman). It is important to note that ovarian stimulation is sometimes provided by physicians who are not infertility specialists (Dresser), and thus may not have the depth of expertise to judge the dosage of these powerful

drugs. They may also not have a sonogram available to view developing follicles.

There has been considerable controversy about a possible relationship between cancer and infertility treatment. However, according to *Pharmacotherapy, A Pathophysiologic Approach* (2002), by Joseph Dipiro et al., "an association between fertility agents and the risk of breast and ovarian cancers has not been confirmed and more studies are needed to clarify any link between infertility treatment and ovarian cancer." (p. 1440).

Multiple Births

At first glance, a multiple birth might be regarded as a welcome event by those who are seeking to remedy the problem of infertility and build their families. Multiple births have been a consistent outcome of infertility treatment using drugs to induce ovulation, and also as a result of *in vitro* fertilization. An increase in the incidence of twins, triplets, and higher multiple births over that observed in the normal pregnant population has been a steady feature of IVF since the birth of the first IVF baby, Louise Brown, in 1978. It has been observed that many infertile couples are delighted on learning that they will be the parents of twins, partly because they can have two children without having to undergo infertility treatment twice. But there are hazards associated with multiple gestation and births, especially when the pregnancy results in the birth of super-multiples (quadruplets or above). The primary hazard associated with multiple gestation and birth is premature birth. The low birthweight of premature babies poses a significant risk to these infants.

The incidence of triplet or higher-order multiples has gone up from 29 per 100,000 live births in 1971 to 174 per 100,000 live births in 1997 (U.S. Centers for Disease Control, 2000). Of these, it is believed that approximately 20 percent are spontaneously conceived, with the remaining 80 percent evenly split between conception by ovarian stimulation and conception by other assisted-reproductive technologies (ARTs). A more recent study of state-specific use of assisted reproductive technologies in 1996 and 1998 indicates that the use of ART is increasing in most states, and that more than half of the infants born as a result are multiple births (U.S. Centers for Disease Control, 2002).

Except in the case of spontaneous twinning, high order multiple births can be minimized in the course of infertility treatment. If a clinician notes that in a given cycle a large number of follicles are maturing, the woman or the couple can be so advised and skip intercourse until the next cycle. Another possibility is to transfer only a small number of embryos back to the uterus for possible implantation in the process of IVF. The United Kingdom, for example, limits the number of transferred embryos to two (Human Fertilisation and Embryology Authority).

Clincally and ethically, the most controversial strategy for avoiding multiple births is reducing the number of fetuses in utero after the pregnancy is underway, which provides more space for a smaller number of fetuses to grow and develop. Although reducing the number of fetuses in utero is not objectionable to some, it can be particularly traumatic for a couple who have been trying to conceive to then be faced with the choice of whether or not to remove some of the fetuses. From a clinical standpoint, multifetal-pregnancy reduction poses serious risks, including the loss of the entire pregnancy. The risk of pregnancy loss increases with the number of fetuses (Alexander; Evans). It is therefore preferable to avoid or prevent the development of a high-order multiple pregnancy in the first place through transfer of only a small number of embryos via IVF, or through the careful monitoring of maturing follicles occurring as a result of ovulation induction (White and Leuthner).

In conclusion, the overriding ethical objective in the use of fertility drugs is to facilitate fertility without causing harm. From a clinical standpoint, this is a balancing act based on careful physical assessment of the couple (and primarily the woman) involved. Ethical practice in this area also involves careful counseling to ensure that the risks are understood and that careful choices are made. The goal of achieving pregnancy and birth must be balanced against the likely health and well-being of children who are born, as well as the ongoing physical and emotional health of the woman and family. To this end, fertility drugs cannot be used carelessly, and pregnancy and number of births alone, particularly in the case of supermultiples, cannot be the sole objectives.

IV. LEGAL AND REGULATORY ISSUES

Reproductive freedom is not a simple concept. Encompassing far more than abortion, it also includes the choice of whether and with whom to procreate, how many times to procreate, and by what means. It includes the choice of the social context (e.g., marital, communal, or solitary) in which the reproduction takes place and, to some extent, the characteristics of the children people will have (gender, presence or absence of certain disease). It is grounded, for some moral philosophers, in self-determination, individual welfare, and equality of expectation and opportunity (Brock).

Noncoital reproduction, that is, reproduction achieved despite the absence of sexual intercourse, allows single, homosexual, and infertile people to start and rear families. Often, it entails such controversial techniques as extracorporeal maintenance of an embryo, screening and storage of gametes, or the reproductive assistance of men and women who do not plan to maintain a relationship with the child they help to conceive or gestate.

Thus, new reproductive technologies enable individuals to exercise more reproductive choices. This, in turn, invites exploration of the depths of cultural relativism and the meaning of genetic linkage; the preference for the heterosexual couple as the paradigm for family life; the role of the state as the regulator versus facilitator of individual aspirations; and the role of the state and the professional as the gatekeeper to the technologies that permit people to circumvent infertility or conventional forms of procreation.

Under U.S. law, states can outlaw or regulate certain aspects of reproductive technologies. Areas for possible state intervention include protection of the extracorporeal embryo; protection of patients (and their resulting children) who seek to use reproductive technologies; regulation of contract (i.e., *surrogate*) motherhood; definition of family forms and familial relationships in light of gamete transfers and use of contract birth mothers; and limitation on commercialization of the techniques. But the extent to which states can ban or regulate noncoital reproduction depends on the extent to which procreation is protected by state and federal constitutions, and the extent to which ancillary practices, such as payment for gametes or services of a contract mother, are viewed as part of the act of procreation or as independent acts of commercial negotiation.

In the United States, the more zealously procreation is guarded by constitutional guarantees and the more broadly the definition of procreation is drawn, the more compelling and narrowly drawn must be state efforts to restrict use of noncoital procreation. Those restrictions, when they exist, will be manifested in both common law and statutory law, usually with regard to the fields of contracts, property, or family law. Because the details of such law vary tremendously from state to state, this article focuses primarily on the overarching constitutional issues that limit state policymaking and lawmaking in this field, and compares national responses.

Is There an Affirmative Right to Procreate?

The right to procreate, that is, the right to bear or beget a child, appears to be one of the rights implied by the U.S. Constitution. It is grounded in both individual liberty (*Skinner v. Oklahoma,* 1942) and the integrity of the family unit (*Meyer v. Nebraska,* 1923), and is viewed as a "fundamental right" (*Griswold v. Connecticut,* 1965), one that is essential to notions of liberty and justice (*Eisenstadt v. Baird,* 1972).

The U.S. Supreme court has not explicitly considered whether there is a positive right to procreate—that is, whether every individual has a right to actually bear or beget a child and thereby has a claim on the community for necessary assistance in this endeavor. It has, however, considered a wide range of related issues, including the right of a state to interfere with procreative ability by forcible sterilization (*Skinner v. Oklahoma,* 1942), the right of individuals to prevent conception or to terminate a pregnancy (*Roe v. Wade,* 1973; *Webster v. Reproductive Services,* 1989; *Planned Parenthood v. Casey,* 1992), and the right of individuals to rear children in nontraditional family groups (*Moore v. City of East Cleveland, Ohio,* 1977).

Since the 1942 *Skinner* decision, lower courts have accepted the notion that states may not forcibly sterilize selected individuals unless such a policy can withstand strict constitutional scrutiny. The basis for requiring this level of scrutiny is the assertion that the "right to have offspring," like the right to marry, is a "fundamental," "basic liberty." Further, the *Skinner* and *Eisenstadt* decisions arguably hold that the right to use contraception or to be free of unwarranted sterilization is an aspect of individual, rather than marital, privacy. As stated in *Eisenstadt:* "If the right to privacy means anything, it is the right of the individual, married or single, to be free of unwarranted government intrusion into matters so fundamentally affecting a person as the decision to bear or beget a child" (*Eisenstadt v. Baird,* 1972).

But the right to privacy is no longer the primary justification for abortion rights, or, by extension, reproductive rights. The 1992 *Planned Parenthood v. Casey* decision specifically based its opinion on "liberty" (rather than privacy) rights, and concluded that abortion remains protected from state efforts to prohibit abortion. The emphasis on "liberty" language changes the focus of abortion rights from one of limitations on governmental power (as discussed in "privacy"-based decisions) to one of individual control of one's person. The opinion attempts to explain why abortion is an essential "liberty" for women because it permits control of one's body and one's personal destiny.

Justice Antonin Scalia's dissent mocks this attempt. After reciting the list of phrases used elsewhere by his colleagues, such as "a person's most basic decision," "a most personal and intimate choice," "originat[ing] within the zone of conscience and belief," "too intimate and personal for state interference," Scalia complains that "the same adjectives can be applied to many forms of conduct that this Court … has held are not entitled to constitutional protection—because, like abortion, they are forms of conduct that have long been criminalized in American society. Those adjectives might be applied, for example, to homosexual sodomy, polygamy, adult incest, and suicide" (p. 785).

Scalia's dissent highlights the potentially far-reaching implications of what the plurality has written regarding the fundamental importance of controlling one's fertility. The *Casey* plurality opinion lays out an argument for reexamining the 1879 *Reynolds v. U.S.* decision (upholding the power of the state to outlaw polygamous marriage) and the 1986 *Bowers v. Hardwick* decision (upholding the power of the state to criminalize homosexual behavior), a task critical to determining if states can restrict noncoital reproduction to married couples. It also lays the groundwork for cases sure to arise concerning prenatal diagnosis, sex selection, cloning, and (ultimately) parthenogenesis.

What Can States Do To Regulate Reproductive Technologies?

Even assuming that constitutional protection for procreation remains grounded in a fundamental rights analysis, possibilities remain for areas of state regulation of who may use noncoital reproduction and how they may proceed. First, many aspects of noncoital reproduction arguably do not amount to *procreation,* and therefore are more amenable to state control. Donor gametes and surrogacy do not permit an infertile person to procreate; rather, they allow fertile persons to reproduce without partners or to bypass the infertility of their partners.

Artificial insemination by donor (AID), for example, can be used by single or lesbian women who want to become pregnant but who find the thought of sexual intercourse with a man distasteful. Almost half the states in the United States have statutory language governing AID that appears to ignore the possibility of such a use, leaving the legal status of the donor-father unclear (U.S. Congress, Office of Technology Assessment [OTA], 1988b). Canada and France have also had national commissions recommend that single and lesbian women be barred from using donor insemination in order to conceive (Liu; McLean). Because such women could physically procreate without donor insemination, albeit with great discomfort, it can be argued that such restrictions do not impinge upon a fundamental right to procreate and are therefore potentially tolerable.

Of course, the restrictions would still be subject to challenges based on the unequal treatment of single or lesbian women as compared with the married, heterosexual population. AID for a married couple in which the husband is infertile is also nothing more than a medical alternative to the social solution of adultery; the AID itself does not enable the infertile man to procreate. Nevertheless, in Canada, France, and much of the United States, this form of AID is viewed as therapeutic, seemingly because the *unit* of infertility (i.e., the *patient*) is seen as a monogamous, married, heterosexual couple, not as an unmarried individual.

In typical surrogacy arrangements, in which the husband is fertile and the wife infertile, the surrogacy arrangement, like AID, does not permit the infertile wife to procreate, nor is the fertile husband unable to procreate without resorting to surrogacy. Rather, surrogacy allows the husband to procreate without committing adultery and with some assurance, as in the AID scenario, that the couple will be able to retain exclusive custody of the resulting child. As with AID, such a use of contract motherhood is viewed as therapeutic by many. While even this use of surrogacy has engendered opposition ranging from criminalization to mere unenforceability in countries such as Australia, Canada, England, and France, and in some portions of the United States, it has never encountered the same degree of approbation as the so-called surrogacy of convenience, in which a rearing mother finds it useful to hire someone else to carry the child (Liu; McLean).

Indeed, much of the debate surrounding the most famous surrogacy case in the United States, *Baby M* (1988), focused on whether the rearing mother had declined to become pregnant due to career concerns and undue worry about her health, or rather due to legitimate concern that pregnancy would seriously worsen her multiple sclerosis. This debate exemplifies the increased willingness of the American public to regulate or ban surrogacy when it is not perceived as a cure for a medical problem such as infertility, a sentiment reflected in the constitutional analysis that permits greater state regulation where the right to procreate is not directly implicated.

Egg donation to a woman who cannot ovulate but who can carry to term does not technically allow the recipient to procreate, as she will not *reproduce* in the genetic sense. But it does allow her to experience pregnancy and childbirth, which for women are intimately associated with genetic procreation. In terms of both biological significance (gestation is, of course, a biological activity) and emotional impact, this would seem to be close to procreation, even in its more narrow definition. Thus, it is difficult to categorize this activity in terms of whether it allows an infertile person to *procreate.*

Despite this fact, there is considerable hesitation about permitting egg donation. Whereas sperm donation is widely accepted, egg donation entails significantly more medical discomfort and even risk on the part of the donor. This in turn raises the specter, at least in the United States, of increased payments for the donation. For some, such payments represent an undue incentive to undergo medical risks, as well as an unacceptable commercialization of human gametes. Nevertheless, at least in California, there is a thriving egg donation practice.

Even those aspects of noncoital reproduction that clearly involve procreation can be regulated or banned, if there is a sufficiently compelling state interest. It is true that artificial insemination by husband (AIH), and in vitro fertilization (IVF) using a couple's own gametes (whether or not a contract mother is hired to carry the child to term), permit an otherwise infertile man or woman to procreate genetically. By bypassing the fallopian tube defect or permitting intrauterine insemination of the husband's concentrated semen, these techniques actually help infertile individuals to participate in the act of reproduction. But a compelling state interest in the protection of embryos and fetuses, for example, could justify significant restraints on even AIH and IVF.

Is There a Compelling State *Interest* in Embryos and Fetuses?

The most likely claim for a compelling state purpose to outlaw or regulate IVF is that of protection for the extracorporeal embryo, whether or not accompanied by a contract with a gestational surrogate.

The *Webster v. Reproductive Services* (1989) and *Planned Parenthood v. Casey* (1992) decisions indicate that the U.S. Supreme Court is now quite tolerant of symbolic legislative statements concerning the sanctity of embryonic life and of

significant restrictions on the exercise of constitutionally protected rights, such as abortion, in the name of protecting these early life forms. It seems likely that the court would uphold state statutes, such as the one in Louisiana that regulates management of extracorporeal embryos. Such restrictions may include prohibiting nontherapeutic experimentation on the embryo, embryo discard, and unnecessary creation of *surplus* embryos for the purpose of experimentation. It might also attempt to regulate transfer of embryos. By declaring that life begins at conception, as was done in the Missouri statute upheld in Webster, and by equating the rights of embryos to the rights of children, states could demand that embryo transfers be viewed as adoptions.

This was the approach taken by the trial court in the case of *Davis v. Davis* (1992), a Tennessee divorce case that struggled with determining the legal status of several frozen embryos that were left over from unsuccessful IVF treatments and became the subject of a divorce dispute. Characterizing the question as one of child custody, and viewing the embryos as children, the trial court then awarded custody to the parent whose actions would be in the best interests of the embryos. By assuming that embryos have "interests," and then defining one of those interests as an interest in being born, the trial court awarded the embryos to the wife, who intended to have them implanted in her womb in the hope of bringing them to term.

By contrast, the appellate court backed away from the characterization of the embryos as *children* and the resulting "best interests" analysis. Without ever explicitly calling the embryos property, the court proceeded to treat them as property held jointly by the couple, and thereby concluded that disposition of the embryos must be by agreement because each party had an equal property interest in them.

The Tennessee Supreme Court reviewed available models for disposition of the embryos when unanticipated contingencies arise. Those models range from a rule requiring, at one extreme, that all embryos be used by the gamete-providers or be donated for uterine transfer (such as is required under an as yet unchallenged Louisiana statute), and, at the other extreme, that any unused embryos be automatically discarded. The Tennessee Supreme Court, when it considered the *Davis* case, was aware of the *Planned Parenthood v. Casey* (1992) decision, which reiterated the *Roe* (1973) holding that a state may express an "interest" in a fetus. Unfortunately, like *Roe, Planned Parenthood v. Casey* fails to identify what this interest might be or why it arises, leaving the *Davis* court with little guidance on how to extend the state interest argument to nonabortion settings.

Numerous commentators have struggled to identify this state interest (Joyce; Tooley). Many begin with the premise that a sufficiently detailed biological understanding of embryo potential will yield an answer:

> [E]very living individual being with the natural potential, as a whole, for knowing, willing, desiring, and relating to others in a self-reflective way is a person. But the human zygote is a living individual (or more than one such individual) with the natural potential, as a whole, to act in these ways. Therefore the human zygote is an actual person with great potential.… (Joyce, p. 169)

But others argue that the genetic blueprint of a person cannot be entitled to the same moral standing as that of the person himself or herself, because any inherent "right" to live is premised on the idea that it is in the "interest" of the entity to continue existing (Tooley). Where, as with a zygote, there is no self-concept, there can be no "interest" in continuing to exist, no "desire" to continue to exist, and therefore no "right" to continue to exist.

Such an argument refutes the *Davis* trial court's treatment of the frozen embryos as children with an interest in being brought to term. But the appellate court's assumption that they must therefore be treated as property is equally unjustified. Society may choose nonetheless to grant rights to the zygote or fetus, for any number of reasons, if such steps do not unduly impinge on another liberty recognized by society, such as the liberty of men and women to control their reproductive futures.

In fact, Justice John Paul Stevens takes on this issue in his concurring opinion in *Planned Parenthood v. Casey:*

> Identifying the State's interests—which the States rarely articulate with any precision—makes clear that the interest in protecting potential life is not grounded in the Constitution. It is, instead, an indirect interest supported by both humanitarian and pragmatic concerns. Many of our citizens believe that any abortion reflects an unacceptable disrespect for potential human life and that the performance of more than a million abortions each year is intolerable; many find third-trimester abortions performed when the fetus is approaching personhood particularly offensive. The State has a legitimate interest in minimizing such offense.… These are the kinds of concerns that comprise the State's interest in potential human life. (*Planned Parenthood v. Casey,* 1992, 120 L. Ed. 2d 674 at p. 739)

Struggling with the task of expressing a state interest in embryonic life without unduly impinging upon the reproductive rights of adult men and women, the Tennessee Supreme Court in the *Davis* case concluded that embryos

are neither children nor property, but occupy an intermediate status based on their potential for development. This, in turn, would not convey a right to be born under either state or federal constitutional law but would demand some protections. These include implantation where possible, freedom from unnecessary creation or destruction, and dignified management.

The Tennessee court's characterization of an intermediate status for embryos is the most intriguing part of the opinion, as it did not present a coherent theory of that status and its implications. There are, of course, models of intermediate property status. Animals, for example, are treated as property with no "right to life," but at the same time are protected from cruel and painful treatment by their owners. Works of art may be owned, but "moral rights" possessed by the artist in some jurisdictions prohibit defacing or destroying the art. Land may be owned subject to numerous restrictions on use that would permanently destroy some publicly valued attribute. Which, if any, of these models describes the intermediate status held by the embryos? And on what basis? This is indeed the key question left totally unanswered by the Tennessee court. As it stands, though the opinion gives some narrow, nearly regulatory guidance to IVF clinics, it offers little to those wondering in general whether other restraints on embryo creation and management are in order.

Other countries have struggled with the same dilemma. Most often, as in England and Australia, the compromise solution is chosen, in which limited experimentation is permitted on unavoidably abandoned embryos. Deliberate creation of embryos for the purpose of experimentation is frowned upon. Occasionally a stricter view is adopted, as in Germany, where embryo experimentation is simply banned. Generally, however, where embryos are to be created in order to permit implantation and gestation, even extracorporeal maintenance or embryo freezing is tolerated (U.S. Congress, OTA, 1988b; Liu; McLean).

What is the State Interest in the Children Conceived Noncoitally?

Related to state interest in the protection of extracorporeal embryos is its interest in protecting the children born following noncoital conception. This takes its most frequent form in suggestions for limiting use of these technologies to married couples, on the theory that being born into a single-parent home is harmful to a child. On this basis, almost two-thirds of physicians surveyed in 1987 and a number of states either explicitly or implicitly deny artificial insemination services to unmarried women (U.S. Congress, OTA, 1988a, 1988b).

While some may deplore this practice, the fact that unmarried persons are not considered a "suspect" class in constitutional jurisprudence (i.e., they are not considered a class in need of special protection from discriminatory legislation because they are fully able to use the political system to protect their interests), means that such discriminatory practices are largely immune to constitutional challenge as an abridgment of their right to equal protection of the laws. Unless procreation, and specifically the use of artificial insemination, is viewed as a fundamental right, such persons will be limited to challenges under state and federal civil rights statutes in their pursuit of equal access to these technologies.

To the extent that the right to procreate implies a right to create a family, constitutional law from the nineteenth century remains unchallenged in its support for criminalization of family forms, such as polygamy, that fly in the face of Western European tradition. While there have been twentieth-century cases in support of broadening the definition of *family,* there has not yet been any case in which the right to marry is extended beyond a heterosexual couple. Thus, whatever the right to privacy entails, it does not appear to guarantee the right to form familial relationships that achieve the same legal recognition as that bestowed by marriage.

Generally, current interpretations of constitutional law appear to support the assertion that for married couples there is a right to privacy embedded in the wording and history of the constitution and that such privacy extends to reproductive decision making free from unwarranted governmental intrusion. While case law suggests that individuals are entitled to this privacy in equal measure, judicial hostility to claims of a right by homosexuals to marry or engage in sexual activity (*Bowers v. Hardwick,* 1986), by minors to have unrestricted access to abortion (*Hodgeson v. Minnesota,* 1990), and by physicians to give full information concerning abortion (*Rust v. Sullivan,* 1991) suggest limitations on Supreme Court extension of this right.

Indeed, much of the state activity concerning contract motherhood has been directed at protecting the children conceived through these arrangements. In the event a surrogate changes her mind, a custody dispute can break out between the birth mother and the genetic father. Reluctant to extend parental status to the adopting mother without terminating the parental status of the birth mother, but also determined to see the child placed in the safest home, courts have been in a quandary. Most often the solution has been to refuse to use the contract as the basis for a custody decision, and instead to rely on traditional family notions of child welfare. Next, courts have generally refused to terminate the birth mother's status as a presumptive legal parent. But despite these findings, most courts also award custody to the

genetic father and his wife, as it is this couple who is usually better able financially and socially to convince the court that they can provide a secure home for the baby (U.S. Congress, OTA, 1988b; McLean).

Other Concerns Regarding Contract Motherhood

Another state interest in surrogacy stems from the fact that the contracts typically entail promises by the contract mother to refrain from certain behaviors such as drinking, smoking, or the use of illicit drugs, as well as affirmative promises to follow prescribed prenatal care regimes and to undergo prenatal testing for fetal health. Enforcing such contract promises raises constitutional issues, requiring a relinquishment of significant autonomy on the part of the contract mother. This is particularly true with regard to promises to follow prescribed medical care, which may entail submission to invasive tests and even surgery, in the case of cesarean sections.

Surrogacy also raises the specter that the hiring couple might gain what amounts to a property interest in the body of the contract mother. This is particularly true where gestational surrogacy is employed, and the child the contract mother is carrying is genetically related to the hiring parents but not to her. At least one court has been known to issue a "prenatal adoption" order, in which the hiring husband and wife were declared the legal parents of the fetus still within the gestational mother's body (*Smith v. Jones,* 1988). In such a case, the hiring parents would have a legally recognized interest in the development of the fetus. Indeed, as parents they might have a legal duty to protect the fetus from harm, as has been confirmed by cases that hold pregnant women criminally liable for behaviors that threaten fetal health. How to protect fetuses while not compromising the physical integrity and legal autonomy of the gestational mother poses a significant constitutional challenge.

Gestational surrogacy also raises fundamental questions about the definition of parenthood, particularly of motherhood. While the law has consistently given preference to biological parents over nonbiological parents, with specific exceptions carved out for adoption and AID, it has never before been forced to consider the definition of *biological.* As of the mid-1990s, only one state has considered the problem. In California, a dispute developed between a couple (the Calverts) whose gametes had been used to conceive a child who was subsequently brought to term by a hired gestational contract mother named Anna Johnson. The trial and appellate courts both concluded that the genetic relationship, which defines "natural" parent for men, would define the "natural" parent for women. The two lower courts specifically rejected the notion that gestation is a biological relationship formed by the indisputable fusing of maternal and fetal well-being during the nine months of pregnancy that could equally well form the basis for defining the "natural" mother.

California's lower court decisions in *Johnson v. Calvert* (1991), stating that a gestational mother is no more than a foster parent to her own child, are almost without precedent worldwide. Only Israel, bound by unique aspects of religious identity law, has adopted a genetic definition of motherhood. Every other country that has examined the problem—including the United Kingdom, Germany, Switzerland, Bulgaria, and even South Africa with its race-conscious legal structure—has concluded that the woman who gives birth is the child's mother.

The California Supreme Court's 1993 opinion on *Johnson v. Calvert* declined to find either the genetic or the gestational mother to be the definitive "natural" parent. Instead, it chose to view either relationship as a presumptive form of natural parenthood. Then it specifically declined the invitation to have the law reflect what had actually happened, that is, the birth of a child with two biological mothers, one gestational and the other genetic. Agreeing that acknowledging more than one natural mother would be, as the trial court stated, a "recipe for crazymaking," the California Supreme Court said that whichever of the two biologically related women had been the intended mother would then be declared the "natural" mother. It continued by stating that in the event that the gestational and genetic mothers are not the same person, and that the intended mother is neither the genetic nor gestational parent, she would nonetheless be considered the "natural" mother. Thus the court avoided what is at base the most interesting question raised by the use of reproductive technologies: the possibility of declaring more than one woman to be a "natural" parent of a child. To do so, of course, would require escaping the confines of the heterosexual couple as the paradigm for a family and acknowledging that some people become parents by virtue of genetic connection, others by gestational connection, and still others by contract—whether a marital contract with a genetic or gestational parent, or a reproductive technology contract that creates relationships with children conceived with donor gametes or carried to term by contract mothers.

What is the State Interest in Access to Quality Services?

A final and overarching area of state interest lies in consumer access and protection. Only a handful of states have legislation mandating insurance coverage for the most expensive of

these technologies, IVF. Those states, including Arkansas, Hawaii, Maryland, Massachusetts, Texas, and Wisconsin, have responded to political pressure from organized medicine as well as from infertility support groups. But no state has yet asserted that insurance coverage is required by virtue of the fact that procreation is a fundamental right that may, for some people, be exercised only when using an expensive technology. Indeed, in the context of abortion services, the Supreme Court has made clear that states may forbid Medicaid or other public funding of such services, although they are clearly linked to the exercise of a fundamental right. In fact, the *Webster* decision upheld a state prohibition on the use of public facilities for abortion services, even when no public funds are used.

Where IVF and other reproductive technology services are being provided, however, the state may well choose to regulate them for the sake of protecting patients from unscrupulous practices. These may include misleading advertising, inadequate facilities, insufficiently trained personnel, and negligent screening of gamete donors for genetic and infectious diseases that might be transmitted to recipients. Even in the exercise of a fundamental right, the state may enforce regulations designed to protect the patient.

Another consumer issue involves the regulation of commercialization of reproductive technologies. Although sperm donation has continued apace in countries where no payment is permitted, most commentators agree that the availability of donor gametes and contract mothers in the United States would be severely reduced if commercialization were prohibited. Nonetheless, even when viewing access to reproductive technologies as an exercise of freedom to procreate, several state courts have concluded that there is ample state authority to prohibit commercialization (*Doe v. Kelley,* 1981; *Baby M,* 1988). The basis for this conclusion can vary. One line of argument, focusing on surrogacy, characterizes it either as baby-selling or the sale of parental rights, both of which traditionally have been forbidden despite significant libertarian arguments in favor of free markets for both. These prohibitions on selling children or parental rights would easily extend to prohibitions on the sale of embryos, if embryos are characterized as children. Prohibitions on the sale of semen and ova probably could be justified on the same basis as the current prohibitions on organ sales, despite the same line of libertarian arguments.

Other arguments in favor of prohibiting commercialization focus on the effect such activities have on public morals, on the creation of property interests in the bodies of others, and on the fear that the creation of an industry surrounding the sale of gametes, embryos, and reproductive services will create a class of professional breeders. A 1987 survey of surrogacy brokers by the OTA revealed significant discrepancies in economic and educational backgrounds of those who hire contract mothers and those who work as contract mothers (U.S. Congress, OTA, 1988a), leading to the conclusion that the two groups would be unlikely to wield equal bargaining power during the preconception contract negotiations or during postbirth custody disputes.

All of these arguments would probably fail if subjected to the strict scrutiny brought to bear on state interference with a fundamental right. But the reluctance of U.S. courts to view commercialization of reproductive services as an expression of procreative freedom reduces the degree of scrutiny to which state restrictions are subjected. Any rational state purpose will suffice if the restriction interferes with a privilege rather than a fundamental right.

Conclusion

The legal and regulatory issues surrounding reproductive technologies concern the ability of a government to ban or restrict noncoital reproduction because it may harm embryos, children, consumers, or public morals. Where governments choose not to ban the practice, they may wish to regulate it, for example, by limiting what types of prospective parents may use it, which adults will be related to the resulting children, and what kinds of ancillary practices—such as research or commercialization—will be permitted. In the United States, the details of such regulation are a function of state legislation and the resolution of novel cases by the courts. But the federal Constitution places significant limits on how far such legislation or judicial lawmaking may interfere with the opportunity of individuals to exercise procreative choice.

V. GAMETE DONATION

Gamete donation is a procedure that enables those who wish to have children, but who cannot produce or use their own gametes (sperm or eggs), to use gametes provided by others in attempts to procreate. Those at risk of transmitting serious genetic disease to their children and those without a sexual partner (of the opposite sex) may also use the gametes of others to attempt to have children. Sperm donation is carried out by inserting sperm provided by a donor directly into a woman's reproductive tract. Egg (oocyte) donation involves merging eggs extracted from a donor with sperm in a laboratory dish by (*in vitro* fertilization [IVF]) and transferring some of the resulting embryos to a woman's uterus.

While the use of gamete donation has stimulated amazement and curiosity, it has also created significant ethical and public-policy questions. Concerns have been raised about whether this practice might radically alter understandings of marriage, procreation, and parenthood; whether it objectifies and commodifies gamete donors and the offspring who emerge from such procedures; and whether it harms donors, recipients, or the resulting children. There is also a rising concern about whether the procedures associated with gamete donation should be subject to greater oversight and regulation. Egg donation, in particular, is poised to expand in novel directions that will raise ethical and public-policy issues never before considered.

The use of the term *donation* in connection with the provision of gametes is seen as self-contradictory by some, since sperm and egg donors in many instances do not donate their gametes, but are financially remunerated for them. However, since this term is in common usage and is understood to cover both unpaid and paid suppliers, its use will be retained here.

The History of Gamete Donation

Pregnancy following sperm donation was mentioned in Western literature as early as 1790, when the Scottish surgeon John Hunter was said to have artificially inseminated a woman in London. J. Marion Sims, a New York doctor, is believed to have carried out the first sperm insemination in the United States in 1866. The practice was usually kept secret, however, because it was considered shameful and unnatural to introduce the sperm of a man other than her husband into the body of a woman. The first confirmed case of sperm donation took place in the United States in 1884, when William Pancoast, a physician in Philadelphia, inseminated a woman using sperm from a medical student. In 1953, scientists demonstrated that human sperm could be frozen and thawed for insemination to produce a normal child, paving the way for the first commercial sperm bank, which was opened in 1970 in Minnesota. By 1993 it was estimated that more than 80,000 women were undergoing the procedure each year, resulting in approximately 30,000 pregnancies annually.

Oocyte donation was first reported in 1983 in Australia. Since then, use of this procedure has grown rapidly. In 1987 it was reported to be available at 17 programs in the United States; in 1993 there were 135 known programs, and in 1998 this number had doubled to 260 programs. In 1998, a total of 5,273 egg-donation cycles were initiated, with 4,783 transfers of donated eggs to recipients, for a delivery rate per transfer of 41.2 percent (Society for Assisted Reproductive Technology).

The Practice of Sperm Donation

Sperm donation is usually performed in a medical setting by a physician using sperm acquired from an anonymous donor. It is also practiced in private contexts by those who do not want professional supervision, although this is considered extremely unsafe as the donor has not been screened for infectious diseases that might affect the woman or the resulting child. This private practice employs sperm from a known or anonymous donor using common household implements. There are three major sources of sperm: large sperm banks that ship frozen specimens nationwide, regional sperm banks with a more local distribution area, and pools of donors retained by individual practitioners.

As long as physicians could use friends, colleagues, and informal networks to acquire sperm, supply was not a problem. When these sources became insufficient in the 1980s, medical students were given a modest financial incentive to *donate* sperm. Payment represented closure of the transaction, and donor anonymity was guaranteed (Daniels). Donors today are primarily young single males students who are found by word of mouth and through advertising in college and local newspapers, in magazines, and on the Internet. Sperm banks attempt to recruit a pool of donors exhibiting a variety of physical, mental, and ethnic characteristics. Donors are matched with recipients on the basis of physical and other features as far as possible, while a few sperm banks specialize, offering sperm from donors of high academic or athletic ability.

Practice guidelines of the American Society of Reproductive Medicine (ASRM; formerly the American Fertility Society) recommend that sperm donors undergo medical screening that includes testing for infectious and sexually transmitted diseases. Until the 1980s most insemination with donated sperm was performed with fresh sperm, which

were only sometimes tested for venereal disease. That changed dramatically in 1988 when the Centers for Disease Control, concerned about the transmission of AIDS, called for donors to be tested for HIV antibodies at the time of donation and again after their sperm had been frozen for six months before their gametes could be used. This rule was designed to reduce the risk of transmitting HIV through sperm from infected donors who did not have detectable antibodies at the time of donation. Practitioners now only use frozen sperm.

Meanwhile, according to ASRM recommendations, the recipient is also screened medically and tested for cystic fibrosis carrier status. Her partner is clinically evaluated and tested for HIV antibodies, and both are to be offered psychological counseling.

In the United States, sperm donors are paid for their time and expenses, with payment in 1998 ranging from $35 to $50 per unit. The Human Fertilisation and Embryology Authority (HFEA) of the United Kingdom currently allows a fee of U.S.$23 per donation, but it is moving toward completely phasing out payments to gamete donors. Sperm donors are not paid in New Zealand, Sweden, and France.

The Practice of Egg Donation

Egg donation is a more complex, onerous, and risky procedure than sperm donation—both for donor and recipient. Both must follow drug regimens to stimulate the production of multiple eggs and the donor must undergo an intrusive egg-recovery procedure. Consequently, egg donation is necessarily offered under medical auspices through *in vitro* fertilization (IVF) programs affiliated with academic medical centers, community hospitals, and private practices.

Egg donors must undergo the same drug regimens and egg-recovery procedures as women who undergo IVF. An average of thirteen eggs is collected from each donor, and up to twenty-five eggs have been reported extracted at one time. These eggs are fertilized with sperm *in vitro.* Some of the resulting embryos are then inserted into the uterus of the recipient, who has been injected with drugs to prepare her uterus to accept embryos. The remaining embryos may be frozen for later use by the recipient, donated to medical research, donated to others, or discarded.

Egg donation involves medical risks to the donor of varying degrees of severity. As a consequence of the use of fertility drugs, 1 percent of donors experience ovarian hyperstimulation syndrome (OHSS), which can lead to kidney or liver failure, cardiorespiratory dysfunction, or stroke, among other effects. In addition, 10 to 20 percent of donors experience moderately severe hyperstimulation syndrome, while approximately one-third are affected by milder forms of this syndrome. According to some studies, there is an association between the use of ovulation-stimulating drugs and ovarian cancer. Laparoscopy, which is used to extract eggs from donors, also carries minor risks. Even when there are no complications, the procedure is highly uncomfortable and time-consuming. Recipients of donated eggs, studies suggest, are at increased risk of pregnancy-related complications such as preeclampsia, diabetes mellitus, and anemia, as well as HIV infection.

When egg donation began, it was usual to acquire eggs from anonymous donors who were undergoing IVF and were willing to part with spare eggs. As the practice grew in the late 1980s, and as more donors were needed, infertility specialists sought eggs from known donors who were relatives or friends of recipients and were willing to contribute eggs out of a spirit of altruism. To meet the ever-increasing demand for eggs, they then moved to married women under thirty-five years of age who were not known to the recipient couple, and who had already had as many children as they wanted. Such women, it was reasoned, had exhibited that they were fertile and they were less likely than childless women to attempt to claim the resulting children in the future. Some of these women received financial compensation. Gradually, practitioners realized that they achieved better results using the eggs of young women and began to advertise for college women to serve as donors, for these women were presumed to be healthy, fertile, and in need of extra funds. Donated eggs are now derived primarily from healthy young women who are specifically recruited for this purpose, followed by relatives or friends of the prospective parents, and lastly from infertility patients undergoing IVF who agree to donate extra eggs to others.

Guidelines of the ASRM and the national advisory board on ethics in reproduction (NABER), a private body that is independent of practitioners and that has developed standards for egg donation, recommend medical screening of recipients and psychological evaluation of both recipients and their partners. They also call for medical screening of donors and a genetic evaluation based largely on the donor's stated medical history. Whether HIV antibodies might be transmitted by the donor to the recipient cannot be resolved in egg donation by direct testing of eggs because donated eggs cannot currently be frozen and quarantined for the 180 days required for retesting for HIV antibodies. However, recipients of donated eggs can have the resulting embryos frozen and used six months later if the egg donor tests negative for HIV antibodies at that time. The disadvantage of this is that freezing embryos lessens the chances of

successful embryo implantation. Psychological counseling is also recommended for the donor and her partner by both the ASRM and NABER.

Clinics in the United States vary greatly in how much information they offer to recipients about donors. At many programs, matches are made by physicians and nurses on the model of anonymous sperm donation. Recipients are informed about the donor's physical characteristics and given some additional nonidentifying information, and donors usually learn nothing about the recipients. At some centers, brokers recruit and screen donors for a fee. Recipient couples choose an anonymous donor from a list of candidates provided by these brokers. At still other centers, information is provided to donors and recipients about one another and they are urged to meet, a practice known as *open donation* that echoes a growing trend toward *open adoption.*

The cost of egg donation combined with *in vitro* fertilization in the United States rose from about $9,000 per attempt in 1991 to about $20,000 in 2001 (not including donor payment). Donors in the United States are reported to have been paid amounts ranging from $1,500 to $10,000. Some are said to have been offered $50,000 and $100,000. Egg donors in England are currently paid the equivalent of $23 and, as with sperm donation, such payments are to be phased out.

Ethical Issues

Ethical issues raised by the practice of gamete donation tend to fall into two major categories. There are those that focus on underlying conceptual questions, such as whether gamete donation is, in principle, ethically acceptable, and whether this procedure might radically alter understandings of procreation, marriage, and parenthood. Other questions are more oriented toward the consequences of gamete donation, such as its safety; its possible psychological import for donors, recipients, and children; and whether adequate informed consent has been obtained.

Procreation and the Marital Relationship

The use of gamete donation has sparked powerful philosophical differences that center on two features of procreation that many deem essential: it is exclusive and it is embodied. There was a public uproar in 1909 when it was revealed that sperm donation had been carried out by a physician some twenty-five years earlier, and the practice was condemned as a form of mechanical adultery. Some secular and religious critics voice similar concerns today, holding that the use of reproductive materials provided by individuals outside the marital relationship intrudes upon the exclusive union between spouses that is normative in marriage, and is therefore wrong. "There is, generally, strong rabbinic opinion that AID [artificial insemination by donor] should be condemned as 'an act of hideousness' or 'an abomination' or 'human stud farming'" (Rosner, p. 133). Such critics of third-party gamete donation believe that procreative acts that take place in a context other than marital fidelity are diminished and distorted. However, other commentators, including some within the Jewish tradition, accept gamete donation, maintaining that the exclusive relationship between husband and wife remains unchanged when gametes from a third party are used to achieve fertilization (Mackler). Thus, some members of a Church of England working party declared that this procedure is ethically acceptable because "there is no offence against the married partner, there is no breaking of the relationship of physical fidelity, and there is no relationship with a person outside of marriage" (Church of England, p. 57).

The other feature of procreation of special concern to critics of gamete donation, that it is embodied, is undeniably set aside in gamete donation—no act of sexual union takes place between those who will be the rearing parents of the resulting child. Many natural-law theorists hold that it is wrong to replace sexual intercourse with methods of assisted reproduction, particularly when they involve third parties, for to do so wrongly separates the procreative and unitive or loving ends of sexual intercourse. The Roman Catholic Church, in particular, rejects gamete donation because it is thought to erode the unity of body and spirit in the procreative process (Congregation for the Doctrine of the Faith). The Protestant theologian Paul Ramsey (1913–1988) once declared that an ethic that regards "procreation as an aspect of biological nature to be subjected merely to the requirements of *technical* control while saying that the unitive purpose is the free, human, personal end of the matter pays disrespect to the nature of human parenthood" (p. 33). The use of gametes derived from third parties outside a marriage is prohibited in Islamic law, as this risks inadvertent consanguinity ("being of the same blood") dilutes the purity of the family line, and could create confusion about the identity of a child's genetic parents and about a child's heritage (Serour).

Proponents of gamete donation respond that to insist on physical union between man and woman in procreation is to derive ethical norms too simply and narrowly from the usual physical structure of human reproduction. Furthermore, it is to ignore that the use of donated gametes can uphold, rather than violate, the loving dimension of the relation between marital partners and lead to responsible

parenthood (Laurtizen, pp. 9–12). It is sufficient that love and procreation are held together within the marital relationship as a whole.

Feminist scholars, in particular, have expressed concern about the metaphorical disembodiment that gamete donation can entail for women. Some of those who have donated gametes maintain that they are not treated as whole persons, but are divided into unrelated parts, each of which is subjected to manipulation in order to produce a child. A woman's body can thus be treated as "a field to be seeded, ploughed, and ultimately harvested for the fruit of the womb" (Raymond, pp. 61–62). Supporters of gamete donation and assisted reproduction respond that neither current ethical analysis nor public policy views women as "fetal containers" (Robertson, pp. 192, 228–229). While they acknowledge that the legitimate needs and interests of women must be recognized, they argue that new technologies such as gamete donation expand the freedom of women and assure them a large measure of control over their reproductive lives.

Parenthood and Family Relationships

Those who challenge the use of donated gametes argue that in a world where the rearing mother or father is no longer the biological source of gametes, there is no obvious answer to the question who are the "real" parents of the child. They argue that the use of third-party gametes thus vitiates lines of kinship and descent that situate individuals within particular and extended familial relationships (Meilaender). Further, when gamete donation is used to enable single women to have babies with donor sperm, and when postmenopausal women to give birth to children using donated eggs, traditional notions of the family are confounded (Cahill).

A second line of argument presented by these critics is that those who engender a biological relationship to a child, as do gamete donors, bear responsibility for the well-being of children who result. It is wrong, they maintain, for men and women to provide their gametes to couples and then leave without concern for the child who emerges. (O'Donovan). Some argue forcefully that sperm donation, in particular, institutionalizes the socially problematic phenomenon of paternal abandonment (Callahan).

Those in the opposite camp respond that while the biological connection is important to parenthood, it is not essential. In adoption, for example, the biological relationship between parent and child is sundered, and yet the practice is well accepted. It is also acceptable, therefore, to allow such separation in gamete donation. If those using gamete donation will provide a stable and caring environment in which the welfare of the child is a central focus, as is presumptively the case in adoption, there is no reason to adjudge gamete donation wrong. In this view, nurturing is of greater significance to parenthood than biological rootedness. Thus, while proponents recognize that gamete donation challenges traditional understandings of the family, they accept this as reflecting contemporary social realities (Robertson, pp. 121–122). Critics respond that this procedure is distinct from adoption, for it amounts to intentional preconception abandonment of future children by donors, as opposed to giving up already born biological children out of necessity (Cahill). Moreover, they maintain that the biological connection of children with their parents and extended family is a significant factor affecting their sense of self that ought not be disregarded.

The use of gamete donation to enable older women to have children has come under special scrutiny, not only because it raises issues of safety for mature women and the children they might bring into the world, but also because of concerns about its impact on the family. Some commentators maintain that egg donation is making biological limitations of aging irrelevant, and this, in turn, is confounding traditional notions of the family as women old enough to be grandmothers give birth to babies. Yet others observe that men have been known to father children in their mature years without criticism, and that there is no reason that the same should not be true of women. Older parents, they argue, may stretch the usual concept of the family, but they do not destroy it. Even so, the risks of egg donation and pregnancy for older women and their children can be serious. NABER and the New York State Task Force on Life and the Law recommend caution about the use of egg donation in women of relatively advanced reproductive age, maintaining that the risks to the woman and the best interests of resulting children must be considered.

Secrecy and Anonymity

Whether it is wrong to keep the use of gamete donation secret has become a pressing ethical, social, and psychological issue. Secrecy in gamete donation is said to place a lie at the center of family life, and therefore to be destructive. Studies show that any lifetime secrets impose a burden on the family members and have a detrimental psychological and social impact on the resulting children. The risk of unexpected disclosure of the circumstances of a child's conception hangs over the family that has concealed this information. Some psychologists maintain that it is important to the healthy development of children that they know their biological origins (Baran and PanNor; Nachtigall). They believe that disclosure of the participation of a gamete

donor in the conception of a child improves, rather than weakens, family relationships. Moreover, in a world in which genetic information is of increasing importance, children who do not know of a source of some of their genes are denied information that might be important to their health. The primary reason for concealing this information is that the children who spring from gamete donation might be stigmatized as different. Such stigmatization is decreasing, however, in a world in which families are more often composed of members of varying biological origins.

If secrecy were abjured in families, it would be necessary either that rearing parents and the resulting children at maturity know the identity of their gamete donor, or else have a certain amount of information about him or her that could lead to identification if all involved are amenable to this. Yet identifying donors has been controversial. Perhaps the oldest argument against doing so is that potential donors would be fearful of having a child born with the assistance of their gametes later appear at the front door, or that they might be held responsible for the support of such a child. Many donors would therefore decide against donating, which would diminish the pool of available donors. In addition, recipients fear that donors would seek them out and either claim the children or attach themselves to the children (Cohen, 1996). This is of particular concern when relatives are gamete donors. Coercion within families could surface, as could bad feelings if donation were followed by an adverse outcome.

For such reasons, the identity of those who donate gametes is generally not revealed to recipients. The Ethics Committee of the American Fertility Society formally embraced the principle of anonymity of sperm donors in 1994 in order to encourage men to donate and to safeguard them from unwittingly becoming responsible for the support of the resulting children.

Enthusiasm for maintaining anonymity, however, appears to be diminishing. Surveys indicate that donors are increasingly willing to be contacted after a child born of their gametes turns eighteen if they have assurance that they will have no financial or familial obligation to the child. NABER has proposed that egg donation centers move toward a policy of offering both known and confidential donors to those seeking eggs, and that donors be required to provide information about their medical history and genetic health. Children born of donated gametes would be given access to this information at the age of eighteen, if they so requested, and donors would have the option of providing either relevant identifying or nonidentifying information to them. NABER has also recommended that a centrally coordinated network of registries be established in the United States that would keep records about donors in either identifiable or coded form, depending on the choice of the donor (National Advisory Board on Ethics in Reproduction, pp. 290–291, 300).

Commodification of Procreation and Children

There is growing concern that egg donation, in particular, is being left adrift amidst a stream of commerce, and that procreation is being commodified. The current marketing of egg donation, critics contend, relegates human beings to the status of commercial objects and their gametes to that of products. Some see the current practice of paying significant sums to egg donors as coming uncomfortably close to baby buying, and they maintain that this flies in the face of the accepted view of children as individuals endowed with an underlying dignity. Several commentators observe that gametes, as the means of making new life possible, are not negligible body products that ought to be bought and sold in the open market (Lauritzen; Radin; Cohen, 1999; Shanley). Moreover, they argue, to offer large sums of money to egg donors amounts to a form of undue inducement that can vitiate the voluntary decision of donors to donate eggs. Some feminists argue that poor women, in particular, should not be enticed to turn their reproductive capacities into a commodity.

Defenders of paying women for their eggs outright maintain that women have the right to sell "products" of their bodies if they so choose. State intervention to prohibit the sale of eggs, in their view, would violate the individual liberty interests of such women. Moreover, prohibiting payment to donors would only compound the problems of those who are less well off by depriving them of a source of income (Harris). It is not the sale of human eggs that is wrong, in their view, but the fact that a bidding war for them has emerged with no industry-wide standards that set a fair price. The most prudent social policy would be to regulate the market for human eggs to ensure that egg donors receive appropriate pay for their time and endeavors. (Resnik).

Several review groups that have addressed this question advocate financially reimbursing gamete donors only for their time and inconvenience. Their primary justification for this approach is that it upholds human dignity and avoids undue inducement of women to donate their eggs. It is fair and reasonable, they maintain, to compensate donors for their expenses, travel, lost wages, and, to some extent, the risks that they incur in going through the donation procedure (National Advisory Board on Ethics in Reproduction, 1996; New York State Task Force on Life and the Law,

1998; Ethics Committee of the American Society of Reproductive Medicine, 2000). The ASRM suggests that appropriate compensation for egg donors would amount to $5,000, and that amounts up to $10,000 might be justifiable. It is inappropriate to offer larger amounts to potential egg donors, the society holds.

Oversight

Some legal commentators maintain that individuals have a constitutionally protected right to reproduce, a right that extends from coital reproduction to such methods of assisted reproduction as gamete donation. The use of gamete donation should thus be a matter of individual decision, and the state should play only a limited regulatory role to ensure safety and prohibit uses that would substantially harm others (Andrews; Ethics Committee of the American Fertility Society, 1994, p. S13; Robertson, pp. 41, 119–123). Others agree that individuals have a right to reproduce coitally that lies in a sphere protected from most state intrusion, but they reject the view that methods of assisted reproduction clearly fall under the aegis of this right. They are concerned about the use of gamete donation without sufficient regard for the interests and health of donors, recipients, and the resulting children. Some have therefore recommended that there be national standards and a federal regulatory system governing this and other forms of assisted reproduction (Rao; Massie; Cohen, 1997).

Yet no federal laws govern the procedures of gamete donation in the United States, and no review of novel assisted-reproductive techniques is required by federal regulation. IVF clinics that practice gamete donation are not required to set up institutional review boards or to review innovative treatments under the regulations of the Department of Health and Human Services. The Clinical Laboratory Improvement Amendments of 1988 covers only the laboratory analysis of sperm for purposes of quality control. The Food and Drug Administration requires registration, but not licensure, of sperm banks, although it has indicated that plans to develop guidelines for screening donated sperm to prevent transmission of communicable diseases. Under the Fertility Clinic Success Rate and Certification Act of 1992, data regarding clinic-specific pregnancy and delivery success rates for assisted-reproductive procedures, including oocyte donation, are collected and published by the Centers for Disease Control along with various professional societies (Society for Assisted Reproductive Technology). This produces useful information, but does not regulate procedures of gamete donation. Thus, there is a dearth of federal oversight of the methods and materials used for sperm and egg donation.

There is some state law regulating sperm donation but the vast majority of states do not require sperm banks to be licensed. There is almost no state law regarding egg donation. Judicial holdings in this area have been limited and have focused on deciding who should serve as the rearing parents of children born of gamete donation. In the private sector, a voluntary association of tissue providers, the American Association of Tissue Banks, has developed detailed standards for sperm donor screening, the ASRM has published practice guidelines for egg and sperm donation, and NABER has developed recommendations for egg donation. However, these guidelines do not have the force of law and offer no mechanism for surveillance or enforcement.

Commentators and review groups observe that in a market-driven environment that has been blighted by occasional scandals and misrepresentations, there is a compelling need to provide oversight of the use of gamete donation and other methods of assisted reproduction in the United States (Annas; ISLAT Working Group; National Advisory Board on Ethics in Reproduction; Cohen, 2002; New York State Task Force on Life and the Law). NABER, in 1996, called for a national regulatory body to license and monitor the quality of services of infertility centers and proposed that in the interim a task force composed of practitioners, outside experts from various disciplines, and lay persons should develop uniform intercenter policies to inform and safeguard donors, recipients, and resulting children (National Advisory Board). It also recommended numerous changes in professional guidelines and standards, as well as state and federal law. In addition, in 1998, the New York State Task Force on Life and the Law identified major problems in the provision of gamete donation and drafted guidelines and model consent forms to improve information given to donors and recipients. It, too, offered detailed recommendations for changes in professional standards that would provide some degree of uniformity in practice, and it proposed changes in state law to protect those involved in gamete donation and the children born of these procedures. Also in 1998, the ISLAT (Institute for Science, Law and Technology) Working Group recommended a federal law that would set a minimum standard for the provision of assisted-reproductive technologies and urged that noncompliance should result in criminal or civil liability. Few of these proposals have been adopted.

There are now at least twenty legal jurisdictions around the world that have enacted legislation regarding the uses of the new reproductive technologies. Countries that allow gamete donation combine the prohibition of certain procedures with licensing requirements to limit who may perform reproductive procedures. The use of eggs from donors, for

instance, is prohibited by law in Germany, Norway, Sweden, Switzerland, and Japan. Countries that have adopted uniform standards for the infertility industry, such as the United Kingdom and Australia, began by appointing a commission or committee to study the issues and make legislative recommendations, and they then acted upon those recommendations.

Future Directions

Demand for donated eggs will increase in the future, not only to accommodate ever greater numbers of couples and individuals seeking to have children, but also to bolster new areas of research. Investigative programs, such as those in basic human embryology, embryonic stem cells, cloning, and cryopreservation of human eggs, will require large quantities of human eggs before they can proceed. Other sources of human eggs, in addition to living donors, are therefore under investigation for both clinical and research uses.

Researchers have begun to delve into the possibility of using fetal eggs, derived from aborted fetuses and matured *in vitro*, for clinical egg donation programs. Some have prophesied that this could lead to the development of *egg farms,* in which some of the thousands of eggs in a young woman's ovaries that would otherwise fall by the wayside could be salvaged to increase the number of eggs available for personal use or the use of others (Gosden, p. 152). It is not yet known whether the early female eggs, which normally are subject to a high degree of degeneration, can develop into mature eggs capable of giving rise to a normal fetus after fertilization. Moreover, an aborted fetus could be the carrier of a metabolic or genetic disorder that could manifest itself in the resulting child. If such eggs were used to overcome infertility, this would raise concern about the psychological well-being of the resulting children, who might experience harm either from being told that their genetic mother was an aborted fetus or from not being told of this. Since there is currently no compelling need to use fetal oocytes, the ASRM has recommended that this avenue of investigation not be pursued (Ethics Committee of the American Society of Reproductive Medicine, 1997, pp. 6S–7S).

Frozen, stored ovaries are another possible source of human eggs for clinical use. A slice of ovary contains thousands of immature eggs, and ovarian tissue could be removed during surgery for ovarian cyst or endometriosis, or during prophylactic surgery for ovarian cancer. Freezing and storing ovarian tissue currently appears more promising than freezing mature eggs. Moreover, storage of ovarian tissue is relatively easy. This is an experimental procedure that is under development and, consequently, there has been little comment about its safety or its import for the interests of the resulting children.

Because women are currently the sole source of eggs that can be used to create human embryos, and because there is a paucity of eggs for research, women will increasingly be called upon to provide eggs for investigative purposes. This raises significant ethical questions. Women asked to contribute eggs to stem-cell research or research cloning, for instance, would receive neither health benefits to themselves nor the satisfaction of assisting in the birth of a child to others (Baylis). Their primary motivations for undergoing egg donation procedures in such cases would either be the satisfaction of assisting medical science or the prospect of financial reward. If such research were carried out in the public sector under current federal guidelines for stem-cell research that had been extended beyond current restrictions on the sources of such lines, women would be barred from receiving financial compensation for their endeavors and risks in donating eggs. They would provide eggs solely to assist medical research. Thus they would constitute human subjects participating in nontherapeutic investigations that expose them to more than minimal risk, and the Common Rule requiring full, written, informed consent would apply. However, it is clear, commentators have observed, that the common rule for informed consent is currently not being adhered to in either federally or privately funded research when deriving eggs from women to create embryos from which stem cell lines are developed. Therefore, they argue that to protect the voluntary choice and health of women, fully informed consent should be rigorously sought in the future from women whose eggs are used in scientific research, no matter who provides those eggs or what the source of funding for that research.

VI. CONTRACT PREGNANCY

Contract pregnancy, often also called *surrogate motherhood,* consists of a complex set of practices in which women employ their distinctive reproductive powers to give birth to children on the understanding that others will take on the responsibilities and prerogatives involved in the rearing of the children. The controversies surrounding such practices extend even to issues of labeling. Women who provide their ova as well as their abilities to gestate and deliver babies to this enterprise are sometimes referred to as *full surrogates,* as contrasted with *partial surrogates,* who gestate and give birth to children conceived in vitro, typically with the gametes of the commissioning man or couple. For reasons of clarity, the phrase *genetic-gestational* is used in this entry to refer to those women who have agreed to provide both their gametes and their wombs; *gestational* alone indicates those women whose role is to sustain and deliver a child to whom they are not genetically related. More significantly, some writers have argued that referring to women who have carried a fetus to term and delivered a child as *surrogates* slights their status as mothers, and prejudices the discussion of disputes concerning parental status between the birthgiver and the commissioning party in favor of the couple or individual who secured the birthgiver's services. For this reason the term *contract pregnancy,* coined by Laura Purdy, is adopted here, although it should be noted that not all such arrangements are explicitly contractual. The understandings under which women act may well be highly formal arrangements, brokered by intermediaries and involving payment, but they may also be quite informal, with no intermediaries or compensation.

Apart from matters of nomenclature, controversies concerning contract pregnancy have, in practice, revolved around disputes concerning the enforceability of agreements when one (or more) of the parties involved has undergone a change of heart, namely: contract birthgivers who find themselves no longer willing to relinquish custody of the children they have borne, or commissioning parties who have changed their minds about wanting to parent the child born of the arrangement they initiated. In theory, the chief disagreement concerns the conditions that confer parental responsibility—that is, how the elements of gestation, genetics, desire, and intention should be weighed when their customary connections have been purposefully sundered. Other disagreements arise over whether women or children are harmed or wronged by contract pregnancy, whether contract pregnancy involves the commodification of children or of the parent–child relationship, and whether desires on the part of adults to rear children to whom they are in some way biologically related ought to be honored in light of the needs of existing children who lack parents. It has also been suggested that contract pregnancy offers important reproductive options to people who have not previously enjoyed them—women who have undergone hysterectomies and gay men, for example—and that by expanding the ways in which families can grow (and, in principle, the ways in which people can be related to each other), contract pregnancy can add important value to human lives.

Disputes about Motherhood

The incidence of contract pregnancy is not centrally monitored, but empirical studies by Helena Ragone (1994) suggest that most such arrangements prove satisfactory, at least to the adults who are centrally involved. Nevertheless, three prominent court cases exemplify the deeply unsettling controversies that can arise when the strands of motherhood are pulled apart and the affected parties disagree about how to weave them together again. The first two cases discussed below involve a dispute between the commissioning parties and the birthgivers, in a genetic-gestational contract pregnancy and a gestational pregnancy, respectively; the third case involves a disagreement between the man and the woman who constituted the commissioning party.

IN THE MATTER OF BABY M. Contract pregnancy became a matter of public concern as a result of the *Baby M* case, probably the most notorious of contract pregnancy disputes. A 1985 agreement between Mary Beth Whitehead and David Stern, providing that Whitehead should, for financial considerations, conceive, bear, and then surrender their child to the sole custody of Stern, led to the birth of Melissa Stern. The contract was voided on appeal to the New Jersey Supreme Court in 1988, after a drawn-out dispute between Whitehead and the Sterns that featured Whitehead fleeing with the child from New Jersey to Florida. Whitehead was recognized as the child's legal mother, contracts of the sort in question being found contrary to New Jersey public policy and law. Custody, however, was awarded to Stern and his wife, Elizabeth Stern, on a determination that the "best interests of the child" would thus be served. Whitehead was granted visitation rights.

JOHNSON V. CALVERT. Anna Johnson agreed to be implanted with an embryo created from the gametes of Crispina and Mark Calvert on the understanding that the Calverts would rear the ensuing child. In September 1990, before the birth of the child, Johnson challenged the contract. The Supreme Court of California upheld the lower court's ruling in favor of the Calverts, on the grounds that while both "genetic consanguinity" and giving birth are legally recognized means of establishing a mother–child relationship, "when the two means do not coincide in one woman, she who intended to procreate the child—that is, she who intended to bring about the birth of a child that she intended to raise as her own—is the natural mother under California law." Johnson's visitation rights were terminated.

IN RE MARRIAGE OF BUZZANCA. Luanne and John Buzzanca arranged for an unnamed woman to gestate an embryo donated by third parties and agreed to rear the resulting child. Just prior to the child's birth, John Buzzanca filed for divorce, maintaining that he had no parental responsibilities to Jaycee, the child to be carried to term on his estranged wife's behalf. The trial court, accepting the stipulation that the birthgiver was not Jaycee's mother and reasoning that the Buzzancas' lack of a genetic tie to the child ruled them out as well, concluded that Jaycee "had no lawful parents." The appeals court disagreed, ruling in a 1998 decision that "the intent to parent as expressed in the surrogacy contract" established Luanne and John as Jaycee's legal mother and father, and finding John Buzzanca responsible for her support.

Three Analytical Clusters

These cases illustrate various forms of disputes about who counts as a parent, and in virtue of what considerations. Given the deep significance for many people of biological connections to their children, bioethicists have been quite concerned to resolve these matters, and a variety of approaches have been explored. These approaches may be grouped under three headings, according to whose interests are deemed most crucial. The first cluster centers on the *adult parties* involved as competent makers of contracts. These analyses address themselves with the features the contracts should have in order to avoid moral and practical problems. The second cluster focuses especially on the position of *women* in these arrangements, with particular attention to the woman who accepts the commission. These approaches portray women as operating in what is in general a hostile social environment and are skeptical that women's interests will be reliably served or protected by contract pregnancy. The third cluster centers particularly on the claims that the *children* born of these arrangements should be able to make against their parents, drawing on the notion that children have a moral stake in how the responsibilities of the adults who brought them into being are assigned.

Contracts and Commodification

A clearly argued version of the first model provided in a 1988 article by Bonnie Steinbock, contends that there is no sufficient reason to outlaw contract pregnancy or hold such contracts unenforceable. Steinbock maintains that these arrangements ought to be seen as a prenatal version of adoption. Among the safeguards she proposes is that a birthgiver ought to be allowed an opportunity after giving birth to change her mind about surrendering custody of the child to the commissioning party, just as a new mother is allowed to reconsider whether she will give up her child for adoption.

The most significant challenge to contract pregnancy, as Steinbock sees it—the concern that such practices involve a mother's relinquishing her standing as a parent for money—could be obviated by mandating that any payment be for "risk, sacrifice and discomfort" (Steinbock, p. 49) involved in pregnancy, and hence would be made even if the pregnancy ended in a stillbirth. Should the mother change her mind about giving up her child, she would not, however, be entitled to any remuneration for those sacrifices.

With commodification thus deflected as a criticism of contract pregnancy, none of the other concerns Steinbock surveys—for example, potential emotional damage to the mother or the child as a result of their involvement in these arrangements—strike her as sufficient to justify state action against the practice. While the possibility that some women will undergo a change of heart cannot be dismissed, it would be intolerably paternalistic for the state to refuse to allow women to make contractual agreements they believe to be in their own best interests because of concerns that they were too prone to mistake what those interests are. Nor is there any reason to believe that any distress suffered by children would be so intense as to make it reasonable for them to wish that they had never been born via these arrangements (which, of course, are the only possible arrangements that would have led to the birth of precisely those children).

Steinbock does not explicitly discuss gestational contract pregnancy, so it is not clear whether such cases would be understood along the lines of her prenatal adoption model, nor whether gestational birthgivers who change their minds would be able to retain any claim to parental standing they might have, losing merely the money that had been agreed upon. This suggests one difficulty with an approach to contract pregnancy that attempts to adapt standing models of assigning parental rights and duties, such as adoption, to resolve contractual disputes. It seems unlikely

that any account of contract pregnancy that does not explicitly grapple with what it is that makes a woman a mother in the first place (in the sense of conferring parental responsibilities and prerogatives upon her) will be altogether satisfactory.

Nor is it clear just how a contract pregnancy that includes substantial economic transactions can be insulated from the concern that what is bought and sold is the baby, rather than the gestational services. Steinbock insists that payment be made even in cases in which the pregnant woman loses the child, thereby underscoring the claim that the money is not a quid pro quo for the infant. In a 1990 article, however, Elizabeth S. Anderson argues that commercial surrogacy devalues children insofar as it regards maternal connections to children as commodities to be exchanged and trivializes a woman's own evolving perspective on her pregnancy by providing her with fiscal incentives for severing whatever emotional links to the child she may develop. If the argument that any payment is solely for inconvenience and risk were to stand against Anderson's points, it would seem that the payment should be made regardless of whether the birthgiver is willing to relinquish her parental relationship to the child. She has, after all, faced risk and inconvenience to bring into the world a child to whom the contracting party has a parental relation. That such an arrangement would severely diminish the attractiveness of the contract pregnancy in the first place strongly suggests that the payment cannot be regarded as mere compensation for the birthgiver's trouble. The whole point of the arrangement is that the child should be given up at birth, rather than becoming a part of the birthgiver's family. So it seems that the would-be parents are paying for more than the birthgiver's inconvenience and risk. Their incentive for paying rests on the assurance that they will have custody of the born child.

Women, Exploitation, and Altruism

The issue of turning children or parental relationships into commodities is a serious challenge to the moral and legal propriety of contract pregnancy. Janice Raymond, however, points out in a 1990 article that even when money does not change hands—an arrangement she calls "altruistic surrogacy"—coercive forces are present in society in general and in families in particular that can influence women to act against their own better judgment and interests. Her argument thus serves as a significant instance of the second, woman-focused model of analysis. While the point has often been made that women who are potential contract birthgivers are likely to be less socially powerful than the men or couples who seek to reproduce through their agency, Raymond focuses on expectations of feminine—and particularly maternal—altruism that cut across class distinctions and are in her view among the most powerful of the forces that oppress women. While not denying that "women can give freely," Raymond insists on the sociological complexity of "gift giving," arguing in particular that the connections between altruism and femininity can distort individual choice and reinforce unjust patterns of social status. She ties these cautions about altruism to a broader criticism of contract pregnancy. The practice depicts women as "reproductive conduits," "incidental incubator(s) detached from the total fabric of social, affective and moral meanings associated with procreation" (Raymond, p. 11).

Do concerns of this kind constitute reasons to forbid or restrict women's freedom to enter into such contracts as a matter of law? This depends in part on whether women are able to resist coercive or manipulative pressures that may well be more present in altruistic than commercial contexts, and whether altruistic forms of surrogacy can be conceptualized in ways that do not support, and in fact undermine, objectionable connections between women and altruism. By the same token, whether contract birthgivers are mere "reproductive conduits" may hinge on whether contract pregnancy can be absorbed into the social, affective, and moral fabric to which Raymond alludes—perhaps by revaluing brightening and motherhood in ways that are themselves less prone to reinforce women's subordination. While such refiguring of social meanings seem latent possibilities within the practice of contract pregnancy, it is unclear whether or to what extent they are being realized in individual cases. Nevertheless, Elizabeth F. S. Roberts's ethnographic research, published in 1998, suggests that at least some contract birthgivers are indeed engaged in forging their own, new understandings of what it is to bear a child. These understandings may in turn help destabilize traditional understandings of family and motherhood that have been oppressive for women.

Children and Parenthood

Focusing on the moral role of children in contract pregnancy arrangements, James Lindemann Nelson and Hilde Lindemann Nelson have argued that parental responsibilities arise from parents' causal relation to their children. Because parents have brought about their children's existence, and because their children's existence is initially one of vulnerability and dependence, parents are responsible for their children's well-being. If they cannot fulfill their responsibility, they may give up the child for adoption, but they may not deliberately create a situation in which they put it out of their power to look after their children. Their responsibility cannot be relinquished solely as a matter of

agreements between adults that are prompted by their own interests. Nelson and Nelson further argue that because biological ties with children are seen as precisely the justification for such practices as contract pregnancy, it is only fair to assume that children too will have an interest in relationships with those to whom they are connected by ties of biology.

As with Steinbock's position, the implications of this position for cases of gestational surrogacy are unclear, and the situation might seem to be even more murky in cases where the commissioning couple are neither the genetic nor the gestational parents, as in *Buzzanca.* What kind of causal involvement with the child's emergence into the world is sufficient to establish at least a presumptive set of moral responsibilities? Further, the position at least leaves open the question why a person whose causal involvement is sufficient to ground such responsibilities cannot discharge them simply by taking steps to ascertain that the parties to whom she will relinquish her responsibilities are likely to be good parents. Regarding this latter question, a distinction between prediction and performance might be invoked. The acts of another can only be predicted, but one can exercise substantial amounts of control over one's own performance. May one divest oneself of the ability to see to it that the needs of a child for whom one is responsible will reliably be met? What constitutes a good enough reason to relinquish one's moral responsibilities to one's offspring? Setting aside concerns about commodification, concerns about exploitation of women, and concerns about the deep distress occasioned by a change of mind, it remains to be asked whether an altruistically motivated interest in helping others to procreate is sufficient to initiate human reproduction with the intent not to participate in raising the resulting children. Two further questions remain as well: Is it justifiable to ask someone else to put herself at the personal and moral risk involved with contract pregnancy in order to have or expand a family? Is it important that biologically linked children could not otherwise be brought into the family?

Reassembling Motherhood

Insofar as questions of this sort can be answered empirically, there seems reason to believe that contract pregnancy has afforded a way for infertile people longing to have children of their own to meet women who are gratified by the opportunity to help them realize their goal. That this process sometimes backfires rather spectacularly, as in the *Baby M, Johnson v. Calvert,* and *Buzzanca* cases, would not seem a decisive reason to regard the process as immoral or so flawed as to outlaw it. The enterprise is attended by moral risks, however, even in the majority of cases in which everyone walks away feeling satisfied. Giving birth by contract cuts the connections among the genetic, gestational, and intentional elements that constitute motherhood, yet there is no settled, reflective consensus regarding what kind of comparative priority such elements should have when they are sundered. The popularity of such contracts certainly puts force behind a particular answer to the priority question—it strongly privileges the intentional. Given that a rollback toward an answer more influenced by genetic or gestational elements is unlikely in the absence of a showing of serious harm, those concerned about contract pregnancy might consider how the moral risks of this practice might be minimized, and how such pregnancies might achieve moral gains that go beyond the gratification of private impulses.

VII. SPERM, OVA, AND EMBRYOS

The technical ability to freeze sperm, embryos, and eventually ova for long periods and then thaw them without destroying their biologic potential offers several new reproductive options for both fertile and infertile individuals. It makes the donation of eggs, sperm, or embryos to treat infertility a more efficient and safe procedure. It also allows individuals and couples to preserve sperm, eggs, and embryos to protect against future reductions in gametic viability due to age, disease, or occupational exposure, and permits posthumous reproduction to occur.

As with any technological deviation from the natural mode of conception, these techniques raise both medical questions of safety and efficacy and ethical, legal, and social questions about prohibition, restriction, or regulation of these practices. Once cryopreservation is medically established as safe and effective, its ethical, legal, and social acceptability depends on a general acceptance of noncoital and assisted means of reproduction, with specific issues relating to the particular technique in question.

Sperm

Cryopreservation of sperm is now well established medically and socially as a commercial enterprise. Sperm banking occurs as an aspect of infertility practice, or as an option for men who foresee damage to their gametes as a result of disease or occupational exposure. In the former case, a commercial sperm bank recruits sperm providers, screens them medically and socially, and usually pays them a fee for their sperm (technically they are vendors rather than donors of sperm though the latter word is commonly used to describe their role). The sperm is then distributed to doctors or others who practice artificial insemination with donor sperm, who in turn resell or distribute it to recipients.

A main legal and ethical issue with regard to this practice is the duty of the sperm bank to screen sperm donors and their sperm for infectious diseases, including the human immunodeficiency virus (HIV). Guidelines of the American Fertility Society, the main professional organization of physicians treating infertility, now recommend that donated sperm be screened for HIV diseases. Because there may be a six-month gap before HIV transmission shows up on antibody screening tests, screening requires that the donated sperm be quarantined for six months so that a second test can be performed on a sample to ensure that it is not HIV-infected. Failure to screen in this way is unethical and could make the sperm bank legally liable for transmission of HIV to recipients and offspring.

There are no laws that restrict to whom sperm banks may sell their sperm, and in the United States, the buying and selling of sperm is not generally covered by federal or state laws against selling organs, though several European countries prohibit the practice. Thus a bank could sell sperm to a single woman or representative organizations for use in inseminating single women. Despite fears that a bank or physician who provides sperm to an unmarried woman could be held liable for financial support of a child born as a result, no such legal liability has yet been imposed. While some persons find artificial insemination of single women to be unethical, and the practice is prohibited in some countries, it can allow women who otherwise could not bear children to reproduce, and unmarried women who are committed to reproduction in this way have been shown to be able childrearers.

Commercial sperm banks also provide service to individuals or couples who wish to store sperm for later use because of treatment of disease, occupational exposure, or fear of later impotence. Because no legislation specifically applies to this practice, its legal status would depend upon basic contract law. The depositor would be entitled to keep the sperm in the bank and retrieve it under conditions specified in the contract of deposit. Thus sperm could be released to the depositor or to his designee posthumously, if that is envisaged, and the bank would perhaps have no obligation to maintain the sperm past a specified time if failure to pay storage charges should occur. Clear specification of rights and duties in the original contract is essential. While posthumous release of stored sperm to the appropriate designee could lead to the birth of a child without a rearing father, this situation is similar to the insemination of an unmarried woman and should be treated similarly.

Whether a child born posthumously will be able to share in a deceased's estate is a matter of state inheritance law that does not affect the ethical, legal, or social acceptability of the practice.

The bank would, of course, have a legal duty to return the correct sperm to the depositor. At least one case has arisen in which the bank returned the wrong sperm, which led to the birth of a child who was not of the same race as the depositor. In such instances, suits for damages are likely to be successful. An important issue will concern damages, because there is no way to establish that in fact the lost gametes would have implanted and produced a child. In addition, some states regulate the operation of sperm banks as medical or clinical laboratories to protect the health and safety of consumers of their services.

Many of the issues that arise with commercial sperm banks would also apply to physicians who recruit sperm donors directly. They too would have ethical and legal duties of reasonable care to assure that donors have been tested for genetic and infectious disease. They would also be free to inseminate single women and use sperm posthumously, if that is the clear intention of the parties.

Ova

The ability to freeze and then successfully thaw ova has not yet been developed, due to the larger size of the ovum and the great amount of fluid in it. Once this ability is developed, egg banking will occur.

Frozen ova have less ethical significance than frozen embryos. Once the technical ability to freeze and thaw ova safely is developed, they will play an important role in enabling women to initiate pregnancies through in vitro fertilization (IVF), which involves hormonal stimulation of the ovaries to produce ova, often many more than are needed for fertilization at that time; freezing the extra ova will minimize the need for additional cycles of egg retrieval. Rather than inseminate all eggs retrieved in a cycle of IVF treatment, many couples will prefer to freeze extra eggs, which can then be thawed and inseminated for later attempts at pregnancy. Cryopreservation of ova, rather than embryos, may thus become the preferred method of storage.

Once ova freezing and banking begins, the same issues that currently arise with cryopreservation of sperm will occur. Commercial ova banks, which may be associated with sperm and embryo banks or exist independently, will be established. No doubt such banks will both buy or procure eggs from women and then resell them to doctors and couples in need of an egg donation. The main issues will then concern what the precise arrangement is between the donor and the bank concerning subsequent use, whether the bank will be responsible for genetic and infectious disease screening, and whether the bank will be responsible for any rearing costs of offspring.

With eggs that have been frozen for subsequent use in initiating pregnancy in an infertile couple, the agreement between the woman or couple and the storage facility will be of paramount importance. The depositor of the eggs will be the owner and will control release or discard of cryopreserved ova within the limits of the storage facility's policies. Thus the contract between the depositor and the facility would largely control deposits of eggs prior to disease treatment or occupational exposure or to use then or at a later time. As long as the depositor has paid storage charges, she would be entitled to have the eggs stored, to expect reasonable care to be taken in their maintenance, and to have the eggs released, transferred, or discarded as directed. Posthumous release and use of stored eggs should be as acceptable as posthumous release and use of stored sperm. As with sperm banking, failure of payment could lead to the bank taking the eggs out of storage, but it would not be entitled to transfer them to other persons in lieu of payment unless there were a specific agreement to that effect. Professional or even legislative regulation of ova banking to ensure standards of health and safety can also be expected.

Embryos

Cryopreservation of embryos (sometimes referred to as preimplantation embryos or *pre-embryos*) is now a well-established adjunct to IVF programs. Standard IVF treatment often produces more eggs than can be safely fertilized and placed in the uterus at one time. Rather than fertilize only the number of eggs that could be safely transferred or fertilize all retrieved eggs and discard the surplus, cryopreservation allows all eggs to be fertilized, a safe number such as two or three placed in the uterus, and the rest frozen for later use. At a later time, the frozen embryos can be thawed and placed in the uterus, donated to others, or discarded. Although the success rate is not as great as with fresh embryos, the pregnancy rate of both fresh and frozen embryos from a single egg-retrieval cycle is 15 to 20 percent greater than the rate from use of fresh embryos alone. Until the ability to freeze and thaw ova is developed, the excess eggs retrieved in a cycle of IVF treatment are likely to be inseminated and then cryopreserved for use during a later cycle.

The main issues that arise with cryopreservation of embryos concern the ethical and legal status of embryos and the locus of dispositional authority over frozen embryos. While some persons have argued that embryos are persons or

moral subjects with all the rights of persons, and others claim that embryos are merely tissue with no special status or rights, a wide ethical and legal consensus in the United States, Europe, and Australia views embryos as "deserving of special respect, though not the respect due persons." As a result, embryos may be created, frozen, donated, and even discarded or used in research when there is a valid need to treat infertility or pursue a legitimate scientific goal and rules concerning consent of the gamete providers and institutional review board approval have been followed.

With regard to dispositional authority over frozen embryos, it is now well established that the couple providing the gametes has dispositional authority within the limits of state law and the conditions of storage set by the IVF program or storage facility. If they agree to have embryos created from their gametes cryopreserved, they are *owners* of the embryos and may decide on any disposition of frozen embryos that their agreement with the storage facility and applicable statutes permit.

Since the frozen gametes are the joint property of the persons providing the gametes, their joint consent is needed for disposition until they relinquish or transfer their dispositional authority to others. To maximize their control over embryos and to introduce administrative efficiency into the operation of embryo banking, they should also give written directions at the time of storage for disposition of frozen embryos in the future if the providers have died, divorced, are unavailable for decision, or are unable to agree between themselves on disposition.

In such cases, the IVF program or embryo bank should be able to rely on this prior agreement in decisions concerning stored embryos. This will give advance control to the parties and clear directions to the bank and minimize costly disputes about what to do with stored embryos. Although no court has yet been faced with a case directly involving a disputed contract, there have been cases recognizing the right of the depositing couple to remove their frozen embryo from a bank against the bank's wishes. There is also legal authority recognizing the validity of such advance contracts for disposition in case disputes arise.

The *Davis v. Davis* case (1992) illustrates the wisdom of giving effect to the prior agreement. A couple had frozen seven embryos pursuant to their efforts to have children via IVF. They subsequently decided to divorce but could not agree on disposition of the frozen embryos. The husband opposed thawing them and using them to start pregnancy, while the wife insisted that she or another person have them placed in her. The Tennessee Supreme Court finally resolved this issue by ruling that an agreement between the parties for disposition in the case of divorce would have been binding, and that in the absence of such an agreement, the relative burdens and benefits of a particular solution must be examined. In that case if the party wishing to retain the embryos had other means of obtaining embryos, such as by going through IVF again with a new partner, that party's wish to have children could still be satisfied without foisting unwanted parenthood on the party who wished that the embryos not be used. On the other hand, if there was no other way for that party to be reasonably able to produce embryos, so that the existing embryos were the last resort or chance to have offspring, then they should be entitled to use them. In that case, fairness would require that the objecting party not have to provide child support. In the facts presented to it, the court ruled in favor of the husband, who did not want frozen embryos implanted after divorce, because the wife had alternative ways to reproduce.

Ethical and legal codes for assisted reproduction in other countries have not yet addressed the problem that arose in the *Davis* case. A country could take the position that all embryos must be preserved, or that provision of gametes for IVF is a commitment to have all resulting embryos placed in the uterus. However, the American preference to have the parties control disposition in the case of divorce or disposition by prior agreement might also be recognized, for it maximizes the procreative liberty of the parties directly involved.

The authority of the gamete providers over the disposition of frozen embryos can be limited by law or the policies of the banks or facilities where frozen embryos are stored. For example, some European countries (Spain and Germany) prohibit embryo discard and research, while others (Great Britain, for example) limit the period of storage to a maximum of ten years or the reproductive life of the woman, whichever is longer. While U.S. legislation on these issues is largely absent, the Ethics Committee of the American Fertility Society (1986) has recommended a similar maximum period of storage, and individual embryo banks and programs for religious or administrative reasons have imposed limitations on dispositions that involve discard, donation, or release of frozen embryos to other programs. As long as the storage facility makes clear its restrictions on disposition of frozen embryos, it may impose these restrictions on couples who request storage of embryos at that facility.

Conclusion

Cryopreservation of sperm, ova, and embryos offers individuals options to extend or enhance their reproductive ability and should presumptively be recognized as adjuncts of their procreative liberty. If this view is accepted, principles

of informed consent and contract will inform and regulate most of the transactions and activities that occur with cryopreserved gametes and embryos. In some cases legislation to protect the parties' wishes and ensure the health and viability of stored gametes and embryos may also be desirable.

VIII. ETHICAL ISSUES

The introduction of in vitro fertilization (IVF) in 1978 sparked anew an intense ethical debate about the use of innovative reproductive technologies that had raged a decade earlier. Questions were raised about whether these technologies would harm children and parents and alter people's understanding of the meaning of procreation, family, and parenthood. Gradually the controversy subsided as healthy children were born from these procedures; committees in at least eight countries issued statements indicating that they considered the use of IVF ethically acceptable in principle (Walters). Arguably, one reason for this readiness to embrace IVF and other new reproductive techniques was that they enabled couples to create offspring in a way that seemed an extension of the natural way of procreating. Although IVF involved joining sperm and ovum in a glass dish, the resulting embryo, once implanted, went through a natural period of gestation that culminated in the birth of a child. A second reason was that these technologies, with the exception of artificial insemination by donor, allowed people to have children who were genetically their own. Louise Brown, the first child created through IVF, resulted from the union of the gametes of her biological parents. Third, the children born of these new means of reproduction were born into traditionally structured families. These techniques were assumed to have been developed for use by married couples who, with the new baby, would form what was ordinarily defined as a nuclear family.

In the 1990s, these rationales for accepting novel reproductive technologies are being challenged by medical advances and a changing social environment. Human intervention in the procreative process has become more frequent, more complex, and more highly technological. Oocytes can be removed surgically from one woman and, after fertilization, transferred to another in the procedure of oocyte donation. Women can lend their wombs to others for the incubation of children who have no genetic connection to such "surrogates." Embryos created in vitro can be cryopreserved and stored for use in future years by their genetic parents or by others. Consequently, it is difficult to argue that such innovative measures are mere extensions of the natural way of reproducing. Parthenogenesis (stimulating an unfertilized egg to develop and produce offspring by mechanical or chemical means), cloning (deriving genetically identical organisms from a single cell or very early embryo), and ectogenesis (maintaining the fetus completely outside the body) are on the horizon. Furthermore, third, fourth, and fifth parties, such as oocyte donors, surrogate mothers, and (some suggest) even fetuses and cadavers, are joining sperm donors to assist those who are childless to have offspring. New forms of assisted reproduction are increasingly being used to create children who are not tied to those who will raise them by biological or hereditary links. Finally, these technologies are no longer used almost exclusively to

create traditional nuclear families. Unmarried heterosexual and homosexual couples and single women and men now have greater access to them. Such scientific and social changes give new emphasis to the older unresolved ethical questions about the uses of these technologies and raise new questions. Ethical questions raised by the use of the new reproductive technologies The initial ethical question created by these technologies is whether they ought to be used at all. Different religious traditions vary tremendously in their judgments about the licitness of the use of these novel techniques. The Roman Catholic church declared the use of new reproductive technologies morally unacceptable (Catholic Church) because they separate the procreative, life-giving aspects of human intercourse from the unitive, lovemaking aspects, and these, according to Catholic teachings, are morally inseparable in every sexual act. The creation of a child should involve the convergence of the spiritual and physical love of the parents; fertilization outside the body is "deprived of the meanings and the values which are expressed in the language of the body and in the union of human persons" (Catholic Church, p. 28).

Certain other religious groups, such as the Lutheran, Anglican, Jewish, Eastern Orthodox, and Islamic, view some of these methods as ethically acceptable because God has encouraged human procreation (Lutheran Church; Episcopal Church; Feldman; Harakas; Rahman). According to these bodies, it is sufficient that love and procreation are held together within the whole marital relationship; each act of sexual intercourse need not be open to the possibility of conception. Still other religious groups hold that there is no necessary moral connection between conjugal sexual intercourse and openness to procreation, and consequently they accept the use of the new reproductive technologies with few qualifications (Smith; Simmons; General Conference). In Hindu thought, for instance, although there is no authoritative teaching on this subject, the mythologies of ancestors appear to allow IVF, oocyte donation, embryo implantation, and surrogacy (Desai).

Feminists, too, are split about the use of the new reproductive technologies. Some argue that these novel methods define and limit women in ways that demean them, for example, as "fetal containers." They maintain that the desire of many women, both fertile and infertile, for children is, in large part, socially constructed (Bartholet, 1992; Williams). The cultural imperative to have children drives infertile women to undergo physically, emotionally, and financially costly treatment. They are thrust into the hands of a predominantly male medical establishment that uses women as "living laboratories" whose body parts they manipulate without regard to the consequences (Rowland). Male experts sever what was once a continuous process of gestation and childbirth for women into discrete parts, thereby fragmenting motherhood (Corea).

In contrast, other feminists argue that the new reproductive technologies enhance the status of women by providing them with an increased range of options. By circumventing infertility and providing women with alternative means of reproducing, these technologies extend reproductive choices and freedoms (Jaggar; Andrews; Macklin, 1994). In their view, the charge that surrogacy exploits women is paternalistic because it questions women's ability to know their own interests and to make informed, voluntary, and competent decisions (Macklin, 1990); women have the ability and right to control their bodies and to make autonomous choices about their participation in such practices, these feminists argue.

Some people recommend adoption over the use of the new reproductive technologies because they view the latter as physically and emotionally debilitating and unlikely to succeed, whereas adoption, while not easy, provides a home and family for children in need (Bartholet, 1993). Yet adoption is a second choice for many infertile couples because of its perceived drawbacks. These include the declining number of healthy children available for adoption, the long and emotionally draining wait, the expense, and the difficult and often frustrating system with which adoptive parents must deal (Lauritzen). Although the use of assisted reproduction presents some of the same problems as adoption, it offers what some infertile couples consider distinct advantages: It allows them to have children who are genetically related to at least one of them and (except in the case of surrogacy) makes the experience of pregnancy and birth available to the woman. The desire to reproduce through lines of kinship and to connect to future generations exerts a powerful influence, as does the hope of experiencing the range of fulfilling events associated with pregnancy and childbirth (Overall).

Individual Choice, Substantial Harm, and Community Values

A central issue in the debate about the use of reproductive technologies concerns the scope that should be given to individual discretion over their use. Some philosophical commentators, emphasizing personal autonomy, enunciate a broad moral right to reproduce by means of these technologies (Bayles; Brock). They borrow from legal discussions of the right to reproduce, which some legal theorists take to include the liberty to use methods of assisted reproduction (Robertson, 1986; Elias and Annas, 1987). To

limit individual choice about noncoital means of reproduction, the state must show that the use of specific reproductive technologies threatens substantial harm to participants and the children born to them (Robertson, 1988). The philosophers influenced by such legal positions maintain that individuals have great leeway in their choice of whether to procreate, with whom, and by what means. They have a right to enter into contractual arrangements giving them access to these technologies and to utilize third parties in their reproductive efforts. Those who take this approach concede that substantial adverse effects on others, particularly the children, would justify restricting individual use of assisted reproduction.

Since the primary reason for accepting these innovative methods is to bring children into the world, a major consideration in assessing them is whether or not they harm these children. Critics contend that these techniques may cause social and psychological problems to the resulting children because of confusion they engender over divided biological parentage and the social stigmatization to which they may be subjected (Callahan, 1988). John Robertson responds that this criticism is logically incoherent. When the alternative is nonexistence, he argues, it is better for the children to have been born—even though they may experience some harm from the means used to bring them into the world—than never to have existed at all (Robertson, 1986). In most cases, the difficulties they face are not so great as to render life a complete loss.

There are several problems with this influential response. One is that it justifies allowing almost any harm to occur to children born as a result of the use of these techniques in that it can almost always be said they are better off alive. Moreover, this argument presupposes that these children are waiting in a world of nonexistence to be summoned into existence and that they would be harmed by not being born. Since children do not exist at all prior to their arrival in this world, there are no children who could be harmed by not being born. When we say that it is better for a child to have been born, we do not compare that child's current existence with a previous one. Instead, we make an after-the-fact judgment that life is a good for an already existing child, even though that child may have suffered some harm from the technology used to bring him or her into the world. Critics of the use of the new reproductive technologies, however, make a before-the-fact judgment about children who do not exist, but who might. They maintain that it would be wrong to bring children into the world if they would suffer certain substantial harms as a result of the methods by which they are created. This is a logically coherent claim that justifies considering whether the new reproductive technologies severely damage children born as a result of their use.

The criterion of avoiding substantial harm, while valid, may provide inadequate ethical constraints on various ways of employing the new reproductive arrangements. The criterion is derived from a position that especially prizes individuality, liberty, and autonomy—quite possibly at the cost of values that are served by the building of families and communities, and by accounting for the common good (Cahill). Taking respect for individual freedom as the primary value, according to Allen Verhey, runs the danger of reducing the value of persons to their capacities for rational choice and denying the significance of the communities that shape them. People are not just autonomous individuals, they are also members of communities, some of which are not of their own choosing. Freedom is insufficient for an account of the good life in the family. Thus, it may be morally legitimate to recommend limits to individual choice about assisted reproductive techniques, not only to protect the children born of these methods but also to uphold basic community values. What is at issue, he suggests, is what kind of society we are and want to become (Verhey).

Ethical Issues Related to the Introduction of Third Parties

The introduction of third parties into procreative acts, according to some critics, imperils the very character of society by threatening the nuclear family, the basic building block of U.S. society (Callahan, 1988). Religious commentators and groups, in particular, have expressed concern about the effect of the use of gamete donors and surrogates on the relation between married couples within the nuclear family. Richard McCormick, a Roman Catholic theologian, argues that when procreation takes place in a context other than marriage (as when single women use artificial insemination by donor, for example) and another's body is used to achieve conception (as in the case of surrogacy, for example), total dedication to one's spouse is made more difficult; in Roman Catholic terminology, it also violates "the marriage covenant wherein exclusive, nontransferable, inalienable rights to each other's person and generative acts are exchanged" (Ethics Committee, 1986, p. 82).

In Islamic law, artificial insemination by donor is rejected on grounds that the use of the sperm of a man other than the marriage partner confuses lineage and might also constitute a form of adultery because a third party enters into the procreative aspect of the marital relation. The practice is highly controversial in the Jewish religion because (1) some consider it a form of adultery; (2) some take the resulting

child to be illegitimate; and (3) if the donor is unknown, the practice might eventually result in incestuous marriage between siblings. Most other religious groups that have commented on surrogacy also reject it because it depersonalizes motherhood and risks subjecting surrogates and procreation itself to commercial exploitation. Such practices will lead people to regard children as products who, in Oliver O'Donovan's terms, are "made" rather than "begotten."

Those who wish to counter concerns about adultery distinguish between adultery and the use of a gamete or womb contributed by a third party to assist a married couple to have a child. A necessary element of adultery, they contend, is sexual intercourse; neither gamete donation nor surrogacy involves sexual contact between the recipient and the donor. Moreover, unlike adultery, no element of unfaithfulness need inhere in participation in gamete donation. Indeed, a couple may participate in gamete donation just because they have a strong commitment to their marriage, rather than out of disdain for it (Lauritzen). When only one parent can contribute genetically to the procreation of a child, but both can nourish and nurture a child, this argument runs, it is ethically acceptable for them to have a child by means of third-party collaboration.

The use of third parties in the provision of the new reproductive technologies leads to confused notions of parentage, critics note, since it severs the connection between the conceptive, gestational, and rearing components of parenthood. It can be difficult to predict who will be declared the rearing parent in different reproductive scenarios, despite the fact that they embrace the same set of facts. For instance, in IVF followed by embryo transfer, the woman who gestates an embryo provided by someone else is considered the mother of the resulting child, but in artificial insemination by donor she is not. Those who respond to this criticism, in attempting to develop a consistent ethical basis for awarding the accolade of parenthood, give priority either to the interests of the children born of these technologies or to those of their adult progenitors.

Those who view the interests of the children as of prime importance argue that genetic connections should constrain the freedom to choose parental status in that biological kinship relations are important to children's development and self-identity (Callahan, 1988). Purposefully to break the link between procreation and rearing, these commentators maintain, harms children born of these procedures because it obscures their identity within a family lineage. Indeed, it has been argued that the biological relationship between gamete donors and the children who result from their contributions carries an obligation for donors to support and nurture those children (Callahan, 1992). Respondents observe that it is not considered wrong to separate the genetic and rearing components of parenthood in such well-established arrangements as adoption, stepparenting, blended families, and extended kin relationships. This precedent suggests that, although the genetic relation may be important, it is not essential to parenthood.

Caring for and raising a child are of greater significance for parenthood than providing the genetic material or gestational environment, according to this view. Consequently, the rearing parent should have moral priority over the genetic parent in the interests of the child (Lauritzen). Others focus on the interests of the parents when the choice is between the genetic and the gestational mother, and they contend that the gestational mother should prevail because of her greater physical and emotional contribution and the risks of childbearing (Elias and Annas, 1986).

Parents who are not the biological progenitors of the children they raise and those who provide them with gametes often fear social stigmatization. This raises the question of whether anonymity and secrecy should be used to envelop all who participate in the use of the new reproductive technologies for their own protection. Anonymity has to do with concealing the identity of the donor; secrecy has to do with concealing the fact that recipients have participated in gamete donation. The practice of artificial insemination by donor has historically been carried out in secrecy with anonymous donors to protect family and donor privacy; oocyte donation, which began with openness about the identity of donors, is moving in that direction as well. The major argument against this development takes the interests of the children as primary and contends that since the personal and social identity of children is dependent on their biological origins, they ought to know about their genetic parents (National Bioethics Consultative Committee). Several countries that accept this argument have adopted regulations allowing children, when they reach maturity, to gain access to whatever information is available about donors who contributed to their birth.

Technologies of assisted reproduction, especially those involving third parties, facilitate the creation of models of family that depart significantly from the traditional nuclear family. As single persons, homosexual couples, and unmarried heterosexual couples increasingly gain access to these technologies, both religious and secular bodies express concern about weakening mutual commitment within the family and about the welfare of the resulting children. Sherman Elias and George Annas observe that "it seems disingenuous to argue on the one hand that the primary justification for noncoital reproduction is the anguish an infertile married couple suffers because of the inability to

have a `traditional family,' and then use the breakup of the traditional family unit itself as the primary justification for unmarried individuals to have access to these techniques" (1986, p. 67). The Warnock Report, developed by a commission of inquiry into the use of artificial means of reproduction in Great Britain in 1984, concluded that "the interests of the child dictate that it should be born into a home where there is a loving, stable, heterosexual relationship and that, therefore, the deliberate creation of a child for a woman who is not a partner in such a relationship is morally wrong" (p. 11).

Some psychologists claim that children who grow up in these nontraditional families will suffer psychological and social damage because they will lack role models of both genders and may consequently develop an impaired view of sexuality and procreation (McGuire and Alexander). Moreover, they argue, two parents are better able than one to cope with the demands of childrearing. Other studies have been used to vindicate the opposite conclusions (McGuire and Alexander). Since few studies have been carried out on the consequences for children of atypical family arrangements that emerge when the new reproductive technologies are employed, it is difficult to provide any clear evidence to support or undermine these opposing contentions. A further concern voiced is that using new reproductive technologies to assist single people and homosexual couples to have children involves a misuse of medical capabilities because these methods are not being employed to overcome a medical problem but to circumvent biological limits to parenthood.

To others, however, the use of new methods of assisted reproduction by single people and homosexual couples mirrors the reality that U.S. society has begun to move away from the nuclear family (Glover). They see the inclusion of homosexual parents within the meaning of family as a move toward greater equality in a society in which those who are homosexual suffer from prejudice and discrimination. If single people and homosexual couples can offer to a child an environment that is compatible with a good start in life, the *Glover Report to the European Commission* maintains, they ought to have access to these techniques, but it is appropriate for those providing them to make some inquiries before proceeding (Glover). The Royal Commission on New Reproductive Technologies of Canada approved of allowing infertility clinics to provide single heterosexual and lesbian women access to donor insemination on grounds that no reliable evidence could be found that the environment in families formed by these gamete recipients is any better or any worse for the children than in families formed by heterosexual couples (Canada, Royal Commission on New Reproductive Technologies).

Ethical Issues Related to Commodification

A concern of special ethical significance is that the introduction of third parties into some of the new reproductive techniques carries with it the danger of commodification of human beings, their bodies, and their bodily products. Giving payment of any sort to surrogates and gamete donors, some argue, risks making them and the children produced with their assistance fungible objects of market exchange, alienating them from their personhood in a way that diminishes the value of human beings (Radin). Third parties who assist others to reproduce should be viewed as donors of a priceless gift for which they ought to be repaid in gratitude, but not in money.

Others argue that persons have a right to do what they choose with their bodies and that when they choose to be paid, their reimbursement should be commensurate with their services (Robertson, 1988). The value of respect for persons is not diminished by using surrogates and gamete donors for the reproductive purposes of others if those third parties are fully informed about the procedure in which they participate and are not coerced into participating—even when they are paid (Harris). There is a presumption on all sides that third parties should not be specifically compensated for their gametes, wombs, or babies. Several groups that have considered the matter, though, such as the Warnock Committee in Great Britain (Warnock) and the Waller Committee in Australia (Victoria), allow third-party payment for out-of-pocket and medical expenses. The American Fertility Society goes further when it maintains that gamete donors should be paid for their direct and indirect expenses, inconvenience, time, risk, and discomfort (Ethics Committee, 1990). It would be unfair and exploitive not to pay donors for their time and effort, John Robertson argues (1988).

Offering large amounts of money to third parties incommensurate with the degree of effort and service that these persons provide may diminish the voluntariness of their choice to participate in assisted reproduction, particularly when they have limited financial means. There is concern that a new economic underclass might develop that would earn its living by providing body parts and products for the reproductive purposes of those who are better off economically. This would violate the principle of distributive justice, which requires that society's benefits and burdens be parceled out equitably among different groups (Macklin, 1994). However, if poor women and men have voluntarily and knowingly accepted their role in these reproductive projects, it could be seen as unjustifiably paternalistic to deny them the opportunity to earn money. The possibility of exploitation of the poor must be weighed "against a possible step toward their liberation through

economic gain" from a new source of income connected to innovative methods of reproduction (Radin).

Ethical Issues Related to the Uses of Embryos, Fetuses, and Cadavers

When the process of fertilization is external, the embryo becomes accessible to many forms of intervention. During the brief extracorporeal, in vitro period, embryos can be frozen, treated, implanted, experimented on, discarded, or donated. Theoretically, embryos that result from IVF could be cryopreserved for generations, so that a woman could give birth to her genetic uncle, siblings could be born to different sets of parents, or one sibling could be born to another. A 1993 experiment in which human embryos were split reawakened concerns about these sorts of possibilities, which had remained dormant since a mid-1970s controversy about cloning human beings (National Advisory Board). (Cloning, either by transplanting the nucleus from a differentiated cell into an unfertilized egg from which the nucleus has been removed or by splitting an embryo at an early stage when its cells are still undifferentiated, results in individuals who are genetically identical to the original from which they are cloned.)

Advocates of embryo splitting view it as a way of obtaining greater numbers of embryos for implantation in order to enhance the chances of pregnancy for those who are infertile (Robertson, 1994). Critics claim that cloning in any form negates what we view as valuable about human beings, their individuality and uniqueness. It risks treating children as fungible products to be manipulated at will, rather than as unique, self-determining individuals. These critics maintain that twinning that occurs in nature is an unavoidable accident that does not involve manipulation of one child-to-be to produce a duplicate (McCormick, 1994). Defenders of cloning respond that the similarity of identical twins does not diminish their uniqueness or their sense of selfhood. In any case, cloned individuals would not be identical in that the genome does not fully determine a person's identity. Environmental factors, such as family upbringing and the historical context, weigh heavily in influencing the expression of genes (National Advisory Board).

It is the potential for abuse of cloning that disturbs most critics. The possibility of cryopreserving cloned embryos suggests the option of implanting cloned embryos and bringing them to term should their already-born twin need a tissue or organ transplant. In another scenario, embryos derived from parents who are likely to produce "ideal specimens" would be cloned and sold on a "black market." Critics condemn such potential applications of cloning because they diminish the value of embryos and of human beings by treating them as objects available for any use by others (National Advisory Board). They are concerned that the deep desire of the infertile for children, in combination with scientific zeal and market forces, will create strong pressure to clone embryos without a view to the ethical considerations involved. In 1993 scientists in the United Kingdom announced the possibility of using for infertility treatment eggs and ovaries taken from aborted fetuses (Carroll and Gosden). The eggs could be fertilized in vitro and then transferred into infertile women who lack viable eggs; the ovaries could be transplanted directly into women to mature and produce eggs.

This would help meet the shortage of oocytes for those who lack their own. Such uses of aborted fetuses, however, are highly contentious and strike some as grotesque. Many who object to abortion on ethical grounds maintain that this procedure, like other forms of fetal tissue use, would encourage the practice. Moreover, it seems self-contradictory for a woman to consent to abortion and at the same time consent to become a grandmother. Children created by this procedure, it could be argued, would know little about their genetic heritage or about their mother, other than that she was a dead fetus, and would therefore be at risk of both psychological and social harm.

Female cadavers provide another potential source of oocytes for those who are infertile. It has been proposed that women consider donating their ovaries for use by others after their death, much as individuals donate organs such as kidneys and livers (Seibel). It may soon be possible to collect immature eggs from cadavers, mature and fertilize them in vitro, and then transfer them into infertile women. This procedure would have an advantage over the use of eggs from aborted fetuses in that the recipient would be able to learn the medical and genetic history of the adult donor. An argument for this practice is that it would allow the continuation of the family's biological heritage and serve to console the grieving family because some aspect of their deceased relative will have been preserved. Postmortem recovery of eggs would be done with the consent of the donor and would therefore respect individual rights and allow freedom of choice for individuals and their close relatives.

This proposal is grounded in an analogy between organ and gamete donation. Yet gamete donation is different in that it involves the provision of an essential factor for bringing a child into existence; it is not life-saving but life-giving. The interests of the resulting children, consequently, provide a major consideration to be taken into account in determining whether such procedures ought to be pursued. The difficulty noted earlier in connection with the introduction of third parties arises in this instance as well.

Children develop their identity and self-understanding, in part, through their relationships with their biological parents. Consequently, they might face serious psychological and social harm if one of their biological parents were a cadaver. Indeed, this concern amounts to a central social concern as well, in that the prospect of using gametes derived from the newly dead in order to create children endangers our perception of the respect due to the dead human body and our view of procreation as ideally grounded in an interpersonal relationship between living persons.

Ethical Issues Related to Access and Justice

Although those able to procreate naturally can decide whether and when to do so, the choice to reproduce among those who need medical assistance to do so is more limited. In part, this is because they enter a healthcare system in which providers have responsibilities both to candidates for infertility treatment and to the resulting child, because they are assisting in the creation of a new human being. Although physicians have a special obligation to respect the autonomy and freedom of those who are candidates for treatment, they are not obligated to provide them with all treatments that they request (Chervenak and McCullough). As one of several groups of gatekeepers of the new reproductive technologies, some physicians use a medicalindications criterion to bar access to these technologies to some patients, as when, for example, the physical risk of pregnancy is too great. Yet many physicians find that they cannot easily separate medical indications from indications that are psychological, social, and ethical. Questions requiring judgments that go beyond those that are strictly medical arise in many situations. These questions include possible treatment for candidates who wish to create "designer babies" of a certain sex, intelligence, and/or race; couples who want to use a surrogate mother for frivolous reasons related to personal convenience; infertile single women who request access to both oocyte and sperm donation in lieu of adoption; women of advanced reproductive age who want to have children despite the risk to their own health; and couples who appear severely dysfunctional and prone to violence and child abuse. Physicians are not usually trained to address ethical questions that arise in such situations. Because physicians have personal and professional biases and are part of a largely unregulated and profitable infertility industry, it might be appropriate to assign the gatekeeper role to a specially trained group of professionals who are not physicians. Another possibility is to utilize guidelines for the use of the new reproductive technologies prepared by physician professional associations, institutional ethics committees, private-sector ethics boards, public ethics commissions, and state and national regulatory agencies; such guidelines should address not only medical but social, psychological, and ethical issues (Cohen, 1994; Fletcher).

Public-policymakers and private healthcare insurance regulators also affect who gains access to the new reproductive technologies. If they define infertility treatment as a response to a disease rather than to a social need, a case for financial support of the new reproductive technologies can be made. Because infertility is a physical condition that impairs normal function, many commentators regard it as something like a disease, the victims of which are in need of help from medical science (Overall). However, it can also be argued that since reproductive technologies do not correct the condition causing infertility, they do not constitute medical treatment for a disease. Yet many well-accepted treatments do not correct the underlying condition but only its symptoms or disabilities. Given the importance to many people of having a biological child and the fact that normal functioning allows this, the claim has been made that infertility should be treated as a disease on a par with other physical impairments. Historically, the *barren* woman or man has not been accorded sympathy; the availability of infertility treatment might disarm similar current discriminatory attitudes toward those who are infertile.

Even if infertility were defined as a disease, however, this would not indicate that its treatment would be ethically mandatory. The U.S. healthcare system does not have infinite resources and cannot provide everyone with every desired or desirable health service. Should the new reproductive technologies be subject to more severe criteria for funding than are set for other medical techniques? Because infertility is a physical dysfunction with significant effects on the life plans of those it affects, it can be contended that a just society should include reproductive technologies among the range of treatments covered. The opposing argument is that the costs of such treatment and its relatively low likelihood of success do not justify its inclusion.

A related issue arises from the fact that only a limited range of people—those with greater financial resources—benefit from the new reproductive technologies. Access depends on economic factors, culture, race, and social class. Those in the United States who are poor have little access to specialty services such as infertility clinics because public and private insurers provide limited coverage. If poor people participate at all in the use of these technologies, they do so as surrogates or occasionally as oocyte donors. Thus, the use of new reproductive technologies has potential for creating further unjust schisms in our society between rich and poor and between one subculture and another. As long as IVF services and gametes are in short supply, questions will arise

about how to select candidates from among those who seek access to the new methods of assisted reproduction. Those persons who are infertile or who carry a serious genetic disease may have a greater first claim than those who are not infertile but who wish to use these methods to select the features of their children or as a matter of personal convenience.

This is because the need of the former is a more basic need, directly related to the goal of remedying a difficulty in normal species functioning. A more refined set of rationing priorities would take account of such factors as the number of children an individual or a couple already has; whether they have a support system in place to assist them to care for a child adequately; and the greater medical risk to certain recipients of treatment, such as women of advanced reproductive age. These considerations would be grounded in the interests of the potential children and of their would-be parents, as well as in the need to distribute the number of children among couples in an equitable way.

Conclusion

Behind many of the ethical issues raised by the new reproductive technologies lie difficult questions about the importance of genetic parenthood, the nuclear family, and the welfare of children, as well as the role that society should play in overseeing the creation of its citizens. Perplexity about how to resolve these questions is due, in part, to the speed with which these technologies are being developed. There is a growing concern that they are being created too rapidly, before the old technologies, such as artificial insemination, have been integrated into the ethical and social fabric. As the rate of reproductive change accelerates, the ability to provide ethical safeguards for the creation and use of the new reproductive technologies diminishes. This may be the most persuasive reason to provide some form of direction and regulation of the new reproductive technologies that incorporates defensible ethical limits to their use.

IX. IN VITRO FERTILIZATION AND EMBRYO TRANSFER

In in vitro fertilization (IVF), a woman's ovaries are stimulated with fertility drugs to produce multiple eggs. The physician monitors the woman's response by examining urine samples, blood samples, and ultrasound imaging. After giving her an injection to control the timing of the egg release, the physician retrieves the eggs in one of two ways. In a laparoscopy, done under general anesthesia, the surgeon aspirates the woman's eggs through a hollow needle inserted into the abdomen, guided by a narrow optical instrument called a laparoscope. In the more recently developed transvaginal aspiration, done with local anesthesia, the physician inserts the needle through the woman's vagina, guided by ultrasound.

After they are retrieved, the eggs are placed in separate glass dishes and combined with prepared spermatozoa from the woman's partner or a donor. The dishes are placed for twelve to eighteen hours in an incubator designed to mimic the temperature and conditions of the body. If a single spermatozoon penetrates an egg, IVF has occurred.

A fertilized egg subdivides into cells over a period of forty-eight to seventy-two hours. Microscopic in size, it is generally called a pre-embryo or an embryo after it has divided into two or more cells. When the embryos have divided into four to sixteen cells, they are placed in a hollow needle (catheter) that is inserted into the woman's vagina. The embryo or embryos are released into the woman's uterus in the procedure known as embryo transfer. Implantation in the uterine wall, if it takes place, will occur within days after transfer; a pregnancy is detectable about two weeks after the transfer.

In established IVF clinics, the odds that a continuing pregnancy and birth will occur after embryo transfer are 20 to 30 percent. Because problems can arise at all stages of IVF, such as the inability to retrieve eggs or secure fertilization, the odds are less if they are calculated from the time fertility drugs are first given. Data from several national registries indicate a delivery rate of 9 to 13 percent if calculated from the starting point of hormonal stimulation (Cohen, 1991). The birthrates tend to cluster among clinics, so that some clinics account for a large percentage of the total births while others have few or no deliveries (Medical Research International). Tens of thousands of embryo transfers are carried out each year internationally, and thousands of babies have been born. Clinicians reported over 12,000 deliveries following IVF in one five-year period (1985–1990), and in one country (the United States) alone (Medical Research International).

Present and Future Variations

The first birth following IVF occurred in England in 1978 (Steptoe and Edwards). The technique was originally designed to circumvent blocked or damaged fallopian tubes in women trying to become pregnant. During the late 1970s and early 1980s, physicians combined the male partner's sperm and the female partner's eggs and transferred the embryos shortly after fertilization. If the couple had a large number of embryos, physicians either transferred all at once, which created the risk of a multiple pregnancy, or disposed of extra embryos, which wasted the embryos and was morally problematic.

The start of embryo freezing in the early 1980s has given physicians greater control over the number of embryos transferred at once. Two to four embryos are transferred in the first IVF cycle and the remaining embryos, if any, are frozen for later thawing and transfer. Embryo freezing saves the woman from the hormonal stimulation of repeated start-up IVF cycles, and it allows embryo transfer when the woman's body has returned to a more natural state. By enabling the transfer of a small number of embryos at once, it reduces the odds of a multiple pregnancy and the subsequent risk this poses to the woman and the fetuses. Controlled transfer of embryos is arguably less morally problematic than the selective abortion of fetuses in a large multiple pregnancy. The birth of the first infant to have been frozen as an embryo took place in Australia in 1984. Embryo freezing is now a routine option in IVF.

Another variation that has increased the flexibility of IVF is the use of donated sperm, eggs, and embryos to

circumvent fertility problems such as low sperm count in the male partner, lack of ovulation in the female partner, or lack of fertilization with the couple's own eggs and sperm, or to help couples at high risk avoid passing on a serious genetic disorder to their children. Sperm and embryo donation are more straightforward than egg donation, which is complicated by the need to synchronize the menstrual cycles of the donor and recipient. Women are either paid for their services in donating eggs or they donate in the course of their own medical treatment. In addition, some women donate eggs for their sisters or other close relatives. Donation of eggs or sperm raises questions about, among other things, confidentiality of medical records, the child's sense of identity, and the psychological well-being of the donor.

The embryos in IVF can be transferred to a surrogate if the genetic mother does not have a uterus or cannot carry a child to term for other reasons. Although the surrogate is usually unrelated, there have been instances of embryo transfer to the sister or even the mother of a woman who cannot carry a fetus to term. In the latter case, the surrogate is the child's gestational mother and genetic grandmother.

Sperm microinjection is another technique used in connection with IVF. If the male partner has low sperm count or poor sperm quality, a healthy spermatozoon can be manually inserted into the egg with special microinstruments. This alternative to sperm donation allows the transfer of embryos genetically related to the couple. This and other microsurgical procedures remain experimental and infrequent.

Another procedure for IVF is the examination of sperm, eggs, and embryos for chromosomal and genetic abnormalities. Preimplantation diagnosis has been conducted on an experimental basis in the United States, Britain, and other European countries. It is being developed for couples at high risk for passing to their children a genetic disorder such as cystic fibrosis or Tay-Sachs disease but who will not terminate a pregnancy and are therefore not candidates for prenatal screening.

Preimplantation diagnosis includes polar-body analysis (analyzing the DNA of the first polar body of the human egg), trophectoderm biopsy (examining extra-embryonic cells surrounding the inner cell mass), and embryo biopsy (removing a single cell from a four- or eight-cell embryo). It also includes chromosomal analysis to select only female embryos for transfer to couples who are at high risk for passing on a sex-linked disease, such as hemophilia, to male children. Pregnancies and births have been reported following embryo biopsy and sex preselection. Many variables remain to be worked out in preimplantation diagnosis, and physicians urge caution before expanding it in the IVF setting (Trounson). Correcting genetic flaws after they have been diagnosed is a distant, though foreseeable, possibility (Verlinksy et al.).

Ethical Issues in IVF

A recurring and unresolved issue in IVF involves the status of the embryo (McCormick). The Ethics Advisory Board, set up by the U.S. Department of Health, Education and Welfare, and later disbanded without its recommendations' being acted on, issued a report in 1979 stating that "The human embryo is entitled to profound respect, but this respect does not necessarily encompass the full legal and moral rights attributed to persons" (U.S. Department of Health, Education and Welfare, p. 107). The Warnock Commission issued a report in Britain in 1984 that also accorded the embryo a "special status," though not the same status "as a living child or adult" (Warnock).

The notion that the embryo is an entity with a special status deserving special respect is contested by those who regard the embryo as fully a human being from the moment of conception. An instruction issued by the Vatican concluded that the "human being must be respected—as a person—from the very first instant of his existence" (Catholic Church; Shannon and Cahill). The unique genetic makeup of the embryo, among other things, is given as evidence of its individuality.

Beliefs about the embryo's status are central to conclusions about what in IVF is permissible and what is not. Some observers who regard the embryo as a human being believe IVF is ethically acceptable provided all embryos are transferred and given a chance to survive. Others believe external fertilization is always immoral. If the embryo is regarded as a human being, it has "full human rights," including the right not to be experimented upon without its consent (Ramsey, 1972a, 1972b). Even if one regards IVF as no longer experimental, the conclusion of immorality still extends to IVF's variations, which begin as experimental procedures posing the risk of higher-than-normal embryo loss.

If, on the other hand, the embryo is regarded as only potentially a human, fewer ethical strictures on IVF techniques apply. The Ethics Advisory Board concluded that IVF was ethically acceptable for married couples and that research on human embryos was acceptable provided the research was designed to establish IVF safety, would yield "important scientific information," complied with federal laws protecting research subjects, and proceeded only with the consent of tissue donors. No research was to take place beyond the fourteenth day after fertilization. After fourteen days, the embryo begins to develop an embryonic disk or "primitive streak" and is no longer capable of spontaneous

twinning, which means it is on the way to becoming a single individual.

IVF has been criticized as a fundamentally dehumanizing technique that takes place in a laboratory, involves the scientist as a third party, is geared to the production of human beings, and is aimed at conquering nature and producing a "quality" child (Kass). The language of IVF and its business and marketing overtones contribute to a situation in which tissues and children are treated as commodities to be produced and in which intimacy is devalued (Lauritzen). The Vatican instruction concluded that IVF is unnatural because the sperm are secured by masturbation and the union takes place outside the body. Tissue donation is especially illicit, as it is "contrary to the unity of marriage, [and] to the dignity of the spouses" (Catholic Church).

Some feminists have expanded on this theme by criticizing laboratory conception as an intervention that divides reproduction—once a continuous process taking place naturally within the woman's body—into discrete and impersonal parts subject to a male-dominated medical profession (Arditti et al.). They argue that in IVF, women are perennial research subjects in an unending set of techniques that have significant emotional costs (Williams); that IVF benefits men and compromises women; and that it curtails women's autonomy and magnifies gender-based power differences in society (Wikler). Other feminists support IVF if it is bounded by feminist ethics and if it builds women's control over reproduction rather than taking it away (Sherwin).

IVF's variations challenge notions of the family, the interests of the potential child, the distribution of societal resources, and the rights of prospective parents. Tissue donation from relatives creates new biological if not legal relationships—for example, when a sister donates an egg to a sister for IVF or a brother donates sperm for his brother's IVF attempt. Embryo freezing creates the prospect of some embryos being stored indefinitely or transferred in a later generation, possibly endangering the resulting child's sense of identity. It also sets the stage for custody disputes and conflicts over the disposition of unwanted embryos (*Davis v. Davis,* 1992).

Embryo diagnosis for genetic defects raises safety questions for the embryo and potential child. Conceivably, it will lead to screening for many genetic problems and not just the life-threatening disorders envisioned now. On the one hand, discarding embryos after tests reveal a genetic abnormality might be less morally contentious than aborting pregnancies, at least for those who believe the embryo has a lesser status than a fetus. On the other hand, discarding "defective" embryos may blunt societal sensibilities and invite fertile couples into the costly and uncertain IVF procedure. The ability to preselect embryos according to sex raises concerns that the technique will be used for nonmedical reasons to give couples a child of their preferred gender, which may be male (Wertz and Fletcher).

IVF is highly selective in the people it can help. An expensive procedure covered by few insurance companies, it is available primarily to affluent couples. Critics question the wisdom of directing scarce resources to an elective and costly procedure with low odds of success (Callahan). Others advise paying more attention to preventing infertility in the first place (Blank). Aggressive marketing of IVF, including marketing that distorts success rates to make them seem greater than they actually are, arguably creates needs by making couples feel they ought to try IVF because it is there to try and by interfering with alternatives such as adoption or stopping efforts to conceive.

Concerns about the support of IVF and embryo research have been integrated into formal policy in a number of countries (Knoppers and LeBris). For example, the British Human Embryology and Fertilisation Act of 1990 created a licensing authority to conduct on-site visits to clinics in which human embryos are manipulated, review research proposals, and ensure that quality control is maintained in the laboratories (Morgan and Lee). A restrictive law in Germany, by contrast, makes criminal a range of techniques not therapeutic for the embryo, including sex preselection for nonmedical reasons ("German Embryo Protection Act"). Among the international documents relating to embryo manipulations are a recommendation from the Parliamentary Assembly of the Council of Europe that the Council of Ministers provide a "framework of principles" governing embryo and fetal research ("Parliamentary Assembly"), and a set of principles relating to IVF and its variations ("Council of Europe").

Fifteen states in the United States mention embryos in their statutes, but legislators passed most laws with abortion and fetuses in mind rather than IVF and embryos. Some of these laws would presumably make embryo research illegal, but their constitutionality has not been tested (Robertson). In 1989 the U.S. Supreme Court reviewed Missouri's abortion statute but declined to address the constitutionality of the statute's preamble that "the life of each human being begins at conception" (*Webster v. Reproductive Health Services*). This definition of personhood appears to contradict the Court's abortion rulings, but by leaving it untouched, the Court left the embryo's legal status unclear.

Several states have passed laws mandating insurance coverage for IVF under certain conditions (U.S. Congress,

Office of Technology Assessment). The federal government does not fund proposals involving human embryos; by law, research must be reviewed by an ethics board ("Protection of Human Subjects"), but no board has replaced the Ethics Advisory Board, which was disbanded in 1979. This has led to a de facto funding moratorium.

Conclusion

Prior to and in the years following the first successful use of IVF, critics argued that it challenged the sanctity of marriage and family, posed the threat of psychological and physical harm to unborn children, involved the immoral destruction of human embryos, made women experimental pawns in research in which men asserted control over reproduction, and introduced the senseless creation of people in an era of overpopulation. It was also said to admit no clear stopping point, use scarce medical resources, and amount to an elective technique that did not cure infertility.

Supporters argued that IVF would spare couples the psychological trauma of infertility, meet the needs of tens of thousands of women with blocked fallopian tubes, lead to knowledge that would help ensure healthy children, and preserve the family by bringing children to couples who truly want them. They responded to criticism by saying IVF was no more unnatural than cesarean births, should not be diminished merely because it did not cure infertility, posed no apparent risks to children, and was not immoral, in that embryos were only potential human beings.

Today, basic IVF has shifted from experimental to standard medical practice. It is widely available, is regarded as safe, and is the only viable way women with blocked fallopian tubes can conceive a baby genetically related to them. New technical additions ensure, however, that external fertilization will remain at center stage in the ongoing bioethics debate over reproductive technologies.

The lasting unanswered questions relate to the high value placed on genetic parenthood, equitable access to techniques across race and class, the impact of laboratory conception on women's control over reproduction, and whether priority ought to be placed on conception in a time when discussions are directed to ways of reducing the gap in medical services available to richer and poorer citizens.

Perhaps most significant, however, is the matter of the limits to be placed on reproductive technologies. It appears that the scope of refinements is nearly endless. Should substantive and procedural limits be placed by government on any of IVF's variations? If so, which, and why? Understanding the reasons for placing limits is as important as understanding the reasons laboratory conception is pursued with such intensity in the first place.

RESEARCH ETHICS COMMITTEES

• • •

The World Medical Association's Declaration of Helsinki (2000) and the Council for International Organizations of Medical Sciences' *International Ethical Guidelines for Biomedical Research Involving Human Subjects* (hereafter, CIOMS *International Ethical Guidelines*) (2002) establish as the international standard for biomedical research involving human subjects this requirement: "All proposals to conduct research involving human subjects must be submitted for review of their scientific merit and ethical acceptability to one or more scientific review and ethical review committees.… The investigator must obtain their approval or clearance before undertaking the research" (CIOMS, Guideline 2). In most of the world this committee is called the research ethics committee (REC). In the United States,

federal law assigns to the committee the name institutional review board (IRB), and the authority and responsibility for approving or disapproving proposals to conduct research involving human subjects ("IRB Review of Research").

History

The Nuremberg Code (1949) and the original Declaration of Helsinki (1964) made no mention of committee review; these documents placed on the investigator all responsibility for safeguarding the rights and welfare of research subjects. The first mention of committee review in an international document was in the Tokyo revision of the Declaration of Helsinki (1975).

In the United States, the first federal document requiring committee review was issued on November 17, 1953. Titled "Group Consideration for Clinical Research Procedures Deviating from Accepted Medical Practice or Involving Unusual Hazard," its guidelines applied only to research conducted at the newly opened Clinical Center at the National Institutes of Health (Lipsett, Fletcher, and Secundy). Very little is known about peer review in other institutions in the 1950s other than that it existed in at least some medical schools. In 1961 and again in 1962, questionnaires were sent to departments of medicine at U.S. universities. Approximately one-third of those responding reported that they had committees, and one-quarter either had or were developing procedural documents (Curran).

On February 8, 1966, the surgeon general of the U.S. Public Health Service (USPHS) issued the first federal policy statement requiring research institutions to establish the committees that subsequently came to be known as RECs (Curran). This policy required recipients of USPHS grants in support of research involving human subjects to specify that

> the grantee institution will provide prior review of the judgment of the principal investigator or program director by a committee of his institutional associates. This review shall assure an independent determination: (1) Of the rights and welfare of the … individuals involved, (2) Of the appropriateness of the methods used to secure informed consent, and (3) Of the risks and potential medical benefits of the investigation.

The evolution of the federal government's charges to the committee and of its recognition of the need for diversity of committee membership was reflected in several revisions of its policy between 1966 and 1969 (Veatch; Levine, 1986); these will be further discussed below.

Purpose

The purpose of the REC is to ensure that research involving human subjects is designed to conform to relevant ethical standards. Historically, the REC's primary focus was on safeguarding the rights and welfare of individual research subjects, concentrating on the plans for informed consent and the assessment of risks and anticipated benefits. In 1978 the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter, National Commission) added a requirement that the REC ensure equitableness in the selection of research subjects (Levine, 1986). The National Commission was concerned primarily with protecting vulnerable subjects from bearing a disproportionately large share of the burdens of research. Subsequently, as participation in some types of research became perceived as a benefit, RECs also assumed responsibility for ensuring disadvantaged persons equitable access to such benefits (Levine, 1994).

A source of continuing controversy is whether the REC has an obligation to approve or disapprove the scientific design of research protocols (Levine, 1986). Those who argue that they do or should have such an obligation point out that the leading ethical codes establish a requirement for good scientific design. Moreover, these observers argue, the REC's obligation to determine that risks to subjects are reasonable in relation to anticipated benefits necessarily relies on a prior determination that the scientific design is adequate, for if it is not, there will be no benefits and any risk must be considered unreasonable.

Opponents to assigning such an obligation to the REC, while conceding these two points, argue that the REC is not designed to make expert judgments about the adequacy of scientific design. RECs are generally competent to appraise the value of the science—what the Nuremberg Code calls "the humanitarian importance of the problem to be solved"—but not the validity of the methods or the results (Freedman; Veatch). In general, responsibility for assessment of scientific validity is, and ought to be, delegated to committees designed to have such competence—such as scientific review committees either within the institution or at funding agencies such as the National Institutes of Health (Levine, 1986; IOM).

Membership

The surgeon general's 1966 memo called for prior review by "a committee of [the investigator's] associates," what was commonly called "peer review." As of 1968, 73 percent of committees were limited in membership to immediate peer groups: scientists and physicians (Curran).

On May 1, 1969, USPHS guidelines were revised to indicate that a committee constituted exclusively of biomedical scientists would be inadequate to perform the functions now expected of it: "The membership should possess … competencies necessary in the judgment as to the acceptability of the research in terms of institutional regulations, relevant law, standards of professional practice and community acceptance."

Regulations of the U.S. Department of Health and Human Services (DHHS), first promulgated in 1974 and since revised several times, maintain the spirit of the 1969 policy and in addition require gender diversity; at least one nonscientist (e.g., lawyer, ethicist, member of the clergy); and at least one member who is not affiliated with the institution (commonly and incorrectly called a "community representative"). Persons having conflicting interests are to be excluded; this concern is also reflected in the CIOMS *International Ethical Guidelines*' requirement for "review committees independent of the research team."

According to Robert M. Veatch (1975), the REC is an intermediate case between two models of the review committee: The "interdisciplinary professional review model," made up of diverse professionals such as doctors, lawyers, scientists, and clergy, brings professional expertise to the review process, while the "jury model … reflects the common sense of the reasonable person." In the jury model "expertise relevant to the case at hand is not only not necessary, it often disqualifies one from serving on the jury" (Veatch, p. 31). Veatch conceded that in order to perform all of its functions, the REC requires both professional and jury skills. He argued, however, that the presence of professionals makes it more difficult for the REC to be responsive to the informational needs of the reasonable person or to be adept at anticipating community acceptance.

John A. Robertson (1979) recommended correcting the "structural bias" of professional domination by introducing a "subject surrogate," an expert advocate for the subjects' interests. DHHS regulations require that if an REC "regularly reviews research that involves a vulnerable category of subjects … consideration shall be given to the inclusion of … [persons who know] about and [are] experienced in working with these subjects" (IRB Membership). For research involving prisoners, the regulations require that at least one member of the REC be either a prisoner or a prisoner representative. There is unresolved controversy over whether persons with AIDS should be appointed to serve on all RECs that review research in the field of HIV infection (Levine, Dubler, and Levine).

In the United States the Institute of Medicine (IOM) endorsed the recommendation of the National Bioethics Advisory Commission (NBAC) that "at least 25 percent of [the IRB's] membership should be reserved for unaffiliated [with the institution] members and those who can provide nonscientific perspectives" (IOM, p. 96). The IOM further expressed its support for the current trends in the United States to enhance the education of REC members and to certify them as competent by independent agencies.

Locale

In the United States the first RECs were established in the institutions where research was conducted. The 1966 surgeon general's policy statement required a committee of "institutional associates." In 1971 the Food and Drug Administration (FDA) promulgated regulations that required committee review only when regulated research was conducted in institutions; hence their name, institutional review committee. Regulations proposed in 1973 by the Department of Health, Education, and Welfare, forerunner of DHHS, also reflected a local setting in their term "organizational review board." In 1974 the National Research Act established a statutory requirement for review by a committee to which it assigned the name "institutional review board," a compromise between the two names then extant.

RECs are required to comply with federal regulations when reviewing activities involving FDA-regulated "test articles," such as investigational drugs and devices, and when reviewing research supported by federal funds. Moreover, all institutions that receive federal research grants and contracts are required to file "statements of assurance" of compliance with federal regulations. In these assurances virtually all institutions voluntarily promise to apply the principles of federal regulations to all research they conduct, regardless of the source of funding (Levine, 1986; IOM).

These points notwithstanding, each REC has a decidedly local character. Most have local names, such as "human investigation committee" or "committee for the protection of human subjects." Each is appointed by its own institution, and each makes its own interpretation of the requirements of federal regulations. For example, at one university, medical students are forbidden to serve as research subjects, whereas at another, involvement of medical students as research subjects is sometimes required as a condition of approval (Levine, 1986).

In its 1978 report, the National Commission recommended that RECs should be "located in institutions where research … is conducted. Compared to the possible alternatives of a regional or national review … local committees have the advantage of greater familiarity with the actual conditions" (U.S. National Commission, pp. 1–2). The

National Commission envisioned the local REC as an ally of the investigator in safeguarding the rights and welfare of research subjects, as well as a contributor to the education of both the research community and the public.

The FDA's change in regulations in 1981 to require REC review of all regulated research, regardless of where it was done, created a problem for the many physicians who were conducting investigations in their private offices; many of these physicians had no ready access to RECs. In response, private corporations developed noninstitutional review boards (NRBs) (Herman). Although there are reasons to question the validity of reviews by NRBs, they appear to be performing satisfactorily (Levine and Lasagna).

In 1986 the FDA began to waive the requirement for local REC review of some protocols designed to evaluate, or to make available for therapeutic purposes, investigational new drugs, particularly those intended for the treatment of HIV infection. In such cases RECs were offered the option of accepting review by a national committee as fulfilling the regulatory requirement for REC review. Such practices have caused some commentators to question the strength of the government's commitment to the principle of local review (Levine and Lasagna).

Internationally, there is much less commitment to the importance of local review. The CIOMS *International Ethical Guidelines* require REC approval for all research involving human subjects and recognize the validity of review at "the institutional, local, regional or national, and in some cases, at the international level." In many European countries, RECs are regional (McNeill).

Several commentators have expressed concern that in the United States the local institution has too much power in protection of human research subjects. Robertson, for example, warned about "the danger … that research institutions will use [RECs] to protect themselves and researchers rather than subjects" (1979); others point to the close associations between RECs and risk-management offices in many institutions as evidence that RECs are being used in this manner.

Criticisms

Before 1962, "a general skepticism toward the development of ethical guidelines, codes, or sets of procedures concerning the conduct of research" prevailed in the medical research community (Curran, p. 408). In the 1970s several biomedical scientists were harshly critical of the REC system, claiming that it tended to stifle creativity and impede progress (Levine, 1986); survey research, however, showed that only 25 percent of biomedical researchers agreed with the statement that "The review … is an unwarranted intrusion on the investigator's autonomy—at least to some extent" (U.S. National Commission, p. 75). Behavioral and social scientists were considerably less accepting of review, claiming that their research activities were much less likely than those of the biomedical scientist to harm subjects. Some argued that because all they did was talk with subjects, review was an unconstitutional constraint on their freedom of speech (Levine, 1986). With the passage of time, most social and behavioral scientists have recognized the value of the REC's review of work in their fields; they have protested, however, that much of the review of social and behavioral research is unsatisfactory because RECs, in general, tend to inappropriately apply rules and procedures that were designed for the "biomedical model" (IOM).

According to Peter C. Williams (1984), RECs do an inadequate job of ensuring that risks will be reasonable in relation to anticipated benefits. This is inevitable for three reasons:

1. Federal regulations on this standard are written in vague language, in contrast to the clearer direction provided for protecting subjects' rights. Moreover, because the regulations permit consideration of the long-range effects of applying knowledge as benefits but not as risks, they create a bias in favor of approval.
2. The membership of the committee, dominated as it is by professionals, is likely to place a higher value than laypersons would on the benefit of developing new knowledge.
3. Groups confronted with choices involving risks may be either more or less cautious or "risk aversive" than the average of individuals within the group; this is known as the *risky shift* or *group polarization phenomenon.* Williams (1984) and Veatch (1975) have argued that in the context of RECs, the groups are likely to be more tolerant of higher levels of risk than would be the individuals who comprise the groups.

Several commentators have proposed that RECs could enhance their effectiveness by sending members to the sites of the actual conduct of research to verify compliance with protocol requirements (Robertson, 1979) or to supervise consent negotiations (Robertson, 1982). Others respond that while such activities should be done when there are reasons to suspect problems in specific protocols, routine monitoring activities might be detrimental to the successful functioning of the committee by eroding its support within the institution (Levine, 1986). The Institute of Medicine concurs with the NBAC's proposal that the REC should engage in routine monitoring of the actual conduct of

research, concentrating its efforts on research projects that present to subjects relatively high levels of risks (IOM).

Evaluation

Critics of the REC system claim that there is little or no objective evidence that REC review prevents the conduct of inadequate research. For example, a national survey of RECs revealed that the rate of rejection of protocols is less than 1 in 1,000 (National Commission). Supporters of the system respond that the actual rejection rate is much higher if one includes protocols withdrawn because investigators refuse to modify them as required by RECs. Moreover, rejection rates may be a poor indicator of the REC's quality; protocols may be improved in anticipation of the REC's requirements, and investigators, fearing rejection, may decide not to submit proposals they think might be rejected.

It is very difficult to evaluate the REC's performance objectively; satisfactory subjective evaluations can be made only by experienced REC members and administrators (Levine, 1986). In his excellent theoretical analysis of RECs, published in 1981, Jerry L. Mashaw concluded:

> If [the REC] is to do its core job well, we must live with its inevitable incompetence at other tasks. Moreover, we must also live with the rather vague regulatory standards and with the continuing inability of the federal funding agencies to know for sure whether [RECs] are functioning effectively. If we would have wise judges and paternalistic [skilled in protecting subjects' rights and welfare interests] professionals, we can neither specifically direct nor objectively evaluate their behavior. (Mashaw, p. 22)

RESEARCH, HUMAN: HISTORICAL ASPECTS

• • •

In Western civilization, the idea of human experimentation, of evaluating the efficacy of a new drug or procedure by outcomes, is an ancient one. It is discussed in the writings of Greek and Roman physicians and in Arab medical treatises. Scholars like Avicenna (980–1037) insisted that "the experimentation must be done with the human body, for testing a drug on a lion or a horse might not prove anything about its effect on man" (Bull, p. 221). But records of how often ancient physicians conducted experiments, with what agents, and on which subjects, are very thin. The most frequently cited cases involve testing the efficacy of poisons on condemned prisoners, but the extent to which other human research was carried on remains obscure.

Experimentation was frequent enough to inspire a discussion of the ethical maxims that should guide would-be investigators. Moses Maimonides (1135–1204), the noted Jewish physician and philosopher, instructed colleagues always to treat patients as ends in themselves, not as means for learning new truths. Roger Bacon (1214–1294) excused the inconsistencies in therapeutic practices on the following grounds:

> It is exceedingly difficult and dangerous to perform operations on the human body. The operative and practical sciences which do their work on insensate bodies can multiply their experiments till they get rid of deficiency and errors, but a physician cannot do this because of the nobility of the material in which he works; for that body demands that no error be made in operating upon it, and so experience [the experimental method] is so difficult in medicine. (quoted in Bull, p. 222)

Human Experimentation in Early Modern Western History

Human experimentation made its first significant impact on medical practice through the work of the English country physician Edward Jenner (1749–1823). Observing that dairy farmers who had contracted the pox from swine or cows seemed to be immune to the more virulent smallpox, Jenner set out to retrieve material from their pustules, inject the material into another person, and see whether the recipient could then resist challenges from smallpox materials. The procedure promised to be less dangerous than the more standard one of inoculating people with small amounts of smallpox that had been introduced into Europe and America from the Ottoman Empire in the first half of the eighteenth century.

In November 1789, Jenner inoculated his son, then about a year old, with swinepox. When this intervention proved ineffective against a challenge of smallpox, Jenner tried cowpox several months later with another subject. As he recalled: "The more accurately to observe the progress of the infection, I selected a healthy boy, about eight years old, for the purpose of inoculation for the cow-pox. The matter … was inserted … into the arm of the boy by means of two incisions" (Jenner, pp. 164–165). A week later Jenner injected him with smallpox, and noted that he evinced no reaction. The cowpox had rendered him immune to smallpox. One cannot know whether the boy was a willing or unwilling subject or how much he understood of the experiment. But this was not an interaction between strangers. The boy was from the neighborhood, Mr. Jenner was a gentleman of standing, and the experiment did have potential therapeutic benefit for the subject.

For most of the nineteenth century, human experimentation throughout western Europe and the United States was a cottage industry, with individual physicians trying out one or another remedy on neighbors or relatives or on themselves. One German physician, Johann Jorg (1779–1856), swallowed varying doses of seventeen different drugs in order to analyze their effects. Another, Sir James Young Simpson (1811–1870), an Edinburgh obstetrician who was searching for an anesthesia superior to ether, in November 1847 inhaled chloroform and awoke to find himself lying flat on the floor (Howard-Jones). Perhaps the

most extraordinary self-experiment was conducted by Werner Forssman. In 1929 he passed a catheter, guided by radiography, into the right ventricle of his heart, thereby demonstrating the feasibility and the safety of the procedure.

The most unusual nineteenth-century human experiment was conducted by the American physician William Beaumont (1785–1853) on Alexis St. Martin. A stomach wound suffered by St. Martin healed in such a way as to leave Beaumont access to the stomach and the opportunity to study the action of gastric juices. To carry on this research, which was very important to the new field of physiology, Beaumont had St. Martin sign an agreement, not so much a consent form as an apprenticeship contract. Under its terms, St. Martin bound himself to "serve, abide, and continue with the said William Beaumont … [as] his covenant servant," and in return for board, lodging, and $150 a year, he agreed "to assist and promote by all means in his power such philosophical or medical experiments as the said William shall direct or cause to be made on or in the stomach of him" (Beaumont, pp. xii–xiii).

The most brilliant human experiments of the nineteenth century were conducted by Louis Pasteur (1822–1895), who demonstrated an acute sensitivity to the ethics of his investigations. Even as he conducted his animal research to identify an antidote to rabies, he worried about the time when it would be necessary to test the product on a human being. "I have already several cases of dogs immunized after rabic bites," he wrote in 1884. "I take two dogs: I have them bitten by a mad dog. I vaccinate the one and I leave the other without treatment. The latter dies of rabies: the former withstands it." Nevertheless, Pasteur continued, "I have not yet dared to attempt anything on man, in spite of my confidence in the result.… I must wait first till I have got a whole crowd of successful results on animals.… But, however I should multiply my cases of protection of dogs, I think that my hand will shake when I have to go on to man" (Vallery-Radot, pp. 404–405).

The fateful moment came some nine months later when his help was sought by a mother whose nine-year-old son, Joseph Meister, had just been severely bitten by what was probably a mad dog. Pasteur agonized as to whether to carry out what would be the first human trial of his rabies inoculation. He consulted with two medical colleagues, had them examine the boy, and at their urging and on the grounds that "the death of the child appeared inevitable, I resolved, though not without great anxiety, to try the method which had proved consistently successful on the dogs." With great anxiety he administered twelve inoculations to the boy, and only weeks later did he become confident of the efficacy of his approach and the "future health of Joseph Meister" (Vallery-Radot, pp. 414–417).

Claude Bernard (1813–1878), professor of medicine at the College of France, not only conducted ground-breaking research in physiology, but also composed an astute treatise on the methods and ethics of experimentation. "Morals do not forbid making experiments on one's neighbor or one's self," Bernard argued in 1865. Rather, "the principle of medical and surgical morality consists in never performing on man an experiment which might be harmful to him to any extent, even though the result might be highly advantageous to science, i.e., to the health of others." To be sure, Bernard did allow some exceptions; he sanctioned experimentation on dying patients and on criminals about to be executed, on the grounds that "they involve no suffering of harm to the subject of the experiment." But he made clear that scientific progress did not justify violating the well-being of any individual (Bernard, p. 101).

Anglo-American common law recognized both the vital role of human experimentation and the need for physicians to obtain the patient's consent. As one English commentator explained in 1830: "By experiments we are not to be understood as speaking of the wild and dangerous practices of rash and ignorant practitioners … but of deliberate acts of men from considerable knowledge and undoubted talent, differing from those prescribed by the ordinary rules of practice, for which they have good reason … to believe will be attended with benefit to the patient, although the novelty of the undertaking does not leave the result altogether free of doubt." The researcher who had the subject's consent was "answerable neither in damages to the individual, nor on a criminal proceeding. But if the practitioner performs his experiment without giving such information to, and obtaining the consent of this patient, he is liable to compensate in damages any injury which may arise from his adopting a new method of treatment" (Howard-Jones, p. 1430). In short, the law distinguished carefully between quackery and innovation, and—provided the investigator had the subject's agreement—research was a legitimate and protected activity.

With the new understanding of germ theory in the 1890s and the growing professionalization of medical training in the next several decades, the amount of human experimentation increased and the intimate link between investigator and subject weakened. Typically, physicians administered a new drug to a group of hospitalized patients and compared their rates of recovery with past rates or with those of other patients who did not have the drug. (Truly random and blinded clinical trials, wherein a variety of patient characteristics were carefully matched and where researchers were kept purposely ignorant of which patient received the new drug, did not come into practice until the 1950s.) Thus, German physicians tested antidiphtheria serum on thirty hospitalized patients and reported that only

six died, compared to the previous year at the same hospital when twenty-one of thirty-two patients died (Bull). In Canada, Frederick G. Banting and Charles Best experimented with insulin therapy on diabetic patients who faced imminent death, and interpreted their recovery as clear proof of the treatment's efficacy (Bliss). So too, George R. Minot and William P. Murphy tested the value of liver preparations against pernicious anemia by administering them to forty-five patients in remission and found that they all remained healthy so long as they took the treatment; the normal relapse rate was one-third, and three patients who on their own accord stopped treatment relapsed (Bull). It is doubtful if many of these subjects were fully informed about the nature of the trial or formally consented to participate. They were, however, likely to be willing subjects since they were in acute distress or danger and the research had therapeutic potential.

As medicine became more scientific, some researchers did skirt the boundaries of ethical behavior in experimentation, making medical progress—rather than the subject's welfare—the goal of the research. Probably the most famous experiment in this zone of ambiguity was the yellow-fever work of Walter Reed (1851–1902). When he began his experiments, mosquitoes had been identified as crucial to transmission but their precise role was unclear. To understand more about the process, Reed began a series of human experiments in which, in time-honored tradition, the members of the research team were the first subjects (Bean). It soon became apparent that larger numbers of volunteers were needed and no sooner was the decision reached than a soldier happened by. "You still fooling with mosquitoes?" he asked one of the doctors. "Yes," the doctor replied. "Will you take a bite?" "Sure, I ain't scared of 'em," responded the man. And in this way, "the first indubitable case of yellow fever … to be produced experimentally" occurred (Bean, pp. 131, 147).

After one fellow investigator, Jesse William Lazear, died of yellow fever from purposeful bites, the other members, including Reed himself, decided "not to tempt fate by trying any more [infections] upon ourselves." Instead, Reed asked American servicemen to volunteer, and some did. He also recruited Spanish workers, drawing up a contract with them: "The undersigned understands perfectly well that in the case of the development of yellow fever in him, that he endangers his life to a certain extent but it being entirely impossible for him to avoid the infection during his stay on this island he prefers to take the chance of contracting it intentionally in the belief that he will receive … the greatest care and most skillful medical service." Volunteers received $100 in gold, and those who actually contracted yellow fever received a bonus of an additional $100, which, in the event of their death, went to their heirs (Bean, pp. 134, 147). Although twenty-five volunteers became ill, none died.

Reed's contract was a step along the way to more formal arrangements with human subjects, complete with enticements to undertake a hazardous assignment. But the contract was also misleading, distorting in subtle ways the risks and benefits of the research. Yellow fever was said to endanger life only "to a certain extent"; the likelihood that the disease might prove fatal was unmentioned. And on the other hand, the prospect of otherwise contracting yellow fever was presented as an absolute certainty, an exaggeration that aimed to promote recruitment.

Some human experiments in the pre-World War II period in the United States and elsewhere used incompetent and institutionalized populations for their studies. The Russian physician V. V. Smidovich (publishing in 1901 under the pseudonym Vikentii Veresaev) cited more than a dozen experiments, most of them conducted in Germany, in which unknowing patients were inoculated with microorganisms of syphilis and gonorrhea (Veresaev). George Sternberg, the Surgeon General of the United States in 1895 (and a collaborator of Walter Reed), conducted experiments "upon unvaccinated children in some of the orphan asylums in … Brooklyn" (Sternberg and Reed, pp. 57–69). Alfred Hess and colleagues deliberately withheld orange juice from infants at the Hebrew Infant Asylum of New York City until they developed symptoms of scurvy (Lederer). In 1937, when Joseph Stokes of the Department of Pediatrics at the University of Pennsylvania School of Medicine sought to analyze the effects of "intramuscular vaccination of human beings … with active virus of human influenza," he used as his study population the residents of two large state institutions for the retarded (Stokes et al., pp. 237–243). There are also many examples of investigators using prisoners as research subjects. In 1914, for example, Joseph Goldwater and G. H. Wheeler of the U.S. Public Health Service (PHS) conducted experiments to understand the causes of pellagra on convicts in Mississippi prisons.

One of the few instances of an individual investigator being taken to task for the ethics of his research involved Hideyo Noguchi (1876–1928) of the Rockefeller Institute for Medical Research. He was investigating whether a substance he called luetin, an extract from the causative agent of syphilis, could be used to diagnose syphilis; through the cooperation of fifteen New York physicians, he used 400 subjects, most of them inmates in mental hospitals and orphan asylums and patients in public hospitals. Before administering luetin to them, Noguchi and some of the physicians did first test the material on themselves, with no ill effects. But no one, including Noguchi, informed the

subjects about the experiment or obtained their permission to do the tests.

Noguchi's work was actively criticized by the most vocal opponents of human experimentation during those years, the antivivisectionists. They were convinced that a disregard for the welfare of animals would inevitably promote a disregard for the welfare of humans. As one of them phrased it: "Are the helpless people in our hospitals and asylums to be treated as so much material for scientific experimentation, irrespective of age or consent?" (Lederer, p. 336). Despite their opposition, such experiments as Noguchi's did not lead to prosecutions, corrective legislation, or formal professional codes. The profession and the wider public were not especially concerned with the issue, perhaps because the practice was still relatively uncommon and mostly affected disadvantaged populations.

Research at War

The transforming event in the conduct of human experimentation in the United States was World War II. Between 1941 and 1945, practically every aspect of American research with human subjects changed. What were once occasional and ad hoc efforts by individual practitioners now became well-coordinated, extensive, federally funded team ventures. At the same time, medical experiments that once had the aim of benefiting their subjects were now frequently superseded by experiments whose aim was to benefit others, specifically soldiers who were vulnerable to the disease. Further, researchers and subjects were far more likely to be strangers to each other, with no sense of shared purpose or objective. Finally, and perhaps most importantly, the common understanding that experimentation required the agreement of the subjects, however casual the request or general the approval, was superseded by a sense of urgency so strong that it paid scant attention to the issue of consent.

In the summer of 1941, President Franklin Roosevelt created the Office of Scientific Research and Development (OSRD) to oversee the work of two parallel committees, one devoted to weapons research, the other—the Committee on Medical Research (CMR)—to combat the health problems that threatened the combat efficiency of American soldiers. Thus began what one participant called "a novel experiment in American medicine, for planned and coordinated medical research had never been essayed on such a scale" (Keefer, p. 62). Over the course of World War II, the CMR recommended some 600 research proposals, many of them involving human subjects, to the OSRD for funding. The OSRD, in turn, contracted with investigators at some 135 universities, hospitals, research institutes, and industrial firms. The accomplishments of the CMR effort required two volumes to summarize (the title, *Advances in Military Medicine,* did not do justice to the scope of the investigations); and the list of publications that resulted from its grants took up seventy-five pages (Andrus). All told, the CMR expended some $25 million. In fact, the work of the CMR was so important that it supplied not only the organizational model but also the intellectual justification for creating, in the postwar period, the National Institutes of Health.

The CMR's major concerns were dysentery, influenza, malaria, wounds, venereal diseases, and physical hardships (including sleep deprivation and exposure to frigid temperatures). To create effective antidotes required skill, luck, and numerous trials with human subjects, and the CMR oversaw the effort with extraordinary diligence. Dysentery, for example, proliferated under the filth and deprivation endemic to battlefield conditions, and no effective inoculations or antidotes existed. With CMR support, investigators undertook laboratory research and then, requiring sites for testing their therapies, turned to custodial institutions where dysentery was often rampant (OSRD, 1944b). Among the most important subjects for the dysentery research were the residents of the Ohio Soldiers and Sailors Orphanage in Xenia, Ohio; the Dixon, Illinois, institution for the retarded; and the New Jersey State Colony for the Feeble-Minded. The residents were injected with experimental vaccines or potentially therapeutic agents, some of which produced a degree of protection against the bacteria but, as evidenced by fever and soreness, were too toxic for common use.

Probably the most pressing medical problem the CMR faced immediately after Pearl Harbor was malaria, "an enemy even more to be feared than the Japanese" (Andrus, vol. 1, p. xlix). Not only was the disease debilitating and deadly, but the Japanese controlled the supply of quinine, one of the few known effective antidotes. Since malaria was not readily found in the United States, researchers chose to infect residents of state mental hospitals and prisons. A sixty-bed clinical unit was established at the Manteno, Illinois, State Hospital; the subjects were psychotic, backward patients who were purposefully infected with malaria through blood transfusions and then given antimalarial therapies (OSRD, 1944a). With the cooperation of the commissioner of corrections of Illinois and the warden at Stateville Prison (better known as Joliet), one floor of the prison hospital was turned over to the University of Chicago to carry out malaria research and some 500 inmates volunteered to act as subjects. Whether these prisoners were truly capable of consenting to research was not addressed by the researchers, the CMR, or prison officials. Almost all the press commentary was congratulatory, praising the wonderful contributions the inmates were making to the war effort.

In similar fashion, the CMR supported teams that tested anti-influenza preparations on residents of state facilities for the retarded (Pennhurst, Pennsylvania) and the mentally ill (Michigan's Ypsilanti State Hospital). The investigators administered the vaccine to the residents and then, three or six months later, purposefully infected them with influenza (Henle). When a few of the preparations appeared to provide protection, the Office of the Surgeon General of the U.S. Army arranged for the vaccine to be tested by enrollees in the Army Specialized Training Program at eight universities and a ninth unit made up of students from five New York medical and dental colleges.

Because the first widespread use of human subjects in medical research for nontherapeutic purposes occurred under wartime conditions, attention to the consent of the subject appeared less relevant. At a time when the social value attached to consent gave way before the necessity of a military draft and obedience to commanders' orders, medical researchers did not hesitate to use the incompetent as subjects of human experimentation. One part of the war machine conscripted a soldier, another part conscripted a human subject, and the same principles held for both. In effect, wartime promoted teleological as opposed to deontological ethics; "the greatest good for the greatest number" was the most compelling precept to justify sending some men to be killed so that others might live. This same ethic seemed to justify using institutionalized retarded or mentally ill persons in human research.

Human Research and the War Against Disease

The two decades following the close of World War II witnessed an extraordinary expansion of human experimentation in medical research. Long after peace returned, many of the investigators continued to follow wartime rules, this time thinking in terms of the Cold War and the war against disease. The utilitarian justifications that had flourished under conditions of combat and conscription persisted, in disregard of principles of consent and voluntary participation.

The driving force in post-World War II research in the United States was the National Institutes of Health (NIH). Created in 1930 as an outgrowth of the research laboratory of the U.S. Public Health Service, the NIH assumed its extraordinary prominence as the successor agency to the Committee on Medical Research (Swain). In 1945, its appropriations totaled $700,000. By 1955, the figure had climbed to $36 million, and by 1970, $1.5 billion, a sum that allowed it to award some 11,000 grants, about one-third requiring experiments on humans. In expending these funds, the NIH administered an intramural research program at its own Clinical Center, along with an extramural program that funded outside investigators.

The Clinical Center assured its subjects that it put their well-being first. "The welfare of the patient takes precedence over every other consideration" (NIH, 1953a). In 1954, a Clinical Research Committee was established to develop principles and to deal with problems that might arise in research with normal, healthy volunteers. Still, the relationship between investigator and subject was casual to a fault, leaving it up to the investigator to decide what information, if any, was to be shared with the subject. Generally, the researchers did not divulge very much information, fearful that they would discourage patients from participating. No formal policies or procedures applied to researchers working in other institutions on studies supported by NIH funds.

The laxity of procedural protections pointed to the enormous intellectual and emotional investment in research and to the conviction that the laboratory would yield answers to the mysteries of disease. Indeed, this faith was so great that the NIH would not establish guidelines to govern the extramural research it supported. By 1965, the extramural program was the single most important source of research grants for universities and medical schools, by the NIH's own estimate, supporting between 1,500 and 2,000 research projects involving human research. Nevertheless, grant provisions included no stipulations about the ethical conduct of human experimentation and the universities did not fill the gap. In the early 1960s, only nine of fifty-two American departments of medicine had a formal procedure for approving research involving human subjects and only five more indicated that they favored this approach or planned to institute such procedures (Frankel).

One might have expected much greater attention to the ethics of human experimentation in the immediate postwar period in light of the shadow cast by the trial of the German doctors at Nuremberg. The atrocities that the Nazis committed—putting subjects to death by long immersion in subfreezing water, deprivation of oxygen to learn the limits of bodily endurance, or deliberate infection by lethal organisms in order to study the effects of drugs and vaccines—might have sparked a commitment in the United States to a more rigorous regulation of research. (Japanese physicians also conducted experiments on prisoners of war and captive populations, but their research was never subjected to the same judicial scrutiny.) So too, the American research efforts during the war might have raised questions of their own and stimulated closer oversight.

The Nuremberg Code of 1946 itself might have served as a model for American guidelines on research with human

subjects. Its provisions certainly were relevant to the medical research conducted in the United States. "The voluntary consent of the human subject is absolutely essential," the code declared. "This means that the person involved should have legal capacity to give consent." By this principle, the mentally disabled and children were not suitable subjects for research—a principle that American researchers did not respect. Moreover, according to the Nuremberg Code, the research subject "should be so situated as to be able to exercise free power of choice" (Germany [Territory Under …], p. 181), which rendered at least questionable the American practice of using prisoners as research subjects. The Nuremberg Code also stated that human subjects "should have sufficient knowledge and comprehension of the elements of the subject matter involved as to make an understanding and enlightened decision" (Germany [Territory Under …], p. 181), thus ruling out the American practice of using the mentally disabled as subjects.

Nevertheless, with a few exceptions, neither the Code nor these specific practices received sustained analysis before the early 1970s. Only a handful of articles in medical or popular journals addressed the relevance of Nuremberg for the ethics of human experimentation in the United States. Perhaps this silence reflected an eagerness to repress the memory of the atrocities. More likely, the events described at Nuremberg were not perceived by most Americans as relevant to their own practices. From their perspective, the Code had nothing to do with science and everything to do with Nazis. The guilty parties were seen less as doctors than as Hitler's henchmen (Proctor).

In the period 1945–1965, several American as well as world medical organizations did produce guidelines for human experimentation that expanded upon the Nuremberg Code. Most of these efforts, however, commanded little attention and had minimal impact on institutional practices whether in Europe or in the United States (Ladimer and Newman). The American Medical Association, for example, framed a research code that called for the voluntary consent of the human subject, but it said nothing about what information the researchers were obliged to share, whether it was ethical to conduct research on incompetent patients, or how the research process should be monitored (Requirements for Experiments on Human Beings). In general, investigators could do as they wished in the laboratory, limited only by what their consciences defined as proper conduct and by broad, generally unsanctioned statements of ethical principle.

The World Medical Association in 1964 issued the Helsinki Declaration, stating general principles for human experimentation, and has revised that document four times. The declaration is modeled on the Nuremberg Code, requiring qualified investigators and the consent of subjects. The 1975 revision recommended review of research by an independent committee (Annas and Grodin).

How researchers exercised discretion was the subject of a groundbreaking article by Henry Beecher, professor of anesthesia at Harvard Medical School, published in June 1966 in the *New England Journal of Medicine.* His analysis, "Ethics and Clinical Research," contained brief descriptions of twenty-two examples of investigators who risked "the health or the life of their subjects," without informing them of the dangers or obtaining their permission. In one case, investigators purposefully withheld penicillin from servicemen with streptococcal infections in order to study alternative means for preventing complications. The men were totally unaware that they were part of an experiment, let alone at risk of contracting rheumatic fever, which twenty-five of them did. Beecher's conclusion was that "unethical or questionably ethical procedures are not uncommon" among researchers. Although he did not provide footnotes for the examples or name the investigators, he did note that "the troubling practices" came from "leading medical schools, university hospitals, private hospitals, governmental military departments … government institutes (the National Institutes of Health), Veterans Administration Hospitals, and industry" (Beecher).

Two of the cases that Beecher cited were especially important in provoking public indignation over the conduct of human research. One case involved investigators who fed live hepatitis virus to the residents of Willowbrook, a New York State institution for the retarded, in order to study the etiology of the disease and attempt to create a protective vaccine against it. The other case involved physicians injecting live cancer cells into twenty-two elderly and senile hospitalized patients at the Brooklyn Jewish Chronic Disease hospital without telling them that the cells were cancerous, in order to study the body's immunological responses.

Another case that sparked fierce public and political reactions in the early 1970s was the Tuskegee research of the U.S. Public Health Service. Its investigators had been visiting Macon County, Alabama, since the mid-1930s to examine, but not to treat, a group of blacks who were suffering from secondary syphilis. Whatever rationalizations the PHS could muster for not treating blacks in the 1930s, when treatment was of questionable efficacy and very complicated to administer, it could hardly defend instructing draft boards not to conscript the subjects for fear that they might receive treatment in the army. Worse yet, it could not justify its unwillingness to give the subjects a trial of penicillin after 1945 (Jones).

During the 1950s and 1960s, not only individual investigators but government agencies conducted research that often ignored the consent of the subjects and placed some of them at risk. Many of these projects involved the testing of radiation on humans. Part of the motivation was to better understand human physiology; even more important, however, was the aim of bolstering the national defense by learning about the possible impact of radiation on fighting forces. Accordingly, inmates at the Oregon State Prison were subjects in experiments to examine the effects on sperm production of exposing their testicles to X-rays. Although the prisoners were told some of the risks, they were not informed that the radiation might cause cancer. So too, terminally ill patients at the Cincinnati General Hospital underwent whole-body radiation, in research supported by the U.S. Department of Defense, not so much to measure its effects against cancer but to learn about the dangers radiation posed to military personnel. During this period, the Central Intelligence Agency also conducted research on unknowing subjects with drugs and with psychiatric techniques in an effort to improve interrogation and brainwashing methods. It was not until the 1980s that parts of this record became public, and not until 1994 that the full dimensions of these research projects were known.

Regulating Human Experimentation

The cases cited by Beecher and publicized in the press over the period 1966 to 1973 produced critical changes in policy by the leadership of the NIH and the U.S. Food and Drug Administration (FDA). Both agencies were especially sensitive to congressional pressures and feared that criticisms of researchers' conduct could lead to severe budget cuts. They also recognized that the traditional bedrock of research ethics, the belief that investigators were like physicians and should therefore be trusted to protect the well-being of their subjects, did not hold. To the contrary, there was a conflict of interest between investigator and subject: One wanted knowledge, the other wanted cure or well-being.

Under the press of politics and this new recognition, the NIH and the FDA altered their procedures. The fact that authority was centralized in these two agencies, which were at once subordinate to Congress and superordinate to the research community, guaranteed their ability to impose new regulations. Indeed, this fact helps explain why the regulation of human experimentation came first and more extensively to the United States than to other developed countries (Rothman, 1991).

Accordingly, in February 1966, and then in revised form in July 1966, the NIH promulgated through its parent body, the PHS, guidelines covering all federally funded research involving human experimentation. The order of July 1, 1966, decentralized the regulatory apparatus, assigning "responsibility to the institution receiving the grant for obtaining and keeping documentary evidence of informed patient consent." It then mandated "review of the judgment of the investigator by a committee of institutional associates not directly associated with the project." Finally it defined, albeit very broadly, the standards that were to guide the committee: "This review must address itself to the rights and welfare of the individual, the methods used to obtain informed consent, and the risks and potential benefits of the investigation" (Commission on Health Science and Society, pp. 211–212). In this way and for the first time, decisions traditionally left to the conscience of individual physicians came under collective surveillance.

The new set of rules was not as intrusive as some investigators feared, or as protective as some advocates preferred. At its core was the superintendence of the peer review committee, known as the Institutional Review Board (IRB), through which fellow researchers approved the investigator's procedures. With the creation of the IRB, the clinical investigator could no longer decide unilaterally whether the planned intervention was ethical, but had to answer formally to colleagues operating under federal guidelines. The events in and around 1966 accomplished what the Nuremberg trials had not: They moved medical experimentation into the public domain and revealed the consequences of leaving decisions about clinical research exclusively to the individual investigator.

The NIH response focused attention more on the review process than on the process of securing informed consent. Although it recognized the importance of the principle of consent, it remained skeptical about the ultimate feasibility of the procedure. Truly informed consent by the subject seemed impossible to achieve ostensibly because laypeople would not be able to understand the risks and benefits inherent in a complex research protocol. In effect, the NIH leadership was unwilling to abandon altogether the notion that doctors should protect patients and to substitute instead a thoroughgoing commitment to the idea that patients could and should protect themselves. Its goal was to ensure that harm was not done to the subjects, not that subjects were given every opportunity and incentive to express their own wishes (Frankel).

The FDA was also forced to grapple with the problems raised by human experimentation in clinical research. With a self-definition that included a commitment not only to sound scientific research (like the NIH) but to consumer protection as well, the FDA did attempt to expand the prerogatives of the consumer—in this context, the human

subject. Rather than emulate the NIH precedent and invigorate peer review, it looked to give new meaning and import to the process of consent.

In the wake of the reactions set off by Beecher's article, the FDA, on August 30, 1966, issued a "Statement on Policy Concerning Consent for the Use of Investigational New Drugs on Humans." Distinguishing between therapeutic and nontherapeutic research, in accord with various international codes like the Helsinki Declaration, it now prohibited all nontherapeutic research unless the subjects gave consent. When the research involved "patients under treatment," and had therapeutic potential, consent was to be obtained except in what the FDA labeled the "exceptional cases," where consent was not feasible or not in the patient's best interest. "Not feasible" meant that the doctor could not communicate with the patient (its example was when the patient was in a coma); and "not in the best interest" meant that consent would "seriously affect the patient's disease status" (its example here was the physician who did not want to divulge a diagnosis of cancer) (Curran, pp. 558–569).

In addition, the FDA, unlike the NIH, spelled out the meaning of consent. To give consent, the person had to have the ability to exercise choice and to have a "fair explanation" of the procedure, including an understanding of the experiment's purpose and duration, "all inconveniences and hazards reasonably to be expected," what a controlled trial was (and the possibility of the use of placebos), and any existing alternative forms of therapy available (Curran, pp. 558–569).

The FDA regulations represented a new stage in the balance of authority between researcher and subject. The blanket insistence on consent for all nontherapeutic research would have prohibited many of the World War II experiments and eliminated most of the cases on Beecher's roll. The FDA's definitions of consent went well beyond the vague NIH stipulations, imparting real significance to the process. To be sure, ambiguities remained. The FDA still confused research and treatment, and its clauses governing therapeutic investigations afforded substantial discretion to the doctor-researcher. But authority tilted away from the individual investigator and leaned, instead, toward colleagues and the human subjects themselves.

The publicity given to the abuses in human experimentation, and the idea that a fundamental conflict of interest characterized the relationship between the researcher and the subject, had an extraordinary impact on those outside of medicine, drawing philosophers, lawyers, and social scientists into a deeper concern about ethical issues in medicine. Human experimentation, for example, sparked the interest in medicine of Princeton University's professor of Christian ethics, Paul Ramsey. Ethical problems in medicine "are by no means technical problems on which only the expert (in this case, the physician) can have an opinion," Ramsey declared, and his first case in point was human experimentation. He worried that the thirst for more information was so great that it could lead investigators to violate the sanctity of the person. To counter the threat, Ramsey had two general strategies. The first was to make medical ethics the subject of public discussion. We can no longer "go on assuming that what can be done has to be done or should be.… These questions are now completely in the public forum, no longer the province of scientific experts alone" (Ramsey, p. 1). Second, and more specifically, Ramsey embraced the idea of consent; consent, in his formulation, was to human experimentation what a system of checks and balances was to executive authority, that is, the necessary limitation on the exercise of power. "Man's capacity to become joint adventurers in a common cause makes the consensual relationship possible; man's propensity to overreach his joint adventurer even in a good cause makes consent necessary.… No man is good enough to experiment upon another without his consent" (Ramsey, pp. 5–7).

Commissioning Ethics

The U.S. Congress soon joined the growing ranks of those concerned with human experimentation and medical ethics. In 1973, it created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, whose charge was to recommend to federal agencies regulations to protect the rights and welfare of subjects of research. The idea for such a commission was first fueled by an awareness of the awesome power of new medical technologies, but it gained congressional passage in the wake of newly uncovered abuses in human experimentation, most notably the Tuskegee syphilis studies.

The U.S. National Commission for the Protection of Human Subjects was composed of eleven members drawn from "the general public and from individuals in the fields of medicine, law, ethics, theology, biological science, physical science, social science, philosophy, humanities, health administration, government, and public affairs." The length of the roster and the stipulation that no more than five of the members could be researchers indicated how determined Congress was to have human experimentation brought under the scrutiny of outsiders. Senator Edward Kennedy, who chaired the hearings that led to the creation of the commission, repeatedly emphasized this point: Policy had to emanate "not just from the medical profession, but from ethicists, the theologians, philosophers, and many other disciplines." A prominent social scientist, Bernard Barber, predicted, altogether accurately, that the commission "would

transform a fundamental moral problem from a condition of relative professional neglect and occasional journalistic scandal to a condition of continuing public and professional visibility and legitimacy.… For the proper regulation of the powerful professions of modern society, we need a combination of insiders and outsiders, of professionals and citizens" (Commission on Health Science and Society, part IV, pp. 1264–1265).

Although the National Commission was temporary rather than permanent, and advisory (to the Secretary of Health, Education, and Welfare), without any enforcement powers of its own, most of its recommendations became regulatory law, tightening still further the governance of human experimentation. It endorsed the supervisory role of the IRBs and successfully recommended special protection for research on such vulnerable populations as prisoners, mentally disabled persons, and children. It recommended that an Ethical Advisory Board be established within the Department of Health and Human Services to deal with difficult cases as they arose. This board was inaugurated in 1977 but expired in 1980, leaving a gap in the commission's plan for oversight of research ethics. However, the Office for Protection from Research Risks at NIH exercised vigilance over institutional compliance with research regulations. Finally, the commission issued the Belmont Report, a statement of the ethical principles that should govern research, namely, respect for autonomy, beneficence, and justice. This document not only had an influence on research ethics but on the emerging discipline of bioethics (U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research).

Conclusion

In the United States, and to a growing degree in other developed countries, many of the earlier practices that had raised such troubling ethical considerations have been resolved. Oversight of research has been accomplished without stifling it, and without violating the prerogatives of research subjects. Almost everyone who has served on IRBs, or who has analyzed the transformation that their presence has secured on medical experimentation, will testify to their salutary impact. To be sure, the formal composition and decentralized character of these bodies seem to invite a kind of back-scratching, mechanistic review of colleagues' protocols, without the kind of adversarial procedures that would reveal every risk in every procedure. Similarly, IRB review of consent forms and procedures rarely takes the concern from the committee room onto the hospital floor to inquire about the full extent of the understanding of subjects who consent to participate. Nevertheless, IRBs do require investigators to be accountable for the character and severity of risks they are prepared to let others run, knowing that their institutional reputation may be harmed if they minimize or distort it. This responsibility unquestionably has changed investigators' behavior, and social expectations of them. To be sure, abuses may still occur. IRBs must be ready to minimize the amount of risk involved in certain protocols so as to enable researcher-colleagues to pursue their investigations. But they happen considerably less often now that IRB regulation is a fact of life. Scientific progress and ethical behavior turn out to be compatible goals.

RESEARCH METHODOLOGY

• • •

I. CONCEPTUAL ISSUES

Research in medicine, in the biomedical sciences, and in science in general is defined as "studious inquiry or examination; *esp*: investigation or experimentation aimed at the discovery and interpretation of facts, revision of accepted theories or laws in the light of new facts, or practical application of such new or revised theories or laws" (Merriam-Webster, p. 992). The U.S. federal government's Common Rule for human-subject investigation (CR) echoes Webster's definition; according to the CR, "*Research* means a systematic investigation, including research development, testing, and evaluation, designed to contribute to generalizable knowledge" (Code of Federal Regulations, sec. 102). Research can refer to investigations that involve intentional manipulation of the objects studied, frequently termed *experimental* studies, as well as those inquiries that collect data generated by naturally occurring events, or *observational* studies. This entry focuses on the burdens and benefits scientific research has on human subjects (or perhaps better, on trial participants) and on society, as well as on laboratory animals. Research methodology comprises those general principles and designs used to describe valid and effective inquiries into nature, which includes humans. Research methodology has philosophical, scientific, and social dimensions.

General Aspects of Research Methodology

Beginning with Plato and Aristotle, philosophers have proposed a number of different though quite general approaches to scientific method. Philosophers René Descartes (1596–1650) and Francis Bacon (1561–1626) wrote on the subject in the seventeenth century, but the study of scientific method received its most systematic treatments in the work of the nineteenth-century philosophers and scientists William Whewell, Stanley Jevons (1835–1882, and John Stuart Mill (1806–1873), who forcefully re-presented the methods of agreement, difference, concomitant variation, and others that continue to influence contemporary philosophers; frequently these are referred to as Mill's Methods. Philosophers of science have continued to stimulate the imagination of practicing scientists. Since the early 1960s, Sir Karl Popper's *falsificationist* approach, T. S. Kuhn's account of revolutionary scientific changes as *paradigm shifts,* and the latter's criticisms of traditional rational and gradualist methodology have been cited in a number of scientific research articles.

Research methodology also involves more specific scientific components, including the analysis of different laboratory methodologies (e.g., molecular approaches and pure culture techniques); the utility of various *animal models* of diseases; and the characterization and assessment of the strengths of distinct study designs, ranging from the report of an individual case to the randomized controlled clinical trial (RCT). These scientific components may involve a considerable amount of sophisticated mathematical and statistical analysis. In this entry, both the philosophical and the scientific dimensions of research methodology will be pursued in the context of questions that they raise for bioethics.

A final major aspect of research methodology is the important *social* dimension of systematic empirical investigations. For the purposes of this entry, the term signifys the ethical, legal, political, and religious aspects of research methodology. More specifically, this rubric treats various moral implications of scientific investigation, including vulnerable or hitherto ignored subject populations (e.g., the disabled and women), from both descriptive and normative perspectives, as well as significant interactions among the philosophical, scientific, and social themes.

The Scope of Research

BIOMEDICAL AND BEHAVIORAL INVESTIGATIONS. Biomedical research (generally understood as also including behavioral research in the psychological and social sciences) covers a broad array of disciplines. The term *biomedical* is itself intended to bridge the gap between the more fundamental, *pure,* or *basic* sciences, such as physiology and biochemistry, and the more *applied* sciences, such as pathology and pharmacology. This interpretation, however, leaves the more *clinical* sciences, such as anesthesiology and medicine, less connected with the meaning of science than is appropriate. Better, perhaps, to follow a more expansive definition as found in *Merriam-Webster's Tenth Collegiate*

Dictionary, which gives as one definition of biomedical: "Of, relating to, or involving biological, medical, and physical science" (Merriam-Webster, p. 115). *Dorland's Medical Dictionary* (28th edition) offers as its preferred meaning "biological and medical" (Dorland, p. 199). In accordance with this expanded characterization of the term, virtually all of the natural, behavioral, and social sciences, as well as engineering, can be conceived of as biomedical sciences if the intent is to place them in the service of advancing generalizable knowledge in the domains of medicine and healthcare.

BASIC SCIENCE AND CLINICAL SCIENCE. A common division is found in the departmental organization in medical schools distinguishing between basic sciences, such as microbiology (but also including more applied sciences such as pharmacology), and the clinical sciences such as medicine and oncology, whose practitioners spend much of their time and effort working with patients. It must not be forgotten that studies employing systems ranging from in vitro (*test tube*) inquiries through research on bacterial viruses to animal-model investigations comprise the bulk of research in the biomedical sciences. Preliminary research on new drug therapies, as well as investigations into human immunodeficiency virus (HIV) pathophysiology, falls into this category. In addition, in recent years there has been heightened awareness of the ethical problems generated by the use of animals in biomedical research, and thus it is appropriate to comment briefly on this basic science dimension of research methodology.

In 1976 an important study investigated the type of research that led to the ten most important advances in the treatment of cardiovascular and pulmonary diseases (Comroe and Dripps). The investigators used a broad definition of *clinically oriented* research; studies involving animals, tissues, or cells (including cell fragments) were included in the definition if the author mentioned a possible clinical application even briefly. In spite of this expansive definition, some 41 percent of key articles involved in the development of these ten clinically relevant advances were not clinically oriented; that is, they reported on basic science research. This finding suggests that supporting only *targeted* or *mission-oriented* research is likely to have adverse effects on clinical research advances.

Another intensive investigation, conducted in 1985 by the National Research Council's Committee on Models for Biomedical Research, examined the nature of research methodology in the biomedical sciences and underscored the intimate and reciprocal relationship between research generally characterized as clinical and research generally characterized as basic. This report introduced the general notion of a *biomatrix,* which was defined as a "complex body, or matrix, of interrelated biological knowledge built from studies of many kinds of organisms, biological preparations, and biological processes at various levels" (National Research Council, p. 2). Within such a multidimensional matrix, biomedical research involves *many-many modeling* in which analogous features at various levels of aggregation (e.g., molecules, cells, and organs) are related to each other across various species. The committee suggested that an "investigator considers some problem of interest—a disease process, some normal physiological function, or any other aspect of biology or medicine. The problem is analyzed into its component parts, and for each part and at each level, the matrix of biological knowledge is searched for analogous phenomena.… Although it is possible to view the processes involved in interpreting data in the language of [simple] one-to-one modeling, the investigator is actually modelling back and forth onto the matrix of biological knowledge" (National Research Council, p. 67). The study conducted by Julius Comroe and Robert Dripps, as well as the council's report, thus indicate that clinically relevant advances emerge from research sources beyond those involving human subjects.

Before innovations can be tested on humans, ethical codes and governmental regulation require research involving chemical, cell-fragment, cell, tissue, and intact-animal-model systems. The Nuremberg Code (1947–1948), for example, recommends that human experimentation should be based on the results of animal experimentation. The Declaration of Helsinki (1964, most recently revised in 2000) requires that "medical research involving human subjects must conform to generally accepted scientific principles, be based on a thorough knowledge of the scientific literature, other relevant sources of information, and on adequate laboratory and, where appropriate, animal experimentation" (World Medical Association). These requirements are based on the belief that such inquiries will assist in identifying interventions that are both safer and more effective by the time they are finally applied to human subjects. In the biomedical sciences, including studies involving human subjects, biological diversity and the number of systems that strongly interact in living organisms create considerable complexity. Researchers must often pay special attention to ensuring the (near) identity of the organisms under investigation, except for those differences that are the focus of the scientist's inquiry.

Biomedical investigations involving virtually identical laboratory organisms can yield precise and often nonstatistical results that can then be utilized in more variable human populations. As is discussed in the section below on various study designs, human variability of both genetic and environmental sources will typically require the extensive use of

statistical methodologies to uncover generalizable knowledge that is clinically applicable. In more rigidly controllable laboratory experiments—for example, in the rapidly advancing area of molecular genetics—biomedical scientists can often employ the classical methods of experimental inquiry, referred to earlier as Mill's Methods. These methods can be thought of as attempting to discover the causal structure of the world, and in their application scientists endeavor to identify and compensate for possible confounding factors that, if ignored, can lead to mistaken inferences about causes and effects. Thus all natural scientists attempt to compensate for interfering and extraneous factors, frequently by setting up a control comparison or a control group. Such controls are a direct implementation of what Mill termed the *method of difference* and Claude Bernard (1813–1878), the notable nineteenth-century French scientist and methodologist, the *method of comparative experimentation.*

The method of difference may be stated in a form similar to that in which Mill presented it. Suppose that in Case 1 some phenomenon occurs, and in Case 2, that is identical with Case 1 *except for one factor,* the phenomenon does *not* occur. Then the single difference between the two cases is the effect of that phenomenon, or the cause of that phenomenon, or an indispensable part of the cause of that phenomenon. (See Mill, p. 256, for his original language).

Claude Bernard judged that this focus on only one difference was far too stringent and reformulated the experimental idea as his method of comparative experimentation:

> Physiological phenomena are so complex that we could never experiment at all rigorously on living animals if we necessarily had to define all the other changes we might cause in the organism on which we were operating. But fortunately it is enough for us completely to isolate the one phenomenon on which our studies are brought to bear, separating it by means of comparative experimentation from all surrounding complications. Comparative experimentation reaches this goal by adding to a similar organism, used for comparison, all our experimental changes save one, the very one which we intend to disengage. (p. 127–128)

Bernard referred to comparative experimentation as "the true foundation of experimental medicine."

General Ethical Issues Associated with Research on Human Subjects

The principal ethical controversies in biomedical (including behavioral and social) research have emerged from studies involving human subjects. Before discussing the general ethical requirements of studies involving human subjects, however, it is important to describe briefly the often contentious debate about the terms used to distinguish between different kinds of standard medical practice and research, among them *therapeutic research, nontherapeutic research, innovative treatments,* and *experimentation.*

TERMINOLOGICAL CONSIDERATIONS. It is a fundamental tenet of medical ethics that the well-being of human subjects should be protected. This tenet, together with another general ethical principle frequently associated with the name of philosopher Immanuel Kant (1724–1804), to treat oneself or another human being always as an end and never merely or only as a means, requires that a human research subject be expected to obtain some direct benefit from the investigation, or, if not, to waive such benefit on the basis of a free and informed consent. (This Kantian injunction is sometimes characterized as a principle of *respect for persons.*) The need to clarify the therapeutic/nontherapeutic distinction in the light of such principles should be evident.

Thoughtful scholars have generally agreed about the difficulty of drawing a clear distinction between research and accepted practice, but have differed about the usefulness of various terms proposed to assist with this task. Some find the distinction between therapeutic and nontherapeutic experimentation *crucial,* whereas others find it is better phrased as one between beneficial and nonbeneficial experimentation. Tom Beauchamp and James Childress urge caution with the use of the closely related term therapeutic research since "attaching the favorable term *therapeutic* to research can be dangerous, because it suggests *justified intervention* in the care of particular patients and may create a misconception" (p. 320). Robert Levine, an authority on research involving human subjects, contends that the expressions therapeutic research, nontherapeutic research, and experimentation (in human subject contexts) are "unacceptable" and "illogical" (p. 8). The problem arises in part because it is fairly common that a diagnostic and therapeutic plan involve some variation from the textbook norm, and because it is in only rare cases that biomedical research conveys absolutely no benefit on its subjects.

Levine suggests that we employ the term *nonvalidated practices* as a more encompassing term for innovative therapies, acknowledging that it is the uncertainty associated with variation in the outcomes of diagnostic and therapeutic maneuvers that is the principal issue. This suggestion seems to have been accepted in much of the recent literature, though frequently the narrower term *nonvalidated therapy* is also employed. Though no definitive algorithm can be provided that will unambiguously differentiate the various inquiries and activities discussed in the preceding paragraph,

the general proposal that appears to emerge from the discussion involves three elements. First, the intent of the investigator is critical in determining whether the intervention (or the withholding of an intervention) is to be characterized as primarily beneficial to the subjects or as contributing to generalizable knowledge. A surgeon employing a novel suturing technique in an attempt to save a patient from bleeding to death does not evidence any intent of beginning a research project to evaluate a new operative technique. Second, the degree of variation from standard practice figures in this determination, and this may depend as well on the degree of possible harm that the intervention entails. Even small variations associated with significant harm are more likely to be seen as nonvalidated in contrast to small variations with minor adverse consequences. For example, a physician may believe that he or she must try a powerful immunosuppressive drug, usually used only in the case of potential organ-transplant rejection, to help a patient suffering with severe rheumatoid arthritis. The dangers associated with such drugs and the departure from their normal use argues that this would be a nonvalidated practice. Finally, there is the element of uncertainty, the degree of likelihood of a particular outcome or set of outcomes. These include both anticipated and unintended effects (side effects). Again, the example just cited of the immunosuppressive drug would be relevant here because of the difficulty of anticipating the effects of powerful drugs on systems as complex as the immune system.

For interventions from which the researcher intends to produce new general knowledge, that represent significant departures from accepted practice, and about which there is reasonable uncertainty regarding consequences, including intended outcomes, it would seem mandatory that the researchers develop a formal research protocol to be assessed by an appropriate institutional review board (IRB). Such a multidimensional *sliding scale,* possibly with thresholds that could be specified in particular areas of clinical investigation, may be the best possible mechanism for determining whether to require IRB review in this complex area.

ETHICAL REQUIREMENTS FOR RESEARCH ON HUMAN SUBJECTS. As noted in the preceding section, general principles requiring free and informed consent and a net balance of benefits over harms for the individual subject (unless this is waived by the subject in the interests of greater social benefits) will be assumed in all research contexts, and the present section will examine additional details regarding these requirements. Furthermore, however, in order both to safeguard research subjects and ensure that the resources used will generate valuable knowledge, a research study must conform to scientifically validated principles of design. To begin with, a prospective research project must be evaluated in terms of the risks of harm—physical, psychological, and social—to the subject(s), as well as in terms of the benefits that are likely to accrue to participants. Only studies in which the expected benefits outweigh the expected harms are morally permissible. Further, there must be no alternative and less risky means for the subject to obtain the anticipated benefits. Subjects must be selected equitably, with special sensitivity to the problems faced by vulnerable populations, such as children, prisoners, pregnant women, mentally disabled persons, or educationally disadvantaged persons. In recent years the practice of *community consultation* has developed, which involves meetings with representatives of the at-large subject community (e.g., HIV-infected individuals) to "assure a suitable balancing of the relevant values [such as respect for persons, individual beneficence and justice] in the design and conduct of a clinical trial" (Levine et al., p. 10).

An investigator must also obtain the legally effective informed consent of the subject or of the subject's legally authorized representative. Such consent must be voluntary and not obtained by coercive measures. The consent must be informed; this means that the investigator must specify the purposes of the research and how long the subject is expected to participate and provide a nontechnical description (in terms readily understandable to the subject) of any procedures to be followed, as well as a designation of procedures considered untested or experimental. The subject must also be provided with a description of any reasonable foreseeable risks or discomforts as well as reasonably anticipated benefits. Alternative procedures or courses of treatment that may be advantageous to the participant must be disclosed. Subjects are also to be provided with a statement about the extent of confidentiality of their records and, for research involving more than minimal risk, an explanation of what, if any, compensation or treatments will be available in the event of injury. According to the CR, subjects must be informed about whom to contact for answers about any questions or injuries that may arise in the course of or as a consequence of the research. They are to be told that their participation is voluntary and that they may refuse to participate or may withdraw from participation without any penalty or loss of benefits to which they would normally be entitled. Should the investigator come to believe in the course of the research that harm to the patient has become likely, the patient should be so informed and withdrawn from the project. The above requirements underscore the point that informed consent should not be conceived of only as a one-time event, but is best construed as an ongoing process involving clinical investigators and trial participants.

In certain types of behavioral and social-science research, investigators have maintained that scientifically valid conclusions can be obtained only if the subjects are kept uninformed or even deliberately deceived about the nature of the research. In a well-known example of this type of research, Stanley Milgram's studies on obedience to authority, subjects were falsely told they were causing pain to another human as part of a learning experiment. A majority of subjects proceeded to escalate the level of fictiously inflicted pain to *agonizing* levels on the instructions of the investigator. Subsequently, when the subjects were informed about this feature of themselves as part of the debriefing, they experienced severe, and in some cases, prolonged anxiety reactions (Milgram, 1963). Milgram defended his study against criticism and reported that most of the subjects had a positive view of their participation (Milgram, 1964).

The ethics of such studies continue to be controversial. Levine notes that he himself chairs an IRB that occasionally approves deceptive studies but generally disapproves of deception (Levine). Various guidelines regarding deceptive research methods have been published, such as those by the American Psychological Association, which can be viewed on their website. In response to many unethical research practices, ranging from Nazi atrocities before and during World War II to well-documented cases in the United States, the U.S. government has mandated a set of formal procedures to ensure compliance with ethical requisites. Institutions involved in research on human subjects are required to have their investigations reviewed and approved by IRBs whose composition, procedures, and record-keeping requirements are well-defined in law and governmental regulations. It should be noted, however, that the determination by a duly constituted IRB of the satisfaction of these ethical requirements does not in all cases resolve all ethical and practical stresses generated by research on human subjects. A number of authors have discerned a deeply rooted dilemma that the physician as healer and the physician as researcher confront in a search for generalizable knowledge employing human subjects. This dilemma has its source partly in the respect-for-persons principle cited above and partly in the ethical principle that the physician should do what is best for his or her patient. The dilemma is also most clearly evident in the context of the RCT but can also arise in less stringent research designs, which it will be necessary to discuss before turning to an account of this troublesome research predicament.

Study Designs

THE SPECTRUM OF STUDY DESIGNS IN BIOMEDICAL AND BEHAVIORAL RESEARCH. Diverse research designs guide research in the biomedical, behavioral, and clinical sciences. Since this topic can easily become quite technical and mathematically abstruse, this entry presents only a general introduction to this subject. (For specialized information including indications when, and why, one design is preferable to another, see works on clinical epidemiology and monographs devoted to specific research designs, e.g., Feinstein,; Fletcher et al.; Hulley, et al.; Lilienfeld and Lilienfeld; and Sackett et al.)

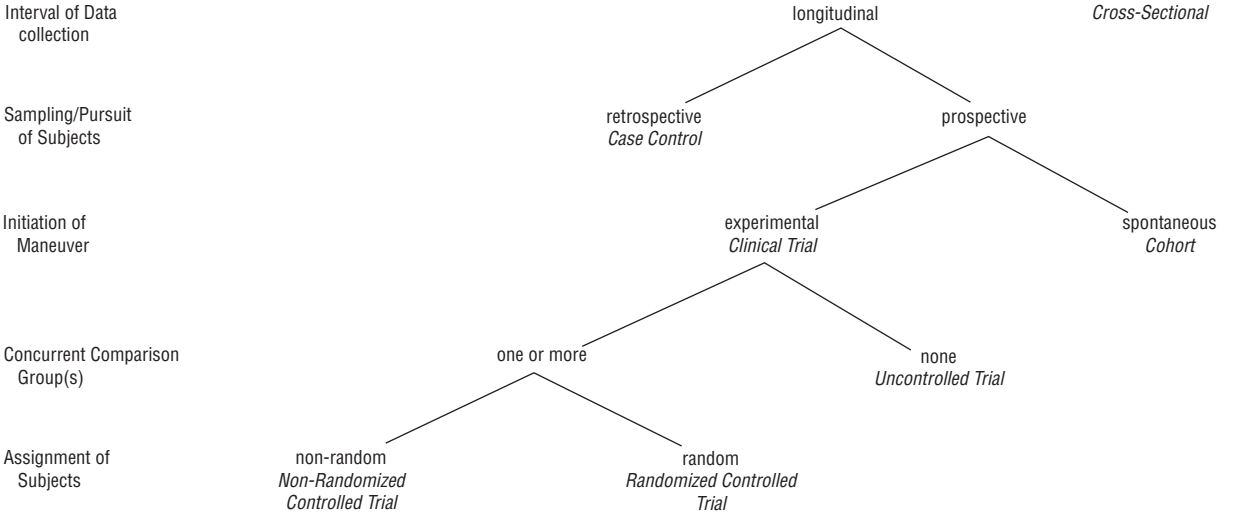
The chart depicted in Figure 1 can be used as a guide to the various research designs found in clinical research. (This figure is based in part on Lilienfeld and Lilienfeld, p. 192, and in part on Fletcher et al., p. 193.) To these designs should also be added the *case report* and the *case series,* in which a biomedically interesting individual's (or small group of similar individuals's) situation is described. Some writers characterize the case report or case series as another design; others view such a small series as conductible using any of the designs described in the chart below. (The use of small numbers of subjects in any trial design, however, raises concerns that errors of interpretation are likely because of chance events. Problems generated by chance events in biomedical research are analyzed using the tools of mathematical statistics.)

The *interval of data collection* refers to the period of time during which data are collected. If one or more populations are studied over a period of time, the study is described as a *longitudinal* one. Alternatively, we may wish to collect information within one time slice, yielding a *cross-sectional* study. Moving to the next line, the investigator may collect data by looking back in time—for example, inquiring (or reviewing chart records) to learn whether the population was exposed to a specific agent. At least one control group is assembled to provide a comparison, again retrospectively. This *case control* design is the type of approach that Arthur Herbst and his colleagues employed in his pioneering inquiry into the causes of vaginal cancer in daughters of mothers who had been given diethylstilbestrol (DES), a synthetic estrogen believed to help prevent miscarriages, during their pregnancies. The case-control type of study is generally thought to be open to a number of potential errors, termed *biases.* Potentially confounding elements therefore need to be monitored carefully.

If the putative active difference between the comparison groups, such as the administration of a new drug, is intentionally introduced by the investigators, a study is characterized as *experimental.* If the suspected active difference occurs by accident or is chosen by the subjects—for example, a subject's decision to begin cigarette smoking or to

FIGURE 1

The Epidemiological Study: Various Research Designs (in italics) Used to Establish Causation in Medicine



SOURCE: Based in part on Lilienfeld and Lilienfield, 1980, p. 192 and in part on Fletcher et al., 1982, p. 193.

reduce blood cholesterol by diet—the investigation is termed a *cohort* study. A longitudinal prospective experimental study is a clinical trial, but such trials may or may not involve a comparison control group. Good examples of uncontrolled types of clinical trials are Phase I and Phase II investigations of new drugs, though occasionally a Phase II investigation may involve randomized controls (see Byar et al.). Phase I studies look at the metabolism and toxicity of new drugs, often in normal subjects, and Phase II inquiries test for preliminary efficacy of a drug or a procedure. The terms Phase I and Phase II were introduced in 1977 by the U.S. Food and Drug Administration (FDA). (For details of the procedures by which toxicity and efficacy of interventions are evaluated, see Gilman et al., chapter 68.)

A Phase III investigation is almost always a RCT. Randomization refers to the process of assigning a patient to one rather than another treatment (or to the control group) by the flip of a coin or a more mathematically sophisticated but analogous procedure of using a table of random numbers. The RCT refers to that form of investigation that involves (1) one or more treatment groups and a control group that will typically receive a placebo (an inert substance) or the standard therapy (i.e., the traditionally accepted therapy); (2) randomized assignment of patients to the two or more groups (possibly after stratification or subgrouping based on known factors that will make a difference) sometimes referred to as *arms* of the trial; and (3) often a single- or double-blind design in which the assignments of the agents or procedures being tested are not known to the patients (single-blind) or possibly also to the treating health professionals (double-blind). (In place of the word *blind,* some accounts use the word *masked.*) In one unusual exception to that rule, the trial of the anti-HIV drug didanosine, or ddI, the whole experimental cohort were given ddI; these subjects were compared with *historical,* or retrospectively identified, control subjects (Waldholz; FDA).

Considerable debate has occurred about the methodological value and the ethical significance of randomization in controlled clinical trials. Various types of studies described above differ in their *strength,* that is, their ability to detect what is actually causing the changes that are being observed. The case series is traditionally the weakest of the research designs; other designs, in order of increasing strength, are the case-controlled study, the cohort study, and the RCT. The principal reason for the increase in design strength is the decrease in the likelihood of bias, or lack of comparability of the matched populations, as one moves from case series through to the RCT.

There are many types of bias, and some of them are quite subtle (Sackett). A major source of bias is selection or susceptibility bias, in which the groups compared have distinctly different outcome probabilities (more specifically, different prognostic likelihoods for the study's endpoint). This type of bias can occur within the study, or it can arise as part of the selection process and affect the generalizability of a study's results. In this type of situation, unrepresentative individuals are selected, and subgroups drawn from the unrepresentative class are then assigned to the arms of the study. An example of this type of bias would occur if only the sickest patients in a study were given the new drug and the better-off patients were assigned standard therapy (or a placebo). Another source of noncomparability is performance bias, in which the interventions in the trial are not reasonably equal. An example would be if the patients receiving the new drug were monitored much more closely and treated for concurrent health problems with no such monitoring and treatment being provided to the control group. A third type of bias is *confounding* bias, in which another, unsuspected causal variable *travels along* with the putative causal variable and actually accounts for the outcome. This could occur in a study to determine the effects of alcohol consumption on lung function, if alcohol drinkers were also much more likely to be smokers and the effect of smoking was not considered by the investigators. Other significant types of bias are detection or measurement bias, where the outcome event is detected differently in the comparison groups—for example, if the test group received MRIs and the control group standard X rays—and transfer bias, in which subject dropouts or reassignments may yield differences in outcome. The arguments for randomization in clinical investigations typically cite the ability of randomized assignment to decrease the likelihood of bias because, many maintain, randomizing will average together, and thus cancel out, factors that are not suspected by the investigators to affect the outcome.

RCTs can generate potential conflicts of interest between the roles of the physician as healer and physician as investigator, including questions about the suitability of placebo controls and its possible resolution using the concept of *clinical equipoise.*

META-ANALYSIS. Human variability, based on both genetics and environment, requires the extensive use of statistical methodologies to uncover generalizable, clinically applicable knowledge. This is in contrast to laboratory investigations in which virtually identical organisms yield cleaner and often *deterministic* results. Besides the variability of the subjects studied, many sources of bias such as the ones described can also lead to incorrect research conclusions.

Under these circumstances, researchers have turned increasingly to a method of clinical trial pooling and interpretation that seems to provide a better means of inferring correct conclusions from repeated clinical investigations. This methodology, known as meta-analysis, uses a set of formal statistical techniques to aggregate a group of separate but similar studies. In contrast to the widely employed scientific practice of summing up such studies qualitatively in a review article, meta-analysis purports to fulfill this summarizing function quantitatively and thus more precisely and objectively. Meta-analysis has been practiced for many years in a variety of scientific disciplines, from physics to the biomedical and the behavioral sciences, but only since the early 1980s has it had a major impact in the clinical arena, particularly in the areas of cardiovascular disease and obstetrics and gynecology (Chalmers et al., 1989; Mann).

Simple introductions as well as accessible authoritative accounts of the methodology are available. (See Mann, for an introduction, and Friedman et al, pp. 310–316, for a more comprehensive overview.) The technique remains controversial even as its use in biomedicine escalates exponentially.

EVIDENCE-BASED MEDICINE. Many of the issues reviewed above coalesce in what is termed *evidence-based medicine* (EBM), which is both a critical methodological approach as well as a kind of social movement. EBM had its origins in the 1980s discipline of clinical epidemiology, and developed rapidly in Canada, the United Kingdom, and then the United States and other countries in the 1990s. Initially EBM saw itself as representing a kind of Kuhnian paradigm shift, urging the replacement of the received view of medical evidence—seen as a combination of clinical expertise and basic science—with evidence based mainly on rigorously evaluated empirical clinical trials. (Haynes). More recently, EBM advocates have taken a more nuanced position on this replacement view though the distinction is still evident in EBMs databases (Haynes). EBM provides evaluations and clinician guidance through its literature, various websites, and electronically available systematic reviews including the Cochrane collaboration. EBM provides grades of recommendation from A (excellent) to D (poor) based on studies's empirical strengths following a detailed assessment protocol based on five *levels* of study types, several of which have sublevels. The levels range from the best (a systematic review with homogenous RCTs as the main element) to the worst (expert opinion without explicit critical appraisal, or essentially based on physiology, whether bench research or general principles). The specifics of these grades, the levels on which they are based, and the definitions of the concepts

involved (such as *homogeneity*) can be obtained at <http://minerva.minervation.com/cebm/>. EBM has not gone uncriticized, both from without and within the movement. One of its founders, Brian Haynes, laments the fact that EBM itself has not, and probably ethically cannot, be subject to its own highest standards of evaluation: a series of homogeneous RCTs in which EBM is utilized as an intervention but is not employed in the control groups of patients (Haynes).

Conclusion

This entry has reviewed a number of conceptual issues associated with current research methodology in the biomedical sciences. It contains a review of research in the basic sciences, such as biochemistry and microbiology, but has concentrated on the clinical sciences, such as medicine, oncology, and virology, since it is in the latter that ethical issues affecting human subjects arise. Scientific research on humans takes place in the context of a complex web of ethical and legal requirements, and the interplay between methodological and ethical/legal components of research has been examined. Ethical and regulatory principles (primarily as affecting U.S. research) have been presented, and several conceptual issues regarding scientific inquiry have been outlined, including different types of research designs. This entry is limited to an introduction to these issues, which become very technical in their details; references to further reading have been provided.

Although scientific methodology has a venerable history, many current issues are of much more recent vintage. In point of fact, the RCT is essentially a post-World War II invention, and the discipline of meta-analysis is a creature of the late 1980s and 1990s. New issues will continue to arise as better methodologies and improved safeguards for human subjects are sought, and the reader is urged to consult on-line bibliographic services, such as the bioethics database at the U.S. National Library of Medicine, in addition to references provided in this entry, to keep up to date with a continuously evolving subject.

II. CLINICAL TRIALS

In the last half of the twentieth century, clinical trial methodology fundamentally transformed the nature of biomedical research. During this period, investigators developed ways to avoid certain biases in research design and to adapt methods of statistical analysis to empirical research. The story of biomedical research's progressive sophistication, however, does not begin in clinics or hospitals, but in a cornfield. Ronald A. Fisher (1890–1962), the famous British statistician, biologist, and geneticist, devised methods for testing hypotheses on how to improve crops (Gigerenzer et al.). By dividing fields into two or more groups, making them as similar as possible in composition and treatment, Fisher hoped to isolate the effects of one feature on the individuals studied. For example, would a fertilizer given to some of the corn improve yield? The resulting differences between groups could then be expressed as probabilities about whether outcomes were due to chance or their different treatment. By studying more individuals for longer periods, confidence levels increase that variations between group outcomes were due to their different treatment.

In the late 1940s, Fisher and others began to adapt and refine these pioneering principles for use with human research, and in 1948 clinical trial methodology was systematically launched into medicine with the testing of streptomycin to treat tuberculosis (Concato, Shah, and Horwitz). Since that time, investigators have used clinical trial methods to evaluate virtually everything affecting patients, including: therapies, diagnostic techniques, prevention of illnesses, vaccines, counseling, health delivery systems, and even the benefits of classical music, pets, and humor on health. In one study, for example, people were divided into large groups; some got a daily aspirin and others a placebo (an inert substance). This helped ensure that groups were treated alike even down to the number of pills that they were given. The group receiving aspirin suffered fewer heart attacks (Steering Committee). Like methods developed in agricultural research, the goal of clinical trial methodology is to compose and treat groups as similarly as possible except for the one feature under study. Investigators attempt to identify other features that are likely to affect outcomes and stratify or distribute individuals with those features equally between groups. For example, the healthiest individuals (whether people, pigs, or parsnips) should be stratified equally among the groups because health often affects outcomes.

To help further ensure that groups are similar, investigators generally use another method, randomization

(nonhuman choice), such as, charts of random numbers, to assign individuals to groups. For example, suppose that investigators want to study the influence of caffeine upon alertness. They know other things affect alertness, such as people's interest in the subject or their intelligence, and the investigators try to stratify people with these variables equally between groups. But the investigators also know that many additional features affect alertness, such as people's sleeping, eating, or television-watching habits. Unable to identify all such variables or distribute people with similar features equally between groups, the investigators try to minimize the impact of these "nuisance" variables and achieve uniform groups through randomization. Even simple random methods, such as flipping a coin to determine group assignments, help ensure that people with distinctive features that could affect results do not cluster in one group. The larger the groups, the more likely that randomization will produce similar groups. The goal of randomization is to combat bias in group assignments by distributing individual characteristics whose effects are unknown equally among the study arms to minimize their influence. In human studies, randomized clinical trials (RCTs) use random assignment to eliminate, through equal distribution, the effects of variables such as nutritional habits, beliefs, attitudes, behavior, ancestry, and education in correlating the variable under investigation with its observed effects. Nonrandomized trials generally seem second best because of the risk of bias in the formation of the groups.

Investigators use other methods in addition to randomization and stratification to make groups similar and to eliminate bias. In single-blind studies, subjects do not know their group assignment, thereby minimizing the effects of their beliefs and expectations about the different modes of treatment. For unbiased results, the subjects should be treated so similarly that they cannot know which treatment they receive. Investigators' subconscious beliefs, preferences, or attitudes may also affect how they take care of individuals or evaluate outcomes. Believing one medicine works best, for example, may affect their estimates of how individuals respond. To combat such biases, investigators may use double-blind designs in which the group assignments are kept from subjects, their clinicians and investigators until after the trial so that clinicians' or investigators' own views will not contaminate the study's results.

Impartial studies can expose bias, prejudice, the flaws of common wisdom, the errors of standard practice, and the harms or benefits of established treatments. For example, in the 1940s and early 1950s doctors believed that giving copious amounts of oxygen to premature infants prevented death and brain damage. By 1953 this common wisdom was being challenged by clinical trials, and by 1954 the link between the lavish use of oxygen and blindness from retrolental fibroplasia was clearly established (Silverman). Other studies uncovered previously unforeseen adverse drug reactions. For example, systematic testing of commonly used antibiotics showed that premature infants receiving sulfisoxazole (gantrisin) had a much higher incidence of death and retardation than other groups. Further investigation revealed that premature infants could not metabolize and detoxify bilirubin, thus causing kernicterus, or neurological damage to the brain (Behrman and Vaughan).

Clinical trials also account for many treatment advances. In three decades of continual evaluation of alternative therapies through clinical trials, childhood leukemia went from a uniformly fatal disease to an often-curable illness. RCTs also demonstrated that coronary artery bypass surgery was ineffective for many of the diseases for which it had been widely used.

In a controlled clinical trial (CCT), investigators compare the outcomes for patients getting one treatment with those who do not. This allows investigators to separate the treatment's effects from other influences. The U.S. Department of Health and Human Services (HHS) cites five kinds of control groups distinguished, in part, upon whether the comparison involves a historical control group (in which patients' outcomes are compared with records from past patients) or a concurrent control group (in which patients' outcomes are compared with patients currently being treated):

1. placebo concurrent control;
2. dose comparison, concurrent control;
3. no treatment concurrent control;
4. active treatment concurrent control; and
5. historical control.

Investigators often regard the double-blind RCT with a concurrent control group getting a placebo as the "gold standard" because it offers the greatest assurances that differences between groups have not been distorted by people's different diagnosis criteria, treatments, observations, measurements, or expectations (Ellenberg and Temple; Temple and Ellenberg).

Gaining General Acceptance: An Example Involving Breast Cancer

Enrolling patients in clinical trials involved fundamental shifts in how to think about patient–doctor relationships. Consequently, it was one thing to work out a good methodology and another to find clinicians and patients willing to participate in CCTs. For example, by 1968, 70 percent of women with breast cancer had radical mastectomy, which

entails removing the breast, lymph nodes, and chest wall muscles on the affected side. Many clinicians believed this gave women their best chance of a "cure" (defined as surviving five years or longer), at no real loss, because in their view, the breast of an older woman was entirely expendable (Lerner). Beginning in the 1970s, these views changed gradually, but many clinicians clung to these beliefs into the 1990s, long after information gained from a series of RCTs showed radical mastectomy as unnecessarily mutilating and disabling. Ultimately, these trials established that removal of only the tumor or the breast, with or without radiation therapy, resulted in survival comparable to that achieved with the radical mastectomy (Fisher). Follow-up studies done twenty-five years later confirmed that there is no advantage to the more mutilating surgery (Fisher et al.).

Getting clinicians to agree to participate and women to enroll in CCTs or RCTs in the 1970s and 1980s was a crucial step to discrediting radical mastectomies. Investigators had to persuade skeptical physicians who believed that the radical mastectomy was necessary to give their patients the best chance of survival. Many clinicians asserted that they had a "therapeutic obligation" or duty to pick what they viewed as the best therapy for their patients. Some were so convinced radical mastectomy was best that they did not inform women of other options, let alone enroll them in RCTs; others did not want to communicate the uncertainties about which therapies were best or feared that informed consent would destroy trust in the doctor–patient relationship (Taylor, Margolese, and Soskolne).

Such paternalistic attitudes increasingly troubled both investigators (how did clinicians know what was best?) and women (do they not have a say about what is best for them?). Women were learning about the controversies over treatment options swirling in the medical literature at the same time that informed-consent policy took root. Consequently, investigators and clinicians had to make room for good informed consent and choice. In response, therapeutic research became an increasingly cooperative venture among doctors, patients, and investigators (Kopelman, 1994; Fisher).

Increasingly, patients and clinicians saw the advantages of participation in multi-institutional research using the same protocols. These large trials proved to have many research advantages, because they can involve many patients and get results quickly, and because they can help neutralize biases that result from distinctive groups of people who use certain institutions. In addition, large trials can even result in improved care for all groups and better fulfillment of consent requirements. This is because these cooperative studies are often designed by experts and include quality-control provisions. In addition, they are also reviewed for approval by many agencies. Moreover, expert panelists review data and stop the trials if early results show clear advantages to some assignments.

By the 1990s, great progress in treating cancer resulted, in part, from doctors' willingness to enroll patients in clinical trials and patients' willingness to participate. Patients often acted from altruism to help the next generation of patients, just as the last generation had helped them. Clinical trials, by this time, were also seen as a way to get good care, leading many people to be eager to enroll and disappointed if they were excluded. Largely gone were the sweeping general denunciations of the 1970s and 1980s when critics claimed an inherent incompatibility existed between these research methods on the one hand and doctors' duties to protect patients, patient's rights and welfare, and good patient–doctor relationships on the other (Fried; Gifford; Marquis; Wikler).

An Imperfect Consensus with Enduring Issues

For clinical trials to be morally acceptable, a consensus exists that they must meet the following conditions:

1. The study is important.
2. Patients or their representatives give informed consent including knowledge of all alternatives, of their right to withdraw at any time, and of clinicians' and investigators' conflicts of interest.
3. Physicians and investigators place the well-being of the patients ahead of research interests.
4. The study has gained appropriate approval from institutional review boards or research ethics committees.
5. A data safety monitoring panel will end studies if it is demonstrated that one or more of the study arms prove better than others and will report significant new findings to doctors or patients.
6. The uncertainty principle or null hypothesis is justified, meaning that the arms of the study are "equally good."

Before a trial begins, then, investigators must do a comprehensive review of the literature to show that all treatments being given and compared have a therapeutic success rate that is acceptably high for all arms, and that it is uncertain whether any one of the treatments being tested is better than any of the others. In addition, it must be shown that no study arm provides what is known to be inferior care (HHS; Beauchamp and Childress; Concato, Shah, and Horwitz; Emanuel, Wendler, and Grady; WMA).

Serious questions exist about implementing these assumptions. Patients have legitimate preferences about how

they want to be treated, and doctors have responsibilities to try to give patients the best care to meet their individual needs, goals, and desires. Controlled trials restrict people's choices and limit the ways therapies can be adapted for them by the methodologies of stratification, randomization, inflexible interventions, eligibility requirements, and single-blind or double-blind study designs. Some of these concerns are discussed below.

PHYSICIANS' ROLES AS CLINICIANS AND AS SCIENTISTS. When physicians enroll patients in clinical trials, they help patients collectively by gaining knowledge but may lose flexibility in tailoring treatments for individual patients. This can create a conflict between doctors' roles as scientists dedicated to conducting the best studies to gain knowledge, and as healers dedicated to adapting treatments to each patient's needs, goals, and values. To address this potential conflict, most agree that physicians should not enroll a patient in a clinical trial if they have reason to believe a patient might, thereby, obtain inferior care (Byar et al.; Chalmers, Block, and Lee; Kopelman, 1986; WMA; Ellenberg; Levine, Dubler, and Levine; Shaw and Chalmers; Zelen, 1990; Emanuel, Wendler, and Grady).

Although agreement exists that doctors should not enroll patients in studies in which they get inferior care, substantive disagreements remain about when arms of studies are considered equally good. One controversy concerns what values to employ in deciding if treatments are "equally good." Investigators tend to measure equality among treatments in terms of easily quantified outcomes such as survival after cancer treatments or reduction of blood pressure. Patients and some clinicians, however, also consider how treatments affect the quality of patients' lives and whether patients think the treatment makes them feel better (Levine, Dubler, and Levine). Views, therefore, about what treatments are equally good differ when people regard different things as relevant benefits and burdens. Hence nausea, hair loss, sexual impotence, weakness, extra costs, inconvenience, or more hospital visits may be more important outcomes from a patient's perspective than from an investigator's perspective in determining when treatments are equally good.

Another controversy that involves how to use the uncertainty principle may be called "the problem of clinician preference," or, should conscientious clinicians with any preference at all for one treatment arm enroll their patients in a clinical trial? Some argue that clinicians have a duty to provide what they believe to be the best available care for patients; consequently, as long as physicians have any preference about which treatment is best for their patients, they should not enroll their patients in clinical trials (Fried; Gifford; Waldenstrom). It is rare that clinicians have no preference whatsoever about what is best for their patients, especially for the treatment of serious illnesses where the outcomes, conveniences, risks, and possible benefits are different. Moreover, if asked, patients will often have preferences even if the clinicians do not, and this could break the tie for doctors. Consequently, these critics find trials, especially RCTs, generally unethical.

In his 1987 article, "Equipoise and the Ethics of Clinical Research," philosopher Benjamin Freedman tried to solve the problem of clinician preference by distinguishing between "theoretical equipoise" and "clinical equipoise." Theoretical equipoise is an epistemic (cognitive) state in which the evidence is exactly balanced, meaning that treatments are of equal value. Clinical equipoise, in contrast, is that state in which the community of expert clinicians is undecided as to the preferred treatment for the given population as determined by the study's eligibility criteria; the study should be designed to disturb clinical equipoise and to terminate when it is achieved. Freedman argued that clinical equipoise is a better way to understand that treatments are equally useful for a particular group and, thus, that the uncertainty principle has been reached. To decide equipoise, then, the focus should not be on the treatment that the particular clinician prefers, but on what the community of clinicians believes to be equally good treatments for some condition given their respective benefits and burdens. A clinician may have a preference for one treatment but respect colleagues with different views. Thus, as the trial begins, treatments (including any placebo arm) must be in clinical equipoise, or be regarded as having equal merit by the community of experts in treating some condition for a certain group. Disagreements should be expected in a rapidly advancing field such as medicine, and it is these disagreements that help explain why trials are important. Exceptions are sometimes made to this policy of requirement equipose if there is no more than minimal risk of harm to the subjects, such as testing the efficacy of nose drops in the common cold.

This solution presupposes agreement or justification about who should be in the community of expert clinicians deciding which treatments are equally good and whether their views adequately represent those of the potential patients. Disputes arise over this, however (Kopelman, 1994). Some people disvalue the views of any but the most acclaimed clinical investigators. Others contend that many perspectives, including those of investigators, clinicians, and patient advocates, represent patients' sometimes differing values. Increasingly, clinical trials are moving out of the academic centers and into private doctors' offices. Clinicians often find such arrangements professionally fulfilling, but they can also be financially lucrative when drug companies,

who typically sponsor these studies, offer monetary incentives to enroll patients. In contrast to academic medical centers, little oversight or accountability exists in private offices, argued Jason E. Klein and Alan R. Fleischman in 2002; but more opportunity exists for patients to misunderstand that they are being enrolled in research programs not necessarily designed for their benefit. Klein and Fleischman argued that financial incentives to clinicians should be limited, patients should have an independent resource to answer their questions, and doctors should be required to disclose potential conflicts of interest. Arguably, in both the academic and private practice settings where there are genuine risks, the treating physician should not be the investigator.

STARTING TRIALS. Disagreements can erupt about the overall benefits of the new treatments or investigational new drugs when compared with standard care or to a placebo. To justify the time, energy, risks, and expense of testing a new therapy for some condition by means of a CCT or RCT, investigators must produce preliminary evidence of its safety, efficacy, and proper dose. Some knowledgeable people are likely to be more impressed with these findings than others, especially for serious diseases with no established treatments (Levine, Dubler, and Levine). Consequently, they disagree about if or when trials should begin. In addition, resources are limited so not all good studies can be funded. These funding choices depend not only upon the merits of the study but also on political and social interests because funding for studies is limited and often comes from tax revenues.

PLACEBO-CONTROLLED RCTS. One of the most persistent controversies concerns the use of the placebo arm in a controlled trial. A placebo is used because people's beliefs and expectations can influence how they react. Suppose there are two groups, and persons in one group get a red pill with specific activity. People sometimes react to getting pills. If one group gets a red pill, and if the two groups are being treated exactly the same, then arguably, the other group should also get a red pill, although without the same active preparation. The red pill might be a sugar pill. As noted, placebo-controlled RCTs are widely regarded as the gold standard for assessing the safety and efficacy of therapies.

A knotty problem exists over whether placebos should be used when there is a proven and effective treatment. Defenders of the use of a placebo arm in such cases cite its enormous methodological advantages in evaluating treatments and justify its use as long as subjects are not made worse off (Varmus and Satcher; Temple and Ellenberg). In one case, for example, investigators wanted to study the safety and efficacy of mood disorder medications adopted long ago without rigorous testing. Some of these drugs have a good track record of abating serious symptoms including suicidal ideation. Disputes arose over whether these drugs should be tested against a placebo because beliefs and expectations affect mood disorders. A distinguished panel of experts could not reach consensus and concluded: "Research is needed on the ethical conduct of studies to limit risks of medication-free intervals and facilitate poststudy treatment. Patients must fully understand the risks and lack of individualized treatment involved in research" (Charney et al., p. 262). Yet obtaining consent for what can be risky studies from such patients may also be problematic because their illnesses often disturb their thought processes.

Perhaps the most contentious debate so far concerned using placebo-controlled trials to study perinatal transmission of HIV/AIDS when a proven and effective therapy existed (Angell; Temple and Ellenberg; Ellenberg and Temple; Lurie and Wolfe). The funding was from rich countries where, because proven and effective therapies were the standard of care, the studies could not be done. Some argued these studies were immoral because the stakes were life and death (Angell; Lurie and Wolfe); others said that the studies were needed and that these poor people were made no worse off by being given local standards of care (Temple and Ellenberg; Ellenberg and Temple; Varmus and Satcher). They maintained this was the most efficient way to obtain urgently needed information to fight the HIV/AIDS epidemic.

In 2000 the influential World Medical Association (WMA) took a stand. It issued a new draft of the Declaration of Helsinki stating that placebos should not be used if there was a proven and accepted treatment. This put the declaration on a collision course with the U.S. Food and Drug Administration (FDA), which often requires the use of placebo despite the existence of a proven and accepted treatment. Defenders also point out that if placebos are not permitted, trials may have to be a great deal larger and therefore more costly.

One possible middle ground is to consider the harm of not having the treatment. If there is only a minor risk of harm, such as minor discomfort or inconvenience to being denied the proven and effective treatment, then studies might be permitted. As potential harms to those on the placebo arm increase, it should become more difficult to approve the study, even with consent from subjects or their representatives.

An entirely different set of concerns exists, challenging the placebo as the gold standard.In their 2001 article, "Is the Placebo Powerless?" Asbjorn Hrobjartsson and Peter Gotzsche questioned whether the placebo is really as powerful as claimed. The placebo itself, they pointed out, was adopted

without testing. They conducted a meta-analysis comparing placebo with no treatment arms, finding that in many cases, there was no difference between them at all. They wrote, "We found little difference in general that placebos have powerful clinical affects. Although placebos had no significant affects on objective or binary outcomes, they had possible small benefits in studies with continuous subjective outcomes and for treatments of pain. Outside the setting of clinical trials, there is no justification for the use of placebos" (Hrobjartsson and Gotzsche, p. 1594). In a 2000 article, John Concato and colleagues also raised doubts about the ascendancy of the placebo-controlled RCT when compared to all other methods. They argued that even observational studies can, when carefully done, control bias as well as an RCT.

Kenneth J. Rothman and Karin B. Michaels, in a 1994 article titled "The Continuing Unethical Use of Placebo Controls," concluded that the FDA's insistence upon viewing the placebo as the gold standard not only has moral problems but also is essentially a political decision. The FDA scientists argued that the placebo-controlled studies make it easier to show statistical significance with smaller numbers of subjects; but larger studies would reduce statistical variability. Unfortunately, this is expensive. Concato and colleagues also objected, stating that it is the drug companies that benefit from the FDA policy of fostering small CCTs and RCTs given that such studies are less costly; it is the patients who bear the burdens of this policy because they are denied proven and effective treatments.

Yet another challenge to the use of placebos as the gold standard comes from those who study complementary and alternative medicines (CAMs). RCTs and CCTs try to eliminate nuisance variables, and they include in this category people's different hopes and beliefs. There is little doubt, however, that these are powerful forces in people's lives. Some argue that research that eliminates hope and belief has limited utility, just because mental attitude is so powerful. In 2002 Kenneth J. Schaffner argued that the study of CAMs "…might lead us to question"

> a standard research design methodology that priorities randomized clinical trials and objective measures of health … and think about the arguments of [the American philosopher Thomas] Kuhn and the disunity of science proponents, and about varying local methodologies … [with their] different evidential standards … CAM can help make us realize both that the influence of the belief systems may have powerful effects on health and that discerning these effects may require a realization of these Procrustean standards. (Schaffner 2002, p. 12)

ENDING TRIALS. The goal of a study is to learn whether different treatments are equally good for certain conditions. But justification for claiming to know something is a matter of degree, and there can be substantial disagreements about where to draw the line for the purpose of saying that it is known that treatments are or are not equally good. Investigators should adopt rules about when to stop at the outset of a study. Although investigators generally do not release preliminary data, there are some exceptions. A data safety monitoring panel is often charged with monitoring the data and deciding if trials should be ended early because people in one arm of the study are doing far worse than others. For example, azidothymidine (AZT) was first tested against a placebo in a double-blind RCT to see if it helped patients with AIDS. Doctors and nurses believed they knew from the abatement of symptoms, which patients were getting AZT and which were getting a placebo. After several months, 16 of the 137 patients in the placebo arm died, whereas only 1 of the 145 patients receiving AZT died. The trial was ended and all received AZT (Beauchamp and Childress).

Deciding when to stop a trial is not an entirely scientific choice but is also a moral decision. Investigators, panels, and journal editors typically require a probability of at most 0.05 (five chances in a hundred) that the observed results between groups occurred by chance, as a ground for holding that *sufficient evidence* exists to say they *know* that the groups are different. Although the 0.05 standard is a reasonable and well-established convention, it should not be misunderstood. As Daniel Wikler (1981) and Loretta M. Kopelman (1986, 1994) have argued, it is at best a moral trade-off between continuing the study so long that some people receive obviously suboptimal care and stopping so early that some people are harmed because insufficiently verified treatments are adopted or discredited. Some will draw that line differently, especially when treatments are tested for serious illnesses with few other means of treatment, as in AIDS research (Kopelman, 1994).

INFORMED CONSENT AND RESEARCH INTEGRITY. For people to enroll in studies, they or their guardians must give informed consent, meaning authorization that is competent, adequately informed, and voluntary. Assuming that people are competent to give consent and do so voluntarily, what do they need to know to give informed consent for clinical studies?

Generally they must be told about the study's nature, purpose, duration, procedures, and foreseeable risks and benefits. Moreover, they need to know about any alternative treatments, inconveniences, additional costs, and extra procedures or hospitalizations resulting from enrollment. They must also be told of their right to withdraw from the study at

any time should they agree to participate (U.S. 45 CFR 46.116). If the study design includes different groups, randomization, or placebos, for example, prospective subjects need to be informed. Consent for therapy or research requires giving people all information that a reasonable person would want to know in order to make a choice.

These widely recognized consent requirements create tensions in relation to the research goals of clinical trials. For example, suppose in testing treatments, one study arm uses surgery with medical management resulting in a faster recovery if there are no complications, and the other study arm uses medical management alone, with fewer risks but a slower recovery. If distinctive groups have special preferences, such as the elderly preferring medical management and the young surgery, then the study of the different treatment results could be biased through self-selection.

Thus, there is a difficulty that may be called "the problem of subject preference": How can people's preferences be accommodated while preserving the scientific integrity of the CCT or RCT? Some criticize regulations on informed-consent doctrine as unrealistic, too individualistic, and shortsighted because they give too much weight to individual choice and make it hard to conduct good studies (Tobias; Zelen, 1979, 1990). Physicians and healthcare professionals, they argue, have a duty to take proper care of patients but are not typically required to educate them about these technical and complex matters; patients should get good treatment given by conscientious professionals, but patients do not need to know how, when, or why investigators evaluate their treatments. Most patients cannot understand the investigation's complexities, they argue, and would be harmed by learning of the uncertainties about what care is best or that they are being studied. Investigators should be free to design the best possible trials consistent with good care, they argue, and the current understanding of patients' rights disrupts clinical trials, thereby slowing medical progress. If people have only the right to good care and not the right to refuse to be enrolled in a study, it would be easier for investigators to conduct research and minimize problems of bias introduced by people's preferences. For example, Marvin Zelen devised schemas in which patients give their consent for a treatment without knowing that the treatment was selected by a random method and/or that they are in a study; other designs prerandomize people to group assignments before consent is sought (Zelen, 1979, 1990).

Such paternalism, in general, and Zelen's designs in particular, has garnered legal and moral criticism (Ellenberg, 1984, 1992; Kopelman, 1986, 1994). It not only denies people self-determination, but, without pertinent information, people do not have means to protect their own well-being. The doctrine of informed consent developed because many patients and activists wanted impartial information and participation in choices about their care, especially when they will be serving as research subjects. For example, statistician Susan S. Ellenberg criticized Zelen's prerandomization schemas in which patients are assigned to groups before consent is sought. She argued that this threatens impartiality in gaining consent, risking that the informational sessions will be shaped to enhance the benefits and minimize the risks of each individual assignment (Ellenberg, 1984, 1992).

On the other hand, others are skeptical that most subjects give genuine informed consent to research (Tobias; Wikler; Zelen, 1979). Most patients, they claim, do not understand the benefits or burdens of their treatment options, let alone the scientifically rigorous methodology used in testing. A related criticism is that investigators do not tell the patients, and most patients do not understand, that at some point in the trial it may become increasingly apparent that some groups are getting suboptimal care (Wikler). Investigators, they argue, put medical advances ahead of subject-patient rights and welfare because those rights typically violate physicians' duties to their patients (Fried; Gifford; Marquis; Wikler). Some support for this view comes from a study that George Annas reports was conducted by the FDA, which carried out spot checks on 1,000 investigations; the FDA found that investigators did not seek informed consent in 213 studies, did not follow their approved research protocol in 364 investigations, and failed to report adverse reactions for 140 test subjects. Unfortunately, the FDA results square with others, reports Annas (Annas).

In contrast to these two positions implying that one must choose between good trials and good informed consent, other commentators argue that clinical trials, including RCTs, can be cooperative ventures between patients and investigators (Freedman; Kopelman 1986, 1994; Levine, Dubler, and Levine; Levine, 1986). They believe that investigators and patients should work together with candor, respect, and trust about the goals and means of the research, and view consent as an on-going process. They maintain that with proper consent some studies (but not all) are morally justifiable. Subjects may *have* to be regarded as partners in a cooperative venture, however, if investigators expect people to enroll and cooperate. People can defeat trials if they do not identify with the investigators' goals. In one case, investigators were testing whether patients infected with HIV who were not yet showing symptoms of AIDS would benefit from AZT. At the end of the trial, researchers estimated that 9 percent of the patients in the placebo arm had been taking AZT. If more patients in the placebo group had secretly taken AZT, investigators might have judged a

beneficial drug ineffective and refused to release it for this use (Merigan). These patients, facing a life-threatening disease, found a way to get the drug they believed useful and inadvertently jeopardized a clinical trial and the welfare of future patients. Poor cooperation results when the subjects fail to identify with the goals of the study, do not understand its importance, or are asked to risk too much in terms of health and convenience (Spilker).

PROTECTION OR ACCESS. During the period from the 1970s to the early twenty-first century, patients and physicians have gone from being wary of participating in CCTs and RCTs to seeking access to them. Studies were increasingly seen as opportunities for good care rather than as dangerous projects from which vulnerable people should be protected (Dresser; Kopelman, 1994). For example, AZT, the first effective drug to treat AIDS, was initially tested for safety and efficacy against a placebo in a double-blind RCT, as has been mentioned. Until the early 1990s, many biomedical research study populations excluded people of color, women, and children in order to "protect" what were considered to be these more vulnerable populations. Advocates argued that this was unfair because enrollment in trials often provides people the only or best available access to adequate or promising care. For example, children with AIDS initially could not get AZT because only adults could be enrolled in studies. Even after some studies showed that AZT was beneficial for treatment of adults, regulations initially forbade its prescription for children because it had not been tested with them (Pizzo). Moreover, a study excluding people of color, females, and children focuses upon a narrow range of the patient population (adult white males), making it uncertain whether the results of a study apply to other groups. There may be differences among groups; if there are, variations might be due to nature, nurture, or a combination of both. A study on depression, for example, conducted exclusively with white men, leaves uncertainty as to whether the results would be the same for other groups who have different social standing, burdens, genes, or physiologies.

More flexible eligibility requirements, advocates argue, would give all groups access to new treatments and would also yield results that more accurately reflect the entire patient population. Opponents respond that this would tend to make it harder to ensure that groups are comparable unless they have more subjects in the group. This would, of course, make the studies more costly. Despite these objections, policies were adopted to address unequal access and to revise eligibility criteria that excluded groups simply to save money and hold down the cost of trials, especially when studies were supported by tax dollars.

Patient-advocacy groups also demanded more access to preliminary information about the safety and efficacy of different modes of care. They wanted less secrecy regarding early trends, especially in cases in which patients have few treatment options for serious diseases. Many patients with severe or chronic diseases, or their families, have learned to follow closely relevant research, and they want greater access to promising new treatments.

These proposals generated a variety of responses (Byar et al.; Levine, Dubler, and Levine; Merigan; Schaffner, 1986; "Expanded Availability," 1990). For example, programs now make some investigational new treatments more available by means of expanded access or a "parallel track" ("Expanded Availability"). In the past, there was a single way, or *track,* for patients to get certain investigational new treatments, namely, participating in the study as a subject. Some people were excluded because they lived too far from the study site(s) or because of age, gender, or prognosis (Dresser; Kopelman, 1994). New programs expanded access or offered a parallel track to make it possible for some patients who are not subjects to have investigational new treatments. Patients with HIV-related diseases, for example, can sometimes obtain investigational new treatments even though they are not enrolled as trial subjects. Some investigators recommend this approach when there are no therapeutic alternatives, when the investigational new treatments are being tested, when there is some evidence of their efficacy, when there are no unreasonable risks for the patient, and when the patient cannot participate in the clinical trial (Byar et al.). This solution presupposes that there is agreement about who should make these verdicts. Community representation on panels that make these decisions may be reassuring to groups advocating more openness.

These and other proposals allow greater flexibility but also may make it harder to conduct and interpret the results (Ellenberg; Merigan). For example, if patients can get the investigational new treatment without enrolling in a clinical trial, some may refuse to participate in the study. Thus, even if these proposed changes are adopted, tensions still exist between individual and collective interests in conducting trials.

Conclusion

The CCT and RCT methodologies are powerful ways to combat the effects of bias. By using these methods, bias can be minimized, but it can never be entirely eradicated. People's beliefs, hopes, duties, prejudices, values, or interests can create biases in their choices about what studies to fund, when to begin and end studies, what measures will be used, how groups are established, and how results are interpreted.

When people consider the adoption of procedures such as copious amounts of oxygen for premature infants (later found to cause blindness), a high premium is placed on protection of the public from someone's idea of *promising* new treatments; when they think of drugs that have proved to help sustain or improve people's lives, however, a high premium is placed on early access. Who should decide the optimal degree of testing or protection needed in order to establish the safety and efficacy of drugs before they are available? This question of access versus protection is a social and moral decision, not just a scientific matter. It is not unlike the decision about how much inspection of foods or buildings is necessary in order to protect the public. When the stakes are high, as in fatal or chronically degenerative diseases with no promising treatments, the disputes about when to begin or end trials are sometimes a tangle of scientific, moral, social, political, statistical, and medical problems.

III. SUBJECTS

Selecting individuals to participate in research involves not only scientific decisions about appropriate entry criteria but also ethical decisions about the distribution of benefits and burdens. In *The Belmont Report* (1979), the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research cited three ethical principles as the foundation of research ethics. The first, respect for persons, and the second, beneficence, have been analyzed more often and in greater depth than the third, justice. Investigators, regulators, and institutional review boards (IRBs) are accustomed to applying the principle of beneficence by examining the risk-benefit ratio and applying the principle of respect for persons by examining informed consent. But the third principle—the selection of subjects as a matter of justice—has often been considered last and in only one of its aspects, the protection of vulnerable groups from exploitation as subjects.

This situation is changing as persons and groups previously excluded from research on grounds of vulnerability

seek access to what they perceive as research benefits, primarily the opportunity to try new drugs for serious and life-threatening illnesses. However, the concept of vulnerability is itself coming under greater scrutiny as being ill-defined and too broad. In his 2001 paper, *Vulnerability in Research Subjects,* Kenneth Kipnis proposed a new taxonomy of vulnerability, which he defined as limitations on the ability to provide informed consent. He outlined six types of vulnerability, based on characteristics of the individual or society:

1. cognitive: the ability to understand information and make decisions;
2. juridic: being under the legal authority of someone such as a prison warden;
3. deferential: customary obedience to medical or other authority;
4. medical: having an illness for which there is no treatment;
5. allocational: poverty or educational deprivation; and
6. infrastructure: limits of the research setting to carry out the protocol.

According to the U.S. National Commission, justice is relevant to the selection of subjects at two levels: the social and the individual. At the individual level, "researchers [should] exhibit fairness: thus, they should not offer potentially beneficial research only to some patients who are in their favor or select only 'undesirable' persons for risky research" (U.S. National Commission, p. 7). At the social level, "distinctions [should] be drawn between classes of subjects that ought, and ought not, to participate in any particular kind of research, based on the ability of members of that class to bear burdens and on the appropriateness of placing further burdens on already burdened persons" (U.S. National Commission, p. 7). Specifically, on the grounds of social justice, classes of subjects should be ranked (e.g., adults before children) and some classes of potential subjects (e.g., prisoners and the institutionalized mentally infirm) should be selected only under certain conditions and should perhaps not be selected at all.

Very few philosophers or other scholars have proposed standards by which to establish priorities in the selection of subjects. Hans Jonas (1970) proposed a "descending order of permissibility" for the "conscription" of subjects. In his view, researchers themselves should be the first to test a new therapy, in that they can best understand the risks and benefits. Believing that very sick or dying patients are particularly vulnerable to researchers' invitations, Jonas opposed using them in research not directly related to their care.

Another approach has been to assert an obligation to participate in biomedical research. Arthur L. Caplan (1984) argued that research is a form of voluntary social cooperation that generates obligations of fairness and reciprocity. If a competent individual voluntarily seeks care in a hospital or institution that conducts biomedical research, he or she benefits from research and should share in its costs (i.e., participate). This obligation is a general one, not an obligation to volunteer for the first available trial or any particular trial.

Selecting the Least Vulnerable

Underlying these different views is the assumption that research is risky or at least burdensome. If this is true, subjects should be selected in a way that protects those whose social, demographic, or economic characteristics make them particularly vulnerable to coercion and exploitation. Volunteering for research is seen as either a duty to be discharged or an altruistic act to be applauded. This emphasis on protecting vulnerable persons is understandable given the signal event in the modern history of clinical research ethics—the cruel and often fatal experiments performed on unconsenting prisoners by Nazi doctors in World War II (Caplan, 1992). Public opinion in the United States also was shaped by the revelations of unethical experiments such as the Tuskegee Syphilis Study of poor black sharecroppers (Jones), the Willowbrook hepatitis B studies at an institution for mentally retarded children (Rothman, 1982), and the Jewish Chronic Disease Hospital studies in which live cancer cells were injected into uninformed elderly patients (Katz, Capron, and Glass). The most influential single article was one by Henry Knowles Beecher, a respected anesthesiologist, published in the *New England Journal of Medicine* in 1966; it described a series of studies at major research institutions that placed subjects at risk and in which the researchers failed to obtain informed consent (Rothman, 1991).

The view of research as inherently risky and of research subjects as inherently needing protection began to change in the early 1980s, but the pendulum may be swinging back to a more cautious view in the light of rare but highly publicized deaths of research subjects. In September 1999 Jesse Gelsinger, eighteen years old, died in a gene transfer. Ellen Roche and Hoiyan Wan, both young "normal, healthy volunteers," died in trials at Johns Hopkins University and the University of Rochester, respectively (Steinbrook, 2002a, 2002b). Research studies at several prominent medical centers were shut down temporarily after deficiencies in their procedures were identified.

The actual risk in most research studies is generally considered to be quite low, but there are no recent data. The

U.S. President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (1982) asked three large research institutions to summarize their experience with research-related injuries. Each group found a very low incidence of adverse effects. In one institution, out of more than 8,000 subjects involved in 157 protocols, only three adverse effects were reported, including two headaches after spinal taps. The definition of "adverse effect" is vague, however, especially among sick people, and it is possible that many adverse effects are not reported because they are deemed unrelated to the research study.

Sharing the Benefits of Research

The benefits side of the equation has assumed greater weight in individual decision making. Patients and advocacy groups are demanding more autonomy and less paternalism in the selection of subjects. Desperately ill patients forcefully argue that they are willing to trade a higher level of risk for the potential benefits of promising new procedures, devices, or drugs. Advocates for women and children point out that the typical exclusion or underrepresentation of these populations in clinical trials means that the drugs, when approved, will be prescribed for them with little direct data about dosage, efficacy, or side effects. These trends have been spurred by the vigorous, sometimes confrontational, efforts of persons with acquired immunodeficiency syndrome (AIDS). This advocacy also has stressed the inclusion of groups with poor access to trials, mainly women and minorities (C. Levine, 1988, 1993).

Increased emphasis on women's health issues has provided some information on subject recruitment. Examining the inclusion of women in clinical trials, the U.S. General Accounting Office reviewed the practices of the National Institutes of Health (NIH) and the Food and Drug Administration (FDA) (Nadel; U.S. General Accounting Office, 1992). In both instances women were found to be underrepresented. The FDA review found that women were represented in every clinical trial of the fifty-three drugs approved by the FDA in the previous three and a half years. For more than 60 percent of the drugs, however, the proportion of women in the trial was less than the proportion of women with the relevant disease. Women were particularly underrepresented in trials of cardiovascular drugs, even though cardiovascular disease is the leading cause of death in women.

In arguing for wider inclusion criteria in clinical trials, patient advocates and some clinicians have noted that in the interest of good medical care, drugs should be tested on the populations that will use them. This belief runs counter to the more traditional research view of subject selection, which focuses on testing drugs in a small, homogeneous population in order to detect differences in efficacy and side effects as rapidly as possible.

Even with broadened inclusion criteria, not all patients who want access to promising new agents can be enrolled in clinical trials because they fail to meet the inclusion criteria, they live too far from a research center, or the trials are already closed. Several other mechanisms have been developed, such as the "parallel track," in which qualified patients who cannot enroll in clinical trials may obtain a promising drug through their physician ("Expanded Availability," 1992). Community-based research, especially in cancer and AIDS, also has made clinical trials more accessible to patients.

The NIH has formalized the movement toward broader selection of subjects by mandating that its research grant recipients include appropriate numbers of women and minorities (Kirschstein). The 1993 NIH Revitalization Act (Pub. L. 103–43) extended the revised NIH policy by requiring the NIH director to ensure that women and members of minority groups are included in each federally funded project. The director may waive the requirement if the inclusion is inappropriate for health reasons, the purpose of the research, or any other circumstance. Cost, however, is not considered a permissible reason to fail to include women and members of minority groups.

This trend has limits, however. The inclusion of pregnant women in clinical trials is still controversial unless the trial is specifically designed to benefit the fetus, such as trials to prevent maternal–fetal transmission of the human immunodeficiency virus (HIV), which is associated with AIDS. Some of the objections to including pregnant women rely on ethical concerns about, for example, placing a fetus, who cannot consent, at risk. Most of the concerns are based on fears of legal liability should the fetus be born with an injury that might be attributed to the investigational drug. Other subject groups for which protection is still deemed essential include children (Levine, 1991), prisoners, and mentally ill persons. Still other groups sometimes cited as vulnerable include elderly people, military personnel, pharmaceutical company employees, and medical students. Although for these individuals some conditions and some protocols might be coercive, in general they can make choices voluntarily. Special procedures have been set up in some instances to ensure voluntariness (see, e.g., Winter, on the U.S. Department of Defense).

From the societal perspective, equitable selection of subjects means that the groups bearing the burdens of

research should also share in its benefits. Opponents of research in prisons argue that the fruits of the research—newly approved drugs—are rarely available in that setting. Similarly, although many drug trials have been carried out in Third World countries, these nations are often so poor or so lacking in healthcare services that they cannot afford to provide the tested drugs to their citizens.

More recently, representatives of Third World countries and of poorly served communities in the United States have been demanding a greater role in the distribution of benefits (Lurie et al.; U.S. National Commission on AIDS; Thomas and Quinn). Their agreement to participate in clinical drug trials is sometimes conditioned on a promise from trial sponsors to provide something of benefit to the population—the drug, if it proves efficacious, or the health infrastructure needed to deliver the therapy. Efficacy trials for vaccines, which require thousands of subjects, cannot be conducted without the goodwill and participation of a community's leaders. Community consultation, in which investigators and community spokespersons collaborate on the design and implementation of a trial, is becoming a frequent strategy for ensuring that the concerns of the pool of potential subjects and their representatives are addressed.

Recognizing the importance of social justice in the distribution of burdens and benefits, the Council for International Organizations of Medical Sciences (CIOMS) guidelines for international research state:

> Before undertaking research in a population or community with limited resources, the sponsor and the investigator must make every effort to ensure that:
>
> - the research is responsive to the health needs and the priorities of the population or community in which it is to be carried out; and
> - any intervention or product developed, or knowledge generated, will be made reasonably available for the benefit of that population or community. (CIOMS, p. 19)

Principal 19 of the World Medical Association's most recent restatement of the Declaration of Helsinki (1964, revised 2000) states: "Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research."

The equitable selection of subjects now includes an assessment of both the need for protecting vulnerable individuals and groups and the importance of allowing them maximum choice in making the ultimate decision to participate. In the future, even more emphasis will be placed on the equitable distribution of the benefits of research.

RESEARCH, MULTINATIONAL

• • •

The term *multinational research* refers to biomedical, epidemiological, or social science research that involves investigators and subjects from more than one nation. The type of multinational research that has raised the most ethical concerns is that in which the investigators or sponsors are from an industrialized country and the research is conducted in a developing country (the "host" country). Two chief ethical concerns have dominated this type of research in the past. The first concern is that research subjects in the host country might be vulnerable by virtue of their low educational level or lack of familiarity with modern scientific concepts and, therefore, open to exploitation in some manner. The second concern is that the cultural norms and practices in the industrialized and host countries may differ, leading to the question of which to adhere to when such norms and practices conflict.

More recently, a third ethical concern has become prominent: the level of care and treatment provided to research subjects during a clinical trial. Should it be identical to what subjects in the industrialized, sponsoring country would receive in a similar trial? Or can a lower level of care be justified based on affordability and a less well-developed infrastructure in resource-poor countries? These latter questions have been prompted primarily by HIV/AIDS research conducted in countries in Africa and Asia. A fourth concern has also risen to prominence in recent years: What, if anything, is owed to trial participants, to the community, or to the host country as a whole when a biomedical research project results in a successful product?

Two trends bring concern about biomedical research ethics in a multinational context to the fore. The first is a vast increase in the number of studies conducted in developing countries and sponsored by the pharmaceutical industry or by governmental agencies of industrialized countries (Brennan; U.S. Department of Health and Human Services). The second trend is the growing gap in the burden of disease between industrialized and developing countries, a result in part of the AIDS epidemic but also stemming from the lack of affordable treatments for diseases such as malaria and tuberculosis in resource-poor countries (Michaud, Murray, and Bloom).

Although the chief ethical concerns of the past continue to require vigilance in the ethical review and conduct of multinational research, the two more recent concerns have generated considerable controversy. A clinical trial conducted in Thailand and other developing countries, aimed at finding an affordable and appropriate treatment to prevent the transmission of HIV/AIDS from pregnant women to their infants, led to fierce debates in leading medical and bioethics journals (Angell; Lurie and Wolfe; Varmus and Satcher; Annas and Grodin, 1998; Crouch and Arras; Lie; Schüklenk). The controversy went beyond the debates in academic journals, leading eventually to a prolonged process to revise two of the leading international ethical guidelines for research: the World Medical Association's Declaration of Helsinki and the *International Ethical Guidelines for Biomedical Research Involving Human Subjects,* prepared by the Council for International Organizations of Medical Sciences (CIOMS) in conjunction with the World Health Organization.

International Research Guidelines and Recommendations

The first international code of ethics for research involving human subjects, the Nuremberg Code, was drafted in 1947 at the Nuremberg Doctors' Trial in response to the atrocities committed by physicians in Nazi Germany in experiments they conducted on inmates of concentration camps (Annas and Grodin, 1992). The purpose of the code was both to acknowledge the importance of research involving human beings and to provide a set of universally applicable rules for protecting human subjects of research from violations of their rights and welfare. The first principle of the Nuremberg Code is: "The voluntary consent of the human subject is absolutely essential." This requires that the subject "be able to exercise free power of choice, without … any element of force, fraud, deceit, duress … or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision." Other principles in the Nuremberg Code require that the proposed research be meaningful and essential, that it be based on prior animal experiments, and that it "avoid all unnecessary physical and mental suffering and injury."

The Declaration of Helsinki, first promulgated by the World Medical Association (WMA) in 1964, with relatively minor revisions in 1975, 1983, 1989, and 1996, adapted and expanded the principles of the Nuremberg Code to apply more readily to clinical research in the medical setting. Until the revision in 2000, the Declaration of Helsinki did not address the special features of research sponsored by industrialized countries and carried out in developing countries. However, the controversy that surrounded the trial to test an affordable drug to prevent maternal-to-child transmission of HIV/AIDS produced a subsequent, related controversy over a provision in the Declaration of Helsinki itself.

Critics of the HIV/AIDS trial in developing countries argued that the trial design was unethical because some of the pregnant women were given a placebo, an inactive substance, thereby withholding from them a treatment proven to be effective in reducing the transmission of HIV/AIDS in the United States. These critics also contended that the trial violated the following provision in the Declaration of Helsinki: "In any medical study, every patient—including those of a control group, if any—should be assured of the best proven diagnostic and therapeutic method. This does not exclude the use of inert placebo in studies where no proven diagnostic or therapeutic method exists" (WMA, II, 3). Whereas critics of the placebo-controlled trials cited the Declaration of Helsinki in support of their contention that the trials were unethical (Lurie and Wolfe), defenders of the trials argued that the Declaration of Helsinki was in need of revision (Levine).

The WMA embarked on a process to revise the declaration, a process that took place over a two-year period and was itself fraught with controversy. In an effort to make the process transparent and democratic, the WMA posted a draft of the revised version on its web site and invited comments. As a consequence of many comments that found the draft unsatisfactory primarily because it weakened the provision requiring that a control group be given "the best proven diagnostic and therapeutic method," the WMA appointed a new drafting committee whose members reinstated the original requirement in slightly different words: "The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists" (WMA, paragraph 29).

The newly revised draft was posted on the WMA web site, once again with an invitation for comments. In October 2000 the WMA adopted the second revised version at its meeting in Edinburgh, Scotland. But that did not end the controversy. A substantial number of influential spokespersons from the research community, the pharmaceutical industry, and U.S. federal agencies that sponsor research objected that adherence to this provision would prevent important research from going forward that could benefit developing countries. In an attempt to compromise between these opposing factions, the WMA issued the following clarification in 2001:

> The WMA is concerned that paragraph 29 of the revised Declaration of Helsinki (October 2000) has led to diverse interpretations and possible confusion. It hereby reaffirms its position that extreme care must be taken in making use of a placebo-controlled trial and that in general this methodology should only be used in the absence of existing proven therapy. However, a placebo-controlled trial may be ethically acceptable, even if proven therapy is available, under the following circumstances:
>
> - Where for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a prophylactic, diagnostic or therapeutic method; or
> - Where a prophylactic, diagnostic, or therapeutic method is being investigated for a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm.…

This clarification did not lay the controversy to rest. Defenders of placebo-controlled trials conducted in developing countries would cite what they consider "compelling and scientifically sound methodological reasons" for using placebo controls. Critics of such trials would then question whether the reasons provided were scientifically compelling and would propose instead a trial design comparing the experimental treatment with a treatment currently and widely used in the industrialized country sponsoring the research. The debate appears intractable, with each side comprising researchers, bioethicists, governmental spokespersons, and others from both developing and industrialized countries.

The same controversial clinical trials that prompted revision of the Declaration of Helsinki created a need to undertake a review and revision of the CIOMS *International Ethical Guidelines,* which were first published in 1993. In part because the CIOMS guidelines were promulgated with the purpose of applying the standards of the Declaration of Helsinki in developing countries, but also because the rapidly increasing amount of multinational research called for a reassessment of the 1993 guidelines, a multistage process was undertaken for the CIOMS revisions.

Predictably, the same debate that arose among defenders and opponents of placebo-controlled trials in the revision of the Declaration of Helsinki surfaced among drafters, members of an appointed steering committee, and commentators who responded to a posting of drafts on the CIOMS web site. The controversial guideline that emerged from this process departs significantly from the strict requirement in the Declaration of Helsinki; it permits clinical trials "in which the comparator is other than the best current intervention, such as placebo or no treatment or a local remedy" (CIOMS, Guideline 11). The justification for withholding the best current intervention is that it "cannot be used as comparator because its use as comparator would not yield scientifically reliable results that would be relevant to the health needs of the study population" (CIOMS, Guideline 11). Critics of this position argue that it is unethical to use placebos when doing so can lead to serious or irreversible harm to subjects in the control group.

Other studies of multinational research were launched at about the same time. The U.S. National Bioethics Advisory Commission (NBAC) launched an international project and in 2001 issued a final report, *Ethical and Policy Issues in International Research.* This report contains a recommendation on the same controversial point:

> Researchers and sponsors should design clinical trials that provide members of any control group with an established effective treatment, whether or not such treatment is available in the host country. Any study that would not provide the control group with an established effective treatment should include a justification for using an alternative design. Ethics review committees must assess the justification provided, including the risks to participants, and the overall ethical acceptability of the research design. (NBAC, Recommendation 2.2)

This recommendation sets up a strong presumption to provide an "established effective treatment" to the control group. But it also contains an escape hatch, allowing the proposal of an alternative trial design, which must be approved by an ethics review committee.

The Nuffield Council on Bioethics in the United Kingdom issued a report on multinational research one year

after publication of the NBAC report. The Nuffield report's recommendation on level of care provided to a control group is also less stringent than the requirements in the 2000 Declaration of Helsinki:

> Wherever appropriate, participants in the control group should be offered a universal standard of care for the disease being studied. Where it is not appropriate to offer a universal standard of care, the minimum standard of care that should be offered to the control group is the best intervention available for that disease as part of the national public health system. (Nuffield Council, paragraph 7.29)

This unresolved controversy about what should be provided to a control group gives rise to a series of philosophical questions about ethical guidelines: When reasonable people disagree on key provisions, what should be done? Should the controversy be resolved in favor of the position held by the majority? Should it be resolved in favor of the more influential party to the dispute? Or should there be no guideline at all on points of major contention among reasonable persons of good will? On the one hand, if a published ethical guideline is systematically violated, it leads to disrespect for or cynicism about the guidelines as a whole. This is the contention of critics of the paragraph in the Declaration of Helsinki requiring that a control group receive "the best current treatment." On the other hand, if a guideline is published and held by some to be exploitative of research subjects in developing countries, it creates a general skepticism concerning the ethical conduct of multinational research. This is the view of defenders of the paragraph requiring the "best current treatment" for the control group in studies in developing countries.

Understanding the Controversy

Opponents on both sides of this controversy are committed to finding appropriate and affordable diagnostic, prophylactic, and therapeutic methods for populations in developing countries. Both sides believe that to be ethical, research must be responsive to the health needs of the population where the research is conducted. That is where their agreement ends.

The chief difference between the two sides from an ethical perspective concerns the obligation to research subjects enrolled in a clinical trial. A study with the identical design of the maternal-to-child transmission study carried out in Thailand could not have been conducted in the United States for both moral and practical reasons. Morally, women outside the trial in the United States had access to an effective treatment, so they would be made worse off if they participated in the trial. Practically, many would obtain the effective treatment from other sources, undermining the study. In contrast, women in the trials in developing countries had limited or no access to a preventive treatment for their infants outside the trial, so those in the placebo group would not be made worse off by participating in the trial. Defenders of the placebo controls contended that women in the control group received the "standard of care" in their country. Critics argued that they could have been provided with the effective treatment, which could then have been compared to the experimental treatment.

As the Thai studies demonstrate, what appears to be a straightforward debate about obligations to research subjects in a clinical trial turns in part into a debate over research methodology. Defenders of the placebo-controlled trials argue that the research question to be addressed is: "In cases where there is no standard treatment whatsoever, is the experimental treatment better than nothing?" To answer that question, the only appropriate research design is one that uses a placebo control. Moreover, some test placebo against standard treatments in the United States because they can make the case that the treatment may not be any better than placebo and it is important to find that out. Critics of these placebo-controlled trials argue that a different research question is meaningful and could be addressed: "Is the experimental drug as good, or almost as good, as the best current treatment used in the United States?" The first group argues that an answer to the latter question is not responsive to the needs of the developing country. The second group replies that given a large enough number of subjects, the use of appropriate statistical tools, and a research design comparing the experimental and the proven treatments, a research question relevant to the developing country can be formulated and answered.

Thus a resolution to this ethical controversy turns, in part, on a methodological issue in the design and conduct of clinical trials. Because researchers and methodologists can be found on both sides of the debate, there is little hope that this type of controversy can be resolved by rational means unless the risks of harm are low.

Providing Posttrial Benefits in Developing Countries

The 2000 version of the Declaration of Helsinki added two new provisions that were not included in the revision issued only four years earlier. These new paragraphs reflect the widely acknowledged fact that much past research conducted in developing countries failed to produce subsequent benefits to the populations of the countries in which the

research was carried out; the benefits of biomedical research typically accrued to the populations in industrialized countries. This imbalance violates the principle of distributive justice, which calls for an equitable distribution of the benefits and burdens of research. Paragraph 19 of the declaration addresses this point: "Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research." And paragraph 30 states: "At the conclusion of the study, every patient entered into the study should be assured of access to the best proven prophylactic, diagnostic and therapeutic methods identified by the study."

Both of these newly added provisions are a response to criticisms that have been leveled against past research sponsored by industrialized countries or industry in which any resulting benefits of the research have accrued to the sponsoring country but not to the population from which the research subjects were drawn. Paragraph 19 of the 2000 declaration seeks to ensure that research is not carried out on inhabitants of developing countries solely for the benefit of inhabitants of wealthy, industrialized countries. Paragraph 30 seeks to ensure that the sponsoring country or industry does not simply pull out when the study is concluded, abandoning research subjects who still need a treatment that has been demonstrated to be effective.

Although these situations might very well occur when research is conducted wholly within an industrialized country, the lack of access to affordable treatments outside a research study is much more prevalent in resource-poor countries. This has been especially true of medications to treat HIV/AIDS. By the year 2000, virtually all pregnant women in the United States had access to effective treatments to prevent HIV transmission to their infants, but those treatments remained out of reach for most inhabitants of most developing countries (Joint United Nations Programme on HIV/AIDS, 2002). Effective treatments to prevent progression of HIV infection into symptomatic AIDS is also available to large numbers of people in industrialized countries, but here again, only a small minority of people in developing countries can afford the cost of these drugs, which remain too expensive for purchase by the ministries of health, as well. (Brazil has been an exception, as the government made a commitment to provide treatments for HIV/AIDS to its entire infected population.)

The requirement that research be responsive to the health needs of the population of the country in which the research is conducted has been a feature of the CIOMS guidelines, which were promulgated specifically with developing countries in mind. The 2002 revision of the guidelines reiterates a requirement in the 1993 version that the research be responsive to the health needs and priorities of the community in which it is carried out. The 2002 revision goes considerably further than the 1993 version by elevating a key provision to the status of a guideline instead of being relegated to the commentary under a guideline:

> *Guideline 10: Research in populations and communities with limited resources*
>
> Before undertaking research in a population or community with limited resources, the sponsor and the investigator must make every effort to ensure that:
>
> - the research is responsive to the health needs and the priorities of the population or community in which it is to be carried out; and
> - any intervention or product developed, or knowledge generated, will be made reasonably available for the benefit of that population or community.

Although the term *reasonably available* has been criticized as being too vague, the guideline nevertheless establishes a presumption for sponsoring countries or industry to seek to ensure access to successful products developed in the course of research conducted in developing countries. The reports of both the NBAC and the Nuffield Council on Bioethics address this issue, but their recommendations permit a failure to ensure access if researchers provide sufficient justification to a research ethics committee.

Preventing Exploitation

The ongoing controversy over what should be provided to a control group and the acceptability of placebo controls, along with the question of posttrial obligations to research subjects, the community, and the country in which the research takes place, have overtaken the main ethical concerns of the past regarding multinational research. Yet those past concerns have not disappeared. The need to prevent exploitation of research subjects is an ethical requirement everywhere, but it becomes more problematic in settings where subjects are illiterate or semiliterate, and where they are unfamiliar with the concepts of modern science as well as the purpose and conduct of biomedical research. Two mechanisms exist to aid in protecting research subjects from violations of their rights and welfare: prior ethical review of research protocols by an independent committee; and an adequate process for obtaining voluntary, informed consent

from individual subjects. Problem exist with regard to the effectiveness of both of these mechanisms in developing countries.

PRIOR ETHICAL REVIEW. The first and most obvious shortcoming is the absence of ethical review committees in many developing countries and in the institutions within those countries (such committees are termed institutional review boards [IRBs] in the United States, research ethics boards [REBs] in Canada, and other names elsewhere). Even where such committees exist, they may be newly established and therefore inexperienced. Even committees that are not recently established may lack adequate education and training for their members. Or they may be staffed with researchers or institutional officials who have a conflict of interest regarding the research to be reviewed. In the poorest countries, institutions lack the resources to make photocopies of the protocols to be reviewed by all the members, and time spent on committee work means loss of income from clinical work for which they would otherwise be paid.

Recent guidelines and reports acknowledge these shortcomings and propose that they be remedied through efforts to build capacity for local or national ethical review in developing countries. For example, a guidance document issued by the Joint United Nations Programme on HIV/AIDS (UNAIDS) contains the following point, titled "Capacity building": "Strategies should be implemented to build capacity in host countries and communities so that they can practise meaningful self-determination in vaccine development, can ensure the scientific and ethical conduct of vaccine development, and can function as equal partners with sponsors and others in a collaborative process" (UNAIDS, p. 15). Although the guideline specifically addresses vaccine research, a similar point appears in many other documents.

The revised version of the CIOMS guidelines issued in 2002 elevates to the level of a guideline the obligation of sponsors of research to engage in building capacity for ethical review (in the 1993 CIOMS guidelines, the obligation appeared under a commentary):

> *Guideline 20: Strengthening capacity for ethical and scientific review and biomedical research*
>
> Many countries lack the capacity to assess or ensure the scientific quality or ethical acceptability of biomedical research proposed or carried out in their jurisdictions. In externally sponsored collaborative research, sponsors and investigators have an ethical obligation to ensure that biomedical research projects for which they are responsible in such countries contribute effectively to national or local capacity to design and conduct biomedical research, and to provide scientific and ethical review and monitoring of such research.

The obligation of sponsoring countries and agencies to build capacity for ethical review of research is included as a recommendation in both the NBAC and Nuffield reports. The NBAC report states:

> Recommendation 5.7: Where applicable, U.S. sponsors and researchers should assist in building the capacity of ethics review committees in developing countries to conduct scientific and ethical review of international collaborative research.

INFORMED CONSENT. The second mechanism designed to prevent exploitation of research subjects is the requirement for voluntary, informed consent from each prospective research subject. All ethical guidelines for research include this requirement, which can pose special problems in multinational research in countries in which customs, traditions, and even the concept of a person vary considerably from those that predominate in the North America and Europe. In some developing countries a substantial portion of the population is illiterate or semiliterate. It is clear that the practice of requiring written, signed consent documents when the research subjects are illiterate is inappropriate. For semiliterate subjects, a written consent document may be appropriate, especially because family members whom the subject may wish to involve in the consent process may be literate.

It is important to distinguish between the requirement that a written document be provided to a prospective subject and the requirement that the subject sign the document. In some countries, the meaning of signing a document is quite different from what it is in North America or Western Europe. Even when the need for individual, informed consent is fully accepted, if the country has a history of oppressive regimes, or if people are fearful, based on their experience, that a signed document might be used against them in some manner, it is appropriate for the research ethics committee to waive the requirement of a signature on a consent document (NBAC).

One challenge for researchers who conduct clinical trials in developing countries is how to deal with practices that depart from the requirements of informed consent in the United States and other industrialized countries. These practices include withholding diagnoses from patients who become research subjects (Sugarman et al.; Kass and Hyder) and not disclosing key elements that comply with the substantive ethical standard of informed consent, such as the use of placebo controls, the process of randomizing subjects into different groups in a clinical trial, and the expected

efficacy (or lack of efficacy) of a method being tested (Sugarman et al.). Even if the custom of routinely withholding complete information from patients with certain diseases might be defended in ordinary medical practice, it poses a severe challenge to the need to adhere strictly to the ethical standard of disclosure required for research involving human subjects. Potential subjects cannot make an informed decision to participate without knowing that they may not receive a proven treatment that will benefit them. To enroll individuals who are not provided with these key items of information deviates from the substantive ethical standard of disclosure required for adequate informed consent.

A different problem arises when research subjects are unacquainted with the concepts and methods of modern science or biomedical research. These problems are addressed in NBAC's 2001 report, *Ethical and Policy Issues in International Research,* which contains several recommendations on informed consent. Recommendation 3.2 urges researchers to seek creative ways of presenting information, for example, by means of analogies readily understood by the population:

> Researchers should develop culturally appropriate ways to disclose information that is necessary for adherence to the substantive ethical standard of informed consent, with particular attention to disclosures relating to diagnosis and risk, research design, and possible post-trial benefits. Researchers should describe in their protocols and justify to the ethics review committee(s) the procedures they plan to use for disclosing such information to participants. (NBAC, p. 40)

It is not sufficient simply to present the information. An important component of the process is determining whether the prospective subjects adequately understand what they have been told. To this end, NBAC has two recommendations:

> Recommendation 3.4: Researchers should develop procedures to ensure that potential participants do, in fact, understand the information provided in the consent process and should describe those procedures in their research protocols.

and

> Recommendation 3.5: Researchers should consult with community representatives to develop innovative and effective means to communicate all necessary information in a manner that is understandable to potential participants. When community representatives will not be involved, the protocol presented to the ethics review committee should justify why such involvement is not possible or relevant. (NBAC, p. 42)

Some have considered it problematic in cross-cultural contexts to require that informed consent be obtained from each individual recruited as a research subject. This has been described as "philosophically and practically difficult" (Christakis and Levine, p. 1783). The problem is characterized as one in which some cultures lack the individualistic concept of a person to which the Western world adheres, so the question of how to apply the respect for persons principle becomes problematic. Debate on this point is illustrated in the following two positions.

The first holds that researchers should adhere to local customs and traditions regarding individual informed consent, and that it is ethical imperialism to insist on Western requirements in other cultures (Newton). The second maintains the opposite view that individual informed consent is a requirement that should not be eliminated or altered: "We see no convincing arguments for a general policy of dispensing with, or substantially modifying, the researcher's obligation to obtain first-person consent in biomedical research conducted in Africa" (IJsselmuiden and Faden, p. 883).

The Nuffield Council on Bioethics report addresses the tension between respect for culture and respect for persons:

> [W]e cannot avoid the responsibility of taking a view when the two aspects of respect—respect for culture and respect for persons—come into conflict with one another. We are of the view that the fundamental principle of respect for persons requires that participants who have the capacity to consent to research should never be subjected to research without such consent. (Nuffield Council, paragraph 6.22)

Those who would subordinate the respect for persons principle to other considerations have not identified a competing ethical principle that deserves a higher ranking. The unstated assumption that respect for cultural tradition may outrank respect for persons construes respect for cultural tradition as an ethical principle on a par with the following three widely acknowledged principles: respect for persons, beneficence, and justice (National Commission). Although an ethical obligation to be culturally sensitive should be honored, a limit is reached when a cultural practice violates an internationally accepted principle of research ethics.

A different sort of problem arises when it is necessary to obtain permission from a community leader or tribal chief in order to enter the community to embark on research. That requirement has to be respected, but it is no different, in principle, from the need in Western culture to obtain permission from the head of a workplace or a school

principal to enter the premises to conduct research. Permission from a tribal chief or village leader may be required but should not serve as a substitute for individual informed consent obtained from each potential subject. The NBAC report contains the following recommendation:

> Where culture or custom requires that permission of a community representative be granted before researchers may approach potential research participants, researchers should be sensitive to such local requirements. However, in no case may permission from a community representative or council replace the requirement of a competent individual's voluntary informed consent. (NBAC, p. 43)

Considerably more problematic is the need to obtain individual informed consent from women in cultures in which the husband or father of an adult woman normally grants permission for her participation in activities outside the home. NBAC's recommendation on this point calls for a presumption to treat men and woman equally in the informed-consent process but allows for a loophole:

> Researchers should use the same procedures in the informed-consent process for women and men. However, ethics review committees may accept a consent process in which a woman's individual consent to participate in research is supplemented by permission from a man if all of the following conditions are met:
>
> a. it would be impossible to conduct the research without obtaining such supplemental permission; and
>
> b. failure to conduct this research could deny its potential benefits to women in the host country; and
>
> c. measures to respect the woman's autonomy to consent to research are undertaken to the greatest extent possible.
>
> In no case may a competent adult woman be enrolled in research solely upon the consent of another person; her individual consent is always required. (NBAC, p. 45)

Here, as in other recommendations, NBAC leaves the ultimate decision on controversial matters to the discretion of the ethics review committee. The Nuffield Council's recommendation on this point is also somewhat flexible.

Unlike the NBAC and Nuffield recommendations, the CIOMS 2002 guidelines do not permit a departure from the need to obtain individual informed consent from the woman only. The commentary under Guideline 16 states:

> [O]nly the informed consent of the woman herself is required for her participation. In no case should the permission of a spouse or partner replace the requirement of individual informed consent. If women wish to consult with their husbands or partners or seek voluntarily to obtain their permission before deciding to enroll in research, that is not only ethically permissible but in some contexts highly desirable. A strict requirement of authorization of spouse or partner, however, violates the substantive principle of respect for persons.

In this, as in other areas of multinational research, what some people take to be ethical imperialism, others consider proper adherence to universally applicable ethical standards.

INDUCEMENTS. In avoiding exploitation when research is conducted in developing countries, there are two important considerations: whether inducements are offered for participation and whether such inducements are undue, that is, so attractive as to diminish voluntariness on the part of subjects who are invited to enroll. When medical treatment is an inevitable part or accompaniment of clinical research, this may provide a strong inducement to enrollment for people without access to medical care. The Nuffield Council report noted that this need not amount to exploitation. The report stated, however, that "when participants are ill and do not have alternative ways of receiving treatment, the possibility for exploitation is greater" (Nuffield Council, paragraph 6.29). The report urged that special care should be taken in determining the type and amount of additional healthcare that may be offered to participants as an inducement.

The NBAC report addresses this concern, distinguishing between, on the one hand, an inducement that may exist because participants receive beneficial clinical care and, on the other hand, the different circumstance that arises out of the "therapeutic misconception"—the belief that the purpose of a clinical trial is to benefit the individual patient rather than to gather data for the purpose of contributing to scientific knowledge. This misconception is widespread even among research subjects in industrialized countries and may be considerably greater in developing countries where people are unfamiliar with scientific research and view medical researchers as healers in whom they place great trust. The NBAC report recommends the following: "Researchers working in developing countries should indicate in their research protocols how they would minimize the likelihood that potential participants will believe mistakenly that the purpose of the research is solely to administer treatment rather than to contribute to scientific knowledge" (NBAC, p. 48).

Guideline 7 of the 2002 CIOMS document permits both monetary payments to subjects as an inducement to

participate in research and the provision of free medical services. CIOMS cautions that the monetary payments should not be so great or the medical services so extensive that they induce people to participate against their better judgment. Any payments or provision of medical services should be approved by an ethical review committee.

Crossing National Boundaries: Ethical Standards and Procedural Variations

Different views exist regarding how conflicts between Western cultural conceptions and norms and those of non-Western cultures should be resolved. This raises the question of how ethical standards should be arrived at and whose standards should be adopted. The 1993 CIOMS guidelines included in Guideline 15 a provision intended to prevent exploitation, titled "Obligations of sponsoring and host countries" in externally sponsored research. This guideline required scientific and ethical review of proposed research "according to the standards of the country of the sponsoring agency, and the ethical standards applied should be no less exacting than they would be in the case of research carried out in that country." This provision prompted the criticism that the guidelines reflected a "Western bias" because of "the assumption that the circumstances … in the developed world are the norm. Thus, the developed world is envisioned as more advanced, not only technologically but also morally" (Christakis and Levine, p. 1781).

This criticism is not shared by the many developing countries that by 2002 had enacted laws or adopted ethical guidelines governing research (NBAC). Most provisions in these regulations and guidelines replicate the CIOMS guidelines and the Declaration of Helsinki. All require that informed consent be obtained from each individual research subject, yet, as outlined in these regulations and guidelines, certain procedures for obtaining consent may diverge from the requirement for written, signed informed-consent forms that is included in the U.S. regulations.

Guidelines issued by the Medical Research Council of South Africa in 1993 include two rules regarding informed consent: (1) research subjects should know that they are taking part in research; and (2) research involving subjects should be carried out only with their consent. Yet these guidelines also say: "It can be proper for research involving less than minimal risk and which is easily comprehended to proceed on the basis of oral consent given after an oral description of what is involved." Similarly, the guidelines issued in 2000 by the Indian Council of Medical Research require that informed consent be obtained from each individual subject. But the guidelines also say that the nature and form of the consent may depend on a number of different factors.

The NBAC international report (2001) makes a useful distinction between substantive and procedural ethical requirement in research. Substantive ethical requirements are those embodied in the fundamental principles of bioethics stated in the *Belmont Report:* respect for persons, beneficence, and justice (National Commission). These substantive requirements are the ones that constitute ethical *standards,* and they should be applied universally. Examples are the requirement to obtain informed consent individually from each adult participant and the need to disclose complete information about the research maneuvers to be performed and the expected risks of those interventions. Procedural requirements, on the other hand, may vary according to cultural and other differences in multinational research. Examples include the requirement that informed-consent documents be signed, and the composition of ethical review committees and their rules of procedure. Attention to the distinction between substantive and procedural ethical requirements shows that the same ethical standards can be applied across national borders, while permitting differences in specific procedures in order to respect cultural variations.

Ethical codes and international guidelines are not likely to resolve all questions or conflicts that may arise in proposing, reviewing, and conducting multinational research. Any differences in judgments made by two or more committees that review a research protocol will have to be negotiated. On some points, codes and guidelines may be insufficiently specific. In other respects, provisions in codes or guidelines that address the same point may vary in minor or even major respects. An example of an unresolved conflict is the difference in existing guidelines and recommendations on the use of placebo controls and the level of care and treatment to be provided to research subjects during and after a clinical trial. As long as unresolved differences remain among parties committed to conducting such research according to the highest ethical standards, it is open to question whether ethical codes or guidelines should attempt to settle the conflict by imposing an unequivocal rule.

RESEARCH POLICY

• • •

I. GENERAL BACKGROUND

Since the 1960s the challenges of human research have received increasing attention and have caused a great deal of concern. In 1966 Professor Henry Beecher captured the attention and aroused the ire of the academic research community in the United States with the disclosure of what he considered unethical research practices at some premier research facilities. Beecher initiated a cycle of disclosure and reaction that has characterized the country's approach to ensuring the well-being of participants in research for more than four decades (Papworth).

Early Criticisms of Research Procedures

Beecher's article came at a time when public investment in research and development, particularly in biomedicine and technology, was growing at an unprecedented rate and the prospects for medicine and the future of biotechnology appeared limitless. The boom in private, corporate-sponsored clinical trials had not yet materialized but was not beyond people's imagination. The disturbing events at the Jewish Chronic Diseases Hospital in New York (Katz), in which a physician scientist injected live cancer cells into unwitting recipients, had been noted by Dr. James Shannon, at that time the director of the National Institutes of Health.

Prompted by that disclosure, in 1966 Shannon moved to require for the first time a mechanism for peer review of proposed scientific research by individuals that was concerned primarily with the well-being and safety of research subjects. However, much of the scientific community remained oblivious or insensitive to the apparent disregard for the safety and the rights of subjects in the research practices of that period. For the first time the scientific community began to realize that scientists could not be allowed on their own to determine how they would conduct experimental studies on other human beings.

The First Cycle of Regulations

Beecher's article and the monumental work subsequently published by Jay Katz just as the U.S. Public Health Service syphilis study in rural Alabama came to light (Tuskegee Syphilis Study Ad Hoc Advisory Panel) evoked strong emotional reactions among scientists, the public, and government regulators. That scientists working for the government could intentionally, for research purposes, allow poor African-American men to live with untreated syphilis for thirty years after the discovery of safe, effective treatment was appalling. Studies of the transmission of hepatitis in institutionalized children at the Willowbrook School (see Katz) underscored the need for special societal and legal protections of those incapable of protecting their own interests, including children. Many people called for new government regulations to protect the safety of research subjects, and the government responded. Within two years Congress passed the National Research Act of 1974, establishing the National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research and laying a course for regulatory action. The act required the U.S. Department of Health, Education and Welfare, the predecessor of the Department of Health and Human Services (DHHS), to codify its policy for the protection of human subjects in the form of regulations.

Almost immediately the perception of scientists and physicians who worked in human research was altered. Activities that once were held in the highest esteem, conducted by individuals who were trusted and respected as much as anyone in society, suddenly were cast in an unflattering light as potential sources of injury and harm from which individuals needed protection despite the potential benefit to humankind of those activities.

The National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research, which

conducted its deliberations over a period of several years before it was disbanded in the late 1970s, attempted to define a set of fundamental ethical principles underlying the responsible conduct of human research first for the general population and subsequently for special populations that were deemed to need special protections, notably children, prisoners, pregnant women, and fetuses. The Commission also recognized the special challenges posed by research involving individuals with mental illnesses and impaired decision-making capability, many of whom were institutionalized at the time of the its discussions.

The Commission did not state a preference for any particular philosophy or ideology, although traditional Western values of individual autonomy and justice were reflected prominently in its Belmont Report. The justification of human experimentation and the attendant exposure of individuals to uncertain risks for little or no direct benefit, but for the benefit of science and society is fundamentally utilitarian. At the time of the Commission's work, feminism, consumerism, and communitarian ethics were not yet part of mainstream thinking and thus were not reflected prominently in the debate. The lack of universality of ethical principles across cultures may limit the generalizability of the Commission's recommendations.

Today most parties to the human research process in the U.S. are at least aware of the commission's Belmont Report and are able to name the principles of respect for persons, beneficence, and justice discussed therein (National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research 1979), but this is a relatively recent development resulting primarily from the requirements imposed by the National Institutes of Health (NIH) that all individuals who participate in human research receive *training* in research ethics and regulatory requirements (National Institutes of Health). The fact that members of the research community would seek training in the responsible conduct of human research only as a condition of receiving funding from a federal agency is an unfortunate commentary on the way in which the research community establishes priorities. This pattern of behavior is what many critics and scholars of the human research process have come to expect and has not been lost on legislators.

The bioethicist Carol Levine once said that human research ethics were "born in scandal and reared in protectionism." That quip often is repeated because it resonates with current perceptions of reality. That statement captures the continuing cycle of disclosure and reaction that has characterized regulatory activities at the federal level, beginning with the amendment of the Public Health Service Act in 1974 and the subsequent promulgation of revised regulations by the DHHS for the protection of human subjects in 1981 (Code of Federal Regulations, Title 45, Part 46).

Although frequently cited as a framework for the ethical conduct of human research, those regulations do not constitute a set of ethical principles. The regulations are a set of rules established under the Public Health Service Act that attempt to operationalize the ethical principles set forth in the Belmont Report. They establish the minimum necessary requirements for implementing and maintaining a system for the protection of human subjects in research, including formal requirements for the establishment and operations of institutional review boards and the processes for obtaining and documenting informed consent, as recommended by the National Commission in 1978.

The DHHS expended considerable effort in crafting those regulations so that they would allow enough flexibility to encompass the wide variety of biomedical, behavioral, and social research it supported. The regulations reflected a well-intended effort to ensure that the ethical principles delineated in the Belmont Report would be applied in a uniform and appropriate manner by all recipients of federal research funds. Unfortunately, the DHHS was unable to establish a uniform set of regulations governing the oversight of all human research under its jurisdiction, most notably excluding privately sponsored clinical trials of new drugs, devices, and biologics performed under the regulatory authority of the U.S. Food and Drug Administration (FDA), which operates under a separate statutory authority, the Food Drug and Cosmetic Act of 1972. Those studies are covered by separate regulations (Code of Federal Regulations, Title 21, Parts 50 and 56) that are substantially similar to but more narrowly focused on clinical investigation than are the Public Health Service regulations. The lack of a uniform oversight process and standards has probably contributed to inconsistent and ineffective implementation and noncompliance with the regulations. This situation has been and is likely to continue to be a source of confusion and frustration to individual investigators, sponsors, institutions, and review boards that attempt in good faith to comply with the requirements of the often overlapping regulations and oversight processes that apply to their activities.

The Common Rule

The situation in the DHHS is compounded in other federal agencies. In 1991 sixteen agencies adopted 45 CFR 46 Subpart A, the main body of the DHHS's regulations, as signatories to the common Federal Policy on Protection of Human Subjects in Biomedical and Behavioral Research, informally known as the Common Rule. Many of those

agencies, including the National Bioethics Advisory Commission (2001c), had noted previously that it had taken a full decade for some of the federal agencies to sign on to those important regulations, yet not all federal agencies have done that, including some that engage in or support human research. Those that have adopted the Common Rule do not always agree fully on the interpretation and application of the regulations and some continue to impose specific additional regulatory and administrative requirements of their own. Thus, research entities and individuals have been left to reconcile the differences as best they can, often with little specific guidance, support, and cooperation from the various federal agencies involved in the support and oversight of human research activities.

Both investigators and institutions, including their review boards, have complained that the complexity and inflexibility of the regulations have made it difficult for them to comply. Although these are contributing factors, there are more likely explanations for the widespread noncompliance discovered when the former Office for Protection from Research Risks (OPRR) began a series of not-for-cause site visits to major research institutions across the country in the late 1990s. The 1998 reports from the Office of Inspector General offered insight into the nature of the problems in the system by noting that institutional review boards "review too much too quickly, with too little expertise" (p. 5). The report also notes the inadequacy of resources provided to support their work.

Problems in the Implementation of the Regulations

Apparently, while implementing the requirements of the regulations, institutions that received research support failed to invest adequately in robust programs for the protection of human subjects despite dramatic growth in their research budgets and their assurances to the government that they would do so.

At most of those institutions funds to support programs for human research protection were allocated to so-called indirect costs as an administrative activity. Within the indirect cost pool the allocation for administration and facilities costs had been capped by the federal Office for Management and Budget (OMB) at 26 percent of the direct costs of research after some institutions had been discovered using those funds for unallowable expenses. As healthcare reform began to affect the flow of clinical revenues that could be used to subsidize research activities, funding for programs for human research protection were marginalized further and in many cases minimized. The overriding goal seemed to be to achieve regulatory compliance at the lowest possible cost. Accordingly, many institutions relied heavily on volunteers (or "conscripts") and part-time personnel, many of whom had little or no formal training in research ethics or regulatory affairs, to fulfill those important responsibilities.

Although it is easy to lay the blame for this situation on the research institutions, that would be unfair. From the outset research institutions, which did not ask for those regulations, considered the required implementation of programs for human research protection an unfunded or at least underfunded federal mandate. The dramatic growth in corporate-sponsored clinical trials that rely heavily on those programs, which was only beginning when the regulations first were adopted, may warrant the consideration of a mechanism through which industry can offset the associated costs at arm's length from the review and approval process as part of a comprehensive funding scheme for human research oversight.

However, without knowledge of the actual costs associated with implementing and maintaining effective programs for the protection of human research subjects, the allocation of appropriate funding for those programs is unlikely if not impossible. Few credible attempts have been made to measure those variables since the 1970s. The little information that is available regarding those costs reflects at best an estimate of what was being expended to support programs of questionable efficacy. Because there is no well-established approach to measuring efficacy, it is unlikely that a rational formula for supporting those programs will emerge in the near future despite the pressing need to develop one.

Public and Private Reports

The current state of dissatisfaction and anxiety that affects almost everyone in the human research enterprise is not a new phenomenon. Almost immediately after the adoption of the DHHS's regulations for the protection of human subjects in 1981, the first of what was to become a long series of reports on the challenges of human studies was issued in 1982 by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research. In the same year a report was issued by the Council for International Organizations of Medical Sciences (CIOMS). That report was followed in 1993 by the report of the President's Advisory Committee on Human Radiation Experiments, several reports from the National Bioethics Advisory Commission (1998, 1999, 2001a, b, and c), the General Accounting Office (1996, 2000, 2001), the Office of Inspector General of the DHHS (1998–2001), the recently disbanded National Human Research Protections

Advisory Committee (2001), and the Institute of Medicine (1994, 2002). Many private organizations have issued reports or guidelines, including the Association of American Universities (2001), the Association of American Medical Colleges (2001), the American Association of University Professors (2001), the American Academy of Pharmaceutical Physicians (2001), the American Medical Association (2000), the American Society for Gene Therapy (2000), the American Society of Clinical Oncology (2002), and the Association of Clinical Research Professionals (2001).

This array of reports covers ethics, regulatory affairs, financial relationships, conflicts of interests, and the responsible conduct of research. Generally, all the reports recognize and emphasize the dependence of human research on the willingness of individuals to participate voluntarily as subjects, acknowledging the key role that trust plays in the relationship between investigators and subjects. They acknowledge the fact that past and present events have undermined that sense of trust and that steps must be taken to rebuild and maintain it. They all offer recommendations, most of which are consistent or at least compatible, yet most observers agree that little progress has been made since the 1970s in implementing those recommendations apart from the adoption of the regulations and the implementation of institutional review boards and informed consent as the "twin pillars" of protection for human subjects. Some people think that those recommendations afford more of an impediment to research than effective protections for human subjects. Many are perplexed that it seems so hard for the scientific community and the government to do what is morally and legally appropriate when doing so is clearly in the interest of science and society.

The Ethical Issues in Human Research

There is no simple solution to this problem, which involves a complex interplay of ethics, economics, and expediency in a system affected by people, politics, and profits. The most fundamental issue is the moral dilemma inherent in human research: In all cases of human experimentation individuals are subject to risks for the benefit of science and society. Human research is an endeavor that exploits some individuals for a greater good, but that exploitation is considered acceptable and even justifiable as long as participation is voluntary and informed and the research is conducted within the well-established ethical framework of respect for persons, beneficence, and justice.

Human research entails a dynamic tension between the interests of those who do research and the interests of those on whom research is done. Can science and society justifiably place their own interests above the interests, rights, and well-being of research subjects? More correctly, should the interests of science and society prevail over those of individual subjects? Even if one identified compelling circumstances in which it would be ethically permissible to do that, those cases probably would be rare. However, it is tempting and easy to allow the pursuit of knowledge, the lure of fame and fortune, advantage in the marketplace, and the chance of academic promotion to color one's judgment and influence one's conduct.

The events the past three decades in which subjects have been harmed and misconduct revealed have shown that not all scientists, institutions, and sponsors are immune to temptation. Breaches of responsible conduct may go unnoticed and unreported, but when they are serious and are discovered and criticized, they evoke a host of reactions, including sorrow, anger, indignation, and defensiveness. The consequences of those breaches are far-reaching and long-lasting, leaving no party untouched. The corrective actions that follow may provide long-term benefits but are painful and costly in both human and financial terms.

The Deaths of Jesse Gelsinger and Ellen Roche

No two cases more aptly illustrate these points than the deaths of Jesse Gelsinger at the University of Pennsylvania in 1999 and Ellen Roche at Johns Hopkins University Medical Center in 2001. Gelsinger, suffering from a genetic metabloic disorder, died in a gene-transfer study just days after receiving an infusion of a corrected gene attached to a virus intended to introduce the new gene into his liver cells. Roche was a normal healthy young woman participating in a study of the mechanisms of airway responsiveness, a study that required inhalation of a chemical that blocked certain pathways of nerve transmission. The second case has been described (Steinbrook) and analyzed (Kreiger and De Pasquale) extensively. The death of Jesse Gelsinger was a critical event because it catalyzed a coalescence of will in the government and public to face the problems of human research directly, particularly the potential impact of financial relationships and conflicts of interests on the well-being of research participants (Shalala).

The Roche case eventually may have an even more far-reaching impact. It is particularly relevant because it involves a failure to protect research participants adequately not only at the level of an individual study but also at the level of an institutional system as judged not only by government

regulators but also by an external evaluating committee of peers selected by the institution. In this case attention was focused not just on an individual's untimely death, the failings of a single investigator, the shortcomings of an institutional review board, and a deficient institutional system for the protection of human subjects: The focus ultimately became the culture of the institution and more generally the culture of science as it relates to the responsible conduct of human research. The message here is the need to move beyond a culture of compliance to a culture of conscience in science (Koski, 2003a).

Resistance to Change

Since the Renaissance the pursuit of knowledge through science has been regarded as a noble profession. Recognizing the importance of the pursuit of truth in science, one might expect scientists to be intolerant of those among them who fail to respect truth or undermine the integrity of science. However, in this regard perception and reality sometimes diverge. Statements of ethical principles and codes of conduct have done much to guide the scientific community, along with the medical profession, in the pursuit of truth, but some members of those professions betray the truth. When a profession is willing to tolerate rather than hold accountable those whose behavior violates the principles and traditions of the profession, the credibility of the principles on which the profession is established are undermined. *Pseudoaccountability,* a term coined by a Jerome Kasirer, results in a profession that traverses the road of good intentions but does not arrive at its destination.

Accounts of Beecher's efforts to publish in the medical literature his concerns about the ethics of research studies conducted in the early 1960s suggest that that was not an easy task. Initial rejections finally gave way to an agreement with the editor of the *New England Journal of Medicine* to publish the paper only after Beecher agreed to limit the number of cases to a small fraction of those about which he was concerned and to withhold identification of the investigators and their institutions. As a respected physician, scientist, and professor at Harvard Medical School Beecher demonstrated courage and integrity in attempting to bring those issues before his peers, but many in the scientific community did not receive his paper enthusiastically.

One can only wonder how human research might be different today if the scientific community at that time had responded with a concerted effort to achieve a higher standard of conduct, promoted integrity with an expectation that all who engage in research involving other human beings would act in accordance with the highest ethical standards, and shown a willingness to hold accountable those who did not live up to those standards. If the scientific community rather than the government had taken action to ensure the well-being of research participants not because it was required to do so by regulations but out of concern for the integrity of science, the continuing pursuit of knowledge, and an earnest desire and commitment to prevent harm to fellow human beings while honoring the rights of others, there might not be regulations on the books requiring them to do so.

Laws and regulations are one way in which a society attempts to influence the behaviors of its citizens. Regulations may be used to prescribe certain actions and prohibit others. However, regulations can be a double-edged sword.

In a 2003 article published in the *Emory Law Journal* Robert Gatter discusses the normative and expressive functions of the law in the context of regulations that address continuing concerns about financial conflicts of interest in human research. Many laws are not directed toward criminal activity, but seek to establish a recognized norm of conduct, and to do so by expressing the normative message through regulations and guidance. The regulations for the protection of human subjects in research are analogous to those involving financial conflict in that they are intended to establish a norm of conduct for investigators and institutions through the expression and application of the ethical principles delineated in the Belmont Report. Laws, however, do not always achieve their desired goals, particularly if the regulated community is resistant to acceptance of the normative standard and the implementation or enforcement provisions make it unlikely that noncompliance will be discovered or punished. As Gatter points out, regulations can evoke "juridification," by which those who are subject to regulations try to find ways to avoid or circumvent them rather than embrace them. Although scientists and physicians may be no less hostile to regulation of their activities than are others, one might expect them to more readily accept such regulation in light of their codes of professional conduct that already express values compatible with those embodied in the regulations.

Since the 1970s researchers have worked within a regulatory framework in which the regulated parties too frequently have viewed the requirements of the regulations as unnecessarily complicated, costly, and onerous administrative impediments to their research activities. That viewpoint, which seems to contrast markedly with the values that society traditionally associates with scientists and the pursuit of knowledge, may reflect changes in the culture of science

that occurred in the second half of twentieth century or may indicate significant juridification, to use Gatter's terminology, of the human research community in response to the imposition of regulations by the government in response to a limited number of high-profile breaches of responsible conduct.

There is no question that the American system for the responsible conduct of human research and the protection of human subjects is undergoing dramatic change. It may be far more difficult to effect cultural change that requires behavioral changes consistent with acceptance of fundamental values than it is to overcome and reverse the juridification that has occurred in response to failures in the normative and expressive functions of the applicable law and regulations.

New Initiatives

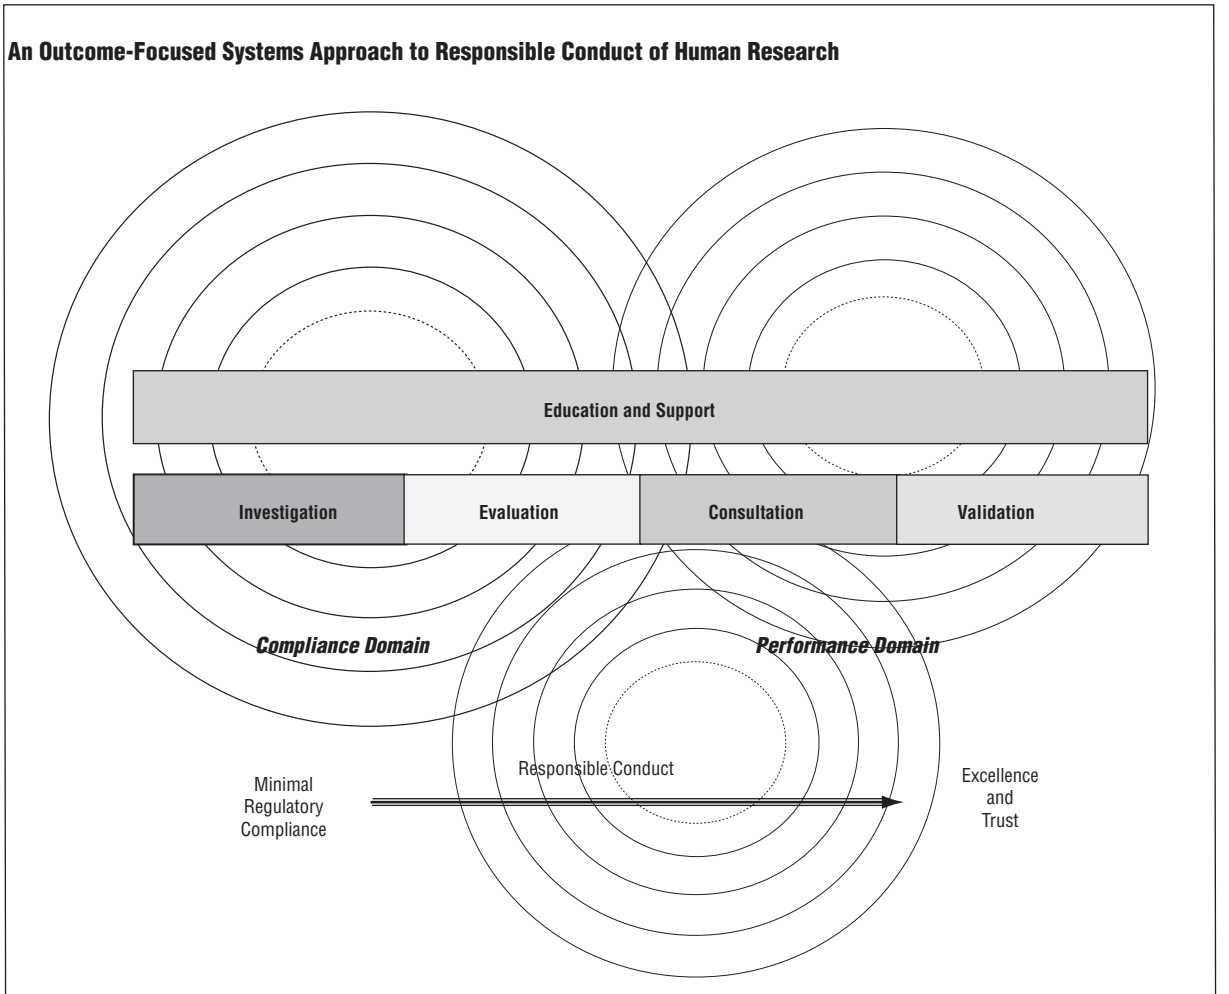
The death of Jesse Gelsinger launched a new cycle of reform in human research and the protection of the human subjects. Although the initial calls were for more stringent regulations and penalties, the DHHS, with strong leadership from the former secretary, Donna Shalala, has taken a different course. In June 2000 the department established a new Office for Human Research Protections (OHRP), replacing the Office for Protection for Research Risks. The new office was placed within the office of the secretary to give it the visibility and autonomy necessary to lead a major remodeling effort to improve the performance and effectiveness of the national system for the protection of human subjects in research. The strategy and approach taken by the DHHS were outlined in September 2000 in testimony delivered before the House Oversight Committee on Veterans Affairs (Koski, 2000).

Those initiatives mark a shift from a reactive, compliance-focused approach to the oversight of human research toward a proactive model focused on the prevention of harm. Recognizing the widely varying and sometimes idiosyncratic behavior of local institutional review boards, the new approach emphasizes education and support as the umbrella under which activities aimed at improving performance are conducted (Figure 1). The goal of current efforts is to move from an approach focused on achieving regulatory compliance to one that attempts to achieve excellence and trust. In this model activities to ensure the well-being of research participants are conducted in two primary domains: the compliance domain and the performance domain. The compliance domain includes both for-cause investigations and not-for-cause evaluations. Both types of compliance oversight activities are intended to ensure accountability and fall generally into the class of quality control and quality assurance processes. In this model the identification of deficiencies should be focused on system failures in an attempt to strengthen processes rather than use punishment or sanctions except in cases of gross negligence or willful disregard for regulatory requirements, thus avoiding the counterproductive impact of a reactive, juridifying approach to regulatory enforcement. Traditionally, these activities have been conducted primarily by government oversight agencies or parties acting on their behalf. Activities within the performance domain generally are classified as quality improvement activities, including continuous quality improvement, largely in the form of consultation and feedback on actual performance. Objective validation processes such as accreditation of institutions or programs and professional certification of individuals provide empirical evidence of proficiency and recognition of excellence. Education and support are overarching activities that work to improve the effectiveness and efficiency of the system. Realization of positive results and appropriate validation of excellence provide incentives to shift resources toward the performance domain. Ultimately, prevention of harm to human participants through responsible conduct builds trust and promotes public confidence in the research process, enhancing voluntary participation in research. Those activities are focused on improving, measuring, and validating the performance of the system in its entirety, utilizing proven continuous quality improvement methods to achieve those goals (Institute of Medicine, 2002).

In the past the government generally waited until it received a complaint from an outside source or a report from one of the institutions under its regulatory authority to initiate an investigation into the circumstances of an event. Those for-cause investigations, many of which were conducted through correspondence alone, were the mainstay of the OPRR's oversight activities. The bulk of its resources were dedicated to review, negotiation, and approval of assurances, documents submitted by entities receiving federal support for research to satisfy regulatory requirements that such a document be filed as a condition of receiving support. Too often those were empty assurances, paper commitments insufficiently backed by substantive actions and resources.

The creation of the OHRP added significant new resources to the office and a reorganization plan that redirected those resources toward enhanced educational programs and the development and implementation of a new quality improvement program through which the office provides consultation and support for institutions that seek to improve their programs for human research protection.

FIGURE 1



SOURCE: Author.

To a large extent that redistribution of resources was made possible by a dramatic simplification of the assurance process. Rather than continue the long-standing practice of negotiating and processing multiple types of assurances and interagency agreements, the office adopted a single standardized federal assurance that could be utilized by all participating federal agencies and was consistent with the original intent of the Common Rule. Significant progress is being made toward establishing a more effective system for the protection of human subjects in research (Koski, 2003b) despite the fact that the regulations adopted since the 1970s remain essentially unchanged. In large measure this progress is a direct result of a renewed willingness in the research community to adopt a more proactive, responsible approach toward the conduct of its activities. Whether this progress continues will be a principal determinant of the nature and scope of future regulatory actions in the area of human research.

II. RISK AND VULNERABLE GROUPS

There are two groups of people considered to be vulnerable research subjects. First, people lacking capacity to give informed consent are vulnerable because they depend on others to protect them, such as young children and adults impaired by trauma, illness, retardation, or dementia. Second, people who are likely to be coerced or manipulated are vulnerable because fear, ignorance, or pressure may account for their agreement to participate. Institutionalized persons, prisoners, members of the military, students, hospital staff, laboratory assistants, and pharmaceutical personnel are frequently cited as vulnerable to coercion or manipulation (U.S. Public Health Service; CIOMS). In addition, the indigent, uninsured, or desperate may be unduly tempted into study participation that they would otherwise reject by financial remuneration. Insofar as participation of vulnerable subjects is problematic, enrolling them in research protocols often requires special justification and safeguards (CIOMS; "Protection of Human Subjects," 45 C.F.R. 46).

Dilemmas of Inclusion vs. Exclusion

It is important to include all segments of society in research, including vulnerable people, so that everyone benefits from research studies. Yet dangers exist in both too many and in too few protections. When too few protections exist, vulnerable people may be exploited. When too many protections exist, however, it is hard to conduct research with vulnerable populations; consequently there is little information about how to diagnose, treat or understand their conditions. Without good research information, people from these groups become neglected. Doctors must then choose between using only modalities that have been tested on the group in question and risk undertreating these subjects, or using untested interventions and risk adverse effects. There are several ways to address this apparent dilemma, and many guidelines adopt some combination of them.

First, all research guidelines require studies to have a strict review by boards known by various names: institutional review boards (IRBs), research ethics committees (RECs), or ethical review committees (ERCs). These boards have discretion to disapprove or approve studies or to adopt suitable additional protections for studies with all or some vulnerable subjects. These committees should be sensitive to various forms of vulnerability (cognitive, environmental, institutional, deferential, medical, economic and social) and respond with appropriate and situationally-appropriate restrictions. The National Bioethics Advisory Commission (NBAC), which carefully distinguishes these different forms of vulnerability, relies upon review board discretion to protect vulnerable subjects because it is flexible (NBAC). But this option has been undermined by high-profile revelations of poor oversight or compliance by some of these review boards. Moreover, confidence in these boards varies according to people's perceptions of whether they represent the interests of vulnerable populations or are seen as favoring the research enterprise or commercial interests.

Second, others favor another approach with special regulatory requirements that must be met before enrolling some or all vulnerable subjects. Such regulations generally exist for infants, children, pregnant women, and prisoners. But critics argue that expanding regulations for other groups could become unwieldy since many, perhaps even most, people may be perceived as vulnerable in some situations (NBAC). If special regulations existed for all or most groups of people who might be vulnerable, it could become unreasonably difficult to approve or conduct research. Moreover, some competent persons, such as pregnant women, object to special restrictions placed upon their freedom of choice.

Third, some guidelines limit risk when subjects are deemed vulnerable. The Food and Drug Administration (FDA, 1997, 4.8.14) stipulates that, when people cannot give consent for trials that do not directly benefit them, risks must be low and other considerations must be fulfilled (i.e., the study cannot be conducted with consenting subjects,

consent is obtained from subjects' legal representatives, IRB approval is gained, the negative impact on the subjects is minimized and low, and the study is not illegal). The Council for International Organizations of Medical Science (CIOMS) limits the risk of harm to vulnerable subjects to a "minimal risk," unless the study offers direct benefit to subjects; in some cases a minor increase over minimal risk is permitted in order to study vulnerable people's disorders or conditions. Critics argue that this policy unreasonably restricts people's choices and opportunities, especially when the vulnerable people are competent adults. As noted, NBAC objects to this proliferation of regulations and maintains that once review boards put safeguards in place, vulnerable subjects should be enrolled in studies on the same basis as other subjects.

While these research approaches suggest some similar ways to protect vulnerable people, the moral and policy issues differ greatly for those who are not legally competent and those who are. NBAC describes these two groups' vulnerability as "intrinsic" and "situational," respectively, and CIOMS refers to them as "absolute" and "relative." Yet this language is misleading. First, many children and legally incompetent adults have the capacity to participate in some tasks but not others, so they are neither "absolutely" nor "intrinsically" incompetent; if they have the capacity to assent, which refers to their permission and is a notion different from legal consent, it generally should be sought for research participation. Second, it is misleading to call people either absolutely or intrinsically incapacitated when, for many members of these groups, capacity fluctuates or it grows, as it does for most for children. Third, legally competent persons may view additional protections and restrictions as unjustified paternalism that places obstacles in their path to gain participation in research on the same basis as others; they deny that their situation or relations make them vulnerable. Because the issues are so different for the two groups, their policy options are discussed separately.

Competent Adults Vulnerable to Coercion and Manipulation

There has been some consensus, at least in theory, about how to protect the rights and welfare of competent adults who are vulnerable to coercion or manipulation. First, since the right to consent is grounded in its utility, fairness, and the right of self-determination, studies should be reviewed to ensure that consent is voluntary and that the risks of research are not unfairly distributed to vulnerable groups (CIOMS; "Protection of Human Subjects," 45 C.F.R. 46). This evaluation should be conducted by IRBs, RECs, or ERCs. Review boards bear a heavy responsibility in recognizing when competent persons may be vulnerable and need additional protection as research subjects. The views of reviewers, however, may differ from those of the potential subjects. One remedy is to assemble a group of prospective subjects and conduct a group consultation to learn their views.

Second, most review boards, investigators, and bioethicists agree that the greater the vulnerability and risk to competent adults, the more specific protections should be adopted; where it is difficult to supervise the voluntariness of vulnerable people's consent, it may be necessary to adopt special regulatory protection. For example, because prisoners live in settings that are inherently coercive and because of past abuses, most guidelines provide additional protections for this population (CIOMS; U.S. "Protection of Human Subjects," 45 C.F.R. 46 Subpart C). In general, research guidelines limit the risk of harm to prisoners to a minimal risk unless the study offers direct benefit to the prisoner subjects (individually or as a class) and requires demonstrated utility, special safeguards, experts' approval, and authorization from the U.S. Secretary of Health and Human Services. In some cases a minor increase over minimal risk is permitted to study their disorders or conditions. These restrictions make biomedical research with prisoners difficult to justify, because there are no diseases unique to them as a class. Given their extraordinary living conditions, however, social or behavioral studies might gain approval.

A third area of general agreement about protecting vulnerable competent adults from coercion or manipulation concerns the importance of avoiding interference with people's self-determination or unjustified paternalism. There is less consensus, however, on how to do this. Competent people may resent paternalistic restrictions of their liberties because someone views them as potentially vulnerable. People may deeply object to being denied options open to others, such as innovative or subsidized care for their illnesses in research programs. Impoverished people, including students, may willingly volunteer for risky studies that pay well. They may argue that if firefighters or fighter pilots receive high pay for taking risks, civilians, too, should have the choice to obtain high pay for taking research risks. They may object to the views of some that payment, other than expenses and tokens, constitutes undue influence and should be prohibited (CIOMS).

DISPUTES ABOUT INCLUDING WOMEN. Perhaps the greatest sustained debate has been over limiting the research options for women of childbearing years or women who are pregnant. One dilemma, as noted, is that if some group is excluded from studies, then it is hard to provide good

treatment options for them. Pregnant women have diseases and conditions that need study for their own sakes as well as for the sake of their fetuses. At issue is who makes the decision, the woman herself or others.

In many but not all guidelines, women of childbearing years and especially pregnant woman are listed as "vulnerable" and sometimes denied opportunities open to others. In its instructions to the IRB, for example, the U.S. federal regulations state that: "When some or all of the subjects are likely to be vulnerable to coercion or undue influence such as children, prisoners, pregnant women, mentally disabled persons, or economically or educationally disadvantaged persons, additional safeguards have been included in the study to protect the rights and welfare of these subjects" (U.S. "Protection of Human Subjects," 45 CFR 46.111[b]). The U.S. Public Health Service's "Consultation on International Collaborative Human Immunodeficiency Virus" also includes pregnant and nursing women on their list of possibly vulnerable groups. The goal of these guidelines is to protect the fetuses, newborns, and pregnant and nursing women from research risk. Such policies are controversial since there is no uniform agreement about how to rank duties to protect the women and her fetus and duties to also honor women's rights of self-determination.

Many regulations view pregnant women and those of childbearing years as "vulnerable" and favor more regulatory protections, even if they restrict women's options. These restrictions include limiting the array of studies in which they can participate to those designed to benefit them or their fetus, or those having low risk and requiring their husbands' consent as well as their own. In the United States, for example, research with pregnant women designed to benefit the fetus requires the consent of the father (unless he is unavailable, incompetent, or incapacitated, or the pregnancy resulted from rape or incest). (U.S. CFR 45 46.203 [e]).

Pregnant women's illnesses need to be studied, and it is not in their interests if regulations make this difficult. For example, without research pregnant women are denied the benefits of learning about how drugs affect them as a group. Second, participation in research may be a woman's only or best means to gain access to subsidized care or to investigational drugs or therapy, so restrictions deny them options or direct benefit that are available to others. It may be an unfair denial of benefits to rule that women cannot be considered as subjects. Third, it seems unfair that men of reproductive age are not similarly excluded from drug studies; yet many drugs cause changes in male germ cells that are mutagenic.

A consensus is developing that where there is a conflict between the health needs of the mother and that of the fetus, the mother should be at liberty to resolve the conflict herself (CIOMS; U.S. 45 C.F.R. 46 Subpart B). Restrictions to protect the fetus sometimes rest upon poorly founded assumptions about what might cause harm to the fetus. Informed consent from any woman, however, presupposes that she is informed of the likely harms or benefits, including those that effect her fetus. Pregnancy and nursing make women neither incapable of consent, like children, nor vulnerable to coercion or manipulation, like students and prisoners.

CIOMS does not automatically include women as vulnerable subjects, separating guidelines for vulnerable groups and those for women. It states that vulnerable subjects are those "incapable of protecting their own interests … they may have insufficient power, intelligence, education, resources, or other needed attributes to protect their own interests" (CIOMS, Guideline 13). For vulnerable persons or groups, CIOMS limits the risk of harm to a minimal risk unless the study offers direct benefit to them; in some cases a minor increase over minimal risk is permitted to study vulnerable people's disorders or conditions. In Guideline 16, CIOMS states, "Investigators, sponsors or ethical review committees should not exclude women of reproductive age from biomedical research. The potential for becoming pregnant during a study should not, in itself, be used as a reason for precluding or limiting participation." In CIOMS's commentary on these guidelines, the committee notes that the general presumption should be to include women and that past practices of excluding them is unjust, but that "it must be acknowledged that in some parts of the world women are vulnerable to neglect or harm because of …social conditioning to submit to authority…." CIOMS also takes a stand on seeking consent from husbands: "In research involving women of reproductive age, whether pregnant or non-pregnant, only the informed consent of the woman herself is required for her participation. In no case should the permission of a spouse or partner replace the requirement of individual informed consent … A strict requirement of authorization of spouse or partner, however, violates the substantive principle of respect for persons." Thus, CIOMS favors women's rights of self-determination and their needs to have drugs and other interventions tested on them. NBAC agrees, and even goes beyond CIOMS, arguing that once review boards put safeguards in place, women and other potentially vulnerable subjects should be enrolled in studies on the same basis as other subjects.

Thus, when vulnerable people are competent, disagreements abound concerning what specific restrictions on their choices are fair, promote their well-being, and respect their self-determination. Too little protection risks their exploitation; too much protection risks unjustified paternalism.

Before limiting the liberty of competent people, reviewers and researchers should use community consultation with members of the potentially vulnerable group to consider if they want such protection, if the probability and magnitude of harm warrants constraints, and if the restrictions are the least invasive to secure their well-being.

People Lacking Capacity to Give Consent

As with the competent people, the ethical basis for research policy with persons lacking capacity to give informed consent concerns promoting their self-determination, fair treatment, and well-being. There are four important policy options that were adopted in the twentieth century, and each offers different approaches to ranking what is fair, most protective of incompetent people's well-being, and most respectful of whatever self-determination they have or may develop. These four policies represent different regulative ideals because they rank these primary values differently, and because they offer different authority principles (stating who decides) and guidance principles (substantive directions about how decisions should be made). The remaining discussion will focus on these options.

THE "SURROGATE" OR "LIBERTARIAN" SOLUTION. The oldest policy adopts no special regulatory protection for people lacking the capacity to consent, and allows the same sort of research with them as with other subjects, if their legal guardians consent. Since guardians have the authority to choose the mode of care, religion, and schooling for their dependents, then, according to this view, guardians should determine whether their charges participate in research.

Critics argue that guardians have no authority to volunteer another for studies that are hazardous or that do not hold out benefit for them (Ramsey; Levine; Kopelman, 1989). Guardians have authority insofar as they promote the well-being of those under their care and prevent, remove, or minimize harms to them. They have discretion about how to do this. In nonresearch settings guardians can allow their children or wards to participate in dangerous activities, such as football, presumably because in their judgement there are also direct benefits to them. This differs from volunteering them for risky research, however, when there are no direct benefits to compensate for the risks and where others benefit from that information. Volunteering to put oneself in harm's way to gain knowledge may be morally admirable. But volunteering to put another in harm's way is not admirable, and violates the guardian's protective role. Critics argue that allowing guardians to enroll their charges in potentially harmful experiments wrongs the charges, sets a dangerous precedent, and has a brutalizing effect upon society.

THE "NO CONSENT-NO RESEARCH" OR "NUREMBERG" SOLUTION. Another policy forbids enrolling people as research subjects without their consent. This view is maintained in the first international research statement, the Nuremberg Code. Its first principle states, "The voluntary consent of the human subject is absolutely essential." It goes on to define consent—in a way that has become fairly standard—as requiring legal capacity, free choice, and understanding of "the nature, duration, and purpose of the experiment; the methods and means by which it is conducted; all inconveniences and hazards reasonably to be expected; any effects upon his health or person which may possibly come from participation in the research" (Germany Military Tribunals).

Composed at the end of World War II, the Nuremberg Code stands as an international response to the horrible, involuntary medical studies done by Nazi physicians in which many unwilling subjects and prisoners were killed or permanently maimed (Proctor). It is uncertain if it was intended as a comprehensive code for research (McCormick). If it is taken as a general policy, however, subjects who lack capacity to give informed consent cannot serve as research subjects.

Critics argue that this policy would cripple evidenced-based medicine for people who cannot give consent, turning them into "therapeutic orphans" (Shirkey; McCormick; Levine). Children, retarded persons, and those incapacitated by mental illness have unique medical problems; thus, studies with normal adult volunteers may be inapplicable. Normal adults cannot serve as subjects in studies comparing treatments for schizophrenia, bipolar illness, or lung disease in premature infants. To test the safety and efficacy of many standard, innovative, or investigational treatments for distinctive groups, and give them due consideration, some members of the groups have to be subjects in controlled testing.

THE "NO CONSENT-ONLY THERAPY" SOLUTION. A third policy permits persons who lack the capacity to give informed consent to be enrolled as research subjects if the studies are therapeutic and offer at least as much direct benefit to subjects as other alternatives, and if guardians consent. This view was represented in the next major international code for research to follow the Nuremberg Code, the World Medical Assembly's Declaration of Helsinki, written in 1964 and revised in 1975, 1983, and 1989. (The Declaration's 2000 revision abandoned the "no consent-only therapy" stance after many years.)

This policy option distinguishes *clinical* or *therapeutic research* (studies seeking generalizable knowledge and intending to provide medically acceptable therapy for the individual) from *nontherapeutic biomedical research* (studies seeking generalizable knowledge and not intended as therapy to benefit the individual directly). Therapeutic studies attempt to benefit the person through prevention, diagnosis, or treatment of disease. Thus, drawing the line at therapeutic research for people who lack capacity to give informed consent seems to defenders to be a good solution to the problem of when to permit incompetent people to serve as subjects (Ramsey).

One difficulty with this third option concerns the difficulty of classifying studies as therapeutic or nontherapeutic in a way that is not arbitrary or misleading. Therapeutic studies often have features that are not a part of routine therapy, such as extra tests, inflexible research protocols, and additional hospitalizations, or visits to the doctor. If these nontherapeutic features increase costs, risks, or inconvenience to the patient, classifying the study as therapeutic may be arbitrary and misleading. Moreover, this classification can be misleading if people assume therapeutic studies are always safe or beneficial. They may have a "therapeutic misconception" based on such labels. Labeling something as "therapeutic" may mask risk, inconvenience, costs, or nonbeneficial features, creating an inappropriate bias for participation.

A second problem is that it seems unreasonable to prohibit important low-risk research especially when it offers nontherapeutic direct benefits to subjects or allows progress for these groups. Subjects would be neither harmed nor wronged if they gained from the experience, liked participating, and were not at risk of harm. Children may enjoy and learn from participating in nontherapeutic studies in which they are asked to do such things as stack similar blocks or identify animals from sounds they make. Yet these nontherapeutic studies could be important for establishing criteria of normal vision and hearing. Adults who are not legally competent may also enjoy and learn from serving as research subjects in nontherapeutic studies. For example, they might like an outing to a research facility, meeting the investigators or learning about the study. In addition, they can benefit indirectly from nontherapeutic studies.

Because this option rules out even low-risk studies it seriously impedes medical progress for these groups including the formation of standards about children's typical growth and development. Such standards presuppose carefully tested criteria distinguishing people with developmental delays or impairments from those with normal growth and development. Establishing such norms requires collecting and analyzing data on the growth and development of large numbers of healthy children. Such safe but important research, however, is forbidden under this policy because it is not therapeutic. Even though these studies establishing norms for growth and development are safe, they are nontherapeutic because they are designed not to benefit the subjects directly but to gain generalizable knowledge. If children stack blocks at play, it is not research; if people test views about how they stack blocks, it is research but may be no more burdensome to the child. Thus, when nontherapeutic studies are needed to promote the well-being of incompetent people as a *group,* and involve little or no risk of harm or inconvenience to them, it is hard to understand how critics can make the case that the subjects are always harmed or wronged by participation.

This option also prohibits epidemiological studies and the investigation of the natural history of disease when there are no therapies. These are among the most important methods for collecting information, so this policy is flawed.

The initial justification for excluding persons who lack the capacity to give informed consent from nontherapeutic research was to honor their rights and protect their welfare. Safe, nontherapeutic research, however, seems neither unfair nor a violation of the rights or welfare of people who lack the capacity to give consent. Failing to do safe but important studies might be unfair and violate their rights and welfare, since it fails to consider all their needs. The Declaration of Helsinki (2000) now permits nontherapeutic studies with guardians' consent and if other subjects cannot be used; no upper level of risk is given unlike the next option.

THE "RISK-BENEFIT" OR "U.S. FEDERAL REGULATION" SOLUTION. A fourth approach allows research on procedures or interventions with incompetent persons when the research holds out direct benefit to them or does not place them at unwarranted risk of harm, discomfort, or inconvenience. Defenders of the fourth option should clarify what risk is unwarranted. This policy uses risk assessment to set priorities between the social utility of encouraging studies and the protection of people's rights of self-determination and well-being. To try to set priorities between the social utility of such studies and respect and protection of incompetent people, this option stipulates that the greater the risk, the more rigorous and elaborate the procedural protection and consent requirements. The U.S. federal regulations (U.S. "Protection of Human Subjects," 45 CFR 46 Subpart D) reflect this fourth policy option in the codes for research with children adopted and those proposed (in 1978 but never adopted) for institutionalized people with mental impairment or retardation. The Council for International Organizations of Medical Science has adopted a similar

standard (CIOMS). Under this fourth option, therapy is one of the intended direct benefits that should be taken into account in a risk analysis. Whenever possible, the incompetent persons should give their assent to participate. Assent means affirmative agreement, not just lack of objection.

There are advantages to focusing directly upon the likely benefits and harms of procedures or interventions being studied. First, there are benefits other than therapy that may play a role in deciding if it is reasonable to serve as a subject. A safe, nontherapeutic study that increases a child's understanding of a sibling's chronic illness, for example, might have important lessons about empathy for the child. Those giving consent need to know, of course, the nature and magnitude of the intended benefits (such as education or therapy) or risks of harms associated with the study. Second, calling something "therapeutic" can create the unwarranted idea that participating in the study is in a person's best interest. Risk assessment can reveal hazards, inconveniences, and costs in therapeutic studies that some reasonable people would prefer to avoid.

Using a likely-harms-to-benefits calculation, the U.S. regulations specify four categories of research for children (U.S. "Protection of Human Subjects," 45 CFR 46 Subpart D). IRBs can approve research that they judge to be in the first three categories, and all three generally require the child's assent, if possible, parental approval, and other safeguards such as minimizing risks of harm, having competent investigators and suitable background studies. The first category permits studies with no greater than a minimal risk; the second allows studies with higher risks as long as they are likely to have at least as much direct benefit to subjects as other available therapies; the third category allows research involving a minor increase over minimal risk and no likelihood of direct benefit to each individual subjects, if it is likely to yield vitally important knowledge about the children's disorder or condition. U.S. policy is unique in allowing studies having more than a minor increase over a minimal risk and that do not hold out benefit for the subjects but approval is needed from the federal government. As in the case of the guidelines for prisoners cited earlier, procedural safeguards increase with risk.

There are no final guidelines in the United States for research on those institutionalized as mentally infirm, but there is a proposal about how to treat those institutionalized with impairments like mental illness, senility, psychosis, mental retardation, or emotional disturbances (U.S. Department of Health, Education and Welfare, 1978a, 1978b). It is similar to that proposed for children, except that it allows incompetent adults more authority to decline to participate in studies. The consent or assent of those institutionalized with such impairments must be sought. Those who refuse may not be enrolled in any study that does not hold out direct benefit, without authorization from the courts. CIOMS has a policy that permits enrolling incompetent adults if the study has no more than a minimal risk, others cannot be subjects, the consent of the person or the permission of a responsible family member is obtained, and the research goal is to study the person's disorder or to benefit them.

Unfortunately, this fourth, popular policy option has difficulties. Key terms are either undefined or have vague definitions, permitting broad interpretations about what risks of harm are warranted and what constitutes a benefit. For example, the pivotal concepts of "minimal risk" and "a minor increase over a minimal risk" are problematic (Kopelman, 1989; 2000). The regulations state "'minimal risks' means that the probability and magnitude of harm or discomfort anticipated in the proposed research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests" (U.S. "Protection of Human Subjects," 45 CFR 46 102 I). Many other countries and organizations have adopted a similar definition (Kopelman, 2000).

The first part of the definition is vague because daily risks include dangers from drive-by shootings, playing in traffic, flying in airplanes, terrorists attacks, and weapons of mass destruction. Can one know the nature, probability, and magnitude of these "everyday" hazards well enough to serve as a baseline to estimate research risk? And if one can, what reason exists for regarding them as a morally justifiable baseline? It seems easier to determine whether asking a four-year-old to stack blocks is a minimal-risk study than to determine the nature, probability, and magnitude of whatever risks people normally encounter in their daily lives. Moreover, it is unclear if it is the "everyday risks" refer to those some encounter (called the relative standard) or all of us encounter (called the absolute standard). It is also unclear why everyday risks should be a proper baseline to determine that research risk is minimal. Some people have terrible risks in their daily life, but it would seem unfair to use that to justify higher-risk studies for them than for other people.

The second disjunctive of the definition seems to set a standard for physical interventions that have a minimal risk, especially if it is understood as referring to the routine examinations of healthy persons. The test is whether the risk in the research activity is like that of a routine examination. Accordingly, review boards may not approve *as minimal risk* research such procedures as X rays, bronchoscopy, spinal taps, or cardiac catheterization because they are not part of routine examinations, at least for healthy persons. Review

boards, however, can approve studies that have a minor increase over minimal risk, and some of these procedures have been approved as having a minor increase over a minimal risk if their goal is to study a child's "disorder or condition." The terms "minor increase over minimal risk" and "condition" are undefined and vague with no definition for the crucial upper limit of risk that can be approved by review boards, considerable variation exists in how they are understood (NBAC; Kopelman, 2000; 2002).

Finally, this definition of "minimal risk" offers little guidance about how to assess *psychosocial risks* such as invasion of privacy, breach of confidentiality, labeling, and stigmatization. In routine visits, doctors and nurses ordinarily encounter discussions of family abuse, sexual orientation, and diagnoses that could affect reputations or the ability to get jobs or insurance.

Without clear standards for risk assessment, how effective are these guidelines? A 1981 survey of pediatric department chairs and pediatric research directors (Janofsky and Starfield) found considerable differences of opinion about whether procedures such as venipuncture, arterial puncture, and gastric and intestinal intubation are hazardous. For example, most regarded arterial puncture to have a "greater than minimal risk"; but between 8 and 24 percent thought it had less than a minimal risk, depending on the child's age. An editorial in the *Journal of Pediatrics* found such variation "cause for concern" and said that better standards of risk assessment are needed (Lascari). Two decades later, similar concerns remain (NBAC; Kopelman, 2000, 2002).

In short, this fourth policy is vague and open to very different interpretations. For example, in 1992 the National Institutes of Health appointed a nine-member review board to assess whether a study of the safety and efficacy of synthetic growth hormone (hGH) was in compliance with federal research guidelines. Eighty children whose adult height was projected to be at or below the first percentile would participate with their parents' consent. The children would receive injections three times a week for four to seven years (600 to 1,100 injections), half getting hGH and, for comparison, the other half receiving salt water, an ineffective placebo. Neither the doctors, the parents, nor the children would know who got water and who got the growth hormone. Each year all the children would come to the National Institutes of Health to undergo a variety of tests, including physicals, X rays, nude photographs, and psychological evaluations. Of the nine panelists, a majority held there was a minor increase over minimal risk, but this risk was offset by the health benefits of being in the study. Two others judged there was no benefit to offset the risks, inconvenience, and discomfort to those getting water rather than hGH, but the study was important enough to be justified. One panelist (this author) argued that a study of a terrible disease might justify these risks for the group getting hundreds of water injections; but shortness is no disease, and so the risk is unwarranted.

If there is any consensus that the fourth approach represented by the U.S. rules and others is the best way to set priorities between the need to protect the rights and welfare of people who lack the capacity to give informed consent with the need to encourage research, it may mask different understandings of what constitutes an acceptable risk of likely-harms-to-benefits ratio. There is a lively debate in the literature about how to clarify these thresholds and, not surprisingly, some favor more restrictive definitions than others (NBAC; Kopelman, 2002).

Conclusion

IRBs, ERCs, and RECs should continue to play an important role in protecting vulnerable subjects while making it possible to continue important research, but there are sharp differences about whether additional regulatory protections are needed (NBAC). Without safeguards, vulnerable subjects risk exploitation. Excessive restrictions, however, have dangers as well. They can thwart the advance of knowledge needed to improve medical care for the groups they seek to protect. Where potential subjects are capable of giving legal consent but are vulnerable to pressure or manipulation, their consent should be monitored to see if it is coerced or manipulated, and regulations should be sought only when they can be justified. There is general agreement that competent adults should serve as research subjects whenever possible, and that when people who lack capacity to give consent are enrolled as subjects in biomedical research, the study should be related to their healthcare needs. The guardian's consent should be obtained; and, if possible, the assent or permission of the person lacking capacity to consent should also be sought. Since there are difficulties with each of the four policies regarding subjects lacking capacity to give informed consent, IRBs, ERCs, and RECs will have to consider issues of utility, fairness, and protection without entirely satisfactory guidance.

III. SUBJECTS

Selecting individuals to participate in research involves not only scientific decisions about appropriate entry criteria but also ethical decisions about the distribution of benefits and burdens. The U.S. National Commission on the Protection of Human Subjects of Biomedical and Behavioral Research (U.S. National Commission) cited three ethical principles as the foundation of research ethics. The first, respect for persons, and the second, beneficence, have been analyzed more often and in greater depth than the third, justice. Investigators, regulators, and institutional review boards (IRBs) are accustomed to applying the principle of beneficence by examining the risk-benefit ratio and applying the principle of respect for persons by examining informed consent. But the third principle—the selection of subjects as a matter of justice—has often been considered last and in only one of its aspects, the protection of vulnerable groups

from exploitation as subjects. This situation is changing as persons and groups previously excluded from research on grounds of vulnerability seek access to what they perceive as research benefits, primarily the opportunity to try new drugs for serious and life-threatening illnesses.

According to the U.S. National Commission, justice is relevant to the selection of subjects at two levels: the social and the individual. At the individual level, "researchers [should] exhibit fairness: thus, they should not offer potentially beneficial research only to some patients who are in their favor or select only 'undesirable' persons for risky research" (p. 7). At the social level, "distinctions [should] be drawn between classes of subjects that ought, and ought not, to participate in any particular kind of research, based on the ability of members of that class to bear burdens and on the appropriateness of placing further burdens on already burdened persons" (U.S. National Commission, p. 7). Specifically, on the grounds of social justice, classes of subjects should be ranked (e.g., adults before children) and some classes of potential subjects (e.g., prisoners and the institutionalized mentally infirm) should be selected only under certain conditions and perhaps not at all.

Very few philosophers or other scholars have proposed standards by which to establish priorities in the selection of subjects. Hans Jonas proposed a "descending order of permissibility" for the "conscription" of subjects. In his view, researchers themselves should be the first to test a new therapy, in that they can best understand the risks and benefits. Believing that very sick or dying patients are particularly vulnerable to researchers' invitations, Jonas opposed using them in research not directly related to their care.

Another approach has been to assert an obligation to participate in biomedical research. Arthur Caplan (1984) argued that research is a form of voluntary social cooperation that generates obligations of fairness and reciprocity. If a competent individual voluntarily seeks care in a hospital or institution that conducts biomedical research, he or she benefits from research and should share in its costs (i.e., participate). This obligation is a general one, not an obligation to volunteer for the first available trial or any particular trial.

Selecting the Least Vulnerable

Underlying these different views is the assumption that research is risky or at least burdensome. If this is true, subjects should be selected in a way that protects those whose social, demographic, or economic characteristics make them particularly vulnerable to coercion and exploitation. Volunteering for research is seen as either a duty to be discharged or an altruistic act to be applauded. This emphasis on protecting vulnerable persons is understandable, given the signal event in the modern history of clinical research ethics—the cruel and often fatal experiments performed on unconsenting prisoners by Nazi doctors in World War II (Caplan, 1992). Public opinion in the United States also was shaped by the revelations of unethical experiments such as the Tuskegee Syphilis Study of poor black sharecroppers (Jones), the Willowbrook hepatitis B studies at an institution for mentally retarded children (Rothman, 1982), and the Jewish Chronic Disease Hospital studies in which live cancer cells were injected into uninformed elderly patients (Katz et al.). The most influential single article was one by Henry Knowles Beecher, a respected anesthesiologist, in the *New England Journal of Medicine;* it described a series of studies at major research institutions that placed subjects at risk and failed to obtain informed consent (Beecher; Rothman, 1991).

The view of research as inherently risky and of research subjects as inherently needing protection began to change in the early 1980s. Why? First, consider research at the level of individuals. The empirical question of the actual risk in most research studies has been answered: quite low. The U.S. President's Commission for the Study of Ethical Problems in Biomedical and Behavioral Research asked three large research institutions to summarize their experience with research-related injuries (U.S. President's Commission). Each group found a very low incidence of adverse effects. In one institution, out of more than 8,000 subjects involved in 157 protocols, only three adverse effects were reported, including two headaches after spinal taps. Some of these reassuring results may be due to the vigilance of IRBs and investigators in reducing the likelihood of risk in designing and implementing studies. While risk is always an element that subjects should consider when deciding whether to enter a study, it is often no longer the paramount issue.

Sharing the Benefits of Research

Even more important, the benefits side of the equation has assumed greater weight in individual decision making. Patients and advocacy groups are demanding more autonomy and less paternalism in the selection of subjects. Desperately ill patients forcefully argue that they are willing to trade a higher level of risk for the potential benefits of promising new procedures, devices, or drugs. Advocates for women and children point out that the typical exclusion or underrepresentation of these populations in clinical trials means that the drugs, when approved, will be prescribed for them with little direct data about dosage, efficacy, or side

effects. These trends have been spurred by the vigorous, sometimes confrontational, efforts of persons with the acquired immunodeficiency syndrome (AIDS). This advocacy also has stressed the inclusion of groups with poor access to trials, mainly women and minorities (C. Levine, 1988, 1993). Increased emphasis on women's health issues has provided some information on subject recruitment. Examining the inclusion of women in clinical trials, the U.S. General Accounting Office reviewed the practices of the National Institutes of Health (NIH) and the Food and Drug Administration (FDA) (Nadel; U.S. General Accounting Office). In both instances women were found to be underrepresented. The FDA review found that women were represented in every clinical trial of the fifty-three drugs approved by the FDA in the previous three and a half years. However, for more than 60 percent of the drugs, the proportion of women in the trial was less than the proportion of women with the relevant disease. Women were particularly underrepresented in trials of cardiovascular drugs, even though cardiovascular disease is the leading cause of death in women.

In arguing for wider inclusion criteria in clinical trials, patient advocates and some clinicians have noted that in the interest of good medical care, drugs should be tested on the populations that will use them. This belief runs counter to the more traditional research view of subject selection, which focuses on testing drugs in a small, homogeneous population in order to detect differences in efficacy and side effects as rapidly as possible.

Even with broadened inclusion criteria, not all patients who want access to promising new agents can be enrolled in clinical trials because they fail to meet the inclusion criteria, they live too far from a research center, or the trials are already closed. Several other mechanisms have been developed, such as the "parallel track," in which qualified patients who cannot enroll in clinical trials may obtain a promising drug through their physician ("Expanded Availability"). Community-based research, especially in cancer and AIDS, also has made clinical trials more accessible to patients.

The NIH has formalized the movement toward broader selection of subjects by mandating that its research grant recipients include appropriate numbers of women and minorities (Kirschstein). The 1993 NIH Revitalization Act (P.L. 103–43) extended the revised NIH policy by requiring the NIH director to ensure that women and members of minority groups are included in each federally funded project. The director may waive the requirement if the inclusion is inappropriate for health reasons, the purpose of the research, or any other circumstance. Cost, however, is not a permissible reason to fail to include women and members of minority groups.

This trend has limits, however. The inclusion of pregnant women in clinical trials is still controversial unless the trial is specifically designed to benefit the fetus, such as trials to prevent maternal-fetal transmission of the human immunodeficiency virus (HIV), which is associated with AIDS. Some of the objections to including pregnant women rely on ethical concerns about, for example, placing at risk a fetus, who cannot consent. Most of the concerns are based on fears of legal liability should the fetus be born with an injury that might be attributed to the investigational drug. Other subject groups for which protection is still deemed essential include children (Levine, 1991) and prisoners and mentally ill persons. Still other groups sometimes cited as vulnerable include elderly people, military personnel, pharmaceutical company employees, and medical students. Although some conditions and some protocols might be coercive, in general these individuals can make choices voluntarily. Special procedures have been set up in some instances to ensure voluntariness (see, e.g., Winter, on the U.S. Department of Defense).

From the societal perspective, equitable selection of subjects means that the groups bearing the burdens of research should also share in its benefits. Opponents of research in prisons argue that the fruits of the research—newly approved drugs—are rarely available in that setting. Similarly, although many drug trials have been carried out in Third World countries, these nations are often so poor or so lacking in healthcare services that they cannot afford to provide the tested drugs to their citizens.

More recently, representatives of Third World countries and of poorly served communities in the United States have been demanding a greater role in the distribution of benefits (Lurie et al.; National Commission on AIDS; Thomas and Quinn). Their agreement to participate in clinical drug trials is sometimes conditioned on a promise from trial sponsors to provide something of benefit to the population—the drug, if it proves efficacious, or the health infrastructure needed to deliver the therapy. Efficacy trials for vaccines, which require thousands of subjects, cannot be conducted without the goodwill and participation of a community's leaders. Community consultation, in which investigators and community spokespersons collaborate on the design and implementation of a trial, is becoming a frequent strategy for ensuring that the concerns of the pool of potential subjects and their representatives are addressed.

Recognizing the importance of social justice in the distribution of burdens and benefits, the World Health Organization (WHO) and the Council for International Organizations of Medical Sciences (CIOMS) guidelines for international research state:

> Before undertaking research involving subjects in underdeveloped communities, whether in developed or developing countries, the investigator must ensure that:
>
> - persons in underdeveloped communities ordinarily will not be involved in research that might equally well be carried out in developed communities;
> - the research is relevant to the health needs and responsive to the priorities of the community. (WHO-CIOMS)

The commentary on this guideline states: "If any product is to be developed, such as a new therapeutic agent, clear understandings should be reached about whether and how the product, once developed, will be made available to members of the community in which the research was conducted" (WHO-CIOMS, pp. 38–39).

The equitable selection of subjects now includes an assessment of both the need for protecting vulnerable individuals and groups and the importance of allowing them maximum choice in making the ultimate decision to participate. In the future, even more emphasis will be placed on the equitable distribution of the benefits of research.

RESEARCH, UNETHICAL

• • •

Unethical research is a concept inevitably relative to accepted views concerning research's ethical requirements. For Claude Bernard, an early French exponent of the scientific method in medicine who felt that the principle underlying medical morality requires that persons not be harmed, paradigm cases of unethical research are studies that offer their subjects risks that exceed their potential benefits. The Nuremberg Tribunal, by stating in its first principle of ethical research that the subject's free consent is absolutely essential, added as paradigmatic cases of unethical research those studies performed upon unconsenting persons (Germany [Territory Under Allied Occupation, …]). U.S. regulations that require an equitable selection of research subjects imply that a study that is otherwise ethical (e.g., a study with an acceptable risk-benefit ratio and whose subjects have freely consented) becomes unethical when it unfairly draws its research population from persons disadvantaged by reason of race, religion, or dependency, among others ("Federal Policy").

Examples of Unethical Research

Whichever ethical requirement may be chosen, the history of human research offers grim examples of its violation. During World War II, German researchers performed a large number of experiments in concentration camps and elsewhere. Subject-victims of Nazi research were predominantly Jews, but also included Romanies (Gypsies), prisoners of war, political prisoners, and others (Germany [Territory Under Allied Occupation …]; Caplan). Nazi experimental atrocities included investigation of quicker and more efficient means of inducing sexual sterilization (including clandestine radiation dosing and unanesthetized male and female castration) and death (an area of study Leo Alexander

[1949] termed "thanatology," which includes studies of techniques for undetectable individual assassination—i.e., murder that mimics natural death—as well as mass murder). Among the best-known cases were the hypothermia experiments, which investigated mechanisms of death by freezing and means of preventing it. These studies, motivated by the loss of German pilots over the North Sea, included immersing prisoners in freezing water and observing freezing's lethal physiological pathways.

Beginning in 1932, the U. S. Public Health Service funded a study of the natural progression of untreated syphilis in black men. Four hundred subject-victims were studied, along with 200 uninfected control subjects. The study, whose first published scientific paper appeared in 1936, continued until a newspaper account of it appeared in 1972. Its subject-victims were uninformed or misinformed about the purpose of the study, as well as its associated interventions. For example, participants were told that painful lumbar punctures were given as treatment, when in fact treatment for syphilis was withheld even after the discovery of penicillin (Brandt; Jones).

Numerous other examples of unethical research may be cited, though they have received far less attention. A New Zealand study on women that began in 1966 and was active for at least ten years had macabre similarities to the Tuskegee study. It concerned the natural history of untreated cervical carcinoma in situ (i.e., cancer that had not spread), and as in Tuskegee, its subject-victims were both uninformed and had treatment withheld for the study's duration (Paul). Parallel to the Nazi studies during World War II were those conducted by Japan. They included experimental attacks with biological weapons on at least eleven Chinese cities, and studies conducted on subject-victims that included efforts to induce gas gangrene by exploding fragmentation bombs near the exposed limbs and buttocks of 3,000 prisoners of war who were housed at a detention center known as Unit 731 (McNeill; Williams and Wallace).

Much unethical research comes to light only many years after its conduct, as is true of unethical military research conducted by the United States during and immediately following World War II. At that time, over 60,000 U.S. servicemen were involuntarily enrolled in studies involving exposure to chemical warfare agents (mustard gas and lewisite); at least 4,000 of them were exposed to high concentrations in field experiments and test chambers (Institute of Medicine).

Information about experiments on human radiation response supported by the U.S. government beginning in 1945 came to public attention in 1993. In one study, conducted from 1945 to 1947, eighteen patients considered to be terminally ill were injected with high doses of plutonium to determine how long it is retained in the human body. Military secrecy surrounding atomic energy precluded informed consent. Rather than telling subject-victims they would receive an injection of radioactive plutonium, the investigators told subjects they would receive a "product." Experiments on intellectually handicapped teenagers in a Massachusetts institution involved feeding the subjects very small amounts of radioactive iron and calcium to study the body's absorption of these materials. While the radiation exposure in these studies was low and unlikely to result in harm, the subject-victims were all incompetent, and their parents, who consented on their behalf, were simply asked by the institution to agree to "nutritional experiments." In reaction to news accounts of these and other studies, orders were issued in 1993 to declassify documents relating to unethical exposure of U.S. service personnel and citizens to radiation from atomic-weapons testing after World War II; in 1994 President Bill Clinton appointed a panel to guide a federal investigation into the radiation studies (Mann).

Several themes emerge from the known examples of unethical research. Such studies are likely to be done using disenfranchised or disadvantaged populations as subjects. In the absence of public outcry, unethical research may continue for many years, despite the fact that readers of the scientific literature in many cases have had access to all the facts they need to expose unethical practice (see Beecher). The larger and more egregious studies are especially likely to have been motivated by national security concerns and funded by the military.

Use of Data from Unethical Research

Very early sources reflect differing views on the permissibility of making medical or other use of information derived from unethical practices. The Babylonian Talmud (Shabbat 67b) states that the prohibition on Amorite practices (pagan sorcery) does not forbid actions done for the sake of healing, and it cites several cases of permitted incantations and sympathetic magic. Robert Burton quotes Paracelsus's *De occulta philosophia* to similar effect: "It matters not whether it be God or the Devil, Angels or unclean Spirits cure him, so that he be eased" (Burton, 1628, p. 7). By contrast, Thomas Aquinas prohibits "inquiring of demons concerning the future." Even if demons should know scientific truths, he writes, it is improper to "enter into fellowship" with them in this way (Aquinas).

A large variety of empirical and ethical arguments have been marshaled to oppose the use of data from unethical research. Empirical arguments, which depend upon the facts of particular cases, question the scientific reliability of such

data. For example, Robert Berger, through a close analysis of the Nazi hypothermia data, claims that even by then-current scientific standards, the information is unreliable. He describes incomplete and contradictory data reporting, the absence of a controlling scientific protocol, and the control of the research program by scientifically untrained personnel (including Heinrich Himmler, Commander of the SS). In fact, the principal investigator, Sigmund Rascher, had a previous record of deception and was arrested in 1944 and charged with crimes that included scientific fraud. Some commentators argue that such data may be used, but only when the information is exceptionally reliable and useful. Most or all instances known of data gathered unethically, however, fail to meet this test (see Schafer).

Ethical arguments opposing use of the data are especially numerous. From a consequentialist point of view, unethical studies should be "punished" by "non-use," to discourage future investigators tempted to resort to unethical research practices. Other theories of punishment may be appealed to as well: As a matter of justice, it is argued that unethical investigators should not be rewarded by having the data from their studies used. By expunging the records of unethical research, the society of scientists expresses its solemn condemnation of the methods employed to acquire it; failing to do so would make science complicit with the research studies. Appropriate symbolism may call for the "burial" of this data, as it calls for the burial of the subject-victims from whom the data was derived (see Caplan; Martin; Post).

Rebuttals of these ethical arguments are equally numerous, relying upon the premise that data from unethical research studies may be valuable in principle: Any coincidence between "good science" and "good ethics," these writers argue, is only contingently true. As a practical matter, it is argued, the most serious instances of unethical research could not have been deterred by the punishment of non-use; some of the most heinous research studies were commissioned by governments, especially national security apparatuses. Punishment should be visited upon the investigators who engaged in unethical research; by withholding the use of data, current patients whose care might have been improved by use of that data are made to bear the brunt. Arguments from complicity are rejected because there is no causal connection between the prior acquisition of the data and its current use (the Nazis did not gather information about hypothermia in anticipation of its use by Canadian researchers a generation later); and because the current use of the data, far from being a continuation of the Nazi project, is for humanitarian purposes antithetical to the original Nazi intentions. In that way, the symbolism associated with the use of these data is seen to have a positive, redemptive value, while retaining the data's possible value to science and society (Freedman; Greene).

The debate about the use of data from unethical studies should distinguish the different ways scientific results can be used. Three different meanings for data use have been suggested: reference to data, for example, by scientific publication or citation, to serve as grounding for a scientific argument; reliance upon data in establishing or validating a practice, scientific or technological (including clinical); and using data as suggestive of further areas for inquiry (Freedman). This last meaning, while the most common in practice, has been the least debated; it is unlikely that data, once disclosed, could fail to be used in this way.

Much debate has centered on the first meaning, use of data through publication or citation. Kristine Moe found that the Nazi hypothermia studies had been referenced at least forty-five times in the medical literature (Moe). The *New England Journal of Medicine,* among other publications, has taken the position that it will not publish studies considered unethical by its editor; moreover, it will allow references to unethical research only in articles that focus on ethical condemnation of the research in question (Ingelfinger). Robert J. Levine has argued that a preferable stance would permit the publication of scientifically sound but ethically questionable research, while requiring the simultaneous publication of editorial discussion of the ethical issues raised (Levine).

Use of data in the second sense, as grounding scientific or ethical practices, was central to a 1988 controversy. While considering air pollution regulations on phosgene, a chemical used in plastics manufacture and a component of pesticides, the U. S. Environmental Protection Agency (EPA) withdrew an analysis that made reference to data derived from Nazi experiments after some EPA scientists circulated a protest letter (Sun). Phosgene was a component of some chemical weapons, and the Nazis had studied the response of French prisoners to various levels of phosgene exposure. EPA officials, while recognizing scientific and technical flaws in the data's collection and reporting, held the data to be useful additions to the existing animal toxicology information. Nazi data is often said not to be generalizable to a normal population because it was derived from prisoners under horrible conditions of privation. However, even this aspect of the data was applicable because the EPA's recommendations were designed to minimize risk to those most physiologically vulnerable. Those opposed to use of the data presented arguments based on both fact and value. The data were said to be valueless because of their omission of consideration of vital variables like sex and weight of subject-victims. In addition, some agency scientists felt that

data derived from this source, however valuable, should never be used.

In the majority of cases, the scientific value and impact of unethical research has been modest. Ethically, however, the Nazi, Tuskegee, and other studies have loomed large in raising both public awareness and ethical standards for the conduct of research. Unethical research has found its main use in ethics.

RESPONSIBILITY

• • •

Responsibility has emerged as a central ethical category, directing attention to human beings as moral actors. It highlights the importance for ethical understanding of self-conscious moral commitments, discretion in moral judgment, personal strengths necessary to effective action, a wise

use of the power and authority of societal offices, and accountability to oneself and to fellow human beings, perhaps also to God, for moral judgment and action. Discussions of responsibility do not displace systematic treatments of moral principles, laws, and rules; neither do they set aside critical studies of values worthy of promotion in human affairs. They recast these inquiries in terms of the personal lives and social roles of human beings.

Themes associated with responsibility have long been prominent in philosophical and religious discourse, though in different conceptual forms. Especially important are accounts of the moral and intellectual virtues, of moral character, and of the obedient or resolute wills of the upright (Aristotle; Aquinas; Calvin; Kant; cf. Cohen). Also relevant are themes elaborated in conceptions of moral law, including natural law; in notions of the orders of nature or creation; in interpretations of divine commandments and ordinances; and in treatments of God's covenant with Israel, or of the Christian idea of a new covenant in Jesus Christ (Aristotle; Aquinas; Brunner; Häring). Contemporary accounts of responsibility weave these classic themes together in ways that take account of modern social realities, and that utilize theories of action provided by the human sciences.

In regard to modern realities, the concept of responsibility corresponds to social complexity, which routinely generates problems with more features than any system of moral rules can encompass. It fits well with advanced technologies and high levels of specialization, where expert knowledge and skill are indispensable to moral judgment. Responsibility takes account of open spaces within democratic and free-market settings for individuals and groups to follow independent initiatives in the pursuit of cherished social goals. It accords with modern social theory, which conceives of social institutions—the state, business enterprises, special-interest associations, even families and religious bodies—as the constructions of autonomous individuals contracting for mutual advantage. Finally, responsibility can accommodate reflections on the moral ambiguities of the social and organizational contexts that structure human activity. In respect to each of these characteristics, themes relating to responsibility take on considerable importance.

The concept of responsibility enjoys prominence, then, because it can draw together a wide range of ethical ideas in a fashion pertinent to contemporary social existence. For some thinkers it serves as the unifying principle of a comprehensive ethical theory (cf. Niebuhr; Jonsen). Responsibility virtually becomes the first principle of ethics, so that the admonition "Be responsible!" conveys all that needs to be said about the moral life (Jonsen; cf. Glatzer). The theoretical task is to unfold the dimensions of responsibility in their bearing on personal and social processes.

The dimensions of responsibility appear both in the personal lives of individuals and in the roles, positions, and offices that order social institutions. All of these dimensions may not be explicit in a particular ethical theory, though most enter into discussion at some point. For religious thinkers, responsibility includes relationship to God, which uncovers a theological basis for ethical understanding.

Duties

At the most elementary level, responsible persons are those who recognize and carry out their duties. Duties define the moral requisites of human social existence: what we normally must do, no matter what else we might hope to accomplish, and what we normally may not do, regardless of our larger objectives. Moral duties can be qualified or set aside only when exceptional steps are necessary to secure the values they are designed to protect. Thus, medical procedures normally may not be performed without a patient's informed consent, even if the patient's life is at risk. However, in a medical emergency, they may be performed without consent, provided the patient is unable to respond and there is no one present with authority to decide on his or her behalf.

Duties are formulated as laws, regulations, and rules, perhaps in conjunction with underlying moral principles. Responsible persons abide by moral principles in their personal lives. They pay special attention to principles and rules linked to their social roles: parent, spouse, physician, research scientist, junior executive at a medical center, senator. They support collective efforts to uphold moral standards that order human activities in institutional contexts (cf. Beauchamp and Childress). For those who are religious, moral duties may derive their ultimate authority from divine purposes.

Tasks

Within the constraints of moral principles and rules, responsibility consists in the reliable performance of assumed or assigned tasks. We may speak of our tasks as our responsibilities. Responsible persons know what needs to be done, they appreciate its significance, they proceed on their own, they get the job done, and they do it well (Jonsen).

Some tasks are broad and open-ended: sustaining a good marriage; bearing and nurturing children; promoting the public good as a citizen, public servant, or professional. Others are specialized, such as the practice of pediatric medicine. Some may be narrowly focused, for example, the execution of insurance claims. Even specialized tasks lack

clear limits. When do physicians know enough to be confident that they are providing optimal care for their patients? When have they done enough to promote life, health, and healing? Responsible persons maintain standards of excellence in relation to expectations associated with their social roles. Those who are religious may further connect their tasks with a vocation to serve a wider, divine purpose in all areas of their lives.

General Well-being

In conjunction with explicit moral commitments and role-determined assignments, responsible persons strive for just, fair, and good conditions where they live and work. They seek to bring about and maintain states of affairs that favor human well-being, perhaps the well-being of all creatures. Similarly, they resist and, where possible, seek to change circumstances that do harm to fellow human beings, even to other living creatures. They strive to improve the execution of tasks, and to see that basic moral imperatives are honored in everyday social interactions. Those who are religious may be sustained in their quest for a greater good by their hope in the promises of God.

Thus, a physician's responsibility does not end with patient care or with professional relationships wherein standards of quality care are maintained. It includes a public interest in the healthcare system as a whole, and in its ability to provide appropriate services for all people. More broadly, it embraces the promotion of human health in basic life patterns.

Commitment

Responsibility is about personal commitment. It expresses human care about the moral life (cf. Fingarette). Those who are responsible claim their duties and tasks as their own, as ways of acting that are internal to who they have become and are becoming (Gustafson; cf. Jonsen).

Classic ethical theories dealt with commitment either in terms of moral virtues (Aristotle; Aquinas) or in terms of the resolute will (Calvin; Kant; cf. Novak). Moral virtues are habits, stable ways of acting that accord with the good. They derive their energy from passions that have been *perfected* through disciplined practice, until an actor is disposed to do the good as a kind of *second nature.* In terms of normative content, the central moral virtue is justice, the disposition to grant to each person what he or she is due.

In Judaism and in Reformed Protestant thought, the basic commitment to do the good has been defined not as habit or disposition but as volition, a self-conscious determination to do one's duty in all things. Here the aim is not to shape the passions but to control them. Immanuel Kant gave these latter traditions philosophical form by speaking of the unqualified value of the "good will," that is, the will ever ready to do what the moral law commands (Kant).

Modern psychological theories generally set aside accounts of the self that isolate discrete virtues or particular psychic functions, such as the will. They portray the self as a complex, dynamic process in which a centered unity can be only a relative achievement (cf. Wallwork). Post-Freudian thinkers place special emphasis on the formative power of human relationships in these complex dynamics (cf. Erikson; Winnicott; Kohut; Chodorow). Thus, our moral commitments are integral to the relational bonds that form and sustain us as human beings. We come to understand these commitments through our life stories, including both family stories and the stories of communities to which we belong. It is by means of narrative that we apprehend and claim our moral identities (Taylor; Ricoeur).

Psychological perspectives substantially inform ethical discussions of responsibility (cf. Fingarette; Rouner; Wallwork; Taylor). They render more intelligible seemingly irrational features of human behavior: individuals acting in socially inappropriate ways or in ways that work against their self-conscious purposes (cf. Fingarette). They help us grasp dynamics that leave some persons virtually incapable of consistent care for the good, and hence unable to respond to concrete situations with moral sensitivity. In other instances, persons may profess moral concern, yet find themselves internally torn, deeply ambivalent, or emotionally empty. They lack focused energy to carry out the good they claim to honor.

In classic thought, such cases either revealed bad habits, called vices (Aristotle; Aquinas), or they represented the bondage of the will to sinful inclinations (Augustine; Calvin; Luther; cf. Kant). Modern perspectives introduce notions of pathology to account for this "irresponsible" behavior. They offer neither moral admonition nor judgment but therapy, a supportive relationship wherein a skilled professional helps a patient gain insight into the internal conflicts that impel him or her to destructive behavior. Therapy provides resources for self-discovery that open the way to mature moral concern (cf. Fingarette; Wallwork). Through processes of self-discovery we reconnect with values and relationships that give identity and significance to human life.

Moral commitment involves social roles and offices. Responsible persons incorporate into their personal identities moral principles and values that are linked to positions they occupy. Social roles, like social institutions, are invariably marred by moral ambiguities. They gain their moral import from the fact that despite their ambiguity, they serve

a greater good, at least by minimizing harm. Responsible actors seek to advance the moral promise of their offices while resisting their morally questionable tendencies.

Strength

Responsibility presumes that we have the personal strengths and the requisite skills to carry out our duties and to perform our tasks. Classic traditions of moral virtue and volition focus on distinctively moral strengths. In volitional approaches, the pivotal strength is willpower, the determination to control any fears, desires, even natural inclinations, that might distract us from our duty. Those who are religious seek divine support for moral rectitude.

In theories of virtue, moral strength derives from an ability to harness the passions in the service of purposive activity (Aristotle; Aquinas). On the one hand, responsibility requires personal toughness, perseverance, courage. These strengths stem from a natural, organic combativeness that through practice has been shaped into a virtue. If we lack such strength, the pressures, threats, and risks common to social existence will force us to shrink from the proper performance of basic tasks and duties. For example, a physician might remain silent after witnessing a senior colleague's failure to observe minimal professional standards in practice. Although the physician cares about standards, he or she cannot bear the stresses of a formal complaint. Courage equips us to follow through on our commitments, even those that entail danger.

On the other hand, responsibility requires self-control, the ability to restrain our wants, desires, and feelings when they dispose us to betray our commitments. Here, too, we develop self-control or temperance through practice. We learn to shape our wants and desires to accord with the larger good toward which we aspire. Without self-control we are unreliable. Our desires continually override good judgment, perhaps even impelling us to harmful actions (cf. Aristotle; Aquinas).

Because of an attraction to a patient, a psychiatrist violates sexual boundaries that define professional relationships. A research scientist falsifies research data or makes improper use of the findings of others in order to advance his or her career. In the interest of increased income, a specialist in internal medicine proposes medical procedures of dubious merit to a dying patient. Responsibility requires the discipline to restrain our wants for the sake of our moral integrity.

Modern psychological theories deal with similar phenomena, although with greater emphasis on the complex dynamics, including interpersonal relationships, that figure so prominently in our makeup. As a result, moral strengths appear less as matters of personal accomplishment and more as functions of self-formation in relationships. As inherently social beings, we derive both courage and self-control from human bonds that cohere with our moral purposes (cf. Kohut; Chodorow; Rouner; Glatzer).

Personal strengths are not limited to emotional resources or volitional restraints. They embrace intellectual capacities, general and specialized knowledge, competence in oral and written communication, self-confidence, self-esteem, the mastery of skills crucial to typical tasks, physical strength and agility, energy, stamina, and manual dexterity.

We may not associate all of these elements with the moral life, yet they profoundly affect a person's ability to act. The responsible life includes, therefore, a commitment to cultivate native talents and abilities, and to devise ways of mitigating disabilities. Similarly, social responsibility requires policies that enhance human potential for effectiveness: opportunities for education and advanced training; specialized equipment and physical arrangements for persons hampered by "handicapping conditions"; nondiscriminatory practices regarding race, gender, ethnic origin, age, religious identification, and sexual orientation.

Responsibility for personal strengths includes self-care and discipline in holding personal and professional commitments to manageable levels. Mistakes, indiscretions, intemperate and abusive behavior, even addictive and self-destructive patterns, are more likely when we habitually overextend ourselves. Personal strengths are indispensable to the good we are disposed to do. They also allow us to broaden our moral commitments, perhaps to assume leadership in promoting the common good.

Power

The human capacity to act derives from social offices and positions as well as from personal strengths (cf. Brunner; Bonhoeffer). Responsible persons are attentive to power dynamics that operate in their interactions with colleagues, associates, and employees, as well as with patients, clients, customers, and users of services. They resist abuses of power in these interactions and draw upon the resources of their offices to promote justice and the common good. They model fairness and concern for general well-being in their own activities; they commend similar practices by others.

Judgment

Responsibility involves sound judgment about the good to be done in concrete situations. Our ability to judge depends upon stable moral commitments and personal strengths to

act on those commitments. It is affected by the perceptions of those to whom we are closely related, and also by interests that structure our business, professional, and political activities. Yet judgment is still a distinct skill, a "practical intellectual virtue" cultivated through practice (Aristotle; Aquinas).

Moral judgment operates in a number of ways, all of which involve the creative imagination and accumulated practical wisdom of morally mature individuals. It consists in the interpretation and application to concrete cases of laws, regulations, and rules that define moral duties (cf. Ramsey). These regulations may be borne by the common culture or the culture of professional practice; they may also be codified in public law or in the operating procedures of complex organizations, such as hospitals. The task is to discern what is at stake in these regulations so that they can appropriately inform particular moral judgments. Interpretation generally leads to a search for principles that disclose what is morally at stake in various regulations, for example, the claim that these regulations protect conditions essential to human existence and well-being.

By their very nature, principles, laws, and rules are abstract. It is not uncommon, therefore, to confront cases that are not adequately covered by existing regulations. Moral judgment may then consist in the construction of new rules that can inform our responses to these problem cases. The new rules may represent reformulations or extensions of familiar standards. They may consist of novel directives derived from elemental moral principles. The goal is to furnish stable guidelines for dealing with an emerging class of cases in the context of changing social circumstances. Bioethics continually confronts such challenges as it responds to enlarged technical capacities within biomedical practice.

Some cases are sufficiently distinct that they are best treated as exceptions to the rules. Moral judgment then entails adapting the rules to take account of variables that define the exception. Through experience, we learn to distinguish genuine exceptions from sets of cases that expose problems with existing rules. For the latter, we must rethink the rules, devising fresh formulations suited to the new cases.

In many life contexts, such as biomedical practice, we regularly deal with so many specific variables that general principles and rules cease to prove helpful as guides to moral judgment. Especially important are cases where conflicting values and disvalues are likely to result from any conceivable course of action, such as the treatment of the terminally ill or experiments with promising medical procedures that invariably have negative side effects. Practical wisdom for handling such cases emerges through experience accumulated in the treatment of similar cases. By evaluating a significant number of cases, we increase our ability to isolate variables pertinent for assessing each new case. This pattern of moral judgment is continuous with classic traditions of casuistry, or case reasoning. Casuistry locates moral judgment in the comparative study of recognizable classes of cases that require human decision and action (cf. Jonsen and Toulmin). Medical centers now institutionalize casuistic thinking through case conferences and regular consultations with specialists and advisers.

Responsiveness

H. Richard Niebuhr dramatizes the social matrix of action. We act in response to actions upon us and in anticipation of further responses to our own actions in ongoing social interactions. In this interactive framework, moral judgment involves responsiveness, self-conscious attempts to draw upon the perceptions and experiences of others in our own deliberations (cf. Gilligan). Responsiveness is best realized in conversation among representative actors in a situation. The conversation is not primarily an occasion for debate, in which the stronger positions defeat the weaker until the most cogent prevails. Its purpose is to facilitate vision. It may confirm widely held judgments, yet it may uncover matters that have been concealed, clarify phenomena that have been obscured, and bring to awareness considerations previously passed over.

Responsiveness begins with the attempt to understand what is going on. It does not presume that the morally important issues in a situation are obvious. Through conversation we surface the pivotal issues and construct ways of portraying them to ourselves and others. Historical studies and social analyses inform these efforts. The account we provide of the situation sets the stage for a consideration of appropriate responses.

Responsive judgments are guided by the notion of what is *fitting*. The fitting action may be largely self-evident once we have grasped what is morally at stake in a situation. Yet it may emerge only gradually, through the thoughtful balancing of multiple variables with their negative and positive features. Moral imagination and discernment are as important to this balancing process as are conceptual precision and logical rigor. The reasoning involved, moreover, is often more akin to weaving a tapestry than to forging a chain. Various strands of thinking supplement, complement, and perhaps clash with one another within a complete configuration. A fitting response is integral to that configuration. It consists of the most promising means of negotiating multiple considerations. For Niebuhr, fitting actions are also responses to God, the center of values that bestows authority on all values.

Responsiveness gains moral urgency from the partial, even distorted, nature of all human viewpoints. Biases rooted in special interests plague our most sincere efforts to promote justice. For example, a white male medical establishment gave lower priority to breast cancer than to prostate cancer. In studying heart disease, it focused on male rather than female subjects. Exalting scientific advances and technical achievements, the U.S. healthcare system institutionalizes almost unlimited care for those with comprehensive health coverage while failing to offer basic care for the poor. Other biases—racial, ethnic, religious—have distorted biomedical practices from time to time. We overcome socially mediated biases by responsiveness to the voices of those previously left out of the conversation.

Responsiveness is not merely a personal trait. It can be incorporated into professional, organizational, and institutional practices. We can create contexts for exchanges of views among peers, colleagues, coworkers, support staff, and volunteers. We can regularly seek information from those who receive medical services: patients, clients, consumers, constituents. Within a particular organization, these exchanges promote collaboration on common projects, facilitate coordination among interrelated activities, and enhance both quality and efficiency in performance. As a dimension of responsibility, responsiveness contributes to good management. Similarly, professionals routinely respond to peer judgments through associations, convocations, conferences, and publications, as well as through regular consultations and case conferences. Ideally, they also elicit the active participation of clients to whom they offer their services.

Responsiveness in moral judgment is especially pertinent to the formation of public policy, such as debates about healthcare reform. These debates begin with attempts to interpret "what is going on" and move to proposals for the "fitting" response (Niebuhr). In the United States, controversial policy issues are rarely resolved by a new public consensus on the proper treatment of pressing social problems. Practical accomplishments require compromise. To gain support for new directions in policy, public actors accommodate the special interests of competing groups. In so doing, they consent to measures that fall short of their larger goals. The search for acceptable compromises is crucial to public responsibility.

Accountability

Responsibility embraces accountability for judgments and actions (cf. Jonsen). Because our actions affect the lives of fellow human beings, we have to answer to others for what we do. We must be able to give an account of our intentions and of their moral bases that is credible within the relevant conversational context, whether it be familial, communal, professional, or public. Responsible persons seek feedback from others because they are conscientious about quality performance. Structures of accountability may be formalized in well-defined review processes, including disciplinary hearings, and civil and criminal actions. Yet they also operate in everyday human interactions.

The morally committed have a strong sense of accountability to self. Conscience names the dynamism whereby we answer to ourselves for our fidelity to our commitments. If we violate our own normative standards, we feel guilt. If others have been disadvantaged or harmed by our actions, we recognize a need to apologize, perhaps to make restitution. In religious contexts, accountability involves answering to God as the source and ground of the moral life. We confess our failures, seek forgiveness, and pray for strength to renew our commitments.

Responsibility includes a readiness to hold others accountable for their actions, in the interest of the common good. It will not suffice to be conscientious only about our own actions. Because substantive moral commitments are requisite to human existence and well-being, we must hold one another accountable to those commitments. Accountability is especially important for professionals, who alone are adequately equipped to assess the performances of peers. Likewise, we are obliged to promote mutual accountability in the organizational and communal contexts in which we normally live and work; this includes support for appropriate disciplinary hearings and criminal proceedings.

The notion of accountability directs us to revisit all of the dimensions of responsibility, though with a focus on our obligation to nurture, model, encourage, cultivate, and teach responsibility to fellow human beings, especially the children, youth, and young adults of a coming generation.

RIGHT TO DIE, POLICY AND LAW

• • •

Prior to World War II, death came naturally or accidentally. There was little that doctors could do to forestall it. With the development and application of a variety of drugs and devices, this slowly began to change in the 1950s and 1960s. In addition to the improved medical capabilities, public attitudes toward the respective roles of physicians and patients in making decisions about whether to deploy medical technology also began to shift. In the 1950s and 1960s, influenced by the civil rights and the consumer rights movements, the public gradually shifted the almost sole responsibility for deciding whether and how to treat patients from physicians' hands to the hands of patients or their families.

The Development of Patient Autonomy

Autonomy—or as it is sometimes referred to, self-determination—is the core value that has driven the development of the right to die, as well as the more fundamental right to refuse medical treatment out of which the right to die has grown. Legal recognition of the right of patients to make decisions about the medical care they do and do not wish to receive has deep historical roots. However, the right to make medical decisions is itself of relatively recent vintage, perhaps because until recently there was not a great deal in the way of medical treatment to choose from and certainly not much that was efficacious. Before the last decades of the twentieth century, there was not so much a right of patients to choose but a right to veto what the doctor proposed.

As medical capability has gradually increased, so have efforts aimed at increasing the role of patients in making decisions about whether and how to employ that capability. Autonomy has had a long struggle to dislodge the long-standing dominance of medical paternalism in the doctor-patient relationship. By the last quarter of the twentieth century, patient autonomy had become the prevalent value in law, public policy, and bioethics. However, there remains a considerable gap between theory and actual clinical practice (Solomon, et al.).

Another important trend that has affected the shift in medical decision making is the role of law in society in general. Prior to the twentieth century, law played a much more limited role in resolving controversies among private citizens and lawsuits by patients against physicians were exceedingly rare. These few lawsuits fell into two groups: claims based on an allegation of negligent medical practice, and claims of nonconsensual treatment amounting to a civil battery. Ultimately, these two themes were merged in the 1950s and 1960s in the development of the concept of informed consent to medical treatment.

Originally, the law of battery played the more significant role. Although mostly thought of as a protection against conduct involving violence against another person (and in fact it does provide such protection), battery provides a legal remedy for an intentional, nonconsensual touching of another person that results in either harm or offense. Out of the law of battery developed a right to refuse medical treatment. The relationship between the two is clear: the converse of the right not to be touched—in a medical context, treated—without consent, is a right to refuse treatment. Viewed from a broader perspective, the law of battery could be seen as creating a right of individual autonomy or self-determination, and certainly there is significant judicial authority to support that view.

Prior to the 1970s, the right to refuse treatment existed more in form than in substance. In clinical medical practice, although it is unlikely that physicians frequently forced treatment on unwilling patients, the instances in which they did were of the sort—emergencies, patients lacking in decision-making capacity—that any legal challenged was unlikely to arise. In most instances, the situation was such that either the patient recovered and in retrospect no longer objected to the treatment or the patient died or was otherwise unable to pursue a legal remedy.

The Era of Passively Hastening Death

The two trends— of medicine's increasing ability to stave off death if not provide complete cure, and the increasing recognition of patient autonomy —collided in the Karen Ann Quinlan case in 1975 (*In re Quinlan,*). It is virtually certain that such collisions occurred before the *Quinlan* case, but none of these clinical cases metamorphosed into legal cases with the attendant public visibility of *Quinlan* (Filene).

Karen Ann Quinlan, a twenty-one-year old woman, stopped breathing and was taken to the hospital by emergency medical personnel. Doctors were able—through a variety of medical means that were not available only a decade earlier—to resuscitate her. She was then placed on a ventilator. Because of prolonged oxygen deprivation before she was resuscitated, Quinlan suffered severe brain damage and was ultimately diagnosed as being in a persistent vegetative state, a condition in which her brain stem was still alive and maintained her so-called vegetative functions (digestion, metabolism, etc.), but in which the remainder of her brain had died and along with it the higher brain functions such as awareness and cognition.

When Quinlan's prognosis became clear to her parents, they concluded that Karen would not want to be kept alive in this twilight state in which her corporeal existence was maintained but in which she could no longer, think, feel, perceive, or have any contact with other people or her environment. Therefore, after seeking additional medical consultation and religious counseling, they requested that her doctors discontinue the ventilator that was keeping her alive, and that she be allowed to die naturally.

The doctors, however, refused. They refused because they believed it was contrary to the ethics of the medical profession to do so. The treating physicians and several of the qualified experts who testified in the case asserted that removal from the respirator would not conform to medical practices, standards, and traditions. The physicians also refused because they were concerned that they could be subject to liability for criminal homicide if they did so. In effect, the doctors issued an invitation to Quinlan's parents to sue, which they accepted by filing an action for a declaratory judgment—not a case seeking monetary damages against the doctor, but a case requesting the court to declare that Karen had the right to have life-sustaining medical treatment removed, which would, it was thought, inevitably lead to her death.

The trial court refused to issue such an order, and the Quinlan family appealed to the New Jersey Supreme Court. Although the court's opinion is confused and important portions of it were superseded by later decisions, it did grapple with a number of fundamental ethical and legal issues in an unprecedented way. It prescribed procedures for making end-of-life decisions that did not routinely require judicial supervision, and it endowed physicians and patients'

close family members with substantial discretion to carry out what they believed to be the patients' wishes about forgoing treatment.

The *Quinlan* decision, despite its shortcomings, can be said to be the foundation on which an entire body of law and public policy have been erected concerning end-of-life decision making. This case ushered in what in retrospect should be called the era of passively hastening death because, along with similar cases that followed in its wake for the next fifteen years or more, it established the right of terminally ill and permanently unconscious patients to have their deaths hastened passively, that is by having life-sustaining medical treatment withheld or withdrawn.

The Consensus about Forgoing Life-Sustaining Treatment

The *Quinlan* case was a catalyst to the development of law and policy about the termination of end-of-life medical treatment. It spurred state legislatures to adopt advance directive legislation intended to head off similar litigation. Federal and state commissions were appointed to study and make recommendations on these issues. Other landmark cases were litigated in other states; in the quarter century following *Quinlan,* courts in half the states decided more than one hundred similar cases—and within a decade, a remarkably uniform body of law and policy had emerged.

Each element of this consensus fed the others. Court cases spurred legislative action. Government commissions relied on important court cases and legislation as guidance for their deliberations and recommendations. Further court cases adopted the recommendations of the commissions. Although there are some important exceptions, taken together, these cases, statutes, and commission reports constitute a consistent consensus about how end-of-life decisions should be made.

Although Congress and the United States Supreme Court have played some role in its development, the legal components of this consensus have been almost exclusively state appellate judicial cases and state legislation. By the time the Supreme Court issued its first and only ruling in a case involving the passive hastening of death—the *Cruzan* case in 1990—the consensus was largely developed based on state law. The *Cruzan* ruling did little more than put the Supreme Court's imprimatur on a number of features of the existing consensus.

In the wake of *Cruzan,* Congress enacted the Patient Self-Determination Act (PSDA) in the same year. This law required institutional providers of healthcare to provide patients with information about their decision-making rights—including the right to make an advance directive. However, the Act was entirely procedural in nature; it did not establish any new rights, but only required that patients be told about their already-existing rights under *state* law.

COMPETENT PATIENTS. The centerpiece of the consensus on end-of-life decision making is the unanimous agreement that competent patients have a legal right to refuse treatment. So well established is this right that its existence has been largely assumed by both courts and legislatures. Although no court has ever said that this right is absolute, the manner in which courts increasingly discuss and apply it strongly suggests that they are headed toward that conclusion. In addition to the strong support in law-making institutions, the consensus of the public, of policy makers, of bioethicists, and the healthcare professions also supports a strong right to refuse medical treatment for competent patients.

LEGAL SOURCES OF THE RIGHT. Although in the *Quinlan* decision the New Jersey Supreme Court predicated the right to refuse treatment on a federal constitutional right of privacy, few other courts have based rulings on the right to privacy. It has become clear that this is a particularly weak basis for the right. Later courts have tended to ground the right in the common law—specifically, in the right to be free from unwanted interferences with bodily integrity protected by the law of battery. The United States Supreme Court, when addressing this issue in the *Cruzan* case, stated that the "logic of" a series of earlier cases decided by the Supreme Court suggests that there is a constitutional basis for such a right, but assumed this logic without actually holding that such a right exists. Presumably, this right is grounded in the protection of liberty contained in the Fourteenth Amendment to the United States Constitution, rather than the discredited right of privacy cited in *Quinlan.*

Regardless of the particular constitutional provision in which this right is grounded, the right is one that may only be asserted against individuals or institutions acting as agents of a state or federal governmental entity, and not against private individuals or institutions. Thus, the broadest and firmest legal basis for the right to refuse treatment is state law—state common law, state statutes, and state constitutional provisions—because it usually accords protections against actions taken by private individuals and institutions as well those taken by agents of the state.

HOW ABSOLUTE IS THE RIGHT? It can be said with absolute certainty that no legal right is absolute. In cases predating the *Quinlan* decision—mostly involving the refusal of blood transfusions by members of the Jehovah's Witness

religion—judges readily gave lip service to the right to refuse treatment but exhibited an enormous reluctance to match words with deeds, and exhibited a high degree of creativity in evading the full implications of the right. They did so by finding patients incompetent who might not have been, declaring emergencies on flimsy evidence, and insisting that the state had a strong interest in children having two living parents.

With the passage of time, these efforts to evade the full force of a competent patient's strong right to refuse treatment have substantially dissipated if not disappeared. In a series of legal cases beginning in the late 1980s, courts—especially the Florida Supreme Court (*Wons v. Public Health Trust; In re Dubreuil*), but others too—began gradually to enforce a full-blown right to refuse treatment when Jehovah's Witnesses refused blood transfusions. No longer did judges find patients incompetent primarily because they refused treatment, nor find an emergency to exist simply because a physician says the patient would probably die without a blood transfusion. Courts also recognized that parents of minor children have no obligation to avoid risk-taking behavior simply because they are parents of minor children (*Fosmire v Nicoleau*).

This change in attitude is probably accounted for primarily by the fallout from *Quinlan* and cases like it. As courts increasingly strengthened the right of terminally ill or permanently unconscious *incompetent* patients to refuse treatment, it became increasingly difficult, if not impossible, to justify denying that right to fully competent patients. It is significant that although the objection to medical treatment in the Jehovah's Witness cases was based on religious belief, the decisions themselves were generally grounded on a common-law right to refuse treatment applicable to all, regardless of religious belief.

A parallel trend beginning in the mid 1980s involved non-religious refusers of treatment who also were not terminally ill or permanently unconscious. In a handful of cases beginning in the mid-1980s, permanently disabled, competent patients began to raise the question of whether they had a right to refuse life-sustaining medical treatment. In the landmark *Bouvia* case in California, the court held that a woman in her 30s, a victim of cerebral palsy, had a right not to be force fed by medical procedures even if the refusal led to her death (*Bouvia v. Superior Court*). In three cases in Georgia (*State v. McAfee*), Nevada (*McKay v. Bergsted*), and California (*Thor v. Superior Court*), the highest courts in those states held that quadriplegic accident victims who were being kept alive by ventilators had the right to refuse further treatment and thus die. In all four of these cases, if treatment were continued the individuals were likely, with adequate nursing care, to have a relatively long life expectancy and to remain mentally intact.

Thus, it was not just the patients who were as close to death as they could be while still alive who had the right to refuse treatment and allow nature to take its course, but also patients whose prospects for a meaningful existence were virtually certain.

INCOMPETENT PATIENTS' RIGHT TO REFUSE TREATMENT. A core point of the *Quinlan* decision, which has become a cornerstone of the consensus on end-of-life decision making, is that incompetent patients, as well as competent patients, have a right to refuse medical treatment. *Quinlan* and subsequent cases raised two subsidiary issues. The first was whether the termination of life support would raise the prospect of legal liability for criminal homicide on the part of those who terminated treatment. The second was whether or not there were any limits on the right to refuse treatment.

Lack of criminal liability. In the development of the consensus in the courts, in public policy—most notably by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (President's Commission)—and in bioethics, there has been a unanimous assertion that forgoing life-sustaining treatment that results in a patient's death does not constitute a crime as long as there is proper authorization for the termination of treatment, either from the patient, from someone legally authorized to speak for the patient, or from a court.

There are a number of explanations offered in support of this conclusion. One is that when treatment is withheld or withdrawn, there is no *intent* to kill but rather to relieve suffering. Thus there cannot be liability for homicide or aiding suicide because each of these crimes requires intent. Another is that the *cause* of death is not the conduct of the party who withholds or withdraws treatment (or who authorizes the termination), but the patient's underlying illness or injury. It can be asserted that the patient is not killed, but rather is allowed to die when life-sustaining treatment is forgone.

A third explanation is that when life-sustaining treatment is forgone, there is no liability for assisted suicide because the kind of act required for assisting—"affirmative, assertive, proximate, direct conduct such as furnishing a gun, poison, knife or other instrumentality" (*Bouvia v Superior Court,* p. 306)—does not exist. This explanation is less successful if the crime to be charged is homicide because an omission to act when there is a duty to do so, as might be

the case when the actor is a physician or other healthcare professional, will support liability for homicide equally well as an act would (*Barber v. Superior Court*).

The fourth explanation given is that there is no criminal liability because the patient is exercising the legal right to refuse treatment. It is clear that this is not an explanation at all but a restatement of the question. Nonetheless, it is probably the best explanation. No liability, either criminal or civil, should arise as a result of a patient's death from forgoing life-sustaining treatment if this occurs in the exercise of a legal right to refuse treatment either by the patient or someone with legal authority to speak on his behalf. To conclude otherwise would be, in effect, to eliminate the right itself.

Limits on incompetents' rights: countervailing state interests. That there is a legal right of incompetent patients to forgo treatment does not mean that there are no limitations on that right. The courts have identified a number of countervailing societal interests that, in theory at least, may be invoked in opposition to the forgoing of treatment. These interests, recited in virtually every legal opinion on forgoing life-sustaining treatment, are:

1. the preservation of life;
2. the prevention of suicide;
3. the protection of third parties;
4. the ethical integrity of the medical profession.

In practice, these societal interests have not been accorded significant weight if the patient is terminally ill or permanently unconscious (or if the patient is competent). As to the preservation of life, the prevailing legal view is that of the New Jersey Supreme Court in *Quinlan*: "the State's interest … weakens and the individual's right to privacy grows as the degree of bodily invasion increases and the prognosis dims."

The prevention of suicide is not a significant matter because of the virtually unanimous view that the forgoing of life-sustaining treatment is not suicide. However, in instances in which a person is very seriously disabled but not terminally ill or permanently unconscious, some courts are more reluctant to permit the forgoing of life support unless there is clear and convincing evidence of the patient's refusal of treatment in circumstances such as these, prior to losing decision making capacity (*Martin v. Martin*; *In re Edna M.F. v. Eisenberg*; *Wendland v. Wendland*).

As previously mentioned, one of the ways that courts found to circumvent the right of Jehovah's Witnesses to refuse blood transfusions was to invoke the societal interest in the protection of the children of these patients. In the case of minor children, however, the view is beginning to prevail that even though it is desirable for them to have not just one but two living parents, many other children do not, and in any event, to impose medical treatment on an individual in furtherance of this interest is to deny that person the choice of which risks to take, a choice assigned to adults—even those with minor children—in virtually all other circumstances. The interests of other close family members are just too attenuated to prevail in the face of the strong right of individuals to make their own medical choices.

Likewise, the judicial view is virtually unanimous that the forgoing of life-sustaining treatment does not offend the ethical integrity of the healthcare professions because these professions no longer hold the belief, if they ever did, that the sole goal of treatment is cure. In cases where cure is impossible or even highly unlikely, "the prevailing ethical practice seems to be to recognize that the dying are more often in need of comfort than treatment" (*Superintendent of Belchertown State School v. Saikewicz,* p. 426). And, returning to basics, "if the doctrines of informed consent and right of privacy have as their foundations the right to bodily integrity … and control of one's own fate, then those rights are superior to the institutional considerations" (*Superintendent of Belchertown State School v. Saikewicz,* p. 427).

Decision making procedures for incompetent patients. A central issue in *Quinlan* was the issue of how the right to refuse treatment is to be exercised when the patient is literally incapable of doing so. The two extremes that the court had available were to require that all such decisions be reviewed by a court, or that they take place in the privacy of the doctor-patient-family relationship without any oversight. Rather than choosing either extreme, the court settled on a middle ground: decisions to forgo life-sustaining treatment were ordinarily to be made in the privacy of the clinical setting without judicial involvement. However, to provide some safeguards against inappropriate decisions, the court mandated that the decision receive approval by a multidisciplinary ethics committee. This was a novel approach adopted from a law review article written by a physician just one year earlier (Teel).

One serious difficulty with this approach was the assumption that hospitals had ethics committees when in fact very few did. However, by mandating the use of an ethics committee, the court set in motion a movement for most healthcare institutions to create them. Another problem was the fact that, although the committee was labeled an ethics committee, the role the court assigned to it was to confirm the patient's prognosis, a medical function for which such a multi-disciplinary committee was unsuited. The more fundamental criticism, however, was that ethics

committees had no clear moral authority to make or even review decisions about forgoing life-sustaining treatment.

As a consequence of these difficulties, no other court or legislature mandated the use of ethics committees in end-of-life decision making. In the *Saikewicz* case, decided just a year after *Quinlan,* the Massachusetts Supreme Judicial Court required that such decisions always be made by courts, because

> questions of life and death seem to us to require the process of detached but passionate investigation and decision that forms the ideal on which the judicial branch of government was created. Achieving this ideal is our responsibility and that of the lower court, and is not to be entrusted to any other group purporting to represent the "morality and conscience of our society," no matter how highly motivated or impressively constituted. (*Superintendent of Belchertown State School v. Saikewicz,* p. 435)

However, practical—and some philosophical—considerations ultimately won out. No other law-making body concurred in this position and within just two years, the Massachusetts court itself backed away from it. Requiring judicial review of all decisions to forgo life-sustaining treatment is too cumbersome, slow, and time-consuming. More fundamentally, it creates a tremendous intrusion by instruments of the state into the very private process of dying.

Thus, after a very heated debate, a consensus developed that all procedural aspects of the decision making process—the determination of whether or not the patient lacks decision making capacity, the designation of a surrogate decision maker, and any review of the decision about forgoing treatment—should ordinarily be made in the clinical setting. An ethics committee may play a role if the parties choose to have it do so, but it is not legally mandated. And in situations in which there is intractable disagreement among participants in the decision-making process about administering or forgoing treatment, or if there is a serious conflict of interest, the courts are available to adjudicate the issue.

Decision making standards for incompetent patients. One of the central tenets of the consensus concerns the standard by which a surrogate may make a decision for a patient who lacks decision-making capacity. In theory, surrogates could be empowered to exercise complete discretion—to make whatever decision they wish, for whatever reason they wish. Rather than according such unfettered discretion, courts have sought guidance from the values in which medical decision making is grounded, the primary one being autonomy. When competent patients make medical decisions for themselves, they are guided by their own values and goals. On the assumption that decision making for incompetent patients should be similarly guided, the courts have invoked autonomy as the guiding principle for decision making by surrogates as well.

The difficulty, of course, is that when the patient lacks decision-making capacity—and in many instances lacks even rudimentary communication capacity—the patient's values and goals cannot be determined contemporaneously. To honor and implement autonomy, the courts have mandated that surrogates attempt to determine what the patient would have decided if the patient were capable of deciding. Some believe, however, that this is an elusive and ultimately futile search and that for individuals for whom autonomy is lost, decision making must be based on other values (Dresser; Harmon).

The predominant standard that has evolved and been adopted is referred to as the *substituted judgment* standard. It requires the surrogate to determine what the patient would have wanted had the patient actually given thought to the matter—in other words, the patient's *probable* wishes.

A small number of courts (most notably, the New York Court of Appeals) reject the substituted judgment standard altogether and insist that decision making for patients who lack decision-making capacity must be made on the basis of their *actual* wishes, that the evidence adduced to establish their wishes be clear and convincing, and that the statements made by the patient have been uttered under "solemn" circumstances and not merely be casual or offhand remarks, such as those made in reaction to the treatment of another (*In re Westchester County Medical Ctr.* [O'Connor]). Those adhering to this standard are preoccupied by the possibility of an erroneous decision to allow a patient to die—that is, a decision that does not reflect the patient's own wishes—and that in the case of uncertainty, it is better to err on the side of keeping the patient alive.

The opposing view recognizes that prolonging life can entail undesired effects as well, as expressed by U.S. Supreme Court Justice William Brennan in a dissenting opinion in the *Cruzan* case:

> Dying is personal. And it is profound. For many, the thought of an ignoble end, steeped in decay, is abhorrent. A quiet, proud death, bodily integrity intact, is a matter of extreme consequence.… Such conditions are, for many, humiliating to contemplate, as is visiting a prolonged and anguished vigil on one's parents, spouse, and children. A long, drawn-out death can have a debilitating effect on family members.… For some, the idea of being remembered in their persistent vegetative states rather than as they were before their illness or accident may be very disturbing.

Sentiments such as these have motivated other courts and the President's Commission to permit surrogates to forgo life-sustaining treatment in the absence of any information concerning the wishes of the patient, on the basis of the *best interests* standard. These authorities take the position that while autonomy is the predominant value, it is not the only one, and that when autonomy cannot be effectuated because of ignorance of the patient's wishes, the patient's *welfare* must govern instead. In such a case, the surrogate is obligated to do what is best for the patient, which entails a weighing of the benefits of continued treatment against its burdens. If the burdens predominate, the surrogate may authorize the termination of treatment (*Barber v. Superior Court; In re Conroy*).

Family members as surrogates for incompetent patients. An important corollary of the views that decisions about life-sustaining treatment should ordinarily be made in the clinical setting without outside supervision, and that the patient's own views should govern decision making, is the presumption that close family members are the appropriate persons to speak for the patient. When a decision needs to be made whether to administer or forgo life-sustaining medical treatment, physicians should turn to close family members, who have moral and legal authorization to decide for the patient, even if they have not been appointed as guardians by a court or designated by the patient to be their spokesperson. This presumption is based on the belief that close family members best know the patient's actual or probable wishes (substituted judgment) and when they do not are most likely to act for the patient's welfare (best interests).

Advance directives in decision making for incompetent patients. Because of the centrality of the patient's wishes in decision making and the inability to ascertain those wishes in precisely the instances in which that information is most needed, the use of advance directives in end-of-life decision making has taken on a very high degree of importance. An advance directive is a device by which competent individuals make their wishes known about treatment if, at some future time, they should lack decision-making capacity. This is best done through a formal written instrument which either gives instructions about future medical treatment (referred to as a *living will*), appoints another person (*agent* or *proxy*) to make such decisions (referred to as a *health care power of attorney*), or both.

In the wake of the *Quinlan* and similar judicial decisions, it became readily apparent that it would be useful, if not essential, for individuals to have an advance directive. In 1976, the same year that *Quinlan* was decided, California became the first state to enact legislation to provide a firm legal basis to assure the validity of advance directives. For many years, there was some uncertainty about the validity of an advance directive without such legislation. By the end of the twentieth century, however, every state had enacted some type of advance directive legislation.

Some uncertainty continues to surround the use of advance directives. Advance directive statutes can be very limiting. Perhaps the most restrictive requirement is that before an advance directive becomes effective, the patient must be in a *terminal condition* or *permanently unconscious.* However, some individuals may wish to engage in advance healthcare planning for other conditions that they find particularly troublesome, such as dementia. It is still open to question in law, at least in some states, as to whether such "nonconforming" advance directives are legally enforceable.

The theory of healthcare decision making, based as it is on individual autonomy, would seem to allow individuals to issue instructions—especially instructions to forgo life-sustaining treatment, such as feeding tubes—to cover such situations. However, a highly defensible position, as stated more or less explicitly in the statutes themselves, is that the statutes do not create legal rights to refuse (or consent) to healthcare, but merely provide a mechanism for doing so. The Uniform Health Care Decisions Act, a model law drafted by the National Council of Commissioners on Uniform State Laws, lacks the restrictions found in most advance directive statutes, but must be adopted in an individual state before it has the force of law, and so far it has not been.

Perhaps the largest obstacle to the efficacy of advance directives—to which the previously-mentioned PSDA was seen as a solution—is that most people do not have them, either out of ignorance of what they are or of their importance, or because of an aversion to planning for death, exhibited also by the failure of many people to buy life insurance or write wills.

Forgoing Artificial Nutrition and Hydration

In the *Quinlan* case, the legal question was whether Karen Quinlan could be allowed to die from the withdrawal of the ventilator that was keeping her alive. After the New Jersey Supreme Court answered this question in the affirmative, and her physicians gradually withdrew her ventilatory support, she continued breathing on her own, contrary to the medical assumption on which the case had been decided. Thereafter, she was kept alive by a feeding tube, raising the question of whether her parents could authorize the termination of the feeding tube as well.

Because they did not seek to do so, this question remained unanswered until 1983, when it arose in the California case of *Barber v. Superior Court.* In this case,

physicians were subjected to criminal prosecution for the termination of a feeding tube from a patient diagnosed, like Quinlan, as being in a persistent vegetative state. This case, for the first time in a judicial forum, raised the question of whether it is permissible to withhold or withdraw nutrition and hydration. It is also the first of only two criminal prosecutions that have ever occurred for forgoing life-sustaining treatment with the consent of someone legally authorized to make such decisions for the patient.

Opponents of permitting the forgoing of nutrition and hydration usually raise two major objections. First, nutrition and hydration is not a medical procedure but basic sustenance, and thus should not be treated the same as, for example, a ventilator. In this view, one is no more morally entitled to remove nutrition and hydration from an incompetent patient than from a young child who cannot provide itself with nourishment. Perhaps the best legal rejoinder to this claim was issued in the *Cruzan* case by U.S. Supreme Court Justice Sandra Day O'Connor, who addressed the question by declining to answer it. Rather than entering into the debate about whether nutrition and hydration provided by a feeding tube was or was not a form of medical treatment, she observed that regardless of how it is characterized, when provided to an unwilling patient it constitutes a restraint on individual liberty. Since it is certainly contrary to individual autonomy to force feed a competent patient, it is contrary to the individual autonomy of an incompetent patient as well, when the patient's surrogate refuses it based on the patient's previously expressed wishes.

The second objection is that death resulting from the forgoing of nutrition and hydration amounts to killing, rather than letting nature take its course, and is therefore unlawful and immoral. The standard rejoinder to this is that there is no difference between termination of nutrition and hydration and other treatments. When a ventilator is terminated, the patient dies because his injury or illness prevents him from breathing and that is the cause of death. Similarly, feeding tubes are placed in, and only removed from, patients whose injury or illness prevents them from eating in the ordinary way, and thus it is the injury or illness, rather than the actions of the individual who removes the feeding tube, which is the cause of death.

Actively Hastening Death

The distinction between passively and actively hastening death has been central to the development of the consensus about end-of-life decision making. The former is equated with forgoing life-sustaining treatment, which includes both withholding treatment not yet begun and withdrawing treatment that is in progress. Actively hastening death consists of both active euthanasia (sometimes referred to as mercy killing) and assisted suicide. Active euthanasia is the direct ending of a human life, by a lethal injection, for example, whereas assisted suicide is defined as giving another the means by which that person ends his or her own life, such as providing a prescription for a lethal dose of medication which the person then ingests. Both legal and ethical thought have, for the most part, drawn a bright line between passively and actively hastening death, holding the former to be both morally and legally licit and condemning the latter as killing, and thus immoral and illegal.

The reasons for viewing passively hastening death as not constituting a crime were previously discussed. By contrast, when death is actively hastened—whether by the patient with assistance from another (assisted suicide) or directly by another (active euthanasia)—it is usually said that criminal liability cannot be avoided because all of the elements of a crime—act, intent, causation, consequence—are present. In the case of active euthanasia, to wit, the actor commits an *act,* with the *intent* of bringing about the patient's death, which is the *cause* of the patient's *death.*

From a legal, political, and policy perspective, this reasoning has been essential to the development of the consensus. It was simply not possible politically for legislatures or courts to have characterized forgoing life-sustaining treatment as killing and then to have attempted somehow to permit it. It was far simpler and more palatable to the public and to judges themselves to legitimate passively hastening death by denying that it was killing. Similarly, it would simply have been too great a leap from existing mores to legitimate actively hastening death, had any judge or legislator even wished to do so, because it involves practices that traditionally have been viewed as killing, even when done with merciful motives.

With the passage of time and increasing clamor for the legalization of actively hastening death—or at least for the legalization of suicide assisted by a physician—the weaknesses in the reasoning used to distinguish passively and actively hastening death have gradually become more apparent. Nonetheless, with a few exceptions both in the United States and other countries, legal barriers to actively hastening death remain.

Beyond the Consensus: The Legalization of Actively Hastening Death

Although the bright line between passively and actively hastening death is part of the bedrock on which the ethical, legal, and policy consensus about forgoing life-sustaining treatment has been grounded, it has not been immune from

challenge. These challenges have come in writings by ethicists, in litigation, and in legislation.

It has occasionally been asserted that a physician is prohibited by law and ethics from undertaking an act that would end a patient's life because it constitutes killing, but is permitted to omit treating a patient because he or she is merely allowing nature to take its course and the patient to die. Both the courts and public policy makers (President's Commission) have been quick to correct this misunderstanding. Certainly taking an affirmative act to end the patient's life, such as giving the patient a lethal injection, is a legal wrong; omitting is also a legal wrong if there is a duty to act, and a physician is under a duty to treat unless excused from doing so by the patient, the patient's surrogate, or a court. Thus the categorical distinction between wrongness of acting and rightness of omitting is fallacious.

The same is true of withholding and withdrawing treatment. It has sometimes been thought that withdrawing treatment is a wrong because it involves an act, but withholding treatment is legally and ethically acceptable because it involves an omission. Again, if there is a duty to act, withholding is a legal wrong, unless properly excused. However, withdrawing treatment, even though it involves an act, is not considered killing because, unlike the administration of a lethal substance to the patient, withdrawing treatment merely allows nature to take its course. On policy grounds, the distinction between withdrawing and withholding is an especially pernicious one, because permitting treatment to be withheld but not withdrawn would discourage physicians from trying to treat some patients thought to be hopelessly ill out of fear that once started, treatment could not later be stopped, even if it were ineffective in reversing the patient's condition.

While the weaknesses in the reasoning that supports passively hastening death but rejects actively hastening death have long been apparent (Rachels), they have been papered over by the courts and justified by policy analysts when this has seemed necessary to achieve what some see as the desirable result of not legitimating actively hastening death. Some recognize the desirability of permitting actively hastening death in individual cases but oppose legalization, preferring to leave it to the private actions of doctors and patients, and to allow the legal system to exercise discretion in not prosecuting those truly merciful cases that come to its attention. The difficulty with this approach is that because the legal outcome for those who provide assistance or engage in mercy killing is so uncertain and so potentially serious, few will be willing to take the chance. Consequently, actively hastened death will not, in fact, be available to those whose conditions may warrant it, or else will be available on an arbitrary basis.

Apart from those who see actively hastening death as killing and condemn all killing as wrong, the primary concern seems to be a practical one. If actively hastening death becomes legally acceptable, there will be no way to draw lines to confine it to those for whom it might be appropriate, on both policy and ethical grounds, and it will become susceptible to widespread abuse through incremental extensions of existing accepted practices. For instance, if physician-assisted suicide becomes legal, what reasoning can confine actively hastening death to those who can self-administer the instrumentality of death? There will be individuals whose claims to actively hastening death are equally high, but who are no longer able to end their own life and thus must have someone end it for them. If actively hastening death is then extended to this group, there will be individuals who lose their decision-making capacity before being able to have their lives ended. Should not, in the name of equity, individuals be allowed to execute an advance directive requesting that their deaths be actively hastened when they are no longer able to do so themselves, and when they meet the conditions specified in the advance directive? And if this becomes permissible, then surely an actively-hastened death will be permissible for individuals whose wishes were never committed to paper but can be intuited by relatives using the substituted judgment standard. And if such evidence is lacking, then perhaps the best interests standard should be applied to permit an actively hastened death as it sometimes is to allow for passively hastened death. While this may not be the bottom of the proverbial slippery slope, it is far enough to demonstrate to many the lack of wisdom of ever stepping onto the slope by legitimating any form of actively-hastened death.

Proponents of taking the first step, however, believe first that it is merely a logical extension of the same process that recognized the legality and ethicality of passively-hastened death. Further, they believe that taking one step, or even more than one, does not necessarily entail a commitment to taking the next step. Experience and policy considerations may suggest limitations even where logic might dictate otherwise. Finally, proponents point to the inequity of permitting the terminally ill who depend on life-sustaining medical treatment to have their lives ended, but not permitting the same merciful release from suffering to the terminally ill who may have an equal claim but who happen not to be dependent on life-sustaining medical treatment.

Legalization of Physician-Assisted Suicide

Events began to overtake logic in the 1990s in the United States. Efforts to legalize physician-assisted suicide through voter initiatives took place in five states; all but one failed to

win passage. Oregon voters approved a ballot initiative in 1994, which did not go into effect until 1997 because of efforts to overturn it in the courts and through a second voter initiative. Bills have been introduced into the legislatures of many states to legalize physician-assisted suicide, but none received very much support until 2002 when the Hawaii legislature narrowly defeated such an effort.

Several lawsuits have been filed seeking to declare unconstitutional state laws making assisted suicide a crime. Lower federal courts invalidated such laws in Washington state and New York state, at least when the person seeking assistance in dying was competent and terminally ill, and when the person rendering the assistance was a licensed physician. The two cases, *Washington v. Glucksberg* and *Vacco v. Quill,* were reversed by the United States Supreme Court in 1997. The Court held that there is no federal constitutional right to physician-assisted suicide—that states are constitutionally permitted to make assisted suicide a crime, but it is also constitutionally permissible for a state to legalize physician-assisted suicide, as Oregon had done.

All of the discussion of legalizing actively hastening death in the 1990s took place against the backdrop of the activities of Dr. Jack Kevorkian, a retired physician who publicly announced that he would aid individuals in ending their lives. He publicized many of his cases—totaling well in excess of one hundred until he was imprisoned in 1999. The high visibility of his activities was taken as a defiant invitation to legal authorities to file criminal charges against him on several occasions, but none were successful until he went beyond aiding patients' deaths and administered a lethal substance to a terminally ill man and then gave a videotape of the event to a national television network, where it was publicly broadcast. He was then indicted for murder, tried, and convicted.

Another important component in discussions of legalizing actively hastening death has been the experience with the open practice of active euthanasia in the Netherlands since the early 1970s. Until 2001, voluntary active euthanasia by physicians for competent terminally ill patients has been formally illegal, but actively practiced and not prosecuted by the authorities—if the physician complied with guidelines proposed by the Minister of Justice and the Secretary of Health—and supported by the Royal Dutch Medical Association. In that year, the Netherlands formally legalized voluntary active euthanasia along lines quite similar to the informal practice that had previously prevailed.

Dr. Kevorkian's activities were widely viewed as highly irresponsible by both supporters and opponents of the legalization of actively hastening death. Nonetheless, most admit that his activities—as well as the developments in the Netherlands—did have the consequence of helping to open public debate on this issue. One of the undoubtedly salutary consequences of the public debate has been an acknowledgement and realization that the medical profession has been laggard in providing adequate palliative care—especially pain relief—to terminally ill individuals, and that there has been inadequate education of physicians about these issues. In the view of many, improvements in these areas are not only necessary to relieve the suffering of the dying, but they may also go a long way in derailing the legalization of actively hastening death. Others, however, see these two approaches as complementary, rather than working in opposition to each other.

THE OREGON EXPERIENCE WITH PHYSICIAN-ASSISTED SUICIDE. Physician-assisted suicide was legalized by a voter initiative in Oregon in 1994 and went into effect in November 1997. The law does not actually refer to physician-assisted suicide; the title of the law is the Oregon Death with Dignity Act, but in fact physician-assisted suicide—or, as some prefer to call it, physician aid-in-dying—is the practice that is made legal. The law permits a competent terminally ill patient to have a physician prescribe a lethal dose of medication for the patient to self-administer; it does not permit the physician or anyone else to administer the medication (active euthanasia).

In the first four years of its operation, 140 (2001: 44; 2000: 39; 1999: 33; 1998: 24) people obtained lethal prescriptions from their doctors and 89 (2001: 19; 2000: 27; 1999: 27; 1998: 16) used them to end their lives. The remainder died without using the prescriptions. The death rate for those using a lethal prescription varied between six and nine per ten thousand, which is in the same range as the death rate of individuals who die otherwise. Most patients suffered from cancer. The three most commonly mentioned reasons that patients wanted to end their lives were loss of autonomy, a decreasing ability to participate in activities that made life enjoyable, and losing control of bodily functions. The overwhelming proportion of patients died at home.

Fears that people who would avail themselves of physician-assisted suicide would do so because of lack of alternatives were not borne out by experience. More than three-fourths of patients were also enrolled in a hospice care program, and all had some form of health insurance. Likewise, patients who used physician-assisted suicide were similar in terms of age and race to those who died without using it. Patients who used physician-assisted suicide were also better educated. However, more women died in this manner than men with comparable disease, and those who died in this way were more likely to be divorced and possibly

not have as good family support systems (Oregon Department of Human Services).

Opponents of the legalization of physician-assisted suicide in Oregon have mounted several efforts to have the law invalidated. The first was a lawsuit challenging the constitutionality of the law, which delayed its implementation for three years. While this lawsuit was pending, opponents were able to put an initiative to overturn the original legalization on the Oregon ballot in 1997. Although the original approval was by a 51 percent to 49 percent margin, Oregon voters underscored their approval of the physician-assisted suicide legalization by refusing to repeal the law by a 60 percent to 40 percent margin. However, shortly after the law went into effect, the director of the federal Drug Enforcement Administration (DEA) ruled that it was a violation of the federal controlled substances act for doctors to use controlled substances in the implementation of the Oregon law. This was quickly reversed by the U.S. Attorney General Janet Reno. Bills were then introduced in two sessions of Congress to prevent the use of controlled substances in physician-assisted suicide, but neither was enacted. With a change of administration in 2000, Attorney General John Ashcroft reversed the policy of the former Attorney General and banned the use of controlled substances in physician-assisted suicide. A lawsuit was then filed to prevent implementation of the Attorney General's order, and a federal court ruled that the order was illegal and could not be implemented.

Beyond the Consensus: Autonomy Turned Upside Down

Although patient autonomy is the foundation on which the consensus around end-of-life decision making has been built, autonomy has encountered a serious challenge in the form of so-called futility cases. These cases reverse the usual right-to-die cases. In those cases, competent patients or family members have determined that further treatment is unwarranted and challenged physicians who have wanted to continue to provide treatment. In futility cases, physicians and other healthcare professionals conclude that further treatment is unwarranted, but are met by resistance from competent patients—or, more likely, family members of incompetent patients—who insist that treatment be continued. Despite the raft of literature on this subject, there has been very little contribution to resolution of this debate by either courts or legislatures. Most likely, situations of this sort are eventually resolved in the clinical setting either by the patient's death, for the patients involved are usually very critically ill, or by a realization by family members over time that further treatment will not improve the patient's condition.

Future Challenges for Policy Makers, Legislators, and Health Professionals

The consensus about forgoing life-sustaining treatment has become well-accepted in public policy, law, and clinical practice. Despite the fact that half of the states have not yet experienced a major legal case, it does not seem likely that these states will make major changes in the consensus.

The same sort of stability is not likely to exist with respect to actively hastening death. Coming decades are likely to witness continuing challenges to the prohibition on assisted suicide in the courts, in state legislatures, and through ballot initiatives. Acceptance in law is likely to be very gradual, if it occurs at all. However, the influence of the movement to legalize actively hastening death will continue to be felt in improved efforts at providing alternatives in the form of hospice care, palliative care, and the more judicious use of pain relief medications, even if they might hasten death.

S

SCIENCE, PHILOSOPHY OF

• • •

Philosophy of science as an autonomous subject is a product of the twentieth century. Its development stemmed from the great intellectual challenges of the quantum and relativity theories, but philosophical issues surrounding such theories as psychoanalysis, evolutionary theory, Marxist and capitalist economics, the ethics of human experimentation, and the enormously increased importance of science as an intellectual endeavor led to a great expansion of the field.

Work within philosophy of science tends to fall into two approaches. The first sees science as a testing ground for traditional philosophical problems. Chief among these traditional problems is this: Can we have any knowledge that is certain and in terms of which all other knowledge in the area can be justified (*foundationalism*), or are all claims to knowledge uncertain (*fallibilism*)? Within the realm of things that can be known by empirical investigation, it would seem that science has the best claim to secure knowledge. Philosophers of science have thus devoted a considerable amount of time to what kinds of scientific methods are effective in producing such reliable knowledge. On the other hand, many philosophers, especially in recent times, have denied that science does actually produce a privileged body of knowledge, and have argued that all scientific knowledge is a product of its historical and social context.

The second approach to philosophy of science focuses on issues that are peculiar to individual sciences. Of particular interest here is the possibility of reducing biology to chemistry or physics, and of reducing some of the social sciences, especially psychology, to biology. If these reductionist projects were to be successful, then issues that currently appear to be peculiarly biological, such as the question of what makes something a living organism, would turn out to be merely a question of degrees of complexity, and not specifically biological at all. In addition, the moral issues that pertain to humans and animals because of their psychological characteristics would be approached very differently if psychological properties were considered to be unreal or merely disguised biological properties. These differences between the sciences are crucial. For example, a great deal of medical research cannot enjoy the unlimited freedom of laboratory experimentation that is characteristic of physics simply because of the ethical constraints its subjects require. Moreover, the variability of its subjects makes universal laws hard to formulate in biology, in distinction to, for example, astronomy.

Predecessors to Contemporary Viewpoints

It was the logical positivists and logical empiricists of the Vienna Circle (1923–1936) and the Berlin school (1928–1933) who succeeded in placing scientific issues near the heart of the philosophical enterprise. (A classic, albeit sententious, presentation of the logical positivists' views can be found in A. J. Ayer's *Language, Truth and Logic,* 1946.) For philosophers such as Moritz Schlick, Rudolf Carnap, Hans Reichenbach, and Carl Hempel, all of whom had a scientific education, the task was to provide a foundation for genuine knowledge, and this foundation was to be as secure as the best science of the time. The logical positivists were squarely within the empiricist tradition, which holds that all genuine knowledge must be reducible in principle to knowledge obtainable by empirical methods, and ultimately to that obtainable through the human sensory apparatus. To

this empiricist view they added a deep concern with language resulting from developments in logic in the late nineteenth and early twentieth centuries. Although the most famous manifestation of their approach was the attempt to eliminate metaphysical claims through the verificationist criterion of meaning (which asserts that a sentence is factually significant to a given individual if and only if he knows what observations would lead him to accept that proposition as true or to reject it as false), their true legacy has been the view that it is by means of logical analyses of philosophical concepts that genuine understanding is achieved. It is no exaggeration to say that philosophy of science since 1950 has been primarily engaged in a struggle to decide which elements of the positivist monolith to retain, and what should be the replacement approaches for those parts that have been rejected.

Falsificationism

An important alternative to the positivist program has been the falsificationist approach of Karl Popper. Although his *Logik der Forschung* was published in 1934, its impact was muted until the expanded English translation appeared in 1959 as *The Logic of Scientific Discovery.* Popper set himself the task of providing a criterion that would distinguish between genuine scientific hypotheses and pseudoscientific statements. A key belief driving Popper's work was his view that the traditional problem of induction could not be solved. Most generally, inductive inference involves reasoning from what has been observed to what has not been observed, a characterization that covers inferences from the past to the future, from observed data to the existence of directly unobservable microentities such as prions, and from finite data sets to the universal hypotheses that represent scientific laws and general theories. Justifying inductive inferences was a serious problem for logical positivism, because the verificationist criterion ruled out all universal scientific theories and laws as meaningless, simply because no amount of finite data could conclusively verify these general claims. Popper instead proposed the demarcation criterion that a statement or theory was scientific only if it was falsifiable; that is, it must be possible to state in advance a set of possible observations which, if observed, would result in the statement or theory being rejected. Theories such as astrology and psychoanalysis were, according to Popper, branded as pseudoscientific on the basis of this criterion because they traditionally accommodated themselves to fit any observations whatsoever. To refuse to relinquish a theory in the face of recalcitrant data is a characteristic feature of scientific irrationality. Popper's brand of falsificationism is comprehensive, for it requires that even reports of observations be falsifiable. Thus, in contrast to the positivists' foundationalism, which is grounded in an empirical base that is certain, falsificationism is a deeply fallibilist position, within which claims to certainty are relinquished at all levels of generality.

Popper was well aware of a point often made by the French philosopher Pierre Duhem: In order to draw out testable predictions from scientific hypotheses, one ordinarily needs to assume the truth of various background assumptions and theories (Duhem). Thus, if the prediction turns out to be false, the force of the falsification could be deflected away from the principal hypothesis onto the background assumptions. Hence the need in the above specification of falsificationism to state *in advance* what would result in the hypothesis being rejected.

Although this strategy removes the force of Duhem's criticism that there are no crucial experiments that can conclusively decide between competing theories, it moves the emphasis away from a method of testing that is based only on logic and empirical data to one where a (human) decision plays a central role, and this introduces a characteristically conventional element into the picture. Falsificationism is primarily a normative methodology, for it prescribes and proscribes courses of action with respect to scientific hypotheses. As historical and sociological studies of science have become increasingly influential, there has been a concomitant emphasis on the need for methodological theories to be descriptively accurate of what scientists do and have done. It is easy to find cases where historically important episodes of science do not fit the falsificationist model, ones where scientists refused to abandon theories in the face of clear counter evidence. The difficult task is to articulate when this furthers broad scientific ends, rather than just narrow personal motives. But to reject falsificationism merely because it is not descriptively accurate of everything done in the name of science would be as misguided as the attempt to turn ethics into a purely descriptive enterprise.

Thomas Kuhn's Work

One of the best known alternatives to the positivist approach is Thomas Kuhn's. Ironically, Kuhn's seminal work *The Structure of Scientific Revolutions* (1996) was originally published in the positivists' *International Encyclopedia of Unified Science* (Kuhn, 1955). Kuhn's strategy was to use the history of science as a proving ground for methodological positions in the philosophy of science. This history, Kuhn claimed, could be divided into two distinct types of periods. There were long stretches of normal science punctuated by brief periods of revolutionary science. To illuminate both kinds of science, Kuhn introduced the concept of a scientific paradigm. This concept, in its mature characterization, consists

of four components. First, there are the symbolic generalizations, those fundamental laws and principles of a science that underpin all theoretical work in the field, such as the laws of genetic replication or the principle of natural selection of species. Second is the metaphysical component of the paradigm, within which the fundamental kinds of things constituting the subject matter of the science are specified, such as atomistic or field-theoretic assumptions in physics, or a commitment to specifically mental properties, as opposed to material properties, in psychology. Third, there are the value commitments. These not only concern what constitutes an acceptable piece of evidence in the science, but what the appropriate goals are for a science, and what the ethical standards are to which one should adhere. Thus, double-blind studies will be considered the standard methodology for drug trials. Fourth, there are the exemplars, those quintessential successes that a scientific field can point to as evidence for the fruitfulness of the first three elements, as, for instance, Newtonian mechanics could point to its success in predicting the existence of the planet Neptune.

Normal science, then, is science conducted entirely within the framework of a single paradigm, whereas revolutionary science consists in the development of a competing paradigm and the process of a scientific community's transfer of allegiance to the new paradigm. A seemingly inescapable consequence of paradigm change in periods of revolutionary science, and one that is deeply disturbing to many, is that the process of change is determined by neither rational argument nor empirical evidence. Because a change in paradigm necessarily involves a change in at least one of the four components already described, there will inevitably be fundamental differences of opinion about whether the old or the new component is preferable, and the remaining three components will frequently not provide a large enough common ground to resolve the dispute in an impartial way. In this way, paradigms are, to use Kuhn's term, incommensurable. There is then a deep difference between Kuhn on the one hand and both Popper and the positivists on the other.

Equally important is the distinction between internal and external descriptions of science. Within both the positivists' and Popper's approaches, the way in which science proceeds ought to be appraised only in terms of influences that are purely internal to the science at hand, including the construction of theories, the invention of new experimental apparatus, and the verification or falsification of hypotheses by empirical data. Any interference by nonscientific factors, such as economic considerations, political pressure, and religious prohibitions, are to be condemned as illegitimate influences to be resisted in practice, and ignored in writing the history of the science. In contrast, Kuhn holds that not only are such influences usually present and causally effective in propelling or impeding the elaboration of a paradigm, but they are frequently important in fixing the values component of a paradigm. Thus, the religious opposition to research on fetal tissue derived from deliberate abortions, the political pressure to direct funds in molecular biology toward acquired immunodeficiency syndrome (AIDS) research, and the decision to allocate significant financial resources to the Human Genome Project are all part of an externalist appraisal of the scientific research concerned. Inseparable from this externalist approach is the shift in emphasis from scientific theories as logical entities whose existence and appraisal are objective matters, and the truth or falsity of which is something to be discovered, to a position where the opinions of a community of scientists are primary, and acceptance of a paradigm is determined by a consensus in that community rather than by the paradigm's truth or falsity. Coupled with the inclusion of externalist factors, this leads naturally toward a focus on the sociology of science, rather than its philosophy as traditionally conceived.

Some further consequences of the Kuhnian approach are worth mentioning. Because of the incommensurability of paradigms, revolutions lead to schisms in the path of science, with a resulting loss of the notion of scientific progress. Comparative judgments of the kind "Paradigm A is superior to Paradigm B" can no longer be made on a uniform scale of comparison, and what remains is technological progress without any necessary concomitant progress toward the truth. Consequently, what has come to be known as the Whig view of the history of science, which sees the development of science as an uninterrupted triumphal march to the peak of contemporary success, has to be abandoned in favor of a contextually sympathetic interpretation of previous theoretical traditions. Finally, if Kuhn is correct, there is no longer anything peculiarly privileged in the scientific enterprise. The development of art, architecture, music, and so forth can all be characterized in terms of paradigms, normal practice, and revolutionary changes, a feature that has not escaped Kuhn's critics.

Contemporary Work in the Field

Perhaps the most important consequence of the collapse of the positivists' domination in the philosophy of science has been the splintering of the field into a number of subsets. One principal division is between those who continue to hold that there are general principles underlying various scientific methods, and those for whom only local, context-specific approaches are feasible. Certain areas of science still seem to be amenable to the first approach. The nature of scientific explanation is a topic of perennial interest, with

various causal and unification approaches (Salmon) serving as the chief contenders to replace Carl Hempel's logical model. How scientific hypotheses and theories are confirmed is the subject of another area of research (Achinstein), with computer-assisted diagnostic procedures in medicine forming a small but important proving ground for inference procedures. There is considerable current interest in causal inference, particularly of the kind used in epidemiology (Pearl). Despite these successes, issues related to the autonomy of particular sciences have increasingly come to the fore. The positivists' orientation towards reducing all sciences to physics, at least in principle, has been replaced by a recognition that at least in practice, and perhaps even in principle, this reduction cannot be carried out. There is now a "philosophy of X" for almost every science, from economics to geology. In particular, the philosophy of biology and the philosophy of medicine are well established subfields with their own problems and methods. Accompanying this trend has been a reduced emphasis on grand unifying theories in favor of local models that capture, albeit imperfectly, the structure of specific systems (Humphreys). This latter approach works well for biological models, within which the sheer number and complexity of the influences on a system and the importance of its historical evolution render simple general theories inadequate.

A second primary division is between those for whom normative, objective, and a priori characterizations of science are desirable and attainable, and those who maintain that such characterizations are inevitably descriptively inaccurate and unrevealing of the true nature of science. Within this latter orientation lie contemporary naturalistic and cognitive approaches to philosophical issues. Philosophers using these methods hold that scientific knowledge from areas such as psychology and evolutionary biology shed more light on why certain methods are successful than can more traditional a priori approaches. For example, instead of specifying a priori the inferences that an ideal reasoner should make in deciding which course of action is appropriate in some clinical setting, a naturalist will investigate the heuristics that underlie reasoning used in clinical practice (Gigerenzer, Todd, and ABC Research Group).

Another dispute is between those who hold that many objects of scientific investigation, such as various psychiatric disorders, are social constructions, and those who hold that there is an objective reality that science investigates (Hacking). Much of this work is interesting and legitimate, but the rejection of traditional norms of rationality has led in certain quarters to a denial that science has any claim to superior methods of investigating the world. The so-called "science wars" between those who seek to maintain the epistemological superiority of science and those who wish to undermine it are an extreme, albeit avoidable (Koertge) consequence of this division.

All of the threads described have made formulating a satisfactory account of scientific progress less easy than it was in earlier periods, especially within the philosophy of biology. The piecemeal framework of models, the attacks on both the rationality of scientific appraisal and the objectivity of reality, the autonomy of multiple sciences—all have made a defense of progress towards a unified scientific account of the world more difficult than one might wish. Nevertheless, mere complexity and locality does not preclude science from accurately describing an objective reality in a systematic and rational fashion.

Summary

Philosophy of science and bioethics share a common concern. Each must draw a line between the prescriptive and the descriptive, between what is rational and justified on the one hand, and what is merely popular opinion and prejudice on the other. Both Galileo and Ignaz Semmelweiss were victims of such antiscientific attacks, the first for advocating the correct theory of the solar system, the second for discovering the mode of transmission of childbed fever. It is thus essential to have some clear distinction between fact and opinion, between the rational evaluation of a hypothesis or ethical view and its mere acceptance, between what is ethically justified and the way individuals happen to act. To use a specific example, it is essential to distinguish between what science can do to allow premature babies to survive and how one can evaluate the quality of life they might expect. This, if nothing else, is why the apparently dry and abstract issues of the foundations of knowledge, of internal and external influences on science, and of fact versus convention bear directly upon matters of more immediate concern.

SCIENTIFIC PUBLISHING

• • •

During the late 1970s and the 1980s, an ethics of scientific publication began to evolve. Competition among scientists for academic rewards and research funds, the continued fragmentation and commercialization of science, and reports of scientific misconduct, as well as increasing governmental and legal interference with the inner workings of the scientific community led many within that community to perceive a need for reforms to guide both the conduct of science and the dissemination of scientific information. Journal editors, universities, professional associations, funding agencies, and governments have taken active roles in debating and setting ethical standards and editorial policies for the dissemination of scientific information. In 1978, a self-appointed group of editors, the International Committee of Medical Journal Editors (ICMJE), representing leading general medical journals, met in Vancouver, British Columbia, to set technical guidelines for the submission of manuscripts. These guidelines, the Uniform Requirements for the Submission of Manuscripts to Biomedical Journals, have evolved to include statements for the ethical conduct of authors, editors, and peer reviewers. While the ICMJE statements set international standards for biomedical publishing, the number of journals that adhere to them is unknown (ICMJE, 1991, 1993b). This entry presents an overview of the major ethical issues in biomedical and scientific publishing.

Editorial and Peer Review

The prestige and influence of biomedical journal publication are closely related to the quality control and selection process that precedes publication. Thus, the essential tasks of medical editing are the selection and improvement of articles submitted for publication. These tasks are generally accomplished through processes of editorial review (evaluation by the journal's editorial staff) and peer review (evaluation by experts in a given field who are considered the authors' "peers"). These two processes may overlap, particularly when an editor is also an expert in a manuscript's topic, but editorial review usually focuses on the appropriateness, clarity, and priority of articles for the journal's readership. Peer reviewers are selected by the editor to assess the quality of an article's scientific and technical content and to offer advice about publication. Since decisions regarding rejection, revision, or acceptance are made solely by the editor, the term *referee* exaggerates a reviewer's advisory role and should be avoided.

Peer review was first used for biomedical publications by the Royal Societies of London and Edinburgh in the eighteenth century, but evolved haphazardly; it was not employed regularly until after World War II (Lock). Two striking aspects of peer review are that it is based almost entirely on uncompensated, voluntary labor and that the peer review system itself has only recently come under scientific scrutiny (Lock; "Guarding the Guardians,"; Rennie and Flanagin, 1994b). Journals follow differing policies about revealing reviewers' identities to authors and authors' identities to reviewers (Lock; "Guarding the Guardians,"; Rennie and Flanagin, 1994b). Some editors believe that disclosure of reviewer identities to authors decreases the potential for bias, while others believe such disclosure leads to less critical reviews. Many biomedical journals do not

attempt to remove the identities of authors or their institutions from submitted manuscripts; studies have shown that author identities may be discerned by reviewers from the paper's content or from bibliographic citations, especially in narrow subspecialties (Lock). On the other hand, these same journals do not reveal the identities of peer reviewers to authors. While most editors are impressed by the care and objectivity usually reflected in reviewer comments and recommendations, the anonymous review of papers whose authors are known obviously involves potential for abuse. To maintain integrity in the peer review process, reviewers are expected to disclose any conflicts of interest involved in their review, and editors are expected to be alert to any signs of bias that may interfere with an objective evaluation of the merits of the paper.

Maintaining the confidentiality of an author's work before publication is an important ethical principle in scientific publishing. Most journals inform peer reviewers that the information in unpublished manuscripts is privileged and should be kept confidential, and also require manuscripts to be either returned to the editorial office or destroyed after review. However, maintaining confidentiality depends on an honesty among editors, authors, and reviewers that is nearly impossible to guarantee. Conscious or unconscious intellectual theft by peer reviewers may occur but cannot be measured. Journal editors have a particular responsibility to maintain strict confidentiality about the peer review process, editorial decisions, and all manuscript submissions.

How well do the processes of editorial and peer review work? Many persons involved in publishing recognize the improved quality of articles that have been revised after review, and this has been clearly demonstrated with regard to improvements of study designs and statistical methods ("Guarding the Guardians,"; Rennie and Flanagin, 1994b). Nevertheless, both editorial and peer review are based on human judgments that carry the potential for bias and error.

One form of publication bias is the tendency for papers with statistically significant "positive" results (for example, those showing that a new treatment works better) to be published in favor of papers with statistically nonsignificant "negative" results (for example, those showing that a new treatment does not have any effect or does not work any better than other treatments). Studies have shown that such publication bias exists, but its extent is unknown and controversial ("Guarding the Guardians,"; Rennie and Flanagin, 1992, 1994b). Prepublication bias (the tendency of authors not to submit negative results for publication because the findings are incomplete or nonsignificant or because funding runs out) and postpublication bias (bias in the reception and interpretation of published research data by researchers, funding agencies, editors, and the media) may be more substantial problems. All of these forms of bias can lead to inappropriate medical policies and treatment decisions, especially with new or controversial therapies. Hence, the evaluation of scientific results should be based on their quality and importance, not on their direction.

Authorship

Despite the fact that university promotion committees evince some shift in the emphasis from the quantity to the quality of publication, academic pressures to publish remain. In many academic circles, achievement is still measured by the length of an individual's bibliography. As a result, authorship of an article published in a peer-reviewed scientific journal carries considerable merit, and consequently, considerable responsibility (Rennie and Flanagin, 1994a).

During the past several decades, the meaning of authorship has become diluted as the number of names appearing in scientific article bylines has grown. Authors have justified lengthy bylines by the increasing specialization of science and the need for collaboration among many subspecialists. But the once-accepted practices of adding the names of a department chair or laboratory chief to the end of bylines (guest authorship), and hiring someone to write up a paper without credit (ghost authorship), have caused many editors to adopt formal policies to curtail inflated bylines (Huth, 1986a, 1986b; Lundberg and Flanagin; Rennie and Flanagin, 1994a) and limit the number of names that can appear in a byline without formal justification.

In 1985, the ICMJE recommended that only those persons who have participated sufficiently to take public responsibility for the work should be authors and that "authorship credit should be based solely on substantial contributions to (a) conception and design, or analysis and interpretation of data; (b) drafting the article or revising it critically for important intellectual content; and (c) final approval of the version to be published" (ICMJE, 1991). Each of these criteria must be met by each person listed in the byline, and the authors must state that they meet these criteria in the cover letter accompanying each submitted manuscript. In the latter half of the 1980s, a number of medical journals, including the *Annals of Internal Medicine* and the *Journal of the American Medical Association* (JAMA), began requiring authors to sign authorship statements based on the ICMJE criteria. Anyone who does not meet these conditions but has contributed or assisted significantly can be recognized in an acknowledgment within the article, if he or she has given written permission to be so named (ICMJE, 1993b).

Group authorship results when investigators from many different institutions or participants in study groups, consensus conferences, or working groups prepare reports of their works. Frequently these groups comprise hundreds of investigators, technicians, and specialists. While it is conceivable that each of these individuals contributed critical time and information to the overall work, it is unlikely that each meets the ICMJE authorship criteria. In these cases, those participants who do meet the authorship criteria can be listed with the name of the study group in the byline. Those participants who do not qualify for authorship are then listed in a group box or in an acknowledgment. If all of the participants do meet the criteria for authorship, then the group name can be listed as the sole byline, with the individuals composing the group named in a separate box or the acknowledgment.

Unlike the definition of authorship, there are no established standards for order of authorship, although a number have been proposed, ranging from alphabetical listings to mathematical formulas for determining individual contribution levels and ranking. Many editors agree that authors should be listed according to how much they contributed, with the author who contributed the most listed first and the author who dontributed least listed last (Huth, 1986a, 1986b; Riesenberg and Lundberg). In addition, a number of publications and indexes limit the number of names to be published in a reference list to three, six, or ten. But there is still no consensus on the order of authorship, mostly because there are no widely accepted objective measures of individual coauthors' contribution levels. Editors recommend that authors determine the order of authorship before writing their papers, or before beginning their study, with an agreement to reevaluate the order later if necessary. Editors also recommend that authors solve disagreements over order among themselves, since the authors are in the best position to determine levels of contribution (Riesenberg and Lundberg; ICMJE, 1991).

Duplicate Publication

Another result of the pressures to publish and a driving force behind the need for ethical standards in scientific publication is the practice of duplicate publication. Also known as multiple, dual, or redundant publication, duplicate publication is the simultaneous or subsequent publication of the same article or major parts of an article—methods, results and data, discussion, conclusions, and graphic or illustrative material—in two or more journals or other media, including electronic journals and databases, without notifying the editors (Huth, 1986a, 1986b; ICMJE, 1993b; Iverson et al.). The types of duplicate publication range from selfplagiarism (publishing two or more identical articles or large parts of an article in different journals without citing each article in the texts and references lists) to "salami slicing" (dividing up different parts of the same study for publication in different journals) to sequential publication (reporting follow-up of the same study with additional subjects but without new results). Word-for-word duplication is uncommon, as duplicators usually attempt to alter or disguise the similarities.

Duplicate publication should be distinguished from secondary publication, in which an article or abbreviated version is subsequently republished, in the same or another language, with the consent of both editors. The secondary article should include a footnote on the title page, informing all readers that the information was published previously, and a complete citation to the primary article. Duplicate publication may violate copyright law, and it is unethical for an author to submit duplicate papers to different journals without notifying the editors. By doing so, authors clutter the literature with redundant information; waste the valuable time and resources of editors, reviewers, and readers; and prevent other authors from publishing their work because of limited journal space. To discourage such practices, many scientific journals state in their instructions for authors that they will only consider papers that have not been previously published or submitted to other journals, and some journals will publish notices of duplicate publication, publicly admonishing those authors who publish duplicate articles in violation of the journal's written policies (Iverson et al.).

Conflicts of Interest

Reflecting the increasing commercialization of science and the public doubts about researchers' once hallowed and rarely questioned integrity, financial conflicts of interest are now recognized as another ethical problem for authors and editors. During the 1980s, the public's trust of the scientific community diminished as a result of a number of public scandals and government investigations of biomedical researchers' ties to drugs with potential public health benefits and high financial rewards for stockholders and manufacturers (Relman; Lundberg and Flanagin; U.S. Congress). These cases have generally involved researchers being biased by their direct but undisclosed financial interests, such as stock ownership and paid consultancies. However, there are several other potential sources of author bias: funds from granting agencies, any research or material support, employment, money paid for expert testimony, and honoraria paid for public speaking.

Recognizing that not all financial interests will bias an author, editors disagree over how to handle these financial interests. Most journals publish an author's source of funding or material support, but that is usually because the funding institution requires that it be published. Some journals require authors to disclose all financial interests relevant to the work reported in their submitted manuscripts. If a manuscript is subsequently accepted for publication, the editors of these journals will determine whether it is necessary to publish such financial interests. In this manner, readers can judge for themselves the author's potential for bias from a financial interest just as they can judge an author's potential for intellectual bias based on his or her previously published works or specialty status (Rennie et al.). In 1990, the *New England Journal of Medicine* instituted a stringent policy prohibiting anyone with relevant financial interests from publishing editorials or review articles in that journal. Critics have argued that such prohibition is scientific censorship.

In 1989, the American Federation for Clinical Research and the Association of American Medical Colleges recommended full disclosure of all relevant financial interests and the possible divestiture of any stock or equity in a company that makes a product the researcher is studying (U.S. Congress). The Editorial Policy Committee of the Council of Biology Editors (CBE) recommends that authors disclose all relevant financial interests to the editors at the time of manuscript submission, and that editors disclose authors' financial interests to reviewers and readers when appropriate (CBE). There is no consensus among editors for the need and extent of such disclosure. In 1993, however, the ICMJE approved a statement that all participants in the peer review and publication process disclose any conflicting interests (ICMJE, 1993a). Some journals with disclosure policies have applied the basic principles of disclosure to everyone in the editorial process, including editors, editorial board members, and in some cases, reviewers (Relman; Rennie et al.).

Fraudulent Publication Resulting from Scientific Misconduct

The publication of a fraudulent article remains the most serious transgression of the ethics of scientific publication. The once generally accepted view that scientific misconduct was rare and committed by a few deviants has been replaced by a view, unsubstantiated, that it is more common and can involve respected scientists from leading institutions. Scientific misconduct has been defined as plagiarism (presenting another's ideas without attribution), fabrication (presenting data or facts that do not exist), falsification (changing or selecting certain data to obtain a desired result, misrepresenting evidence or facts, or misrepresenting authorship), or other serious deviations from accepted practice in the proposing, conducting, or reporting of research (U.S. Department of Health and Human Services). Policy makers have disagreed over the merits of including the phrase *deviations from accepted practice* in the definition. Some argue that the phrase is too vague and thus open to misinterpretation and overuse (Committee on Science); others argue that it must be included to address misconduct that would not technically be considered plagiarism, fabrication, or falsification. Examples of such deviations include misuse or theft of privileged information by a reviewer or editor, submitting a paper listing several coauthors who are unaware that they are named as coauthors, misrepresenting publication status of articles in a bibliography, or failing to perform funded research while filing reports stating that such work has been done (U.S. Department of Health and Human Services).

Variations in the definition of fraud have caused some confusion, but most editors acknowledge a major difference between fraud and unintentional errors. Although unprofessional and in some cases unethical, the following usually are not considered fraudulent: errors in study design or application of methods, inappropriate use or interpretation of statistics, faulty interpretation or overgeneralization of study results, failure to cite relevant literature or studies, duplicate publication or fragmentary reporting of results, prepublication release of information, publication bias, failure to disclose intellectual or financial conflicts of interests, or violations of experimentation rules protecting humans or animals.

Plagiarism is probably more commonly acknowledged, since it is easier to detect and prove. Detecting and proving falsification or fabrication of data in a published article is not so easy, and it carries grave ethical and legal consequences for editors, authors, institutions, and funding agencies. While an editor has a duty to see that questions of fraud are appropriately and confidentially pursued, the Association of American Medical Colleges, the National Academy of Sciences, and the ICMJE recommend that primary responsibility for investigating cases of suspected fraud rests with the author's institution or funding agency (Association of American Medical Colleges; Committee on Science; ICMJE, 1991). If it is determined that a fraudulent paper has been published, the journal should print—in a timely manner—a retraction, written by the author(s) or an appropriate representative of the institution. Since the validity of any previous work by the author of a fraudulent paper cannot be assumed, the editor must ask the institution to verify the validity of any of the author's articles previously published in the journal or to retract them (ICMJE, 1991).

Protecting Patient Rights

The two major issues regarding patient rights in medical publishing are requirements for the ethical conduct of published research and the protection of patient confidentiality. A now well-established principle followed by all credible medical journals is that reports of experimental investigations of human or animal subjects must include a statement that the research project has been approved by an appropriate institutional review board (IRB). For investigators not covered by a formal ethics review board, the report should state that the researchers have followed the principles of the Declaration of Helsinki (World Medical Association), which includes requirements for freely given informed consent and for the review of the research protocol by a committee independent of the investigator and the sponsor. Many journals also require an additional statement of the manner in which informed consent was obtained from human subjects, since informed consent is a central tenet for ethical research.

Many editors now agree that journal publication should protect patient confidentiality. For example, placing a black bar over the eyes in a facial photograph does not effectively disguise identity. Patients may also be identified from detailed case descriptions. In 1991, the ICMJE published expanded guidelines for the protection of patients' right to anonymity (ICMJE, 1991). These guidelines state that identifying information should be avoided unless it is essential for scientific purposes; informed consent should be obtained for the publication of identifying descriptions or photographs; changing patient data should not be used as a way of securing anonymity; and journals should publish editorial policies to preserve patient confidentiality (ICMJE, 1991).

One problematic area regarding patient anonymity is the publication of pedigrees from genetics research, since the family as a whole or individual family members can sometimes be identified from pedigree information. Following the ICMJE guidelines, identifying information should be deleted if possible, but pedigree data should not be altered. Pedigree publication is complicated by the fact that a large number of family members may be involved, not all of whom may have given consent for, or even be aware of, the collection of family data. A requirement for informed consent for publication from each individual member of a large pedigree may be impossible to meet, particularly if family members disagree about publication. Whether some kind of group consent would be ethically permissible, or whether identifiable pedigrees should not be published without the consent of each individual family member, remains an unsettled issue.

Release of Information

Scientific journals play a major role in informing the public, as well as health professionals, about biomedical developments. This function involves a balance between the timely release of information and the adequate evaluation of the quality of the information. Conflicts sometimes occur between scientists, who want rapid dissemination of new or controversial research findings; editors, who as gatekeepers want to make sure that only accurate and valid scientific information is released; and the news media, which compete with each other to be the first to publicize new scientific information. The process of scientific publication after peer review takes time. Some investigators have chosen to short-circuit this traditional process by announcing results at a news conference rather than waiting for a paper to be evaluated by a scientific journal. Advocates for a particular disease (acquired immunodeficiency syndrome [AIDS], for example) have also pressed for faster release of research results. Even if well-intended, such attempts to bypass careful evaluation and publication may result in the dissemination of misinformation (Angell and Kassirer).

In 1969, Franz Ingelfinger, then editor of the *New England Journal of Medicine,* promulgated a policy (subsequently known as the *Ingelfinger rule*) that manuscripts would be considered for publication only if their substance had not been submitted or reported elsewhere. Other journals adopted similar policies to discourage both duplicate publication and the public dissemination of results before peer review and publication. Such policies have been criticized as self-serving on the part of journals, but they usually exempt presentations at scientific meetings (including published abstracts and media coverage from such meetings) and the rare situations when an appropriate public health authority determines that there is an immediate need for dissemination. Some medical journals also ask news media to observe a press embargo for a brief period to allow physician subscribers to read and evaluate information before their patients begin seeing it in the media.

Copyright

Copyright protection covers text and illustrative material—whether in print or electronic (digital) format. U.S. copyright law provides that the creator of a written work, the author, owns all legal rights to that work for his or her life span plus fifty years, unless the author transfers those rights to another party. Two exceptions to individual copyright ownership are works prepared by employees of the U.S. government and works made for hire, in which an individual, either by an employment mandate or by contract, agrees in writing that all work prepared within the scope of

employment or contract is the property of the employer or contractor (*Copyright Law of the United States of America*). Different countries have different copyright laws, but the Universal Copyright and Berne Conventions protect works published and distributed in other countries.

Most journals require authors to transfer copyright to their publishers before publication, giving the publisher exclusive rights to the work after publication. Therefore, anyone who wishes to reprint or adapt from an article (in part or whole) must receive written permission to do so from the publisher. However, certain uses of a published work without permission from the owner—such as photocopying for teaching, scholarship, or research purposes—may not be an infringement of copyright under the provisions of "fair use." Fair use can be difficult to justify in court and must take into account the following factors: (1) the purpose of the use, including whether it is educational or commercial; (2) the nature of the copyrighted work; (3) the amount of the copyrighted work to be used; and (4) the effect of use on the potential marketability or value of the copyrighted work (*Copyright Law of the United States of America*).

Rights to Unpublished Data

Unlike rights to copyrighted work, rights to unpublished data are difficult to define, and most ethical dilemmas concern access to rather than ownership of such information. Unpublished scientific data include written and electronic laboratory notes, experimental materials, project records and observations, databases, descriptions of methods and processes, analyses, and illustrative material. Traditionally, unpublished scientific data have been owned by their creators—the scientific investigators—and most scientists believe they have a duty to share data with their peers and, when appropriate, with the public. Any data reported in a published article become the property of the publisher, but rights to relevant, supportive data not reported in a published article (sometimes called raw data) are not transferred to the publisher. Problems arise when investigators, institutions, the government, and the public compete for control of and access to the same data. For example, who should have first rights to publication of research data: the principal investigator, the coinvestigators, or the institution that funded the research? Legally, the investigator controls access to unpublished data, except under the following circumstances: (1) the investigator is an employee of an organization that claims rights to any work conducted by its employees; (2) the investigator is under federal contract or has received a federal grant to perform the work; or (3) a court decides that public interest in the data outweighs the interest of the owner (CBE). Government or industrial sponsorship of research may impose specific restrictions on data control and sharing, particularly when such data are proprietary or commercial. This area of law will continue to evolve as electronic technology makes data ownership and access more difficult to define and control by narrow standards and laws.

While it is generally agreed that data must be kept in an accessible format for a reasonable period of time, no standard has been universally accepted, because different types of data from different specialties require various modes and spaces for storage, which can be prohibitively expensive. Some institutions have recommended three or five years, and longer periods for data that support publications (Committee on Science). The National Research Council Committee on National Statistics recommends and many journals require that editors have access to data during the peer review process, which means that the data must be maintained until publication (CBE). Some journals require authors to provide data to editors for their evaluation if requested, but this requirement does not have a time limit. Some journals require authors to send their data to national or international storage centers at the time of publication.

Disputes over who has rights to use scientific data have caused ethical dilemmas for editors. For example, what should an editor do with a manuscript from an author that reports an analysis of unpublished data originally collected and analyzed by another author? The ICMJE and the Committee on National Statistics recommend that editors consider such secondary analyses on their scientific merit as long as full credit and appropriate citations are given to the original data collections (ICMJE, 1991; CBE). Other open questions concern the nature of sharing data, which is a vital part of the scientific enterprise. Should there be restrictions on the access, use, and citation of unpublished works by other authors and investigators? Most scientists and editors would argue that such restrictions would stifle scientific exchange. But what about access to unpublished data by those outside the scientific community, such as representatives of the media, the courts, and people with commercial interests? Many of these questions are currently under debate, and whether or not access will be widened or restricted is difficult to predict.

Advertising

Advertisements for pharmaceutical products and medical/laboratory devices provide major financial support for biomedical publications. Advertising income is essential for many large biomedical publications since their costs would not be met by subscription revenue. Whether this situation represents one aspect of the success of the free enterprise

system or a major ethical problem for editors is a matter of controversy.

To protect a journal's integrity and credibility, complete separation between advertising and editorial decisions is essential, and advertisers should have no influence on editorial content. Advertisements, including advertorials, should have a distinct appearance or labeling so that readers can readily distinguish them from editorial content, and ads for a product should not be placed adjacent to editorial material dealing with the product or disorders for which it might be used (Rennie). Publication of industry-sponsored journal supplements is problematic, since the supplement's editorial content may be selected or influenced by the sponsor to favor their products, and the review process may not be as rigorous or as independent as it is for the journal's regularly published issues.

The accuracy of advertisements in medical publications is more controversial. The purpose of advertisements is promotional, and studies have shown that the prescribing behavior of physicians is indeed influenced by advertisements. Because of their effect on the health of the public, advertisements for drugs and medical devices are regulated by a government health agency in many countries. In the United States, this responsibility lies with the Food and Drug Administration (FDA), which reviews and approves marketing and *labeling* (the package insert that describes the indications and side effects of a drug) but does not routinely review or approve advertisements prior to their dissemination. However, the FDA does review advertisements after publication and can require companies to withdraw or publicly correct ads that it determines to be inaccurate or misleading.

The standards by which print advertisements should be judged and the method of enforcing standards remain unsettled. Some have recommended the development of multidisciplinary review boards, such as the Canadian Pharmaceutical Advertising Advisory Board, to review and approve medical advertisements before their dissemination.

Enforcement of Ethical Standards

The enforcement of ethical standards in scientific publishing is a responsibility shared among authors, institutions, funding organizations, peer reviewers, and editors. Authors are primarily responsible for upholding the scientific commitment to a search for truth, accepting responsibility and credit for the work that bears their names, and fully disclosing any conflicts of interest. Institutions where research is performed and organizations that fund research share the main responsibility for ensuring that studies are designed and conducted ethically, and also for investigating and sanctioning allegations of misconduct. Peer reviewers are charged with performing objective and timely appraisals of papers submitted for publication, while maintaining strict confidentiality and disclosing their own conflicts of interest. Editors should exercise sound judgment and objectivity in selecting papers for publication, maintaining vigilance for any ethical problems, and ensuring that authors, reviewers, and institutions fulfill their responsibilities. Clear ethical standards and implementation policies are certainly desirable, and editors have taken the lead in setting standards and policies (U.S. Congress). Yet the ethics of scientific publication is based on trust, and obsessive "policing" of the research community and the publication enterprise could be counterproductive. Persistent emphasis on the importance of maintaining ethical standards in the entire research process, from initial research ideas to their eventual publication, should be an expectation shared by all involved in that process. However, defining and enforcing such standards will be an even greater challenge as the electronic revolution extends the traditional boundaries of authorship and scientific publication.

SEXISM

• • •

Sexism is the failure to give equal weight to women's interests. It is the antithesis of feminism, a moral, political, and social movement that seeks justice for women. Sexism is important because it undermines the welfare of one-half of the human population and is a major source of women's oppression.

Each of these terms—interests, justice, welfare, oppression—is theory-laden, suggesting a particular way of understanding the origins and remedies for wrongful sex- and gender-based distinctions. This entry is eclectic but relies primarily on the liberal language of rights and interests.

Women have two kinds of rights, the ones shared with men by virtue of their common humanity, and the ones required by virtue of their differences from men. Sexism fails to recognize these rights by assuming, on the basis of inadequate evidence, that there are morally relevant differences between women and men, or by overlooking morally relevant differences that call for different treatment.

Medical treatment of heart disease in women is an example of both kinds of sexism. On the one hand, ignoring contrary evidence, practitioners have assumed that heart disease is not a women's problem. On the other, they have refused to take seriously the possibility that heart disease might manifest itself differently in women than in men. Consequently, heart disease in women is underdiagnosed, treatments are geared toward men's needs, and women needlessly suffer and die more often than men.

Although sexism can be a result of inattention, or a deliberate policy of subordinating women's interests to those of men or children, it may also result from historically embedded social institutions that naturalize assumptions about gender. A key assumption is that biology determines women's nature, whereas men construct themselves. Woman's inherent function is to nurture children and men. Women therefore do not elicit the respect due to rational persons with legitimate life-plans of their own; their interests are relatively unimportant, and may be subordinated to others with which they come in conflict. The consequences range from abortion, infanticide, and starvation for female Indian children, to more subtle but still significant losses for Western women. Among these are lack of representation in positions of public power and prestige, longer hours of work for less pay, lack of sexual or reproductive freedom, less advanced healthcare, and less leisure, pleasure, and financial and physical security.

No thoughtful person wants to be seen as sexist. But because of widespread negativism about feminism, many people believe that there is neutral territory between the two. However, where women's interests are affected there is either a (feminist) commitment to count them equally or there is a (sexist) discounting of those interests. Neutrality can exist where gender is not at issue or where it is difficult to determine whether sexism is at work.

Oppression, Discrimination, Sexism

Oppression is the systematic and unjust subordination of some people by others. Sexism is a major source of women's oppression. Oppression may be based on superior power, without any attempt at justification. However, it is usually predicated on the alleged inferiority of a class of people, such as women, the poor, people of color, the elderly, homosexuals, or adherents of certain religions. In principle, recognizing the wrong of one kind of oppression implies recognizing the wrong of other types, but in practice these connections are often ignored.

Because many mainstream thinkers (consciously or unconsciously) accept sexist assumptions, they are unconvinced of women's oppression, and they doubt evidence alleged to support the claim that such oppression exists. Even when the facts (e.g., women's lesser wealth) are undisputed, they are attributed to the consequences of women's inferiority, their autonomous choices, or to social necessity.

Feminists respond by arguing that these defenses are mere rationalizations, and that there are systematic and interlocking patterns of sex and gender relationships that disadvantage women. Sexism leads to the high valuation of qualities associated with men but not women. Also, pervasive patterns of gender socialization affect women's capacities (such as strength or mathematical achievement) and mean that women's choices may not be as autonomous as they seem. Moreover, many of women's disadvantages are rooted in the sexist failure to recognize the special rights that need to be granted because of the differences between women and men. Social and political arrangements allegedly based on necessity are essential only for men's convenience. Relegating women to inferior positions is therefore unjustified, and constitutes oppression.

Discrimination is an effective tool for creating and maintaining oppression. Discrimination can be used descriptively or normatively. Descriptive discrimination among concepts and entities is essential for thought and language. Such distinctions are usually considered to reflect the world, and are thus *natural.* However, categories may depend on choices about what characteristics count for inclusion and so morally significant groupings may instead be constructed (e.g., race). Normatively, discrimination always implies wrongful treatment of members of a group. The constructed nature of some descriptive groupings may facilitate the creation of normative ones. Thus, for example, conceptualizing the class of potentially pregnant women may make it easier to discriminate against them in the workplace or in medical research.

Recognizing Sexism

Sometimes it can be difficult to determine whether a decision or policy is sexist or feminist. For example, selective abortion of female fetuses is often cited as a paradigm case of sexism. But different contexts can render the same act sexist or feminist. Aborting a female because of the belief that boys

are superior to girls is sexist; aborting a female to prevent a girl's suffering can be feminist.

In addition, it is important to distinguish between legal and moral contexts. Because motivation is difficult to determine in legal contexts, sexism in law is most successfully rooted out by a focus on disparate impact. Moral investigation, however, can and must delve further into motivation and intention.

Is it sexist to abort female fetuses to ensure that there are both male and female children in a family? If "balance" is a pretext for ensuring the birth of a boy to secure the alleged social benefits only he can provide (e.g., continuation of the family name), then it promotes and maintains a sexist world. But what if the decision to abort is based on the reasonable belief that social pressures generally lead girls and boys to develop somewhat differently (no matter what the family environment), and that raising them is likely to be an equally desirable, but different, experience?

Baseline Assumptions

Evaluating whether assumptions that underlie decisions are sexist can be challenging. For example, it would be sexist to exclude women from drug trials because they are different from men in relevant ways, but not because they are alike in those ways. But which assumption is it reasonable to start with in the absence of knowledge? Assuming that the sexes are alike could be just another instance of taking males as the norm, without paying attention to ways that females might be different. Assuming they are different could be just another instance of the belief that females have more in common with the females of other species than with male humans. A similar quandary arises for race.

Inquiry suggests that women are harmed by their exclusion from clinical trials because such exclusion can result in poorer healthcare. Do cholesterol-lowering drugs or aspirin prevent heart disease in women? Nobody knows because the original research was done in men, and only at the very end of the twentieth century did the relevant studies begin for women.

Digging into the history and culture of medicine reinforces this conclusion. In the past, women were not admitted to most medical schools because they were considered fit only for nursing or midwifery. Harvard University began accepting women only in 1945, when World War II had reduced the number of male applicants; women could not exceed 6 percent of each class until the 1970s. Sue Rosser and Eileen Nechas and Denise Foley were pioneers in documenting obstacles facing women in medicine in the twentieth century. Adriane Fugh-Berman describes a dispiriting range of problems she encountered at a leading medical school. Among them were medical disinterest in women's bodies (breasts were discarded on the first day of anatomy class) and welfare (students were taught that women can have a satisfactory sex life without orgasms). Some professors did not see women students as equals and refused to teach them certain procedures or topics (sexually transmitted diseases). Male students compounded the hostile environment by harassing and threatening with rape the members of a women's study group. A survey of recent literature on problems women encounter in medicine shows that there is still much room for progress.

In 2003 women still experience substantial sexism as consumers of healthcare, as the aforementioned example of heart disease shows. Stereotypes about women's nature (irrational, focused on reproduction) may continue to lead healthcare researchers and providers to sometimes dismiss what women say about their symptoms (e.g., in women with AIDS, or menstrual pain). It may also encourage the development of procedures that put women disproportionately at risk in what should be joint ventures with men (contraception, infertility treatment). More generally, until the end of the twentieth century, researchers emphasized conditions that affect men, ignoring such complaints as dysmenorrhea, incontinence in the elderly, and nutrition in postmenopausal women. At the same time, medicine has also tended to inappropriately medicalize the bodily experiences connected with reproduction: menstruation, pregnancy, childbirth, and menopause. Medicine has also promoted and reinforced the assumption that only women —not men or society at large—are responsible for babies's health.

Is there any evidence to suggest that women's exclusion from research (and the failure to analyze studies they did participate in by sex) is a result of concern for women? No. It appears that women have been excluded either for researchers's convenience or due to concern about harm to possible offspring (or concern about liability for such harm). Men have been assumed to lack hormonal cycles that would confound study results; women however, engender the opposite assumption. But men appear to have their own hormonal cycles, and if women's cycles affect outcomes, being excluded harms the latter. Also, some researchers have had easier access to male populations (the military, prisons). But ease of access does not justify ignorance about the medical care of women. Excluding women because of possible pregnancy accepts the stereotypes that women are ignorant about their bodies, and careless about the welfare of fetuses; the exclusion of women also ignores the evidence that sperm are affected by exposure to toxins. Non-sexist drug trials would thus regard women and men as equally likely to risk harm to offspring. Both would therefore need

to be warned against reproduction, and both sexes ought to be trusted to heed those warnings to the same degree. Abandoning women for such sexist reasons is especially unjust when research is publicly funded. It follows that women should be included in experimentation, and that results should be analyzed by sex. Excluding women from health studies could be seen as a feminist position only when there are excellent reasons for believing that to include women would create more harm than good for women as a class.

In conclusion, the concept of sexism points to the ways that women's interests are systematically discounted in comparison with those of men. Sexism is a kind of discrimination that oppresses women as a class. Groundless stereotyped assumptions about women and the unjust failure to take seriously both the ways that women resemble men and the ways that the two sexes differ play a central role in sexism. Women have been seriously harmed by sexism in medicine, and only in the last decades of the twentieth century have the women's health movement and practitioners in the field of women's health begun to rectify this wrong. Bioethics, which, among other tasks, critiques the healthcare system, was itself quite blind to sexism in healthcare until the 1990s; sexism in bioethics remains a serious problem, as overtly feminist bioethics literature is marginal.

SEXUAL BEHAVIOR, SOCIAL CONTROL OF

• • •

The twentieth century witnessed an explosion of knowledge about the physiology, psychology, and sociology of human sexuality, thanks to the revolution in public acceptability of discourse about sexual conduct and the freeing of scholarly interest that followed the trailblazing works published in the late Victorian era by Richard von Krafft–Ebing (1939 [1886]), Havelock Ellis (1901), and Sigmund Freud (1955a [1895], 1955b [1905]). However, controversy still rages over the basic issue of how sexual behavior is molded, encouraged, and discouraged by social customs and practices. Are males naturally more aggressive in seeking sexual contact than females, or is this a product of social patriarchy? Is homosexuality caused primarily by biological factors, or is it largely caused by social experiences during formative

stages of the child's development? Is cultural permissiveness responsible for the dramatic increase in reports of sexual harassment and abuse, or are changing mores encouraging victims to name parents, doctors, and priests who were in the past able to hide their misconduct under a cloak of respectability?

The answers to these questions are not only empirical, they are also ethical and political. Allegedly scientific beliefs about the *naturalness* of certain sexual acts often reflect unacknowledged cultural biases, and thoughts and theories affect the behavior they label, characterize, and implicitly valorize or demean. As feminists and historians such as Michel Foucault (1990) have pointed out, the neutral scientific language of medicine is no guarantor of the moral innocuousness of theories about gender and sexual behavior; to the contrary, claims of scientific objectivity about these topics are apt to be all the more dangerous morally for pretending to be value-free.

Theories of sexual behavior cannot avoid assumptions about power and domination that too frequently perpetuate injustices. Thus, sexologist Alfred Kinsey's claim that males are naturally more aggressive in initiating sex (Kinsey, Pomeroy, and Martin) is not merely the objective scientific statement it purports to be, but a statement that supports the power of men over women in society. Anyone who is concerned about power and justice needs continually to scrutinize and critique so-called scientific claims about human sexuality by attending to how they perpetuate social stereotypes that are not universal and, by assigning more value to the experiences of certain people (e.g., white heterosexual males), help to empower some and disempower others. One would expect social ethicists to be sensitized to these issues, but the most influential recent theorists of justice (e.g., John Rawls, Ronald Dworkin, Robert Nozick, Michael Walzer) scarcely even mention gender justice, much less consider sexual roles a central matter for ethical scrutiny (see Susan Okin's 1989 work). One reason for this neglect is the traditional public/private dichotomy that assigns sexual behavior to a private arena outside the concerns of the social theorist. Employment of this dichotomy in the past to keep cases of domestic rape and child abuse out of American courts, on the grounds that they occur within a zone of privacy protected from public scrutiny, shows that it is scarcely an ethically neutral matter for a social scientist to point out how individuals' sexual lives are influenced by a social ethos that makes such distinctions.

Essentialism and Constructionism

Theories about human sexual behavior in its social context range along a continuum stretching from essentialism (or naturalism) on the one hand to social construction theory on the other.

Essentialism attributes certain sexual and gender behaviors to the unchanging nature of the human species. According to this perspective, what is natural is *good*; what is social is *artificial* and tends to be *bad* insofar as it inhibits realization of the proper natural end of sexual conduct, be it erotic pleasure or procreation. Thomistic natural-law theory is explicitly essentialist in identifying procreation as the natural end of human sexuality, but modern sexologists assume essentialism in contending that a wide variety of pleasurable erotic acts are no less natural than heterosexual intercourse. Kinsey, for example, uses an essentialist argument when he draws on the sexual behavior of other mammals, "primitive" cultures, and human physiological capacities to contend that masturbation and homosexual acts are natural expressions of sexuality and, hence, irrationally condemned and punished by society. Kinsey also employs essentialist arguments, citing mammalian data, in support of such dubious contentions as that male extramarital coitus is more natural than female extramarital coitus (Kinsey, Pomeroy, Martin et al.; Irvine). American sexologists William Masters and Virginia Johnson assume essentialism in viewing sex exclusively in terms of physiological responses unencumbered by social and psychological factors. It is not an issue for Masters and Johnson that the socialization of Western women has discouraged female sexuality; rather the woman's naturally superior sexual responsiveness to the male, as evidenced by her capacity for multiple orgasms, is what counts for them (Irvine). What is missing in the sexologist's essentialist view of culture as an impediment is any acknowledgement of the multiple ways cultures give meaning to sexual behaviors and structure sexual and gender relationships beyond physiological responses.

According to social constructionists, sexual behavior and gender roles are products of a specific history, culture, and set of social institutions. French social scientist Émile Durkheim succinctly expressed the constructionist emphasis on the primacy of culture over biology when he argued, at the end of the nineteenth century, that if an adolescent did not have cultural concepts to identify sexual desires, he or she might feel a vague urge but not know what it was, much less how to act on it (Durkheim; Wallwork, 1972, 1984). A second main feature of the social constructionist approach involves situating sexual role behavior within the prevailing economic and political system, with its male-dominated hierarchies of status and power. The constructionist perspective encourages exploration of the ways in which widespread cultural beliefs about sexual behavior (and the research projects they inspire) serve to perpetuate a patriarchal vision of human nature, social institutions, gender, and sex

roles. Constructionists note with concern that the focus in research has more often than not been on the male sexual experience; Masters and Johnson's research, for example, limits sexuality to genitally-oriented orgasm (Masters and Johnson). Feminist critics Alice Rossi (1973) and Leonore Tiefer (1978) complain that research focusing on genital physiology as the standard of sexual involvement evidences a "phallic fallacy" that implicitly devalues the pregenital or nongenital sexual experiences of women, such as the emotionally intense erotic feelings associated with looking at the beloved or anticipating a reunion with him or her.

The obvious strength of social constructionist theory is that it is able to account for the considerable diversity of sexual behavior and the meanings associated with such behavior cross-culturally, and to link these meanings to other role relationships. The power of society to mold human sexuality is evident in how nonerotic body parts—for example, crushed feet among the Chinese of a former era, the naked foot and even shoes in medieval Europe, and hair—have been eroticized by different peoples at different times (Stoller). The power of social custom is also obvious when one contrasts the negative conception of homosexuality in the Judeo-Christian West with its positive evaluation among Melanesian societies and certain African tribes. Among the Sambia in the New Guinea highlands, boys from prepuberty to their mid-teens are expected to engage in oral-genital sexuality with the older teenage males with whom they live as a prerequisite to becoming heterosexual adult males (Herdt and Stoller). Because Sambians believe semen is essential for males to grow and mature physically, the ingestion of semen is deemed essential to becoming an adult heterosexual male and to fathering children.

Even within the same society, there are fads and fashions of sexual behavior. For instance, since the 1960s there has been a dramatic increase in oral-genital behavior in the United States (Janus and Janus; Walsh). Among contemporary males in the West, premature ejaculation is defined as a dysfunction for which medical treatment is often sought; but in many developing countries males are expected to reach orgasms quickly (in fifteen to twenty seconds in the East Bay society in Melanesia, for example) and those who take a "long time" are ridiculed (Reiss).

But it would be a mistake to assume from the considerable evidence for the importance of the elaborate cultural ideas, stimulants, and norms that surround the biologically limited range of sexual behaviors of which the human body is capable that social constructionists are winning the battle with essentialists. In fact, the nature–nurture pendulum, which swung back and forth several times in the twentieth century, was swinging back again toward the nature pole as the century ended. During the 1980s, 1990s, and 2000s, biological explanations have been on the ascendancy in many scientific circles. Sociobiologists challenge the constructionist assumption that most sexual behavior is determined by culture, arguing instead that certain basic mammalian and primate traits that lie beneath the social surface determine the configuration of human sexual behavior (Wilson). At the same time, the biologizing of psychology is well underway, as physiological models and research strategies are held to offer the best route to understanding traditional subjects of psychological inquiry such as mental illness and sexual orientation.

Interactionist Model

The most plausible position on the essentialism-constructionism debate would appear to be that the biological factors in sexual desire, such as genes and hormones, do not act alone but instead interact with environmental factors, such as visual or auditory erotic stimuli, the significance of which depends in turn upon the individual's subjective erotic sensitivities, identities, fantasies, cognitive schemata, and behavioral patterns. These subjective factors, which lead some people to be excited by depictions of sadomasochistic acts and others not, are themselves influenced by the way a unique individual with certain inherited strengths and vulnerabilities interacts with significant others and specific sociocultural environments during the various psychosexual, ego-social, and cognitive stages of development. Biological factors certainly play a role; for example, testosterone appears to influence the intensity of sexual desire. But biological factors do not invariably cause sexual motives or behavior, for testosterone is itself highly responsive to environmental stimuli. Nurture, psychological development, subjective fantasies and beliefs, erotic stimuli, moral and aesthetic standards, social roles and expectations, and ego strengths and weaknesses all mold the range of the individual's sexual potentialities in certain directions rather than others. This molding is clear from the inability of biologists and sociobiologists, who study determinants that have operated within the species for thousands of years, to explain changes in sexual customs within a single generation or variations in sexual customs that occur in the same gender cross-culturally. Unfortunately, researchers have not yet developed a theoretical model sufficiently complex and nuanced to integrate and assign proper weight to all the multiple factors, including the individual's self-control, that influence human sexual behavior. The sociological point of view adopted here, which falls at the constructivist end of the essentialism-constructionism continuum, remains one among several plausible selective perspectives on social control of sexual behavior. Others are history, anthropology, ethnography, psychoanalysis, and social psychology.

Social Control Requirements

Sexual behavior, defined broadly as any action or reaction involving erotic arousal or genital responses, is viewed by most sociologists as sufficiently problematic to require some degree of social control. One explanation often proffered for this social-control requirement, whether as controlled permission or regulated prohibition, is that at some point in the distant past human beings lost the preformed automatic sexual instincts of the lower animals—that is, the sexual control that is in nature—and came to depend upon culture and social institutions to guide the varied reproductive and nonreproductive behaviors that are considered sexual. The loss of preformed instinctual patterns of sexual behavior, by freeing human beings from the comparatively rigid behavior patterns of other animals, helped to create the great adaptability of the human species to its changing environment. It also meant, with the human female's loss of the periodic estrus of other mammals, that the human female and male were potentially capable of sex at any time. Sexual motives came to pervade virtually all aspects of human life in a way that is uniquely characteristic of the species. At the same time, because the sexual drive differs from instinctual needs like respiration, thirst, and hunger, which must be gratified for the individual organism's survival, sexual desire was modified by subtle psychological and social influences.

Social control of sexual behavior has been necessitated in all social units—from the family to the clan, tribe, local community, and state—in part by the serious threats to social stability and maintenance of group life over time created by the potential for sex on demand all the year round. One such threat is incest, which is inimical to the group's evolutionary survival as well as to the psychological well-being and functioning of those who might be victimized by it. Another serious social consequence of sex on demand is the likelihood of children, which every society has a stake in limiting, assigning to families peacefully, and raising, educating, and training to be law-abiding, productive contributors. Still another consequence of sexual behavior that has required its social control is its potential for either reinforcing or disrupting existing roles and status hierarchies by creating strong new social bonds. Any rape or seduction of young girls or boys, or any adulterous relation, is liable to spark violence or some other disruption of the existing social order.

Societies attempt to handle another crucial consequence of sexual liaisons—the transmission of family and communal property, prestige, and power—by means of legalized sexual union in marriage and the begetting of *legitimate children.* Any dramatic increase in the number of illegitimate children and abandoned wives strains the system of distributing limited economic resources, shifting some of the burden from the family onto the rest of the community. The perpetuation of a society's religious ideals, moral norms, and laws is also intertwined with the monitoring of sexual conduct, since the way sexual conduct is controlled is often paradigmatic of the way the society expects individuals to pursue other moral and spiritual goals (Stone). The well-known sexual asceticism of the Puritan, for instance, was only one part of a lifestyle that affected every aspect of the Puritan's life, just as the idealization of female virginity affects every aspect of the life of the traditional Southern Italian villager (Parsons).

IDEALS AND TABOOS. Social control of sexual behavior is exercised most obviously by widely shared, explicit ideals of sexual behavior that form the basis for taboos against inappropriate conduct. Taboos are backed by social punishments ranging from mild disapproval and loss of status to ostracism, imprisonment, and death. Within Judaism, Christianity, and Islam, the standard-of-standards has been heterosexual intercourse in the context of marriage. Accordingly, masturbation, homosexuality, and extramarital sexuality have been condemned and often severely punished. Among the Greeks during the classical period, pederasty was idealized as the purest form of love, but it was also hedged about by rigid taboos. The accepted sexual relationship was limited to an older free man and a pubescent free boy. Oral and anal intercourse were unacceptable, and if a boy allowed himself to be penetrated anally, he lost his rights to citizenship. For the Greek male, what was important was not whether one's partner was male or female, but whether one was dominant or submissive (Foucault).

SOCIAL ROLES. In addition to the values and norms shared throughout a culture, social control is also maintained by the basic institutions of society, especially the family, religion, schools, medicine, and law. An institution is defined sociologically as a stable cluster of values, norms, statuses, and roles that develop around a basic need of society. An important function of an institution is to socialize developing individuals through inculcation of social roles, which are social actions that take account of social expectations. A person's role is not simply what he or she habitually does (for this may not be socially significant), nor even what he or she is expected to do, if an expectation is only what one might predict from past actions. The role is what is expected of him or her, in the sense of what is approved or required, by, say, fashion, tradition, charismatic authority, or standards of rationality.

Gender roles, which indicate how males and females are expected to behave, significantly influence sexual behavior. In Western culture, the expectation has been that the

woman is more passive and receptive, and more attuned to emotional connections, than the male, who is expected to be more aggressive, autonomous, and focused on power. Such gender roles have an effect on sexual conduct, independent of explicit sexual standards. For example, rape is strongly disapproved of in contemporary culture, yet date rape is disturbingly frequent, in part because males are socialized to dominate women in many social situations involving power. Hence, if a male's charm and powers of psychological persuasion fail in a sexual situation, coercion remains as a last resort. Here, as in most sexual acts, erotic desire is only one of several motivations that enter into the behavior. In addition, the need to maintain the male-dominant role identity and the propensity for males in Western societies to turn anger at frustration into aggression and violence are equally powerful motives.

Recently, sociologists have applied *script theory* to sexual behavior in order to account for the more specific patterns that enable participants to make reasonably good guesses about the sequence of events probable in an otherwise loosely structured social situation (Gagnon and Simon; Laumann, Gagnon, Michael, et al.; McKinney and Sprecher). Scripts are mental schemas that enable participants to jointly structure the interaction so that uncertainty is systematically reduced and cooperation enhanced. Sexual scripts enable participants to decode novel situations by reading the meaning of certain actions and to organize the situation into sequences of specifically sexual interactions (e.g., nonverbal courtship behaviors signaling availability, like smiling, gazing, hair flipping, the "opening line," leaning close, and the proverbial invitation to see one's etchings). However, research on conflicts between the sexes in dating and marriage also shows that scripting is far from perfect, that the sexes often miscue each other or are dissatisfied in predictable ways—say, with the male's excessive sexual demands or emotional constriction, or the woman's unresponsiveness or moodiness.

HEALTH CONCERNS. Empirical beliefs—especially medically sanctioned ones—about the consequences of various sexual practices on the individual's health also play a significant role in the social control of sexual behavior. In classical Greece, for example, physicians recommended sexual moderation to prevent the excessive loss of life force in the too-frequent ejaculation of semen. In ancient China, somewhat similar beliefs about the consequences of excessive semen loss led to the cultivation of special techniques of intercourse without ejaculation in order to conserve the *yang* (the positive, light, masculine principle whose interaction with *yin*—the negative, dark, feminine principle—was believed to influence the destiny of creatures and things). And, of course, Western doctors have for centuries warned that masturbation would bring about some dreaded disease, disfigurement, or insanity. By the turn of the twenty-first century, fear of AIDS had dramatically changed sexual behavior, primarily by altering beliefs about the risks of unprotected sexual intercourse (Laumann, et al.). Viagra has altered time-honored myths about impotence, while offering hope for continuing sexual relations into old age. It is one of Foucault's main contentions that medical beliefs, precisely because they are so important to patients, provide physicians with power that historically often has been used to dominate and control unjustly (Foucault).

It is easy to be impressed by the ideals, moral rules, and prudential teachings that are set forth so impressively in explicit doctrine by leading social authorities. But these action guides are not always reinforced by other cultures or even by other institutions in the same cultural context. Complex societies are not systematic cultural ensembles, despite the beliefs of sociological functionalists like Émile Durkheim and Talcott Parsons. Illicit sexual cultures—like red-light districts or the houses of prostitution that flourished in medieval Europe (Ariès and Bejin)—exist side by side with licit sexual cultures, counterbalancing and correcting excessive asceticism, and on some points canceling out the influence of the licit culture. A complex interrelationship often exists between these cultures, so there is often plenty of room for compromises and loopholes. Moreover, the different social-status groups and classes of the same society usually have different sexual cultures. For example, libertine elites concentrated around courts (as in ancient Egypt, classical Greece and Rome, imperial China, India, and Japan) have surrounded themselves with a rich panoply of erotic art, pornographic literature, artificial physical stimuli, toys, and partners not encouraged among lower social ranks (Stone). Consider, too, how Roman Catholic bishops have tolerated the sexual abuse of children and adolescents by priests in flagrant violation of the church's explicit moral teachings (see, for example, the work of the *Boston Globe* Investigative Staff).

Control and Permissiveness

The so-called sexual revolution that occurred in the post–World War II epoch is sometimes viewed—erroneously—as releasing the individual from the constraining pressures of social control. But the new permissiveness is more accurately perceived as substituting new and, in some instances, somewhat different social standards, controls, and permissions for older ones. The most important contemporary cultural standards focus less on the legitimation of sex by marriage and more on the goods of sensual pleasure, intimacy, the

autonomy of the parties (violated in the case of rape and harassment), and the basic equality of partners. Some salient features of the sexual revolution are the greater explicit public acknowledgment of sexuality (for example, in films, advertisements, soap operas, talk shows, and advice columns); the availability of cheap and reliable contraception, particularly birth control pills, which have for the first time in history released women from the fear of unwanted pregnancies; the increased availability of erotic stimulants (e.g., adult magazines, pornographic videos, explicit Internet sites); the rise of feminism and correlative decline in social inequality between the sexes; the increased acceptance or tolerance of sexual behaviors that were formerly disapproved, like masturbation, homosexuality, extramarital sexual affairs, and oral-genital sex; and the increase in teenage sexual conduct and at younger ages (Michael, Gagnon, Laumann, et al.; Laumann and Michael). Around the turn of the twenty-first century, there also emerged a recreational ideology, which holds that the purpose of sexual activity is not procreation or even mutual affection, but physical pleasure.

Although these changes reflect a certain permissiveness, there is evidence that men and women today have higher expectations, demands, and worries about their sexual performance (McKinney and Sprecher; Janus and Janus). The liberating views of sexologists have brought in their train new demands for mutual orgasm and standards of erotic performance that not all couples are capable of realizing at all times. Anger about date rape on university campuses and sexual harassment in the workplace has given rise in the United States to explicit policies, sometimes accompanied by detailed lists of *do's* and *don'ts,* designed to make sure there is willing and verbal consent to each individual sexual act, for example, kissing, fondling of breasts, touching of genitals, intercourse. New policies, grievance procedures, and punishments are proliferating to prevent and punish sexual harassment and rape (Gross). Some professional ethics codes (for example, the new Principles and Standards of the American Psychoanalytic Association) prohibit sexual relations of any sort between professionals and clients, even in situations of mutual consent years after the professional relationship has ended, on the grounds that a misuse of professional authority is likely to have coerced the subordinate in the relationship (Dewald and Clark).

The permissiveness associated with the sexual revolution also coexists with the continuation of strong cultural constraints on frank interpersonal communication about sexual behavior that has disturbing implications for preventing unwanted pregnancies and venereal diseases and for containment of the AIDS epidemic. Western society has a long history of prudishness about sexual topics that stretches back several millennia into the biblical period, when writers of the Hebrew Bible and Christian New Testament used euphemisms like "flesh," "loin," "thigh," "side," and "feet" (for penis), "lewdness" (for female genitals), and "one flesh" (for intercourse) in lieu of explicit sexual terms (Baab). Despite the new sexual permissiveness, and research showing that, for example, 9 percent of American school children have initiated sexual intercourse before age thirteen, that 53.1 percent of students in grades nine through twelve have had sexual intercourse, and that 17.8 percent of high school students have had sexual intercourse with four or more sexual partners (Centers for Disease Control), parents continue to find it difficult to talk with their children in a knowledgeable way about sexual behavior. In a 1987 national survey, 69 percent of adult Americans viewed premarital coitus as "always wrong" for fourteen- to sixteen-year-olds (Davis and Smith). Research suggests that many adolescents perceive their parents as not very well informed about sex and as negative, rigid, and conservative in their attitudes toward sexuality (Metts and Cupach). Although adolescents tell researchers they would like to learn more about sex from their parents, their perceptions as well as the reported attitudes of many parents discourage open communication.

The difficulty parents have communicating information about sex is also found among many professionals charged with conveying information about sex to children, such as schoolteachers, clergy, and physicians. Research shows that adolescents learn most of their information about sexuality, such as petting and sexual intercourse, from same-sex peers, who are often ill-informed about contraception or the prevention of sexually transmitted diseases. However, some studies indicate that some sex education programs are able to convey factual information about anatomical and physiological aspects of sexuality, and to influence understanding of the risks of sexual behaviors (Orbuch; Metts and Cupach). Unfortunately, most teenagers remain unprepared for their first sexual encounters. Much remains to be done in communicating information about how to avoid unwanted pregnancies and infection by the human immunodeficiency virus (HIV) that causes AIDS.

Constraints on open discussion of sexual desires and practices is one factor in the high rates of unwanted sexual contact. Research shows that young men remain reluctant to declare their desire for sexual intercourse to a new date, while young women are less than open about their reluctance. Discussion of contraceptive measures is apparently still difficult for couples who have not had coitus, despite the threat of AIDS (Reiss). The culture of sexual permissiveness

is thus riddled with constraints on forthright discussion of choosing among alternative sexual options. To help counter these constraints, healthcare professions need improved educational programs on human sexuality, more training in public health, and opportunities to cultivate skills of communicating with patients as knowledgeable allies and responsible agents, not as passive recipients of authoritative information and advice.

A peculiar problem with many attempts to control sexual behavior is that the constraints and repressions designed to foster licit or safe sex often themselves contribute to the flourishing of illicit or unsafe sexual behavior, which becomes all the more alluring, exciting, and frequent precisely because it is prohibited. The firmest social controls of sexual behavior appear to be those that acknowledge the unique value of sexual desires, fantasies, and actions in human life in a spirit of tolerance toward nonharmful illicit wishes and behaviors, even as actual conduct is directed toward goals that are compatible with the best interests of the individuals involved and the groups of which they are a part.

SEXUAL ETHICS

• • •

Insofar as bioethics is concerned with human bodily health, it has an interest in the way health is influenced by and contributes to sexual functioning. There is a sense, then, in which bioethics includes sexual ethics, or at least some of the key questions of sexual ethics, such as the meaning of human sexuality and the causes and effects of sexual attitudes, orientations, and activities. Concepts of the human person—of desire and obligation, disease and dysfunction, even of justice and purity—can be found overlapping in various bioethical and sexual ethical theories. Like bioethics generally, sexual ethics considers standards for intervention in physical processes, rights of individuals to self-determination, ideals for human flourishing, and the importance of social context for the interpretation and regulation of sexual behavior. Bioethics specifically incorporates issues surrounding contraception and abortion, artificial reproduction, sexually transmitted diseases, sexual paraphilias, gendered roles and sexual conduct of the medical professionals, and sex research, counseling, and therapy. All of these issues are importantly shaped by moral traditions, so that health professionals frequently find themselves called upon to deal with questions of sexual ethics.

Historically, medicine has interacted with philosophy and religion in shaping and rationalizing the sexual ethical norms of a given culture. Medical opinion often simply reflects and conserves the accepted beliefs and mores of a society, but sometimes it is also a force for change. In either case, its influence can be powerful. For example, from the Hippocratic corpus in ancient Greece to the writings of the physician Galen in the second century C.E., medical recommendations regarding sexual discipline echoed and reinforced the ambivalence of Greek and Roman philosophers regarding human sexual activity. Galen's theories retained considerable power all the way into the European Renaissance. The interpretation of syphilis as a disease rather than a divine punishment came in the fifteenth century as the result of medical writings in response to a high incidence of the disease among the socially powerful. In nineteenth century western Europe and North America, medical writers were enormously influential in shaping norms regarding such matters as masturbation (physicians believed it would lead to

insanity), homosexuality (newly identified with perversions that medicine must diagnose and treat), contraception (considered unhealthy because it fostered sexual excess and loss of physical power), and gender roles (promoted on the basis of medical assessments of women's capacity for sexual desire). Today sex counseling and therapy communicate, however implicitly, normative ethical assumptions. Indeed, so great has been the influence of the medical profession on moral attitudes toward sexual options that critics warn of the "tyranny of experts," referring not to moral philosophers or religious teachers but to scientists and physicians.

The history of sexual ethics provides a helpful perspective for understanding current ethical questions regarding human sexuality. This article focuses on Western philosophical, scientific-medical, and religious traditions of sexual ethics and on the contemporary issues that trouble the heirs of these traditions. A historical overview of sexual ethics is not without its difficulties, however, as critical studies have shown (Brown; Foucault, 1978; Fout; Plaskow).

First of all, while it is possible to find a recorded history of laws, codes, and other guides to moral action regarding sexual behavior, it is almost impossible to determine what real people actually believed and did in the distant past. Or at least the historical research has barely begun. Second, ethical theory regarding sex (e.g., what is to be valued, what goals are worth pursuing, what reasons justify certain sexual attitudes, activities, and relationships) is predominantly theory formulated by an elite group of men. Women's experiences, beliefs, and values are largely unrecorded and, until recently, have been almost wholly inaccessible. The same is true of men who do not belong to a dominant class. Third, what we do find through historical research is necessarily subject to interpretation. It makes a difference, for example, whether one is looking for historical evaluations of human sexual desire or historical silences about sexual abuse of women. Finally, if one takes seriously the social construction of gender and sexuality, it is not clear that any kind of coherent historical narrative is possible. All of these difficulties notwithstanding, it is possible to survey (with appropriate caution) a Western normative and theoretical history regarding sex and to gain from the richness of varying contemporary interpretations. Central strands of this history can be traced to classical Greek and Roman antiquity, Judaism, and early and later developments in Christianity.

Ancient Greece and Rome

GENERAL ATTITUDES AND PRACTICE. Ancient Greece and Rome shared a general acceptance of sex as a natural part of life. Both were permissive regarding the sexual behavior of men. In Athens, for example, the only clear proscriptions applicable to citizen-class men were in incest, bigamy, and adultery (insofar as it violated the property of another man). The focus of sexual concern in the two cultures was significantly different, however. For the Greeks, adult male love of adolescent boys occupied a great deal of public attention, whereas the Romans focused public concern on heterosexual marriage as the foundation of social life.

Marriage for both Greeks and Romans was monogamous. In Greece, however, no sexual ethic confined sex to marriage. Marriage as the expected pattern for citizen-class individuals was based not on the affective bond between husband and wife but on what were considered natural gender roles regarding procreation and service to the city. Male human nature was generally assumed to be bisexual, and the polyerotic needs of men were taken for granted. Concubinage, male and female prostitution, and the sexual use of slaves were commonly accepted. In practice, much of this was true in ancient Rome as well, even though ideals of marital fidelity became much more important. The development of marriage as a social institution was, however, considered a central achievement of Roman civilization. This included a growing appreciation of the importance of affective ties between wives and husbands.

Greece and Rome were male-dominated societies, and for citizens a gendered double standard prevailed in regard to sexual morality. Both Greek and Roman brides, but not bridegrooms, were expected to be virgins. In Greece, the only women who were given some equal status with men were a special class of artistically and educationally sophisticated prostitutes, the *hetaerae.* Generally women were considered intellectually inferior to men. In addition, Greek husbands and wives were unequal in age (wives were much younger) and in education. Wives had no public life, though they were given the power and responsibility of managing the home. In the Roman household, on the contrary, the husband retained power and could rule with an entirely free hand. Here the ideal of the *patria potestas* reached fulfillment. Mutual fidelity was much praised, but in fact absolute fidelity was required of wives while husbands could consort freely with slaves or prostitutes. Although by the first century C.E., women in Rome had achieved considerable economic and political freedom, they could not practice the sexual freedom traditionally granted to men.

Homosexuality was accepted in both Greek and Roman antiquity. Especially for the Greeks, however, it was less a matter of some men being sexually attracted only to men (or, more likely, boys) than a matter of men generally being attracted to beautiful individuals, whether male or female. Desire was of greater interest, as both possibility and problem, than its object; and desire was not essentially differentiated according to the gender of its object. Greek men were

expected to marry, in order to produce an heir. Yet love and friendship, and sometimes sex, between men could be of a higher order than anything possible within marriage (for gender equality obtained between men, despite differences in age). Same-sex relations were not thereby wholly unproblematic, however, as cultural cautions against male passivity attested. Moreover, the ethos tended not to support a positive evaluation of sexual relationships between women. Lesbian relations were often judged negatively because they counted as adultery (since women belonged to their husbands) or because a cultural preoccupation with male sexual desire made sex between women appear unnatural.

In both Greece and Rome, abortion and infanticide were common. Concern about the need to limit population influenced Greek sexual practices at various times, whereas efforts to improve a low birthrate in imperial Rome led to legal incentives to marry and to procreate. Divorce was more readily available in ancient Greece than in Rome, but eventually both cultures provided for it and for the resulting economic needs of divorced women; in Greece, husbands continued to administer their former wives' dowries, while in Rome a woman took her dowry with her.

Scholars today tend to dispute the belief that the last years of the Roman Empire saw a great weakening of sexual norms, a sexual dissipation at the heart of a general moral decline. The favored historical reading is now the opposite: that general suspicion of sexuality grew, and normative restrictions of sexual activity increased. In part, this was the result of the gradual influence of philosophical theories that questioned the value of sexual activity and emphasized the dangers in its consequences.

GREEK AND ROMAN PHILOSOPHICAL APPRAISALS. Michel Foucault's influential history of Graeco-Roman theory regarding sex identifies two problems that preoccupied philosophers: the natural force of sexual desire, with its consequent tendency to excess, and the power relations involved in the seemingly necessary active/passive roles in sexual activity (Foucault, 1986, 1988). The first problem contributed to the formulation of an ideal of self-mastery within an aesthetics of existence. Self-mastery could be achieved through a regimen that included diet, exercise, and various practices of self-discipline. The second problem yielded criteria for love and sex between men and boys. Active and passive roles were not a problem in adult male relations with women or with slaves, for the inferior passive role was considered natural to women, including wives, and to servants or slaves. This was a problem, however, for citizen-class boys, who must come to be equal with men. The solution, according to some philosophers (e.g., Demosthenes), was to regulate the age of boy lovers and the circumstances and goals of their liaisons with men. Others (e.g., Plato) preferred transcending and eliminating physical sex in erotic relations between men and boys.

The aspects of Greek and Roman thought about sex that were to have the most influence on subsequent Western theory included a distrust of sexual desire and a judgment of the inferior status of sexual pleasure, along with the inferior status of the body in relation to the soul. While sex was not considered evil, it was considered dangerous—not only in its excess but also in its natural violence (orgasm was sometimes described as a form of epileptic seizure); in its expenditure of virile energy (it was thought to have a weakening effect); and in its association with death (nature's provision for immortality through procreation made sex a reminder of mortality) (Foucault, 1986).

The Pythagoreans in the sixth century B.C.E. advocated purity of the body for the sake of cultivating the soul. The force of their position was felt in the later thinking of Socrates and Plato. Although Plato moved away from a general hostility to bodily pleasure, he made a careful distinction between lower and higher pleasures (in, for example, the *Republic, Phaedo, Symposium,* and *Philebus*): Sexual pleasure was a lower form of pleasure, and self-mastery required domination over its demands. Plato advocated unleashing, not restraining, the power of eros for the sake of uniting the human spirit with the highest truth, goodness, and beauty. Insofar as bodily pleasures could be taken into this pursuit, there was no objection to them. But Plato thought that sexual intercourse diminished the power of eros for the contemplation and love of higher realities and that it even compromised the possibility of tenderness and respect in individual relationships of love (*Phaedrus*).

Aristotle, too, distinguished lower and higher pleasures, placing pleasures of touch at the bottom of the scale, characteristic as they are of the animal part of human nature (*Nicomachean Ethics*). Aristotle, more this-worldly than Plato, advocated moderation rather than transcendence. However, for Aristotle the highest forms of friendship and love, and of happiness in the contemplation of the life of one's friend, seemed to have no room for the incorporation of sexual activity or even for Platonic eros. Aristotle never conceived of the possibility of equality or mutuality in relationships between women and men, and he opposed the design for this that Plato had offered in the *Republic* and *Laws.*

Of all Graeco-Roman philosophies, Stoicism probably had the greatest impact on later developments in Western thought about sex. Musonius Rufus, Epictetus, Seneca, and Marcus Aurelius, for example, taught strong doctrines of the power of the human will to regulate emotion and of the

desirability of such regulation for the sake of inner peace. Sexual desire, like the passions of fear and anger, was in itself irrational, disruptive, liable to excess. It needed to be moderated if not eliminated. It ought never to be indulged in for its own sake but only insofar as it served a rational purpose. Procreation was that purpose. Hence, even in marriage sexual intercourse was considered morally good only when engaged in for the sake of procreation.

With the later Stoics came what Foucault calls the "conjugalization" of sexual relations (1988, p. 166). That is, the norm governing sexual activity was now "no sex outside of marriage," derived from what others have called the "procreative" norm. Marriage was considered a natural duty, excused only in special circumstances such as when an individual undertook the responsibilities of life as a philosopher. The good effects of marriage included progeny and the companionship of husband and wife. It became the context for self-control and the fashioning of the virtuous life. Plutarch (in *Dialogue on Love*) took the position that marriage, not homosexual relationships, was the primary locus for erotic love and for friendship.

Overall, the Graeco-Roman legacy to Western sexual ethics holds little of the sexual permissiveness that characterized ancient Greece. The dominant themes carried through to later traditions were skepticism and control. This may have been due to the failure of almost all Greek and Roman thinkers to integrate sexuality into their best insights into human relationships. Whether such an integration is possible in principle has been at least a tacit question for other traditions.

The Jewish Tradition

Earliest Jewish moral codes were simple and without systematic theological underpinnings. Like other ancient Near Eastern legislation, they prescribed marriage laws and prohibited rape, adultery, and certain forms of prostitution. In contrast with neighboring religions, the Jews believed in a God who is beyond sexuality but whose plan for creation makes marriage and fertility holy and the subject of a religious duty (Gen. 2:24). At the heart of Judaism's tradition of sexual morality is a religious injunction to marry. The command to marry holds within it a command to procreate, and it assumes a patriarchal model for marriage and family. These two aspects of the tradition—the duty to procreate and its patriarchal context—account for many of its specific sexual regulations.

While the core of the imperative to marry is the command to procreate, marriage was considered a duty also because it conduced to the holiness of the partners. Holiness referred to more than the channeling of sexual desire, though it meant that also; it included the companionship and mutual fulfillment of spouses. In fact, monogamous lifelong marriage was considered the ideal context for sexuality, and in time it became the custom and not only an ideal. Yet the command to procreate historically stood in tension with the value given to the marriage relationship. Thus while the laws of *onah,* of marital rights and duties, aimed to make sex a nurturant of love (Lamm), polygamy, concubinage, and divorce and remarriage were long accepted as solutions to a childless marriage. Only in the eleventh century C.E. was polygamy finally banned (much later in the East), and it was only in the twelfth century that Maimonides explicitly condemned concubinage (Novak, 1992).

Judaism has traditionally shown a concern for the "improper emission of seed" (appealing to interpretations of Gen. 38:9). Included in this concern have been proscriptions of masturbation and homosexual acts. The latter in particular have been considered unnatural (Lev. 18:22, 20:13), failing in responsibility for procreation, beneath the dignity of humanly meaningful sexual intercourse, indicative of uncontrolled (and hence morally evil) sexual desire, and a threat to the stability of heterosexual marriage and the patriarchal family. Lesbian relations were not regulated by biblical law, and in rabbinic literature were treated far less seriously than male homosexuality.

Throughout the Jewish tradition there has been a marked difference in the treatment of women's and men's sexuality (Plaskow). In part, this was because of women's subordinate role in the family and in society. The regulation and control of women's sexuality was considered necessary to the stability and the continuity of the family. Premarital sex, extramarital sex, and even rape were legally different for women than for men. In the biblical period, husbands but not wives could initiate divorce (Deut. 24:1–4), although later rabbinic law made it possible for either to do so. Adultery was understood as violating the property rights of a husband and could be punished by the death of both parties. Women's actions and dress were regulated in order to restrict their potential for luring men into illicit sex. The laws of onah required men to respect the sexual needs of their wives; but the laws of *niddah* (menstrual purity) had the symbolic consequence, however unintended, of associating women with defilement.

The perspective on sex, in all the branches of Judaism, has been an enduringly positive one, yet not without ambivalence. The sexual instinct was considered a gift from God, but it could still be called by the rabbis the "evil impulse" (*yetzer hara*) (Plaskow). The tradition was not immune from the suspicion regarding sex that, with the rise of Stoic philosophies and the advent of certain religious movements from the East, permeated all Middle Eastern

cultures. Interpretations of the relation between sexuality and the sacred have not been univocal, as evidenced in differences between mainstream Jewish thinking and kabbalistic mysticism. Hence, some issues of sexual ethics have not been resolved once and for all. Contemporary developments in the Jewish tradition include growing pluralism regarding questions of premarital sex, contraception, abortion, gender equality, and homosexuality (Borowitz; Feldman; Plaskow; Biale; Posner). Current conflicts involve the interpretation of traditional values, the analysis of contemporary situations, and the incorporation of hitherto unrepresented perspectives, in particular those of heterosexual women and of gays and lesbians.

Christian Traditions

Like other religious and cultural traditions, the teachings of Christianity regarding sex are complex and subject to multiple influences, and they have changed and developed through succeeding generations. Christianity does not begin with a systematic code of ethics. The teachings of Jesus and his followers, as recorded in the New Testament, provide a central focus for the moral life of Christians in the command to love God and neighbor. Beyond that, the New Testament offers grounds for a sexual ethic that (1) values marriage and procreation on the one hand, and singleness and celibacy on the other; (2) gives as much or more importance to internal attitudes and thoughts as to external actions; and (3) affirms a sacred symbolic meaning for sexual intercourse, yet both subordinates it to other human values and finds in it a possibility for evil. As for unanimity on more specific sexual rules, this is difficult to find in the beginnings of a religion whose founder taught as an itinerant prophet and whose sacred texts were formulated in "the more tense world" of particular disciples, a group of wandering preachers (Brown, pp. 42–43).

EARLY INFLUENCES ON CHRISTIAN UNDERSTANDINGS OF SEX. Christianity emerged in the late Hellenistic age, when even Judaism was influenced by the dualistic anthropologies of Stoic philosophy and Gnostic religions. Unlike the Greek and Roman philosophies of the time, Christianity's main concern was not the art of self-mastery and not the preservation of the city or the empire. Unlike major strands of Judaism at the time, its focus was less on the solidarity and continuity of life in this world than on the continuity between this world and a life to come. Yet early Christian writers were profoundly influenced both by Judaism and by Graeco-Roman philosophy. With Judaism they shared a theistic approach to morality, an affirmation of creation as the context of marriage and procreation, and an ideal of single-hearted love. With the Stoics they shared a suspicion of bodily passion and a respect for reason as a guide to the moral life. With the Greeks, Romans, and Jews, Christian thinkers assumed and reinforced views of women as inferior to men (despite some signs of commitment to gender equality in the beginnings of Christianity as a movement). As Christianity struggled for its own identity, issues of sexual conduct were important, but there was no immediate agreement on how they should be resolved.

Gnosticism was a series of religious movements that deeply affected formulations of Christian sexual ethics for the first three centuries C.E. (Noonan). For example, some Gnostics taught that marriage was evil or at least useless, primarily because the procreation of children was a vehicle for forces of evil. This belief led to two extreme positions—one in opposition to all sexual intercourse, and hence in favor of celibacy, and the other in favor of any form of sexual intercourse so long as it was not procreative. Neither of these positions prevailed in what became orthodox Christianity.

What did prevail in Christian moral teaching was a doctrine that incorporated an affirmation of sex as good (because part of creation) but seriously flawed (because the force of sexual passion as such cannot be controlled by reason). The Stoic position that sexual intercourse can be brought under the rule of reason not by subduing it but by giving it a rational purpose (procreation) made great sense to early Christian thinkers. The connection made between sexual intercourse and procreation was not the same as the Jewish affirmation of the importance of fecundity, but it was in harmony with it. Christian teaching could thus both affirm procreation as the central rationale for sexual union and advocate celibacy as a praiseworthy option (indeed, the ideal) for Christians who could choose it.

With the adoption of the Stoic norm for sexual intercourse, the direction of Christian sexual ethics was set for centuries to come. A sexual ethic that concerned itself primarily with affirming the good of procreation, and thereby the good of otherwise evil tendencies, was reinforced by the continued appearance of antagonists who played the same role the Gnostics had played. No sooner had Gnosticism begun to wane than, in the third century, Manichaeanism emerged. It was largely in response to Manichaeanism that Saint Augustine formulated his sexual ethic, an ethic that continued and went beyond the Stoic elements incorporated by Clement of Alexandria, Origen, Ambrose, and Jerome.

THE SEXUAL ETHICS OF SAINT AUGUSTINE AND ITS LEGACY. Against the Manichaeans Augustine argued in favor of the goodness of marriage and procreation, though he shared with them a negative view of sexual desire as in itself an evil passion. Because evil was for Augustine, however, a privation of right order (something missing in what

was otherwise basically good), he thought at first that it was possible to reorder sexual desire according to right reason, to integrate its meaning into a right and whole love of God and neighbor. This reordering could be done only when sexual intercourse was within heterosexual marriage and for the purpose of procreation (*On the Good of Marriage,* 6). Intercourse within marriage but without a procreative purpose was, according to Augustine, sinful, though not necessarily mortally so. Marriage, on the other hand, had a threefold purpose: not only the good of children but also the goods of fidelity between spouses (as opposed to adultery) and the indissolubility of the union (as opposed to divorce).

In his later writings against the Pelagians (*Marriage and Concupiscence*), Augustine tried to clarify the place of disordered sexual desire in a theology of original sin. Although for Augustine the original sin of Adam and Eve was a sin of the spirit (a sin of prideful disobedience), its effects were most acutely present in the conflict between sexual desire and reasoned love of higher goods. Moreover, this loss of integrity in affectivity was passed from one generation to another through the mode of procreation—sexual intercourse. In this debate Augustine argued that there is some evil in all sexual intercourse, even when it is within marriage and for the sake of procreation. Most of those who followed Augustine disagreed with this, but his basic formulation of a procreative ethic held sway in Christian moral teaching for centuries.

Some early Christian writers (e.g., John Chrysostom) emphasized the Pauline purpose for marriage—marriage as a remedy for incontinence. Such a position hardly served to foster a more optimistic view of sex, but it did offer a possibility for moral goodness in sexual intercourse without a direct relation to procreation. However, from the sixth to the eleventh century, it was Augustine's rationale that was codified in penitentials (manuals for confessors, providing lists of sins and their prescribed penances) with detailed prohibitions against adultery, fornication, oral and anal sex, contraception, and even certain positions for sexual intercourse if they were thought to be departures from the procreative norm. Gratian's great collection of canon law in the twelfth century contained rigorous regulations based on the principle that all sexual activity is evil unless it is between husband and wife and for the sake of procreation. A few voices (e.g., Abelard and John Damascene) maintained that concupiscence (sexual passionate desire) does not make sexual pleasure evil in itself, and that intercourse in marriage can be justified by the simple intention to avoid fornication.

Overall, the Christian tradition in the first half of its history developed a consistently negative view of sex, despite the fact that Augustine and most of those who followed him were neither anti-body nor anti-marriage. The statement that this tradition was negative must be a qualified claim, of course, for it was silent or vacillating on many questions of sexuality (e.g., on the question of homosexuality); and there is little evidence that Christians in general were influenced by the more severe sexual attitudes of their leaders (Boswell). The direction and tone that the early centuries gave to the tradition's future, however, were unmistakable. What these leaders were concerned about was freedom from bondage to desires that seemingly could not in themselves lead to God. In a quest for transformation of the body along with the spirit, even procreation did not appear very important. Hence, regulation of sexual activity and even the importance of the family were often overshadowed by the ideal of celibacy. As Peter Brown's 1988 massive study has shown, sexual renunciation served both eros and unselfish love, and it suited a worldview that broke boundaries with this world without rejecting it as evil.

THE TEACHING OF AQUINAS. Thomas Aquinas wrote in the thirteenth century, when rigorism already prevailed in Christian teaching and church discipline. His remarkable synthesis of Christian theology did not offer much that was innovative in the area of sexual ethics. Yet the clarity of what he brought forward made his contribution significant for the generations that followed. He taught that sexual desire is not intrinsically evil, since no spontaneous bodily or emotional inclination is evil in itself; only when there is an evil moral choice is an action morally evil. Consequent upon original sin, however, there is in human nature a certain loss of order among natural human inclinations. Sexual passion is marked by this disorder, but it is not morally evil except insofar as its disorder is freely chosen.

Aquinas offered two rationales for the procreative norm the tradition had so far affirmed. One was the Augustinian argument that sexual pleasure, in the fallen human person, hinders the best working of the mind. It must be brought into some accord with reason by having an overriding value as its goal. No less an end than procreation can justify it (*Summa theologiae,* I-II.34.1, ad 1). But second, reason does not merely provide a good purpose for sexual pleasure. It discovers this purpose through the anatomy and biological function of sexual organs (*Summa theologiae* II-II.154.11; *Summa contra Gentiles* III.122.4, 5). Hence, the norm of reason in sexual behavior requires not only the conscious intention to procreate but also the accurate and unimpeded (i.e., noncontraceptive) physical process whereby procreation is possible.

From the procreative norm there followed other specific moral rules. Many of them were aimed at the well-being of offspring that could result from sexual intercourse. For example, Aquinas argued against fornication, adultery, and

divorce on the grounds that children would be deprived of a good context for their rearing. He considered sexual acts other than heterosexual intercourse to be immoral because they could not be procreative. Aquinas's treatment of marriage contained only hints of new insight regarding the relation of sexual intercourse to marital love. He offered a theory of love that had room for a positive incorporation of sexual union (*Summa theologiae* II-II.26.11), and he suggested that marriage might be the basis of a maximum form of friendship (*Summa contra Gentiles* III.123).

Though what had crystallized in the Middle Ages canonically and theologically would continue to influence Christian moral teaching into the indefinite future, the fifteenth century marked the beginning of significant change. Finding some grounds for opposing the prevailing Augustinian sexual ethic in both Albert the Great and in the general (if not the specifically sexual) ethics of Aquinas, writers (e.g., Denis the Carthusian and Martin LeMaistre) began to talk of the integration of spiritual love and sexual pleasure, and the intrinsic good of sexual pleasure as the opposite of the pain of its lack. This did not reverse the Augustinian tradition, but it weakened it. The effects of these new theories were felt in the controversies of the Reformation.

PROTESTANT TEACHINGS ON SEX. Questions of sexual behavior played an important role in the Protestant Reformation beginning in the sixteenth century. Clerical celibacy, for example, was challenged not just in its scandalous nonobservance but also as a Christian ideal. Marriage and family replaced it among the reformers as the center of sexual gravity in the Christian life. Martin Luther and John Calvin were both deeply influenced by the Augustinian tradition regarding original sin and its consequences for human sexuality. Yet both developed a position on marriage that was not dependent on a procreative ethic. Like most of the Christian tradition, they affirmed marriage and human sexuality as part of the divine plan for creation, and therefore good. But they shared Augustine's pessimistic view of fallen human nature and its disordered sex drive. Luther was convinced, however, that the necessary remedy for disordered desire was marriage (*On the Estate of Marriage*). And so the issue was joined over a key element in Christian sexual ethics. Luther, of course, was not the first to advocate marriage as the cure for unruly sexual desire, but he took on the whole of the tradition in a way that no one else had. He challenged theory and practice, offering not only an alternative justification for marriage but also a view of the human person that demanded marriage for almost all Christians.

According to Luther, sexual pleasure itself in one sense needed no justification. The desire for it was simply a fact of life. It remained, like all the givens in creation, a good so long as it was channeled through marriage into the meaningful whole of life, which included the good of offspring. What there was in sex that detracted from the knowledge and worship of God was sinful, but it had simply to be forgiven, as did the inevitable sinful elements in all human activity. After 1523, Luther shifted his emphasis from marriage as a "hospital for the incurables" to marriage as a school for character. It was within the secular, nonsacramental institution of marriage and family that individuals learned obedience to God and developed the important human virtues. The structure of the family was hierarchical, husband having authority over wife, parents over children.

Calvin, too, saw marriage as a corrective to otherwise disordered desires. He expanded the notion of marriage as the context for human flourishing by maintaining that the greatest good of marriage and sex was the society that is formed between husband and wife (*Commentary on Genesis*). Calvin was more optimistic than Luther about the possibility of controlling sexual desire, though he, too, believed that whatever fault remained in it was "covered over" by marriage and forgiven by God (*Institutes of the Christian Religion,* 2.8.44). Like earlier writers, he worried that marriage as a remedy for incontinence could nonetheless in itself offer provocation to uncontrolled passion.

As part of their teaching on marriage, Luther and Calvin opposed premarital and extramarital sex and homosexual relations. So concerned was Luther to provide some institutionally tempering form to sexual desire that he once voiced an opinion favoring bigamy over adultery. Both Luther and Calvin were opposed to divorce, though its possibility was admitted in a situation of adultery or impotence.

MODERN ROMAN CATHOLIC DEVELOPMENTS. During and after the Roman Catholic Counterreformation, from the late sixteenth century on, new developments alternated with the reassertion of the Augustinian ethic. The Council of Trent (1545–1563) was the first ecumenical council to address the role of love in marriage, but it also reaffirmed the primacy of procreation and reemphasized the superiority of celibacy. In the seventeenth century, Jansenism, a morally austere and ultimately heretical movement, reacted against what it considered a dangerous lowering of sexual standards and brought back the Augustinian connection between sex, concupiscence, and original sin. Alphonsus Liguori in the eighteenth century gave impetus to a manualist tradition (the development and proliferation of moral manuals designed primarily to assist confessors) that attempted to integrate the Pauline purpose of marriage (as a remedy for incontinence) with the procreative purpose. Nineteenth-century moral manuals focused on "sins of impurity," choices of any sexual pleasure apart from procreative marital

intercourse. Then came the twentieth century, with the rise of Catholic theological interest in personalism and the move by the Protestant churches to accept birth control.

In 1930, Pope Pius XI responded to the Anglican approval of contraception by reaffirming the procreative ethic (*Casti connubii*). But he also gave approval to the use of the rhythm method for restricting procreation. Moral theologians began to move cautiously in the direction of allowing sexual intercourse in marriage without a procreative intent and for the purpose of fostering marital union. The change in Roman Catholic moral theology from the 1950s to the 1970s was dramatic. The wedge introduced between procreation and sexual intercourse by the acceptance of the rhythm method joined with new understandings of the totality of the human person to support a radically new concern for sex as an expression and cause of married love. The effects of this theological reflection were striking in the 1965 Second Vatican Council teaching that the love essential to marriage is uniquely expressed and perfected in the act of sexual intercourse (*Gaudium et spes,* 49). Although the Council still held that marriage is by its very nature ordered to the procreation of children, it no longer ranked what the tradition considered the basic ends of marriage, offspring and spousal union, as primary and secondary.

In 1968, Pope Paul VI insisted that contraception is immoral (*Humanae vitae*). Rather than settling the issue for Roman Catholics, however, this occasioned intense conflict. The majority of moral theologians disagreed with the papal teaching, even though a distinction between nonprocreative and antiprocreative behavior mediated the dispute for some. Since then, many of the specific moral rules governing sexuality in the Catholic tradition have come under serious question. Official teachings have sustained past injunctions, though some modifications have been made in order to accommodate pastoral responses to second marriages, homosexual orientation (but not sexual activity), and individual conscience decisions regarding contraception. Among moral theologians there has been serious debate (and by the 1990s, marked pluralism) regarding premarital sex, homosexual acts, remarriage after divorce, infertility therapies, gender roles, and clerical celibacy (Curran and McCormick).

POST-REFORMATION PROTESTANTISM. Twentieth-century Protestant sexual ethics developed even more dramatically than Roman Catholic sexual ethics. After the Reformation, Protestant theologians and church leaders continued to affirm heterosexual marriage as the only acceptable context for sexual activity. Except for the differences regarding celibacy and divorce, sexual norms in Protestantism looked much the same as those in the Catholic tradition. Nineteenth-century Protestantism shared and contributed to the cultural pressures of Victorianism. But in the twentieth century, Protestant thinking was deeply affected by biblical and historical studies that questioned the foundations of Christian sexual ethics, by psychological theories that challenged traditional views, and by the voiced experience of church members.

It is difficult to trace one clear line of development in twentieth-century Protestant sexual ethics, or even as clear a dialectic as may be found in Roman Catholicism. The fact that Protestantism in general was from the beginning less dependent on a procreative ethic allowed it almost unanimously to accept contraception as a means to responsible parenting. Overall, Protestant sexual ethics has moved to integrate an understanding of the human person, male and female, into a theology of marriage that no longer deprecates sexual desire as self-centered and dangerous. It continues to struggle with issues of gendered hierarchy in the family, and with what are often called "alternative lifestyles," such as the cohabitation of unmarried heterosexuals and the sexual partnerships of gays and lesbians. For the most part, the ideal context for sexual intercourse is still seen to be heterosexual marriage, but many Protestant theologians accept premarital sex and homosexual partnerships with general norms of noncoercion, basic equality, and so on. Every mainline Protestant church in the 1990s has task forces working particularly on questions of homosexuality, professional (including clergy) sexual ethics, and sex education. Traditional positions have either changed or are open and conflicted.

Modern Sexology: Philosophical, Medical, Social Scientific

The contemporary shaking of the foundations of Western sexual ethics, religious and secular, is traceable to many factors. These quite obviously include the rapid development of reproductive technologies, none more important than the many forms of contraception. But there have been other factors as well, such as changes in economic structures under capitalism and in social structures following major shifts of population to urban centers. Of important influence, too, has been the rise of the modern women's movement and of movements for gay and lesbian civil rights. Along with these developments, as both cause and effect, there have been significant contributions from disciplines such as history, psychology, anthropology, sociology, and medicine. Philosophy has generally followed these changes, though in the late twentieth century it, too, has contributed to cultural alterations in perspectives on sex.

PHILOSOPHICAL DEVELOPMENTS. As surveyors of the history of philosophy note, philosophers have not paid

much attention to sex. They have written a great deal on love but have left sexual behavior largely to religion, poetry, medicine, or the law (Baker and Elliston; Soble). After the Greeks and Romans, and medieval thinkers such as Thomas Aquinas whose work is philosophical as well as theological, there is not much to be found in the field regarding sexuality until the twentieth century. Some exceptions to this are the sparse eighteenth-century writings on sex and gender by David Hume, Jean-Jacques Rousseau, Immanuel Kant, Mary Wollstonecraft, and Johann Gottlieb Fichte, and the nineteenth-century writings of Arthur Schopenhauer, Karl Marx, Friedrich Engels, John Stuart Mill, and Friedrich Nietzsche. Most of these writers reinforced the norm of heterosexual procreative sex within marriage. Hume, for example, in his "Of Polygamy and Divorce" (1742), insisted that all arguments finally lead to a recommendation of "our present European practices with regard to marriage." Rousseau's La Nouvelle Héloïse (1761) deplored the faults of conventional marriage but strongly opposed divorce and marital infidelity. Kant defended traditional sexual mores, although in his *Lectures on Ethics* (1781) he introduced a justification for marriage not in terms of procreation but of altruistic love, arguing that only a mutual commitment in marriage can save sexual desire from making a sexual partner into a mere means to one's own pleasure. Schopenhauer viewed sexual love as subjectively for pleasure, though objectively for procreation; his strong naturalism paved the way for a more radical theory of sex as an instinct without ethical norms (*The Metaphysics of Sexual Love,* 1844).

Philosophers in these centuries came down on both sides of the question of gender equality. Fichte, for example, asserted an essentially passive nature for women, who, if they were to be equal with men, would have to renounce their femininity (*The Science of Rights,* 1796). But Mary Wollstonecraft in her "A Vindication of the Rights of Women" (1792), and Mill in his "The Subjection of Women" (1869), offered strong challenges to the traditional inequality of gender roles in society. Marx and Engels critiqued bourgeois marriage as a relationship of economic domination (e.g., in their *The Origin of the Family, Private Property and the State,* first published by Engels in 1884). Schopenhauer, reacting to feminist agendas, advocated polygamy on the basis of a theory of male needs and female instrumental response (*On Women,* 1848). Nietzsche, like Schopenhauer, moved away from traditional ethical norms but also reinforced a view of the solely procreative value of women (*Thus Spake Zarathustra,* 1892).

Twentieth-century European philosophers attempted to construct new meanings for human sexuality in the light of new philosophical theories of freedom and interpersonal love. Jean-Paul Sartre analyzed sexuality as an ontological paradigm for human conflict (*Being and Nothingness,* 1943); Maurice Merleau-Ponty tried to challenge this and to go beyond it (*The Phenomenology of Perception,* 1945); Simone de Beauvoir fueled a feminist movement with a stark and revealing analysis of sexism and its influence on the meaning of both gender and sex (*The Second Sex,* 1949). With the exception of Bertrand Russell (*Marriage and Morals,* 1929), it was not until the late 1960s that British and American philosophers began to turn their attention to sexual ethics. Then, however, key essays by analytic philosophers began to appear on issues such as sexual desire, gender, marriage, adultery, homosexuality, abortion, sexual perversion, rape, pornography, and sexual abuse (Baker and Elliston; Shelp; Soble). All of these efforts were profoundly influenced by nineteenth- and twentieth-century contributions from other disciplines.

FREUD AND PSYCHOANALYSIS. The emergence of psychoanalytic theory brought with it new perceptions of the meaning and role of sexuality in the life of individuals. Whatever the final validity of Sigmund Freud's insights, they burst upon the world with a force that all but swept away the foundations of traditional sexual morality. Augustine's and Luther's assertions about the indomitability of sexual desire found support in Freud's theory, but now the power of sexual need was not the result of sin but a natural drive, centrally constitutive of the human personality (*Three Essays on the Theory of Sexuality,* 1905). Past efforts to order sexuality according to rational purposes could now be understood as repression. After Freud, when sex went awry, it was a matter of psychological illness, not moral evil. Taboos needed demythologizing, and freedom might be attained not through forgiveness but through medical treatment.

Yet psychoanalytic theory raised as many questions as it answered. Freud argued for liberation from sexual taboos and from the hypocrisy and sickness they caused, but he nonetheless maintained the need for sexual restraint. His theory of sublimation called for a discipline and channeling of the sexual instinct if the individual and society were to progress (*Civilization and Its Discontents,* 1930). The concern for sexual norms therefore remained, and Freud's own recommendations were in many ways quite traditional. But new work had clearly been cut out for thinkers in both secular and religious traditions.

SCIENCE, SOCIAL SCIENCE, AND MEDICINE. Freud was not the only force in nineteenth- and twentieth-century scientific and social thought that shaped changes in Western sexual mores. Biological studies of the human reproductive process offered new perspectives on male and female roles in

sex and procreation. Animal research showed that higher forms of animals masturbate, perform sexual acts with members of the same sex, and generally engage in many sexual behaviors that were previously assumed to be unnatural for humans because they were unnatural for animals. Anthropologists found significant variations in the sexual behavior of human cultural groups, so that traditional notions of human nature seemed even more questionable. Surveys of sexual activities in Western society revealed massive discrepancies between accepted sexual norms and actual behavior, undercutting consequential arguments for some of the norms (e.g., the fact that 95% of the male population in the United States engaged in autoerotic acts made it difficult to support a prohibition against masturbation on grounds that it leads to insanity).

Modern sexology, then, has incorporated the work not only of sexual psychology but also of biology, anthropology, ethnology, and sociology—the research and the theories of individuals like Richard von KrafftEbing, Havelock Ellis, Magnus Hirschfield, Alfred Kinsey, Margaret Mead, William Masters, and Virginia Johnson. The results have not all been toward greater liberty in sexual behavior, but they have shared a tendency to secularize and medicalize human sexuality. In theory, sex has become less an ethical or even an aesthetic problem than a health problem. In practice, experts of all kinds—physicians, counselors, psychiatrists, social workers, teachers—provide guidance; and the guidance can at least appear to carry moral weight. An example of the intertwining of science, the medical professions, and morality is clear in the long efforts to define and identify sexual deviance or perversion—from Krafft-Ebing in the nineteenth century to the debates in the American Psychiatric Association in the 1970s and 1980s over the classification of homosexuality as a disease.

LESSONS OF HISTORY. Historians, too, have played an important role in the weakening of traditional sexual ethical norms. The very disclosure that sexual prescriptions have a history has revealed the contingency of their sources and foundations. To see, for example, that a procreative ethic rose as much from Stoic philosophies as from the Bible has allowed many Christians to question its validity. Feminist retrievals of elements in the Western tradition have led to critiques of taboo moralities and a consequent need for reconstruction. In an effort to make sense of present beliefs, historians have searched for the roots and developments of these beliefs, and the result has seldom been a reinforcement of the original rationales (Foucault, 1978; Boswell).

But it is not only the history of ideas that has had an impact on contemporary sexual ethics. It is also the historical excavation of the moral attitudes and actual practices of peoples of the past, and an identification of the shifting centers of influence on the sexual mores of different times and places (D'Emilio and Freedman; Peiss and Simmons; Fout). Sometimes referred to as a history of sexuality rather than a history of theories about sexuality or of institutionalized norms for sexuality, this is a task that is barely under way, and it has strong critics. Yet it has already had an impact on, for example, understandings of homosexuality and what can be called the politics of sex. This kind of history also attempts to provide narratives, describing shifts like the one in the United States from family-centered procreative sexual mores to romantic notions of emotional intimacy to a commercialization of sex and its idealization as the central source of human happiness (D'Emilio and Freedman). The history of sexuality and of sexual ethics, no less than the analysis of contemporary sexual norms, thus becomes subject to interpretation.

Interpretive Theories: Sex, Morality, and History

No one may have been more influential in determining current questions about the history of sexuality and sexual ethics than the French philosopher Michel Foucault. His ideas permeate much of the work of other sexual historians as well as philosophers and theologians. Yet his is not the only formative study in the history of sexual ethics, and his conclusions have provoked both positive and negative responses.

MICHEL FOUCAULT: A HISTORY OF DESIRE. Foucault originally planned to write a history of what he called "the experience of sexuality" in modern Western culture. In the course of his work, he became convinced that what was needed was a history of desire, or of the desiring subject. At the heart of this conviction was the premise that sexuality is not an ahistorical constant. Neither is sex a natural given, a biological referent that simply expresses itself in different experiences of sexuality shaped historically by changing moral norms. Sexuality is, rather, a transfer point for relations of power—between women and men, parents and children, teachers and students, clergy and laity, and so forth. Power in this sense is diffused through a field of multiple "force relations immanent in the sphere in which they operate" (Foucault, 1978, p. 92). In other words, sex is not a "stubborn drive" that requires the control of power. Power produces and constitutes sexual desire much more than it ever represses it. Power determines, shapes, and deploys sexuality, and sexuality determines the meaning of sex (Foucault, 1978).

Foucault denied, then, the "repressive hypothesis" as an explanation of the eighteenth- and nineteenth-century Western experience of sexuality. That is, he denied that the Victorian era had been an era of sexual repression and socially enforced silence about sex. He argued, rather, that it had been a time of an expanding deployment of sexuality and a veritable explosion of discourse about sexuality. The questions that interested him were not "Why are we repressed?" but "Why do we say that we are repressed?" and within this, not "Why was sex associated with sin for such a long time?" but "Why do we burden ourselves today with so much guilt for having made sex a sin?" (Foucault, 1978, pp. 8–9). Since the key to these questions was, Foucault thought, to be found in a study of discourse, he began with an examination of what he considered a Western impulse to discover the "truth" about sex. This, in his view, included a striking Western compulsion to self-examination and self-reporting regarding sexual experience, whether in the discourses of religion, medicine, psychiatry, or criminal justice.

To make sense of the connections between power, sexuality, and truth in the modern period, Foucault revised his project to include a study of the variations on sexual themes in other historical periods. His move to the past began with his thesis that a forerunner of modern discourse on sex was the seventeenth-century Christian ecclesiastical emphasis on confession. To put this in perspective, he undertook studies of pagan antiquity and of Christianity prior to the seventeenth century. Thus, volumes 2 and 3 of his *History of Sexuality* address the sexual mores of the fourth-century B.C.E. Greeks and the first- and second-century C.E. Romans (1990 and 1988, respectively). His unpublished fourth volume (*The Confessions of the Flesh*) examine developments within Christianity. The contrasts (and, as it turned out, the continuities) between the different historical periods shed some light on each period and on the overall Western pursuit of the kind of knowledge that promised power in relation to sex, what Foucault called the scientia sexualis.

Foucault came to the conclusion that the sexual morality of the Greeks and Romans did not differ essentially from Christian sexual morality in terms of specific prescriptions. He rejected the commonly held view that the essential contrast between sexual ethics in antiquity and in early Christianity lies in the permissiveness of Graeco-Roman societies as distinguished from the strict sexual rules of the Christians, or in an ancient positive attitude toward sex as distinguished from a negative Christian assessment. Both traditions, he argued, contained prohibitions against incest, a preference for marital fidelity, a model of male superiority, caution regarding same-sex relations, respect for austerity, a positive regard for sexual abstinence, fears of male loss of strength through sexual activity, and hopes of access to special truths through sexual discipline. Nor were these basic prescriptions very different from what could be found in post-seventeenth-century Western society.

Yet there were clear discontinuities, even ruptures, between these historical periods. The reasons for moral solicitude regarding sexuality were different. In Foucault's reading, the ancients were concerned with health, beauty, and freedom, while Christians sought purity of heart before God, and bourgeois moderns aimed at their own self-idealization. The Greeks valued self-mastery; Christians struggled for self-understanding; and modern Western individuals scrutinized their feelings in order to secure compliance with standards of normality. Eroticism was channeled toward boys for the Greeks, women for the Christians, and a centrifugal movement in many directions for the Victorian and post-Victorian middle class. The Greeks feared the enslavement of the mind by the body; Christians dreaded the chaotic power of corrupted passion; post-nineteenth century persons feared deviance and its consequent shame. Sexual morality was an aesthetic ideal, a personal choice, for an elite in antiquity; it became a universal ethical obligation under Christianity; and it was exacted as a social requirement under the power of the family and the management of the modern professional.

Foucault's study of the history of sexuality left open a question with which he had become preoccupied: How did contemporary Western culture come to believe that sexuality was the key to individual identity? How did sex become more important than love, and almost more important than life? He exposed the lack of freedom in past constructs of sexuality, and he critiqued past formulations of sexual prescriptions. But his presentation of current strategies for sexual liberation yielded no less skeptical a judgment. It suggested, rather, that however historically relative sexual ethics may be, moral solicitude regarding sexuality is not entirely a mistake.

CATHARINE MACKINNON: A HISTORY OF GENDERED VIOLENCE. Many Western feminists have shared Foucault's convictions that sexuality is socially constructed and the body is a site of power. Like Foucault, they have exposed continuing roles of medicine, education, and psychology in determining post-eighteenth-century sexual mores. With Foucault, they have emphasized discourse as a key to identifying underlying forces that link power, sexuality, and identity. But feminists fault Foucault for not extending his analytics of power to gender. Legal scholar Catharine MacKinnon, for example, opposes a Foucaultian history of desire on the grounds that the unacknowledged desiring subject is male. A history of sexuality that emphasizes sexual

desire and change misses the enduring aspects of history—the unrelenting sexual abuse of women. History, then, remains silent regarding sexual exploitation, harassment, battery, and rape. Without attention to these unchanging experiences of women, MacKinnon argues, there can be no accurate analysis of sex and power.

A feminist theory of sexuality, according to MacKinnon, "locates sexuality within a theory of gender inequality" (1989, p. 127). It is a mistake, therefore, to adopt the stance that what sex needs is socially constructed freedom, that all sex can be good—healthy, appropriate, pleasurable, to be approved and expressed—if only it is liberated from ideologies of allowed/not allowed. Since sexuality is socially constructed not by a diffuse multiplicity of powers (in Foucault's sense) but by hegemonic male power, it is culturally determined as violent toward women. Pornography is a means through which this social construction is achieved.

Although not all feminists share MacKinnon's radical critique of historical and contemporary sexual understandings and practices, there is significant agreement that sexuality needs norms, and that past and present norms require gender analysis and critique. From this standpoint, a Foucaultian treatment of male discourse regarding sexuality perpetuates a view of sexuality as eroticized dominance and submission; it fails to expose this conflict as gendered.

EVOLUTIONARY INTERPRETATIONS. Foucault and MacKinnon represent interpretations of the history of sexuality and sexual ethics that deny any progress. They refuse to applaud advances in understandings of sexuality or to sanctify the present as enlightened and free. To some extent, they even reject notions of change in history—Foucault arguing for different, but not causally connected, historical perspectives; and MacKinnon focusing on similarities across time and cultures—indeed, a failure to change. Others, however, have charted an evolutionary process across the Western history of ideas about sex and the moral norms that should govern it. Those who believe that contemporary sexual revolutions have liberated persons and their sexual possibilities belong in this category. So do those who acknowledge the significance of advances in biology and psychology and call for appropriate adjustments in philosophical and theological ethics. Thoughtful commentators do not necessarily conclude that there has been real progress, though they identify evolutionary changes (Green; Shelp; Soble).

Richard Posner belongs to this latter group, offering what he calls an "economic theory of sexuality." That is, he relies heavily on economic analysis both to describe the practice of sex and to evaluate legal and ethical norms in its regard. There are, he argues, three stages in the evolution of sexual morality. These stages correlate with the status of women in a given society (Posner). In the first stage, women's occupation is that of "simple breeder." When this is the case, companionate marriage is an unlikely possibility, and practices that are considered "immoral" are likely to flourish (e.g., prostitution, adultery, homosexual liaisons).

The second stage begins when women's occupations expand to include "child rearer and husband's companion." Here, companionate marriage is a possibility, and because of this, "immoral" practices that endanger it are vehemently condemned. When companionate marriage is idealized as the only possibility for everyone, societies become puritanical in their efforts to promote and protect it. In the third stage, women's roles are enlarged to include "market employment." Marriages will be fewer, but where they exist, they will be companionate. Other forms of sexual relationship, previously considered immoral, no longer appear to be either immoral or abnormal. This stage characterizes some Western societies more than others—notably, according to Posner, contemporary Sweden.

A very different kind of evolutionary theory can be found in the philosopher Paul Ricoeur's 1967 analysis of the symbolism of evil in Western history. In this analysis, the Greco-Hebraic history of the consciousness of evil has three moments or stages: defilement, sin, and guilt. The sense of defilement is a pre-ethical, irrational, quasi-material sense of something that infects by contact. Sin is a sense of betrayal, of rupture in a relationship. And guilt is the subjective side of sin, a consciousness that the breakdown of a relationship is the result of an evil use of freedom. According to Ricoeur, sexual morality has appeared historically paradigmatic of the experience of defilement. This association has not been left behind; there remains in the implicit consciousness of the West an inarticulable but persistent connection between sexuality and evil. The result is that ethical wisdom regarding sexuality has remained far behind other developments in Western ethics, even though there has been a significant demythologizing of sex.

Contemporary Ethical Reconstruction

The turn to history may have relativized much of traditional sexual ethics, but the motivation for the turn is more complicated. Given all the factors that have helped to weaken traditional sexual norms, ethical reflection has been left with very little anchorage. Science and medicine help, but they sometimes add to human suffering experienced in relation to sex. Philosophy and religion find their traditions struggling for relevance, for clarity, for reasonable guidance and more than reasoned inspiration. The turn to history has been an effort to find a truth that continues to be elusive.

And history, like other disciplinary efforts, has probably both helped and heightened the need for the quest.

Contemporary efforts in sexual ethics recognize multiple meanings for human sexuality—pleasure, reproduction, communication, love, conflict, social stability, and so on. Most of those who labor at sexual ethics recognize the need to guide sexual behavior in ways that preserve its potential for good and restrict its potential for evil. Safety, nonviolence, equality, autonomy, mutuality, and truthfulness are generally acknowledged as required for minimal human justice in sexual relationships. Many think that care, responsibility, commitment, love, and fidelity are also required, or at least included as goals. With social construction no longer ignored, the politics of sex has become an ethical matter for persons and societies, institutions and professions. New questions press regarding the ways in which humanity is to reproduce itself and the responsibilities it has for its offspring. In all of this, sexual ethics asks, How is it appropriate—helpful and not harmful, creative and not destructive—to live and to relate to one another as sexual beings?

SEXUAL ETHICS AND PROFESSIONAL STANDARDS

• • •

The Hippocratic oath gives early expression to a general prohibition against professionals taking advantage of the vulnerability of clients or patients and their families to enter into sexual relations: "Whatever house I may visit, I will come for the benefit of the sick, remaining free of all intentional injustice, of all mischief and in particular of sexual relations with both female and male persons, be they free or slaves" (Verhey, p. 72). The prohibition was reiterated for mental-health professionals by Sigmund Freud (Schoener et al.). From these roots grows a general prohibition against professional-client sexual relations, including relations between teacher and student, supervisor and supervised, clergy and parishioner, therapist and client, and physician and patient. In some professions, the taboo has been so strong that sexuality is the problem professionals "don't talk about" (Rassieur) or "the problem with no name" (Davidson).

Yet some famous therapists (e.g., Carl Jung) have been notorious for having sexual relations with their clients (Schoener et al.). Studies of various professions indicate a rate of sexual contact between professionals and clients or patients of between 5 and 11 percent (Schoener et al.; Bonavoglia). The phenomenon has become sufficiently widespread to be called a "national disgrace" (Pope and Bouhoutsos) and an "epidemic" (Rutter).

In the ten years following the publication of *Betrayal* (Freeman and Roy), which described one woman's successful lawsuit over sexual misconduct by a psychiatrist, over $7 million was paid out in legal claims. In the face of revelations of misconduct, professional societies began to insert clear prohibitions into their codes: "sexual intimacies with clients are unethical" (American Psychological Association); "the social worker should under no circumstances engage in sexual activities with clients" (National Association of Social Workers); "sexual relations between analyst and patient are antithetic to treatment and unacceptable under any circumstance" (American Psychoanalytic Association). Even in the controversial field of sex therapy, direct sexual contact between therapist and client is discouraged; sexual surrogates are used instead (Masters et al.).

Several jurisdictions have enacted laws making it a felony for a psychotherapist (including clergy) to have sexual contact with a client, and at least one holds the therapist's employer liable if the employer knew or should have known of a history of sexual abuse (Bonavoglia; for statutes, see Schoener et al.). Sexual contact is variously defined, but generally includes not only sexual intercourse but also intimate touching and other sexualizing of the relationship.

The prohibition against professional-client sexual contact rests on three foundations: the likelihood of great harm from the sexual contact, the responsibility of the professional to work for the good of the client, and the vulnerability of the client and the power gap between client and professional, which raises questions even in the absence of demonstrable harm.

There is growing consensus that significant harm is done to patients or clients who enter sexual relations with professionals in whom they have vested trust: "[T]he balance of the empirical findings is heavily weighted in the direction of serious harm resulting to almost all patients sexually involved with their therapists" (Pope and Bouhoutsos, p. 63). A few therapists have argued for the beneficial effects of sexual relations between therapist and client (Shepard; Schoener et al.), but their data have been challenged (Pope and Bouhoutsos; Schoener et al.). Studies of women who have had sexual relations with their gynecologists, psychotherapists, and clergy all point to deleterious consequences including loss of trust, poor self-concept, loss of confidence in one's judgment, and difficulty establishing subsequent relationships (Pope and Bouhoutsos). Several commentators have noted the similarities to incest because of the power of the professional and have argued that the consequences are as deleterious as those of incest (e.g., Fortune, 1989). Others note that women who enter relations with therapists often have a history of sexual abuse, and thus are being revictimized (Rutter; Pope and Bouhoutsos).

Sexual contact between professional and client thus subverts the legitimate goal of the profession—the healing or making whole of one who is wounded and vulnerable (Verhey). There is both exploitation of the client for benefit of the professional and a failure to provide the services implied by the professional role.

However, harm and failure to help are not the only ethical issues at stake. Several commentators argue that the power of the professional is morally relevant (Lebacqz; Lebacqz and Barton). Professionals may hold several types of

power: Asclepian power—the power of professional training; charismatic power—the power of personal magnetism and authority; social power—the power of the role and its authority (Brody). By contrast, the client lacks the power of the role and of its associated training. In addition, female clients facing male professionals generally lack the social power that men have in a sexist context (Lebacqz; Lebacqz and Barton). Clients are vulnerable.

The vulnerability of clients and the power of professionals mean that professionals can take advantage of clients. Sexual relations between professional and client are therefore an abuse of professional power—an illegitimate use of that power for the professional's own ends instead of for the ends of healing the client (Lebacqz and Barton; Schoener et al.; Rutter; Fortune, 1989).

Moreover, the vulnerability of patients or clients and the power gap between client and professional may compromise the freedom needed to give truly informed consent for sexual intimacies (Pope and Bouhoutsos; Lebacqz and Barton). The psychotherapeutic notion of transference (redirecting childhood feelings toward a new object) suggests a special vulnerability that may literally paralyze patients, making them unable to resist a therapist's advances (Freeman and Roy). Noting special vulnerabilities in the sexual arena, Karen Lebacqz and Ronald Barton (1991) propose that sexual intimacies differ from other acts to which patients, clients, and parishioners might continue to consent.

Some argue that vulnerability does not end when therapy ends and that there should be a prohibition on posttherapy sexual contact (Schoener et al.; Rutter). John C. Gonsiorek and Laura S. Brown proposed that sexual relations posttherapy should never be permitted where there was significant transference or where the client was severely disturbed, but might be permitted after two years with former clients who were not disturbed and showed little transference (Gonsiorek and Brown). Such a proposal raises difficult issues regarding who would make this judgment, but it reflects a clear principle that the base for determining whether sexual relations are permissible is the relative power and vulnerability of professional and client. Sexual contact might not be wrong where the power gap is minimized. Although few codes of professional ethics address the posttherapy issue, in 1993, the American Psychiatric Association explicitly addressed it: "Sexual activity with a current or former patient is unethical" (APA).

In a similar vein, Lebacqz and Barton (1991) argue that romantic or sexual relations might be acceptable under circumstances where the power of professional and client is relatively equal and the relationship is under public scrutiny—for example, when clergy date parishioners with whom they are not involved in a pastoral counseling relationship and members of the church are informed.

All commentators agree, however, that "sexualizing … therapy is a betrayal of a trusting relationship" (Pope and Bouhoutsos, p. 54) and that no sexual relationship should be permitted where there is a counseling or therapeutic relationship involved (Pope and Bouhoutsos; Fortune, 1989; Rutter). The professional-client relationship that involves psychotherapy or particular vulnerability on the part of the client is a "forbidden zone" for sexuality (Rutter).

Professional-client sexual contact must be addressed on institutional, not just personal, levels. Professional societies and supporting organizations such as churches are complicit when they fail to punish offenders, try to cover up the problem, blame the victim, and otherwise minimize the issue (Fortune, 1989; Bonavoglia). Underreporting is a significant issue: 65 percent of therapists in one study had seen clients who were sexually abused by a previous therapist; they judged that abuse harmful in 87 percent of cases but reported it in only 8 percent (Schoener et al.). Peter Rutter acknowledges the reluctance of men to blow the whistle on each other (Rutter). Gary Richard Schoener notes that the professional literature "documents more in the way of inaction than of active and creative study leading toward solutions" (Schoener et al.). Professional misconduct damages the profession and institutions as well as individuals (Fortune, 1989). Lack of internal regulation within the professions has led some U.S. state legislatures (e.g., Minnesota) to pass laws that hold institutions as well as individuals responsible for sexual misconduct of professionals (Lebacqz and Barton).

Underlying social and cultural patterns—sexism, the eroticization of domination, and the maldistribution of power in society—are causal factors (Lebacqz and Barton; Rutter). Since Phyllis Chesler's early feminist exposé of therapy in *Women and Madness* (1972), feminists have paid attention to the ways in which traditional therapy often reinforces passive and self-destructive behaviors for women, including behaviors that would make women likely victims of sexual abuse. Dynamics of sexual contact cannot be understood without recognizing sex-role patterning and power imbalances in the general culture (Schoener et al.; Lebacqz and Barton; Brown and Bohn,). Evidence indicates, for example, that male clients may not experience the sexualizing of relationships to be as harmful as female clients do (Pope and Bouhoutsos). Such gender differences may reflect social patterning of male and female sexuality, in which men gain and women lose power when entering a sexual relationship. There is also evidence that women

therapists do not engage in sexual contact with clients as frequently as male therapists do, and that they judge it more harmful (Schoener et al.).

The traditional prohibition against sexual contact between professionals and their clients continues to be reaffirmed in spite of arguments and practices to the contrary. An adequate ethical framework requires attention not only to professional responsibility, harm, and power imbalances but also to institutional structures and to cultural dynamics of sexuality and power.

SEXUAL IDENTITY

• • •

Because some terms are deeply embroiled in controversial debates, the task of defining them itself becomes controversial. So it is with the term *sexual identity.* Providing any definition immediately situates the definer within a particular perspective. One important perspective, which has served as the backdrop of much contemporary discussion, claims that the term refers to the distinct biological types of *male* and *female.* This "traditionalist" definition of sexual identity has sometimes been associated with one or more of the following additional positions: that certain specific and "complementary" psychological attributes and social roles, specifically those of *masculinity* and *femininity,* correspond to each of these distinct biological types; that a "natural" sexual attraction exists between these two biological types; that this attraction is most naturally satisfied through the act of intercourse; and that the act of intercourse, while naturally motivated by attraction, should also be motivated by other concerns, most importantly by love and by the desire to have children within the context of marriage.

These claims have been challenged over the last few decades by feminists, by those advocating various forms of sexual liberation, by gays and lesbians, and by scholars. All of these challenges raise questions about what is meant by *sexual identity.* Some of the positions developed in response to the traditionalist set of views have themselves been challenged. For the sake of clarity, one can group the challenges and counterchallenges around the following set of questions:

1. The sex question: Are there really two distinct biological types, *male* and *female*?
2. The gender question: How should one think about the relationship between biology and psychological attributes and forms of behavior?
3. The sexuality question: What constitutes sexual desire? What are the various ways in which it can be characterized?
4. The sexual ethics question: How ought one think about sexual practices? Which, if any, should be condoned, which prohibited, and why?

The Sex Question

Over the past few decades, many have rejected the claim that there exist two sexes without gradations. Some feminists have argued that, biologically, it is more useful to think of many of the physical characteristics associated with sexual difference as manifested across the human species in a range of degrees, rather than as being associated exclusively with either sex. They claim that only a social desire to emphasize difference has caused us to think of such variations in stark, bipolar ways. Thus, for example, though one often thinks of men as physically bigger than women, many individual women are taller, heavier, longer limbed, and so forth, than many men. Similarly, while one tends to think of women and men as possessing very distinctive hormones, in actuality the situation is more complex. For example, the hormones estrogen and androgen are often thought of as the "female" and "male" hormones, respectively, suggesting that women have one and men the other. In reality, both hormones are found in both women and men, and after menopause, women often exhibit a lower ratio of estrogen to androgen than do men of a comparable age (Spanier). These feminists argue that many of the striking differences we see are at least partially the consequence of social pressures exerted on women and men to manifest such differences. Thus women are encouraged to remove body hair and to buy shoes that make their feet look as small as possible.

Some cultural historians claim that the view of men and women as possessing sharply differentiated bodies has developed only within the last few centuries. Thomas Laqueur, for example, points out that prior to the eighteenth century, women's bodies were thought of as less developed versions of men's bodies. In this *one-sex* view, the vagina was not thought of as different from the male penis but, rather, as an inverted form of it. But during the eighteenth century there emerged a view of *the two-sex body,* that is, of female and male bodies being fundamentally different. With this new development, organs that had previously been referred to by the same name were given separate names. Thus, what had previously been *the testicles* now became differentiated into *the testicles* and *the ovaries.* Others that previously had no name were given names, for example, the vagina. Even parts of the body remote from reproductive functions, such as the skeleton and the nervous system, began to be depicted as distinctive for women and men.

Recent research in biology suggests that differentiating the male from the female is no simple task. Various indicators of maleness and femaleness are individually sometimes ambiguous. Even when all of the indicators are clear, they do not necessarily cohere. For example, within contemporary science the standard distinguishing criterion has been taken to be the presence or absence of the Y chromosome. Most people possess two sets of chromosomes, one from each parent; females are understood to be those with two X chromosomes and males those with one X chromosome and

one Y chromosome. However, there are problems with any neat application of this criterion. Some individuals inherit only one X chromosome but no Y chromosome. Or a piece of a Y chromosome may become attached to an X chromosome, producing an individual with an XXY pattern.

Even those individuals who possess a standard XX or XY pattern may exhibit characteristics that would incline many not to identify them by their chromosomal pattern. An XY individual may have testes that do not secrete the male hormone testosterone, or may have cells that are not sensitive to testosterone. That person will end up looking more like a female than a male (Lowenstein). There are also XY individuals who look female at birth and are raised as girls, but who develop masculine bodily features at adolescence. There are XX people whose adrenal glands secrete large amounts of male hormones. One consequence is clitoral enlargement, causing them to be taken for boys at birth. As adults they may also possess increased muscle mass and hairiness (Lowenstein). In short, recent scientific research has supported the point that even the biological distinction between male and female is not always clear-cut.

The Gender Question

Until the emergence of the second wave of feminism in the 1960s, the term *gender* was used primarily to indicate differences between female and male forms within language. Differences between women and men were commonly indicated by the term *sex,* as in the phrase "the battle of the sexes." Feminists, however, began to use the term *gender* to refer to what they argued were socially constructed differences between women and men. It was felt that the term *sex,* when applied to differences between women and men, suggested that such differences were biological in origin. A new term was needed to refer to differences that were a product of society.

Studies done within the social sciences pointed to the great differences among societies in expectations of what was appropriate behavior for men and women. For example, the anthropologist Michelle Zimbalist Rosaldo noted that there are some societies where women trade or garden, and others where men do; some where men are prudish or flirtatious, and others where women are (Rosaldo, Lamphere, and Bamberger). Psychologists and other social scientists stressed the importance of socialization in structuring an individual's sense of self. Thus, John Money and Anke Ehrhardt (1972) asserted that when children were assigned a gender at birth that did not match their chromosomal sex, it was most likely that their adult sense of self would conform to their assigned gender rather than to their chromosomal sex.

The term *gender* has been very useful in encouraging a greater recognition of the social construction of differences between women and men. Increasingly, however, scholars have been raising questions about how gender should be understood, and particularly how its relationship to sex should be interpreted. Using the term *sex* to describe biological differences, and *gender* to describe socially constructed ones—what R. W. Connell calls the "two realms model"—ignores the fact that biological distinctions are themselves social constructions, at least in part. That modern biology, for example, interprets the penis as an organ distinct from the vagina is a social construction, more a consequence of changing cultural metaphors than of new scientific evidence (Laqueur). The notion of a "pre-social sexed body" (Heyes) which is identifiable in purely biological terms, then, has lost much of its appeal. As a result, the distinction between gender and sex based on the categories of the social and the biological respectively has also lost its force and theorists are struggling with what Connell calls "an additive conception of sex and gender." As she explains, "our new model begins with the observation that human bodies are active players in social lives. They are neither biological machines producing social effects mechanically, nor blank pages on which cultural messages are written" (Connell, p. 463).

Another problem with emphasizing the difference between sex and gender is that the relationship between psychological traits and biological phenomena is still often understood to be that the former follows from the latter. While *gender* emphasizes that many psychological traits are social constructions, it does not necessarily undermine the view that such traits follow from biological differences. All it adds is that the path from biology to psychology proceeds by way of social construction.

Any model that claims that psychology follows from biology has problems accounting for those individuals whose socialization deviates from the norm. In other words, to the extent that gender is still viewed as tied to sex, there remains the problem of explaining the phenomena of girls who grow up exhibiting "masculine" psychological traits and boys who grow up with a "feminine" sense of self. The most striking examples of such cases are transsexuals, people who experience a dramatic misalignment between their physical features and their internalized sense of self. Such people frequently desire physical restructuring of their bodies to bring the physical and the psychic into alignment.

The term *gender* may still suggest, as did the term *sex,* that people's psychic lives and behavior are necessarily unified, that it is appropriate to talk about a male or a female identity. One suggestion has been that we talk about *gender* be used not to describe individual identity, but to describe acts or performances all humans play out (Butler). Such a

model allows one to move the focus of *gender* from the individual to the activity. This type of shift is consistent with an overall tendency on the part of many contemporary scholars to think of gender as a type of social coding that is applied not only to behavior but also to psychic stances and to bodies. A further aspect of this notion of social coding is suggested by Jan Clausen, who describes her experience when she changed from a committed lesbian to a woman involved in a long-term exclusive relationship with a man. Clausen claims that "the notion of sexual identity … implies some expectation about the future" (pp. 97–98); the inclusive approach—that which covers behavior, psychology and the materiality of the body—thus extends over time as well.

The Sexuality Question

At least since the 1890s in industrialized Western countries, one paradigm of sexuality has been dominant: that which describes genital-to-genital intercourse between one male and one female as "normal," and as "abnormal" or "perverse," sexual practices that fall outside that paradigm. "Perverse" practices in this paradigm include but are not limited to the following: voyeurism; exhibitionism; incest (sex between close relatives); oral sex; anal sex; sex with children (pedophilia); sex involving more than two persons; sex between humans and animals (zoophilia); sex with oneself (masturbation); sex involving the use of visual images (pornography); sex with a corpse (necrophilia); sex involving heightening sexual pleasure by dressing in garments associated with the opposite sex (transvestism); sex associated with the giving or experiencing of pain or humiliation (sadomasochism); sex strongly associated with a particular object or part of the body (fetishism); and sex between members of the same sex (homosexuality).

Homosexuality has, in particular, been the subject of much attention and debate. The stigmatizing label *homosexual* has been used to negatively characterize certain individuals since the late nineteenth century (Weeks, 1989); laws have been enacted against homosexuality and people have been jailed for practicing it (e.g., the English playwright Oscar Wilde). During the twentieth century, medical doctors and other scientific specialists have depicted it as a pathology and, as with other pathologies (but not accepted practices), have searched for causes (Bayer).

Much debate has centered on the question of whether homosexuality is a product of genetic inheritance or some other biological trait, or is a consequence of socialization. During the 1960s and 1970s, homosexual men (who increasingly adopted the label *gay*) and homosexual women (lesbians) began to form political organizations to resist the laws, practices, and beliefs that stigmatized them. They argued that homosexuality was not a perversion or a pathology to be outlawed or cured, but a difference in preference or *orientation* that should be tolerated within a free and open society. Since the 1960s, the American psychiatric community has moved away from a description of homosexuality as pathology. In December 1973, the board of trustees of the American Psychiatric Association moved to delete the category *homosexuality* as necessarily a pathology from the second edition of the *Diagnostic and Statistical Manual of Psychiatric Disorders,* retaining the term *ego dystonic homosexuality* to cover those not comfortable with their sexual orientation. In yet another revision, any specific reference to homosexuality was removed altogether, but the term *sexual orientation distress* was retained to permit treatment of those disturbed about their sexuality (Bayer).

More recently, there has been a good deal of interest in studying the possible biological origins or causes of homosexuality. There are two major explanatory pictures, both of which have been variously received with skepticism and approval. The first is the anatomical approach, which claims that one can (or should be able to) find structural differences between heterosexuals and homosexuals. Simon LeVay, for instance, published a study in 1991 showing that the interstitial nuclei of the anterior hypothalamus (INAH) of homosexual men was on average significantly smaller than those of heterosexual men (Murphy). Other candidates for anatomical explanations include the anterior commissure and the suprachiasmatic nucleus (Hamer, 1993). None of these studies have been met with unmixed approval. Some criticisms of the anatomical approach include the claim that sexual orientation is far too complex a phenomenon to be mapped to a single (and seemingly simple) physical cause, concern over the size of the sample pools, and even the attempt to "explain" homosexuality at all (Murphy).

The other possible explanatory story is that of the so-called gay gene. In 1993, Dean Hamer and a team of scientists concluded a study of the genetic make-up of gay men and their family members (most importantly brothers who were also gay) and announced that "our data indicate a statistically significant correlation between the inheritance of genetic markers on chromosomal region Xq28 and sexual orientation in a group of homosexual males" (Hamer, Hu, Magnuson, et al., p. 321). This study has also been criticized: for instance, the demographic homogeneity (and size) of the subject pool has led some to question whether the correlation is really genetic or merely environmental (Kaplan). This concern is made even more problematic by the fact that a precise causal connection between the possession of specific genetic markers and homosexual orientation is still lacking (Murphy). Most disturbing about any attempt to establish a biological link to homosexuality, according to

some theorists, is the very fact that alternative sexual orientations are *in need of* explanation. In other words, the research itself may imply that there is something abnormal, or indeed perverse, about such orientations and thus, something that needs "curing" (Kaplan).

Other questions have been added to the debate, among them whether homosexuality describes a particular kind of person or, more appropriately, a specific type of activity. Social historians have pointed out that the category "the homosexual" was constructed in the latter part of the nineteenth century to depict a specific type of person, followed shortly by the construction of "the heterosexual" (Katz; Halperin). Prior to the creation of "the homosexual," people who engaged in acts one would label as homosexual were not necessarily seen to require a special label. This is at least partially a consequence of the fact that the sex of one's partner has not always been viewed as an overriding feature of the sex act. For example, within many Native American societies, certain men, "the berdache," took on many of the tasks and characteristics associated with women. These men would have sex with other men. However, what was seen as distinguishing the sexual practices of the berdache was not that they had sex with other men but that they took the passive role in sex. Their male partners were not distinguished from men who had sex only with women (Williams). The same distinction between active and passive (or dominant and submissive) is believed by many to be the primary form of categorization of sexuality in ancient Greece (Stein; Kaplan). For such reasons, Eve Sedgwick has observed that, given the many dimensions along which genital activity can be described, it is quite amazing that the sex of object choice has emerged as central during the twentieth century, and has come to define what is meant by "sexual orientation" (Sedgwick).

The Sexual Ethics Question

Just as matters of individual sexual identity have been oversimplified into a single male-female dichotomy, the many varieties of sexual behavior have often been reduced to a simple distinction between normality and perversion.

The condemnation of homosexuality and other deviant sexual activities and "perversions" leads to a discussion of sexual ethics and to the question of alternative sexual paradigms. A paradigm is an exemplary instance that serves as a standard. A sexual paradigm is an example of sexual activity that is taken as a standard for "normal" sexual behavior. The most obvious sexual paradigm is heterosexual genital-to-genital intercourse, but in order to employ this paradigm as a norm, one needs to specify not only the overt activity but the aims and desires of the participants. Is the purpose of sexual intercourse, for example, to produce children? Or to produce pleasure? Or to express love? Or to mark a "conquest"? One can further distinguish between minimalist and murky paradigms of sexuality: minimalist accounts tend to define sexuality as a simple, straightforward desire, while murky accounts dig deeper in order to find hidden or unconscious desires. Thomas Nagel, for example, introduces the minimalist notion of "unadorned sexual intercourse," although he adds that such behavior, "unadorned," may well be perverse, and that a typical sexual encounter involves a complex of communicative gestures. Janice Moulton defines sexuality simply as the desire for physical contact, although she then provides a rich discussion of its many associated meanings. Alan Goldman isolates what he calls "plain sex," which he defines as "a desire for contact with another's body," and rejects accounts that try to define sexuality in terms of any further goal or purpose.

On the murky side, there is the lasting legacy of Plato's *Symposium* and its various discussions of eros. In particular, there is Aristophanes' famous tale about the divine fission of individual human beings out of complete wholes, according to which sexual desire is nothing less than the impossible desire to join together with "one's other half" and become "complete once again," and Socrates' much more effete conception of eros as the love of Beauty as such. Two thousand years of Christian theology have attempted both to chastise and to spiritualize sexuality, and the Tantric traditions of India and Tibet have refined sexuality into a spiritual road to enlightenment. In the twentieth century, Sigmund Freud and Carl Jung profoundly deepened conceptions of sexuality, which is, in their accounts, no mere desire but a focus for the darkest and most explosive secrets of the psyche.

THE REPRODUCTIVE PARADIGM. Biologically, sexuality can be defined in terms of a very specific genetic process, although even that has its ambiguities and confusions. This biological definition and its implied reproductive paradigm play an enormous role in contemporary conceptions of sexuality. Whatever embellishments, variations, and alternatives humans and some other vertebrates have evolved or invented, heterosexual intercourse remains something of an "original text" in our sexual hermeneutics. It can be rejected, refuted, even reviled, but it must, first of all, be taken account of.

One might distinguish here, in line with a three-thousand-year-old moral tradition, between an individual's purpose and what one might call *nature's purpose.* Until the end of the nineteenth century, when teleology or the purposiveness of nature was taken seriously, this phrase could be interpreted literally. In the twenty-first century, in

the wake of increasingly antiteleological conceptions of evolution, the phrase *nature's purpose* must be taken as, at best, shorthand for a complex set of causal processes that are themselves the result of chance and natural selection. Even so, one might distinguish between the various drives and desires favored by natural selection because they increase the likelihood of a more adaptive genotype (what Richard Dawkins calls "the selfish gene"), and the more or less conscious and sometimes articulate desires of an adult human being. But humans are not, like most creatures, mere sexual pawns of cunning nature. Some teenagers may not know of the various consequences and the significance of sexual activity, but for most adults this knowledge is profound, if not extensive, and sexuality may never be free of those associations. But whether or not this is the hidden purpose of *all* sexual desire and activity, it is clearly the conscious and conscientious choice of *some* sexual activity. Building a family is not, for most people, the only purpose of sexual activity; but by having sexual intercourse, it is possible to have children. Whatever creative alternatives may be dreamed up by medicine, one undeniable aspect of sexuality is, and will be, its traditional role in procreation.

The view that sexuality and sexual desire are really aimed at reproduction, even if the sexual participants desire only to perform a particular activity without thinking of the consequences, tends to lead from the minimalist view of sexuality to various murky views. The self-evident desires are no longer taken at face value, and a deeper biological (or theological) narrative, which may not be self-evident to the participants, comes into play. Thus the psychological consequences of thousands or millions of years of evolution manifest themselves in desires that may seem straightforward. Or, behind seemingly simple sexual desire lurks the secret of God's creation and the biblical injunction to be fruitful and multiply. But what links all the murky views is that sexuality does have a purpose or purposes, however they are to be explained, and these purposes are typically not self-evident. According to the minimalist views, sex is best understood as "plain" or "unembellished"; the murky views, on the other hand, insist that sex so understood is not understood at all.

The target of many, if not most, of the minimalist accounts is the restricted reproduction of the procreative paradigm of sexual activity. For two thousand years, the harsher side of Biblical commentary and the Christian theological tradition has insisted that sex is primarily, if not solely, procreative. In this view, the pleasures and desires associated with sexual activity not only are inessential but also are to be minimized. Emphasizing pleasure to the exclusion of the possibility of reproduction—for example, using contraception or engaging in activity that cannot result in impregnation—is forbidden. Essential to sexuality, in the reproductive paradigm, are male ejaculation, female receptivity, fertility, and conception.

THE PLEASURE PARADIGM. In opposition to the reproductive model, with all of its strict prohibitions and limitations, and its suggestions of deep biological drives and purposes, the attractiveness of what one can call the pleasure paradigm is unmistakable. The availability of improved birth control methods since the 1960s has contributed greatly to its appeal. Sex is for pleasure, and what is desired is pleasure. There is nothing murky about this. Indeed, to many people the pleasure paradigm is self-evident. Accordingly, the restrictions on sexuality that limit and direct it toward heterosexual intercourse drop away, and in effect, anything that feels good is acceptable. Of course, one might well object that pleasure is not in itself sexual, and so one might want to circumscribe pleasures that are sexual from those that are not. But, for the defender of the pleasure paradigm, this requirement comes later. First comes the liberation from the restrictions of the reproductive model. Homosexuality, autosexuality, even bestiality seem to be normal on the pleasure paradigm. Heterosexual intercourse is but one of many activities serving the paradigm, and however many couples may continue to prefer it, it does not have any special claim to normality. According to this paradigm, good sex is that which provides maximum mutual pleasure; bad or mediocre sex is that which fails to satisfy either or both partners.

Once the reproduction model has been rejected, there are no longer the restrictions on either the objects or the obvious aims of sexual activity, but neither is it the case that "anything goes." Homosexuality is no longer a perversion of sex, but rape certainly will be. Almost any sexual activity between consenting adults is acceptable, but forcing sex on a person is not. Sexual activities that will not result in conception are no longer secondary, and sex that is conscientiously prevented from resulting in undesired conception becomes the norm. Masturbation becomes part of the paradigm of acceptable sexuality, even though its lacks the dimension of shared sexual enjoyment. The appeal of the paradigm and the cornerstone of most contemporary sexual ethics is the idea that sex ought to be pleasurable and, within moral but not particularly sexual bounds, unrestricted.

We might call the pleasure paradigm the *Freudian* model of sexuality, in order to pay homage to the person most responsible for its contemporary dominance. Sigmund Freud, in his *Three Contributions to the Theory of Sex,* argued that sexuality should be conceived as enjoyable for its own sake, not as a means to further ends, whether natural or

divine. But the centrality of Freud here also suggests that the pleasure paradigm may not be so simple and self-evident as originally suggested: Freud is one of the great contemporary architects of "deep," if not labyrinthine, accounts of the psyche and of sexuality in particular. And so, for him and for us, pleasure and satisfaction are not to be construed so straightforwardly. Pleasure, as Aristotle noted more than two millennia ago, is not just a sensation. It is the "bloom" on successful activity. It accompanies but does not constitute satisfaction. But the difficult question is, Satisfaction of what? And here Freud's theory moves from an apparently minimalist physiological model to an extremely murky deep psychology.

In Freud's early theories, the pleasure paradigm rested on a male-dominated biological foundation, a *discharge* model in which sexual pleasure has its origins in the release of tension (catharsis). But the tensions released in sexual behavior are not merely physiological; they also arise from complexes of ego needs and identifications with various sexual "objects," usually (but not always) other people. Thus Freud distinguished between mere physical gratification and *physical satisfaction.*

The pleasure paradigm, for all of its seeming simplicity, invites murky interpretations. What is it that is enjoyed? What is it that is satisfied? A sensation is not pleasant in itself but in terms of its context, as a love bite on the shoulder by one's lover or a nasty passerby, respectively, makes evident. Indeed, even orgasm is not pleasant in itself, however often that might be fallaciously supposed; an orgasm in an inappropriate context is typically an extremely unpleasant experience. And so the pleasure Freud postulates is no simple release of tension but the satisfaction, often symbolic and indirect, of some of the murkiest of hidden and forbidden desires.

THE METAPHYSICAL PARADIGM. Some of these desires and motives are so profound that they deserve to be called *metaphysical.* Freud's discussion of the Oedipus complex sometimes takes on these ontological overtones, and Jung's various archetype theories surely do. But perhaps the most basic of all metaphysical paradigms of sexuality goes back (at least) to the fable told by Aristophanes in Plato's *Symposium,* and the idea that the gods split what we now call human beings out of complete wholes, with sexual desire being the desire to reunify the divided halves. One need not literally accept the more consciously absurd aspects of the story to appreciate the deep insight captured in the idea of "two out of one" or "merged selves" that Plato's Aristophanes suggested.

Sexual activity is an expression of a profound desire that has very little to do with merely physiological need or satisfaction, and the metaphysical paradigm is, accordingly, very much a part of the contemporary conceptions of romantic love and the idea that two people were "made for each other."

Indeed, despite the prevalence of the pleasure model in much of the current literature, there can be little doubt that much more is usually demanded of sexuality than mere pleasure, even mutual pleasure. People demand *meaningful* relationships. The metaphysical model provides this sense of *meaning.* Pleasure, according to the metaphysical model, is no longer the purpose of sex, although it will surely appear as its accompaniment. But sex without love, no matter how enjoyable, is to be rejected on this paradigm. Even if it is not "perverse" or "immoral," "plain sex" will be meaningless, and the meaning of a relationship is primary in the metaphysical model.

THE COMMUNICATION PARADIGM. Sex is often "meaningful" without love, however, although sometimes those "meanings" are demeaning, as in a sadomasochistic relationship. What is one to say of the many varieties of sexual activity that are aimed neither at reproduction, nor at pure pleasure, nor at expressions of romantic love and togetherness? What of those relationships that seem to thrive on domination and pain? What does it say about current paradigms of love that sadomasochistic relationships are now celebrated and preferred by some of our more avant-garde social visionaries? And what of those many tender encounters that, nonetheless, make no pretenses of love?

To explain such aspects of sexuality, a fourth paradigm is in order: sex as communication, as a physical form of expression of one's emotions and attitudes toward other people. It is a language, for the most part a body language, whose vocabulary consists of touches, gestures, and physical positions. It may be an expression of domination and submission; it may be an expression of respect, fear, tenderness, anger, admiration, worship, concern, or (of course) love. In the 1940s Jean-Paul Sartre defended a truncated version of this model in his classic *Being and Nothingness.* He interpreted all sexuality as the expression of conflict, a war for domination and freedom. But what is communicated in sex is rarely this alone, nor is sex plausibly always an expression of conflict. Nevertheless, Sartre forces us to see something that the defenders of the pleasure and metaphysical paradigms of sex prefer not to see: that sexual relationships, even normal, fully consensual sexual relationships, are not always innocent or loving. Sex is a medium for all sorts of emotions, some of them manipulative and even malicious.

The communication paradigm shifts the emphasis in sexuality from the more physical and sensual aspects of

reproduction and pleasure to interpersonal roles and attitudes, and from expressions of love alone to expressions of all emotions and attitudes. Thus Sartre's model is clearly a communication model, but it is, like Sartre's view of emotions in general, too narrow, emphasizing only the more conflict-ridden and competitive interpersonal attitudes—one of which, he thinks, is love. In this view, certain sexual activities are visibly more expressive of domination and submission, or equality and respect, or resentment and fear, or shyness and timidity. According to the communication model, these nonverbal expressions are essential to sexuality, its very purpose and content. This does not mean, however, that other sexual aspects need be excluded. The intention to impregnate a woman, for example, may be an expression of male domination and conquest, as described in several of Norman Mailer's novels. Pleasure is an important aspect of the communication model, but pleasure for its own sake is not: pleasure—both the giving and the receiving of it, as well as the sharing of it—is vital to the communication of many emotions. But pain may be important as well, and inflicting small amounts of pain, as well as enduring moderate discomfort, is familiar as a means of expression in sex. What distinguishes the communication paradigm from the three more traditional ones is its emphasis on expression of interpersonal emotions and attitudes. These expressions are recognized by the other paradigms, but not as essential and primary.

IMPLICATIONS OF THE VARIOUS SEXUAL PARADIGMS. It is evident that the answers to such questions as "What is normal sex?" and "What is perverse?" are immensely complicated. On a strict reproduction paradigm of sexuality, normal sex is whatever minimal genital activity is necessary to promote conception. All else is either irrelevant or immoral. In fact, of course, the reproduction paradigm is usually defended within the moral institution of marriage, and rarely defended without some reference to both love and mutual pleasure. On the pleasure paradigm, by contrast, whatever gives pleasure (to consenting adults) is normal and acceptable. Perversions of this paradigm provide pain instead of pleasure, ignore the pleasure of the other person, or produce pleasure in a manner that is, in the longer run, harmful. On the metaphysical paradigm, normality is sex as an expression of mutual meaningfulness, such as mutual love. On the communication paradigm, what is normal becomes extremely complex, for one must view the emotions being expressed and the entire psyches of the people involved to make any intelligent judgment.

Human sexuality seems particularly appropriate for expressing the tender feelings of love and affection, but there are circumstances under which this is absolutely inappropriate (for example, with children); and all too often sexual activity that claims the expression of love as its aim may actually be an avoidance of intimacy. Indeed, the common context of sexual activity— two people alone, attending only to one another—is particularly conducive to intimate communication. But if we take two-party sex as our paradigm, then multiple-party sex, insofar as it confuses the communication becomes perversion. Moreover, masturbation, while not exactly perverse, would surely be less than wholly sexual, just as talking to oneself is less than a whole conversation. And perhaps, any form of deceit would be perverse, just as lying is a "perversion" of verbal communication.

Conclusion: The Problem of Normality

So long as biological specification and sexual intercourse alone define sexuality, *normality,* as opposed to *perversion,* seems to be easily defined. Males are equipped with certain obvious features, and females are differently equipped with equally obvious sexual features; *normal* sex is intercourse between male and female. But as more is learned about the complexities of chromosome configuration and the biology of sex, the distinction between male and female becomes increasingly difficult. And as soon as one adds the essential concerns of psychology and the many worlds of cultural norms, practices, and paradigms to the unfolding medical complications, the traditional view of *normality* becomes a Pandora's box of problems.

This confusion extends to the task of defining a *normal* model of sexuality. Of the various cases and models considered in this article, not a single one would be accepted as *normal* in every society and by everyone. Moreover, a pure instance of an ideal type or paradigm is probably nowhere to be found; not even the most pious proponent of a religiously oriented reproductive view would deny the desirability of love, pleasure, and emotional expression in sex, nor would the most enthusiastic hedonist deny the desirability of reproduction on at least some occasions, and perhaps of love and communication as well. And when these four paradigms of sexuality are integrated with the matrix of possibilities that are to be found in the various combinations of gender identity and sexual orientation (and, in the most extreme cases, transsexual biological operations), the result is an enormous number of sexual lifestyles, desires, and activities, every one of which would be insisted upon as *normal,* at least according to some people.

How does one decide what is normal and what is not? In one sense, *normal* simply means *statistically predominant,* and there are still many people who would insist that this is a

proper definition. But it is clear that, in ethical contexts, *normal* also means *morally correct.* But in an area where most behavior is private, and involves only consenting adults and a great many individual differences, the relevance of statistics is easily challenged. Furthermore, what is statistically predominant in one portion of a population may be relatively rare and considered *perverted* in another. If sexual normality includes subjective preferences and psychological as well as biological considerations, then any definition of sexual normality will give priority to certain preferences and paradigms over others. But which ones? The traditional religious standards? The more modern "anything goes between consenting adults" attitude? The current "local standards" criterion of the courts, which assumes that it can be made clear how large or small a domain—a home, a town, or a state—is "local"?

The problem of normality thus becomes a dilemma. It begins with a built-in ambiguity between the statistically dominant and what ethically ought to be. The first is ascertained easily enough, assuming either truthful informants or extremely intrusive investigators; but the second, the quest for a sexual ethics, arises from within diverse psychological, cultural, and personal settings that presuppose many of the norms and attitudes that are to be investigated.

The result of these complexities should not be the abandonment of a search for ethical norms or the rejection of the concepts of normality and perversion. What emerges instead is an extremely complex matrix of considerations to be taken into account, in which tolerance is a wise approach and mutual understanding is the desirable outcome. In other words, what is needed in the examination of sexual identity is not just a good deal of medicine, biology, social psychology, and anthropology. It is also a good deal of appreciation for diversity and complexity. It is with this appreciation for diversity and complexity that the contemporary quest can proceed.

SEXUALITY, LEGAL APPROACHES TO

• • •

This entry discusses law's relationship to sexuality from an American perspective, although the framework suggested here may lend itself to application in other cultural contexts.

Sexual Status and Sexual Conduct

From the point of view of American law, sexuality has two dimensions: status and conduct. Sexuality as status, in law as in the culture at large, contains two primary alternatives—heterosexuality and homosexuality—although recent efforts on the part of those claiming bisexual status to make political alliance with gay and lesbian activists may presage increased legal recognition of this third alternative. Sexuality as conduct also has two principle aspects. The first encompasses explicitly sexual acts, of which intercourse is perhaps the paradigmatic example. Law prohibits intercourse, and sometimes other sexual activity, in a wide variety of situations, either when one of the parties has not consented or is unable to consent, or when the intercourse or other activity, although consensual, offends norms of public decency. Child sexual abuse, sexual assault and rape, statutory rape (intercourse with a woman, or in a few states with an individual, who is considered too young to provide meaningful assent), and incest are uniformly prohibited. Prostitution—the buying and selling of sex—is authorized only in Nevada. Sodomy, both homosexual and heterosexual, is unlawful in a large minority of states. Sex before marriage and outside of marriage is still prohibited in some states, although enforcement of these prohibitions is virtually nonexistent because of the disconnect between the law and prevailing cultural attitudes.

Law also regulates sexual intercourse by controlling or limiting postcoital choices. State limits on access to abortion, a hotly contested issue ultimately adjudicated by the U.S. Supreme Court in *Planned Parenthood of Southeastern Pennsylvania v. Casey* (1992), illustrates one such regulatory measure. Similarly, adult use of contraception remains constitutionally protected, while access to particular contraceptive techniques is regulated on health grounds. President Bill Clinton's reversal in 1993 of the first Bush administration's opposition to the introduction of RU-486, a "morning-after pill" and early abortifacient, provides a dramatic example of the interplay between public policies and medicine. Meanwhile, contraceptive freedom has not been extended to minors, and contraception remains regulated in the nation's high schools (Miller, Turner, and Moses).

In other contexts, law precludes procreation as a consequence of intercourse. The eugenics movement in the United States in the 1920s and 1930s produced laws compelling the sterilization of certain classes of criminals and those with mental disabilities or illness. Although no longer enforced, these laws remain on the books in several states and never have been held unconstitutional. Today, most if not all states provide a mechanism by which those legally responsible for sexually active people determined to be mentally incompetent can petition the state to authorize sterilization or contraception.

The second aspect of sexuality as conduct encompasses sexual displays the law views as expressing or arousing sexual receptivity or interest and thereby offending norms of public decency or order. The sexual displays regulated by law vary in character; they include solicitation, public nudity, and provocative dressing, as well as all forms of pornography. In this arena, too, enforcement is by no means uniform, and constitutional freedoms of speech and expression have created uncertainty with regard to the legitimacy of regulation.

Law's Multiple Relationships to Legal Status and Conduct

Law's relationship to sexuality in part constitutes law's account of what is permissible in the sexual arena—which behaviors are to be encouraged and which are to be discouraged. Legislative statutes help establish guidelines for behavior, while judges determine the constitutionality of the statutory law. This relationship between law and sexuality is importantly shaped, however, by the fact that law's authority is actually invoked in sexual matters by public agencies or private parties in only a small fraction of the possible cases.

The gap between the laws as written and as enforced has a variety of origins. For example, sometimes those who might initiate action against a violator do not know that the law offers them protection. Sometimes the enforcement of legal norms governing private sexual behavior is simply impractical; for example, sodomy, unlike public nudity, seldom comes to the attention of law enforcement personnel. Often, police and prosecutors make conscious decisions not to investigate or prosecute certain offenses for a variety of reasons, including the difficulty or the costliness of prosecution, the behavior of the victim, and the nature of the statute that has been broken (e.g., laws against adultery and premarital sexual contact). Or it may be because enforcing

officers are dubious of the regulation or its particular application. Many rape prosecutions, especially those involving parties who are not strangers, founder for one or more of these reasons. Those who have argued that specific victims of pornography should be allowed to bring civil actions against pornographers and distributors of pornography base their argument, in part, on the reluctance of public authorities to take appropriate action (MacKinnon, 1987).

Those who urge giving private parties greater responsibility for or authority to initiate legal action must also realize that individuals are often unwilling or unable to invoke the law even when they understand that a law has been violated. For example, the trauma of childhood sexual abuse often results in the repression of memory (Ernsdorff and Loftus, 1993). If the memory ever surfaces, it may be long after the statute of limitations has passed. Potential claimants may be fearful of retribution on the part of the one they accuse; this is often true for sexual-harassment claimants and battered women who charge their abusers with physical and sexual violence. They may be anxious about the financial and emotional costs involved in testifying. They may fear having their credibility challenged or their character impugned and may see participation in the legal system as just another opportunity to be victimized. Finally, claimants in some circumstances may be able to resolve the situation without using the formal legal system.

If the law's relationship to sexuality is influenced by the limited nature of actual legal interventions in sexual matters, it is equally influenced by limited public understanding of the legal norms governing sexuality. How social actors perceive law's application to their own or others' sexual status or conduct may derive from actual individual or institutional knowledge of the law or of enforcement practices; but it may equally derive from impressions gleaned from a limited number of personal experiences or from stories emphasized by the media. Generalizations, often derived from limited information, then guide an individual's interaction with the legal system around sexual matters—setting standards for personal conduct, governing expectations about how the system will respond to legal violations, and providing the initiative for involvement in political efforts to change the law or replace its agents.

Given this multilayered relationship between law and sexuality, it is important to appreciate what law does and does not do, as well as how laws are implemented, what they say, and what people understand the law to be.

The Tools of Regulation

In regulating sexuality, the legal system draws on a variety of cultural authorities and principles. The two principal sources of authority guiding legal regulation of sexuality have been morality and medical science. Morals derive from either secular ethical precepts or religion, both of which are complicated by America's religious diversity and the political struggles over the separation of church and state. But when moral and religious precepts are broadly accepted and secularized within society, they become a legitimate basis for legal intervention. The law justifies its intervention by appealing to the secularized form of the moral mandate: to public decency or public order; to the value of life or the state's practical interest in heterosexual unions; to the "degeneracy" of certain sexual practices. When social consensus around a moral issue begins to erode, the link between particular moral notions and their specific religious underpinnings becomes exposed again, and law's endorsement of one side of the debate can be challenged as an improper conflation of church and state. This challenge to the moral basis of law has been most dramatic in the debates regarding abortion and homosexual marriage.

The issues involved in law's reliance on medical science have a different quality, because the concerns here are perceived to be those of knowledge rather than faith. In areas involving sexuality, medical science has provided the law with an understanding of what is necessary to protect public health and welfare and with guidelines concerning sexual status and conduct. In addressing the fundamental issue of sexual identity, medical science has drawn and redrawn the lines between aspects of sexuality that depend upon genetic programming, aspects that are the product of physical or mental disease or malfunction, and aspects that are the product of willed or chosen conduct. Changes in the medical understanding of homosexuality, for example, have in turn been central to legal debates about regulating homosexual relationships and activity. In the abortion arena, the law has looked to medicine for a scientific ruling about the beginning of human life.

The problems inherent in the relationship between law and medical science have two interrelated sources. First, medical science does not stand still, and the law often lags behind the newest research. Compulsory sterilization laws provide a dramatic example. The genetic "science" on which these laws were based has been discredited, and yet not all such laws have been repealed. Second, medical science is not as value-free as the deferential legal community often assumes; many shifts in the medical understanding of sexuality reflect shifts in values more than they do real advances in knowledge.

What of the legal principles governing the regulation of sexuality? Several of those legitimizing interventions have already been spelled out: maintaining public order, decency, health, and welfare. These laws fall within the traditional

police power of the state. Another traditional basis for governmental intervention has been to encourage forms of association and sexuality that promote the state's conception of its interests. Matrimony and childbearing and child rearing within matrimonial relationships are the clearest historical examples. Nevertheless, the concepts of public order, decency, health, and welfare, and indeed of the state's interests, are malleable enough to serve the modern vision of social and family life.

The legal principles limiting regulation of sexuality have traditionally been those of privacy and autonomy, especially those forms of autonomy protected by the First Amendment. Both of these principles reflect a constitutional order that sees government as a threat to liberty; both are prepared to accord some cultural space to sexual activity and expression that deviate from widely held cultural norms to guard against the erosion of liberty.

In the shift from the nineteenth-century Victorian vision to the modern vision, the principles of privacy and autonomy have been pressed into service in new contexts while their hold over other arenas has been challenged. The privacy accorded family life was an important bulwark to the patriarchal authority of the male head of household, but it no longer serves to shield family members from charges of sexual abuse. Instead, privacy now provides the foundation for the constitutional protection given to both abortion and contraception, and efforts are being made to have sodomy statutes ruled unconstitutional on similar grounds.

Since the 1970s, the champions of the modern vision of social and family life have invoked the legal principle of equality. Equality has provided a basis for the abolition of old intrafamilial immunities and has supported the exposure of family abuses. Equality has translated the private pain of sexual harassment in the workplace into a public claim of discrimination when the job itself or other workplace privileges are conditioned on consent to sexual activity, or when the harassment creates a hostile working environment (MacKinnon, 1979; *Burlington Industries, Inc. v. Ellerth,* 1998; *Oncale v. Sundowner Offshore Services, Inc.,* 1998).

Equality has also offered a new analysis of pornography. Whereas previous regulation of pornography depended on the "obscenity" that made it offensive to norms of public decency, the new analysis emphasizes the role pornography plays in endorsing and promoting the sexual objectification of women that denies women equal status in society (MacKinnon, 1987, 1993). This characterization more properly represents what is at stake in regulating pornography. By the mid-1990s, however, none of the municipal ordinances based on it had survived constitutional scrutiny. The violation of women's right to be free of discrimination must still be weighed against the First Amendment freedoms of pornographers, distributors, and users; in this balance, pornography opponents have not prevailed. Importantly, women themselves are divided on this issue; many see the proliferation of pornography as enabling a liberating sexuality for women and support the First Amendment protection of pornography, whereas others remain concerned that pornography fosters male dominance and female subjugation (Strossen, 1993).

Finally, equality is frequently offered by advocates as a basis for outlawing differential treatment on the basis of sexual identity and for providing a protected sphere in which gay and lesbian people can enjoy both privacy and autonomy in their experience of their sexuality (Mohr, "Sexual Orientation and the Law"). This argument has made limited headway within the legal system. While most courts continue to uphold state statutes restricting marriage to opposite-sex couples, a few courts have taken positions favorable to same-sex marriage. In its 1999 decision in *Baker v. State of Vermont,* the Vermont Supreme Court held that "the State is constitutionally required to extend to same-sex couples the common benefits and protections that flow from marriage under Vermont law." The court carefully noted that its decision did not entitle same-sex couples to a marriage license but merely ordered the state legislature to either allow same-sex marriage licenses or "establish an alternative legal status to marriage for same-sex couples."

The controversial *Baker* decision has led some legal commentators to wonder about the futures of traditional and same-sex marriage. Some have speculated that if courts find marriage benefits constitutionally required, then they will likely find the title and status of marriage constitutionally required as well, ultimately leading to legalized same-sex marriages (Duncan). While the issue of legalized same-sex marriages remains unresolved, Hawaii's courts, like Vermont's, have taken steps toward legalizing same-sex marriage, finding the state's same-sex marriage ban to be a form of sex discrimination and directing the state legislature to resolve the issue accordingly (*Baehr v. Lewin,* 1993; *Baehr v. Miike,* 1998). The legal developments in Vermont and Hawaii have been controversial nationally in part because many states fear that the U.S. Constitution's full faith and credit clause (found in Article 4) will require them to recognize same-sex marriages, with potential positive and negative consequences for children, parents, families, social structures, and social values (Gushiken).

Conclusion

In matters relating to sexuality, the law attempts to strike a delicate balance between the impetus to regulate and the

impetus to stay government's hand, while always remaining aware of shifting cultural values. Issues resolved in the direction of regulation in one era may be revisited and resolved in the direction of abstention in another. In the decades to come, it seems likely that the most contested territory is going to involve, first, the extent to which regulation of sexuality will be directed toward achieving the egalitarian vision of social and family life, freeing women and children from sexual exploitation and abuse, and second, the extent to which law will be persuaded to lift the burden of regulation currently imposed on homosexual conduct and give equal protection to those who claim homosexual status.

SIKHISM, BIOETHICS IN

• • •

Origins and Teachings

Sikhism began with Guru Nanak (1469–1539 C.E.), who was born a Hindu in the Punjab, which is still home for the vast majority of Sikhs. The word *Sikh* means *learner* or *disciple,* and today the community numbers approximately 16 million. Nanak was the first of ten personal Gurus. Following the death in 1708 of the tenth Guru, Gobind

Singh, the function of the Guru passed to the scripture and to the community. For this reason the Adi Granth (the Sikh scripture) is particularly venerated by the community.

In the North India of Nanak's day, a popular mode of religion among ordinary people was worship of a God of grace, immanent in all creation and never incarnated as a person or as an idol. This was the Sant Tradition and Nanak provided in his teachings its clearest statement. The presence of God is known through the *nam* (divine Name), mystically manifested in the beauty and order of the world around us, and one's duty is to meditate on the *nam*. This may be done by repeating a particular word or mantra, by singing hymns, or by silently meditating. In so doing one grows ever nearer to God, eventually achieving a condition of perfect union. In this union the cycle of transmigration (movement of the soul, at the death of the body, into a new body) is finally ended.

Those who accepted these teachings from Nanak were the first Sikhs. A line of successor Gurus followed him, the same divine spirit believed to inhabit each of them. The first four successors continued Nanak's teachings concerning the divine Name and, in 1603–1604 Arjan, the fifth Guru, collected their hymns and his own into a scripture, adding to it the works of other members of the Sant Tradition. During the time of the sixth Guru, Hargobind, the community attracted the attention of the Moghuls, at that time the rulers of northern India. By this time the community had grown noticeably large and the Moghuls were becoming suspicious of its increasing numbers. This danger receded, but it returned in the time of the ninth Guru, Tegh Behadur, who was executed by the Moghuls in 1675.

The Foundation of the Khalsa

In 1699 Tegh Bahadur's son and successor, Gobind Singh, inaugurated the Khalsa, a new order loyal Sikhs were summoned to join. Membership in the Khalsa was by an initiation ceremony and by a lifelong vow to maintain certain outward symbols, particularly uncut hair. Emphasis on the centrality of the divine Name was retained, but in place of the strictly inward faith taught by Guru Nanak, the tenth Guru created an organization that proclaimed the identify of his followers to all.

The inauguration of the Khalsa was crucial because it laid down for members an explicit code, or Rahit. Tradition records that the Guru promulgated all that the modern Khalsa observes today. In fact, many of the individual items of the Rahit can be traced to experiences that follow the actual foundation. The essential nature of the Khalsa, however, remains unaffected. Gobind Singh summoned loyal Sikhs to join his Khalsa; the Khalsa Sikh was to be known by certain outward features. These conspicuously included the obligation to bear arms and to retain uncut hair. Men were to add Singh ("Lion") to their name and women were to add Kaur ("Princess").

Ranjit Singh, the Singh Sabha, and Modern History

The eighteenth century, a time of much turbulence in the Punjab, was followed by a settled period during the early nineteenth century. Under Maharaja Ranjit Singh, who became ruler of the central Punjab in 1801, strong government was introduced and during the next twenty-five years, the boundaries were enlarged in three directions. In the southeast, where the British advanced against Ranjit Singh, the border was drawn along the Satluj river, leaving many Sikhs in British territory or in the territory of their client states. Amritsar was not the capital city, but it was confirmed as the principal religious center. Ranjit Singh gilded the two upper storeys of its main temple, converting it into the famous Golden Temple.

His death in 1839 has been interpreted as marking the beginning of a steep decline in Sikh fortunes. In 1849, following two wars, the British annexed the Punjab. In 1873, however, the Singh Sabha (Singh Society) was founded and under its influence, the Sikh community was revived and reshaped. In 1920 the Singh Sabha was taken over by the more radical Akali movement, which was dedicated to the liberation of the gurdwaras (temples). With the partition of India in 1947, the Punjab was divided and the Sikhs in Pakistan moved across to the Indian area. Since then many Sikhs have claimed greater Punjab autonomy. The Indian army assault on the Golden Temple in 1984 led to decade-long demands by many Sikhs for Khalistan, a completely independent state. By 1993, however, these demands had subsided.

The Singh Sabha and the Rahit

The dominant concern of the Singh Sabha reformers was to demonstrate that Sikhs formed an entirely distinct faith and that, in particular, they should not be confused with the Hindus. Special concern focused on the question of how a Sikh should behave. The intention was to show that the ways of the Sikh were emphatically not the ways of the other groups in India.

This required a restatement of the Rahit. According to tradition, Guru Gobind Singh had promulgated the Rahit in all its details, but by the late nineteenth century it had

become impossible to determine his words with precision. The Rahit had been recorded for Sikhs in a number of Rahit-namas (Rahit manuals), none of which was entirely satisfactory. Those present at the founding of the Khalsa in 1699 would know what was required of them, and likewise those who associated with the Guru until his death in 1708. Most of the eighteenth century was, however, charged with warfare and persecution, and Sikhs had little time to record the Rahit that had been delivered to them. Ignorant or mischievous people might have corrupted the received Rahit, and the Rahit-namas could only be trusted after a scrupulous hand excised those portions that misled readers and restored those parts that had been lost.

The Singh Sabha leaders made unsuccessful attempts to produce an authentic Rahit-nama. Eventually, however, an acceptable version, Sikh Rahit Maryada, was issued in 1950, and appeals to this written authority are possible. The Sikhs have no clergy and so the publication of an authoritative text was truly significant. The question of orthodoxy, however, remains. Sikh Rahit Maryada represents the Khalsa version of orthodoxy, that is, the insistence on uncut hair; there is no doubt that since the days of the Singh Sabha, this has been the dominant style. There are, however, Sikhs who do not observe this version, preferring to venerate the Gurus and scripture while cutting their hair. They do not observe the Rahit, yet still insist that they are Sikhs. It is here that Sikh identity becomes difficult to define and with it, the whole question of what constitutes Sikhism. The remainder of this article describes Khalsa Sikhism, but it is important to remember that many who call themselves Sikhs are not members of the Khalsa. This applies particularly to Sikhs living outside India.

Khalsa Regulations

Members of the Khalsa are identified by what are called the Five Ks (uncut hair, a comb, a steel wrist-band, a sword or dagger, and shorts). Smoking and intoxicants are firmly banned, the latter largely ignored but the former strictly maintained. Khalsa Sikhs are insistent on the right to carry a sword, a feature that enhances their reputation for violence. This reputation is greatly exaggerated. The Sikh should draw the sword (or use arms) only defensively, only when the cause is just, and only when all other methods have failed.

In Sikhism the key term when discussing ethical and moral issues is *seva* (service). Little guidance is given regarding health, disease, and the environment other than the most general principles. The objective is simply a life of personal righteousness, largely undefined. *Seva* is primarily considered a duty toward the gurdwara, and consists of obligations performed for the Guru on its holy ground. These include service in the *langar*, the free refectory that all gurdwaras are required to maintain, symbolizing the equality of all people. The concept is, however, further interpreted to mean genuine concern for the needs of others. According to Sikh Rahit Maryada, every Sikh is required to devote his or her entire life to the welfare of others.

In general, Sikhs are directed to see themselves as distinct from other faiths, particularly from all forms of Hindu tradition. This is the case with funerals, which involve a simple rite. Cremation follows death but all who assemble are required to restrict their lamenting. The corpse is dressed in clean garments, complete with the Five Ks, and the ceremony is conducted while hymns are sung. Such practices as laying the corpse on the floor or breaking the skull are sternly forbidden. Specific ethical injunctions are comparatively rare in Sikh Rahit Maryada, although those that are mentioned are clearly intended to be mandatory. The emphasis is, instead, placed on the duty of the individual Sikh to live a worthy life as circumstances of time and place dictate.

With two exceptions, matters of bioethical concern are not spelled out. Sikhs are left to determine them in the light of their religious faith. One exception is that female infanticide is strictly prohibited. This reflects an earlier period in Punjab history. The second exception is that, strictly speaking, initiated Khalsa members should not eat from the same dish as an uninitiated Sikh or one who has renounced the faith. All other issues, such as abortion, birth control, suicide, and euthanasia, are left to the individual or the family to decide.

SMOKING

• • •

From the time when the native peoples of the Americas introduced Europeans to tobacco until the second decade of the twentieth century smoking and other forms of tobacco use focused on questions of production, commerce, and morality rather than on questions of medicine (U.S. Department of Health and Human Services, 1992). The first public policy issues concerning tobacco centered on its role as an important cash crop and a potential source of tax revenue. Medical questions about tobacco use did not materialize because until the 1920s there were no scientific grounds for supposing that smoking endangers the health of smokers. Half a century passed before epidemiologists began to make a case for the dangers of environmental tobacco smoke (ETS) to nonsmokers. Smoking and other forms of tobacco use provide a vivid illustration of how ethical considerations can change over time as scientific evidence and the social, political, and economic dimensions of an issue change.

Scientists began to build the case for the dangers of smoking when A. C. Broders (1920) published an article correlating tobacco use with lip cancer. Subsequent studies repeatedly linked tobacco use, in particular smoking, with a variety of diseases, primarily lung cancer and respiratory diseases. Evidence was derived from epidemiological studies, typically retrospective laboratory studies, and findings at autopsy. In 1957 based on the findings of a federally sponsored study group on smoking and health the U.S. Public Health Service (USPHS) concluded that there was a causal link between smoking and lung cancer (U.S. Department of Health, Education, and Welfare). The USPHS also affirmed a causal link between smoking and numerous other cancers, as well as other diseases in 1964, when Surgeon General Luther Terry issued an advisory report titled *Smoking and Health* (U.S. Department of Health, Education and Welfare).

Since 1964 a wealth of research has demonstrated the deleterious effects of tobacco use on health. Both government and private agencies have been instrumental in publicizing and documenting research findings and their implications, most efficiently through their websites. For example, the Centers for Disease Control and Prevention (CDC) lists all the surgeon general's reports on tobacco and health from 1964 to 2001. These reports summarize the state of research and education on tobacco use at the time of each report. Research articles, tobacco industry documents, tobacco control guideline programs, and educational materials can be accessed through the CDC's site. Other websites—the Agency for Healthcare Research and Quality (AHRQ), the U.S. Department of Health and Human Services (USDHHS), the National Library of Medicine, and the National Institutes of Health (including the National Cancer Institute), as well as private foundations such as the American Cancer Society and the American Lung Association—all provide access to research and educational materials for laypersons and professionals. The importance of tobacco use and exposure as a health risk is demonstrated further in the USDHHS document *Healthy People 2010* (2000a), which cites morbidity and mortality related to tobacco use and ETS as one of the leading indicators of the health of the American people for the next ten years.

Reflection on some of the facts gives one a sense of the ethical and policy problems posed by smoking. Approximately 440,000 deaths in the United States are due to smoking and diseases related to tobacco use (American Lung Association, 2002). Exposure to ETS (also known as passive smoking) increases the risk of cancer in people who have never smoked (Hackshaw et al.). Tobacco use has become a serious pediatric health issue, but in spite of regulation, children and adolescents continue to be able to obtain tobacco products (U.S. Department of Health and Human Services, 2000b). Control of the risks and diseases related to tobacco use has been hampered by continuing efforts by the tobacco industry to promote and market its products without constraints (U.S. Department of Health and Human Services, 2000b; Ong and Glatz).

The negative health effects of tobacco use are widely known and may be widely acknowledged even though individuals may not change their behavior on the basis of that knowledge. The reasons for the lack of behavioral change are many and complex (U.S. Department of Health and Human Services, 2000b). The ethical issues are also complex and have evolved over time and as a result of political and legal factors. Major ethical issues related to smoking and other tobacco use are: (1) the protection of nonsmokers from the effects of ETS; (2) the protection of

children from an addictive product; (3) the scientific integrity of tobacco industry research; and (4) corporate integrity in marketing tobacco products.

In the past ethical arguments about smoking focused on issues of autonomy, paternalism, and societal harm. Smoking as an individual choice was juxtaposed against the restriction of individual smoking behavior as a consideration in protecting the individual from himself or herself and protecting society from smokers. Today the moral issues associated with tobacco use have moved away from individual autonomy and individual values because of the recognition of the significant public health implications of smoking. However, the earlier ethical arguments regarding smoking and tobacco use will be reviewed here to gain a historical perspective.

Ethics and Restrictive Policies: Autonomy, Paternalism, and Societal Harm

Before the harmful effects of ETS were demonstrated, the health risks of smoking suggested that at least some restrictive policies designed to protect smokers from themselves could be ethically justified. Knowledge of the risks that smokers impose on nonsmokers could support public policies designed to keep smokers from exposing nonsmokers to ETS or imposing on nonsmokers the medical costs of smoking. In addition to these two considerations the promotion of health has served as a third impetus for a restrictive policy. For example, in 1992 the Joint Commission on the Accreditation of Health Care Organizations (JCAHO), the chief hospital accreditation agency in the United States, required hospitals to forbid smoking within their premises by 1994 as a condition of accreditation (Center for Disease Control Chronology of Significant Developments). Robert Goodin (1989) used these considerations to develop a vigorous case for a public policy aimed at a total ban on smoking. Today bans on smoking in public places are common and often complement state tobacco control programs that have been shown to be effective, at least in one instance, in reducing the mortality from heart disease attributed to smoking (Fichtenberg and Glantz).

Restrictive social policies that attempt to protect an individual from harming himself or herself have been viewed as paternalistic. At least since John Stuart Mill's (1859) *On Liberty* antipaternalistic sentiment has been widespread in the English-speaking philosophical community, with Joel Feinberg being one of its leading contemporary voices. Feinberg has emphatically rejected legal paternalism, the doctrine that "[i]t is always a good reason in support of a prohibition that it is necessary to prevent harm (physical, psychological, or economic) to the actor himself" (Feinberg, p. xvii). Despite an absence of consensus on what constitutes a competent choice, factors such as coercion, ignorance, mental impairment, and addiction serve as grounds for challenging the competence of a choice. The rejection of restrictive smoking policies on the basis of their paternalistic nature and curtailment of individual autonomy thus was considered a viable moral argument until the addictive properties of nicotine and the extent of children's tobacco use became known. The case for smoking as simply another autonomous value choice became difficult to make for an addictive substance whose use often began in childhood or adolescence.

Ethics and the Public's Health: Protecting Children and Nonsmokers

Although a moral argument based on the freedom to exercise individual autonomy could be made for not restricting competent adults from engaging in tobacco-related behaviors that are detrimental to their health, that argument fails because of the propensity of adult smokers to begin smoking in childhood or adolescence and the known effects of active and passive smoke on nonsmokers, children, and fetuses. According to a 1994 surgeon general's report, most first-time smoking occurs before graduation from high school, and the younger a child is when he or she begins smoking, the greater are the negative health effects (U.S. Department of Health and Human Services, 1994). Smoking and ETS are associated with decreased fetal growth during pregnancy and respiratory problems in school-age children who were exposed to smoke during early development (American Academy of Pediatrics). Children exposed to passive smoke are more likely to develop respiratory and middle-ear problems (Cook and Strachan).

Maternal smoking has been associated with sudden infant death syndrome, and passive smoke has been associated with an increase in hospital admissions among children with cystic fibrosis (Cook and Strachan). Because of these and other significant health risks to children and adolescents, the American Academy of Pediatrics has identified the reduction of children's exposure to both active and passive smoke as a primary goal of preventive health (American Academy of Pediatrics Committee on Substance Abuse).

The moral obligation to protect a vulnerable population is heightened by the dangers of tobacco to children in all stages of development and the fact that those risks are preventable. Although children potentially may be harmed by actively smoking or by their parents' smoking, children are also at risk from ETS outside the home.

The harm from ETS in all age groups is well established. The increased risks of respiratory and heart diseases and the

role of passive smoke as an irritant were summarized in a 1986 surgeon general's report (U.S. Department of Health and Human Services, 1986). More recent meta-analyses of epidemiological studies have continued to affirm ETS as a cause of lung cancer (Hackshaw et al.) and have provided further evidence of the negative cardiac effects associated with ETS (He et al.). The continuing confirmation through scientific evidence of the detrimental health effects of passive smoking and the recognition of nicotine as addicting have moved smoking from the realm of personal value choice to the realm of public health.

The ethics involved in public health issues may differ in some respects from those involved in clinical medicine in that obligations to society as a whole may be different from or conflict with obligations to an individual patient. Although some conflicts between the rights of society and the rights of individuals may entail controversy, the overwhelming scientific evidence for the detrimental effects of tobacco has effectively eliminated controversy and promoted consensus among health professionals. The evidence justifies the imposition of restrictions such as workplace bans and restrictions on smoking in public places, whereas the lack of a total ban allows adult individuals to make the choice to smoke. Rather than being viewed as restrictions on personal liberty or intolerance of diverse values, those restrictions can be seen as analogous to the imposition of speed limits to protect the public's safety on highways. Occasional challenges to the scientific evidence still appear, but it is recognized increasingly that one reason for the public's (and some health professionals') delay in accepting the scientific evidence regarding the negative effects of smoking was an active campaign by the tobacco industry to market tobacco use aggressively and discredit scientific evidence about its negative health effects (Ong and Glantz).

Scientific Integrity and Corporate Morality

Since the 1990s confidential tobacco industry documents have become public as a result of litigation and increased public knowledge about the health effects of active tobacco use and ETS. Those documents demonstrate the efforts of the tobacco industry to publicly deny its own research results confirming the dangers of ETS, alter data to support its desired conclusions, and discredit legitimate scientists whose work demonstrated negative effects of ETS (Barnes et al.). Elisa K. Ong and Stanton A. Glantz describe how between 1993 and 1998 lawyers and marketing firms employed by Philip Morris directed a campaign to distort epidemiological standards with contrived concepts of *sound science* in order to attack legitimate scientific evidence on the negative health effects of tobacco use. Because further regulation of the tobacco industry appeared inevitable, the industry's goal was to raise the standards for scientific proof of harm so that legitimate studies demonstrating harm could never reach those standards and thus could be dismissed as *junk science* (Ong and Glantz).

The campaign was insidious but lost its force when epidemiological organizations refused to agree to some of the statistical standards being pushed by the tobacco industry (Ong and Glantz). This example of the tobacco industry's unethical attempts to manipulate public opinion is only one of many. Policies related to the sale of tobacco to foreign countries also raise difficult issues, including the promotion of cigarettes to children or to people who lack adequate information about the risks of smoking. Vigorous opposition by tobacco companies to efforts to inform Third World consumers about the effects of smoking and attempts to manipulate those efforts have exacerbated the problem (Emri, Bagci, Karakoca, Baris). Corporate morality leading to conflicts of interest and potential harm to individuals remains an unresolved problem.

Legal Regulation of the Tobacco Industry

All defensible theories of just laws recognize the harmfulness of a conduct to others as a good reason for regulating that conduct (Feinberg). In the environment of recognized health risks and the deceptive marketing practices of the tobacco industry lawsuits and regulations have become increasingly common.

Historically, legal decisions and regulations have been decided for and against both the tobacco industry and consumers. For example, the Federal Cigarette Labeling and Advertising Act of 1965 required the warning label that is familiar today but at the same time prohibited warning labels on cigarette advertisements for a period of three years (Center for Disease Control). The Controlled Substance Act of 1970, regulating addictive substances; the Consumer Product Safety Act of 1972, regulating hazardous substances; and the Toxic Substances Control Act of 1976, regulating injurious chemicals, specifically excluded tobacco from their lists of hazardous or addictive substances (Center for Disease Control). Other notable regulations include policies and laws in 1973, 1987, and 1989 to segregate and then ban smoking on domestic airline flights and bans on smoking in government workplaces in 1987, 1994, and 1997 (Center for Disease Control). The CDC website provides a summary of the numerous government regulations pertaining to tobacco since the early twentieth century (Center for Disease Control).

Over the years legal battles by individuals against the tobacco industry were fought with varying degrees of success, but eventually more consumers began to prevail in the courts. Although most disputes were heard in lower courts, two cases involving state laws, cigarette advertising, and injury or potential injury reached the U.S. Supreme Court and resulted in rulings that were partially favorable to each side (*Thomas Cipollone*; *Lorillard Tobacco Company*). In a third case, a victory for the tobacco industry, the U.S. Supreme Court ruled that the U.S. Food and Drug Administration did not have the authority to regulate tobacco products as it did other drugs.

By the mid-1990s four individual states had sued the tobacco industry to obtain reimbursement for healthcare costs related to tobacco use. In an effort to avoid more lawsuits the six major tobacco companies entered into an agreement with the attorney generals and representatives of the remaining forty-six states, along with U.S. territories and the District of Columbia. This so-called Master Settlement provides billions of dollars in payments to states from the tobacco industry beginning in June 2000 and extending over the following twenty-five years (Wilson). In addition to settlement payments, provisions of the Master Settlement include the prevention of industry targeting of children and adolescents in advertising, the regulation of tobacco industry lobbying, and public access to industry records and research (Wilson).

Since the last two decades of the twentieth century the changes in the ways in which the public thinks about and uses tobacco have been sweeping. The moral considerations of individual personal choice and freedom in smoking have become issues of public health, the protection of children, the integrity of science and scientists, and the morality of corporations. On January 27, 2003, Philip Morris changed its name to Altria Group, Inc., to demonstrate, it claimed, "To better clarify its identity as the owner of both food and tobacco companies that manage some of the world's most successful brands" (according to <http://www.philipmorris.com>). However, the moral tensions between the industry and the public continue. What the industry changes will mean in the long term remains to be seen.

SOCIAL MEDICINE

• • •

Throughout most of medical history the physician's role has been seen predominantly as a personal one in which, for the most part, the one-to-one patient–physician relationship is the one that is considered in medical ethical principles. Although the shocking evidence of physician participation in genocidal activities during World War II led to new ethical statements, such as the Declaration of Geneva, that place physicians' behavior in a social context, such statements nevertheless largely remain codifications of the ethical behavior of a physician toward a particular patient.

Origin and Meaning of Social Medicine

Enlargement of the role of the physician to include social and community aspects of disease prevention, diagnosis, and treatment is of relatively recent development, and is referred to as *social medicine.* Many definitions of social medicine have been attempted, the more generally accepted ones reflecting the relationship of social factors to disease and death. Today there is a general consensus that social medicine represents the study of the medical needs of society and the interaction of medicine and society, along with the practice of inclusion of social factors in public health, preventive medicine, and the clinical examination and treatment of patients.

The concept grew from a variety of experiences over the centuries. In seventeenth-century London, weekly "Bills of Mortality" listing the previous week's deaths began to be published. Incomplete and inaccurate as they were, they inspired John Graunt (1620–1674) and, later, Edwin Chadwick (1800–1890) to relate social and economic circumstances to death rates.

Similarly, in Italy, Bernardino Ramazzini (1633–1714) documented the relationship of disease to a series of occupations. In the nineteenth century, these inchoate efforts came together into social-policy constructs. In Austria, Johann

Peter Frank (1745–1821) published a monumental six-volume work on medical policy as a governmental endeavor—to ensure clean water and sewage disposal, for example, and to promote other regulatory efforts for the benefit of society. Chadwick, in Britain, urged government to take responsibility under the Poor Laws to protect the health of the growing population impoverished by increasing industrialization (Chadwick).

The industrial revolution fostered turmoil throughout Europe and increased the awareness of social causation of disease and death as it brought about far-reaching changes in the lives of working people. Friedrich Engels's study, *The Condition of the Working Class in England in 1844,* described the relationship of diseases such as tuberculosis, typhoid, and typhus to malnutrition, inadequate housing, contaminated water supplies, and overcrowding (Engels; Waitzkin).

The early nineteenth century therefore saw the beginning of a transformation of the physician's role (Rosen, 1974). As physicians increasingly recognized the impact of social factors on their patients' health, they saw that helping individual patients made it necessary to assess and respond to the social aspects of their lives along with everything else that might cause or prolong their patients' illnesses.

The term *social medicine* was first used in 1846 to mean "all those aspects of medicine that affect society" (Guérin, p. 203), but its popularization in Europe is usually attributed to Rudolf Virchow (1821–1902; see Erwin Heinz Ackerknecht's 1953 work, and George A. Silver's 1987 work). Virchow, who later became a highly respected pathologist (known by his colleagues as the "Pope of Medicine"), was an early exponent of the importance of social factors as contributors to disease. In 1847, at the Prussian government's request, Virchow investigated a severe typhus epidemic in rural Upper Silesia. In his report he recommended a series of dramatic economic, political, and social changes that included increased employment, better wages, local autonomy in government, agricultural cooperatives, and a more progressive tax structure. He described disease causation as multifactorial, including the conditions of people's lives. To be effective, he argued, a healthcare system must go beyond treating pathological problems in individual patients, and health professionals therefore must take responsibility for political action. In a radical medical-political newspaper he edited, the masthead read: "The physician is the natural attorney of (advocate for) the poor." Virchow insisted that "medicine is a social science, and politics nothing but medicine on a grand scale" (Silver, 1987, p. 85).

Early on, social medicine was basically an approach to medical practice; proponents recognized the effects of social conditions and took them into consideration in dealing with illness in patients. During the first half of the twentieth century, when Alfred Grotjahn published his *Soziale Pathologie* (1912) and René Sand his *Vers la Médecine Sociale* (1952), social medicine became more than an aspect of medical practice. These works, among others, established the importance and perhaps even the predominance of social factors in disease causation, maintenance, and remission. A whole new field of scholarly study emerged that understood health, disease, and the role of medicine in these terms. Beyond the traditional ethic of a physician's responsibility to a patient or to other physicians, social medicine, which was concerned with the relationship between health and the conditions of society, imposed an added discipline of responsibility to society (Grotjahn; Sand).

The discipline was further refined by John Ryle, professor of medicine at Cambridge University, who included social factors in the analysis of the varied responses of patients to illness. Since individual responses were influenced by the patient's family, work, and economic circumstances, he regarded the study and clinical application of these factors as part of the practice of social medicine (Galdston; Ryle). Ryle wrote that social medicine

> embodies the idea of medicine applied to the service of man as socius, as fellow or comrade, with a view to a better understanding and more durable assistance of all his main and contributory troubles which are inimical to active health.… It embodies also the idea of medicine applied in the service of societas, or the community of man with a view to lowering the incidence of all the preventable diseases and raising the general level of human fitness.

As it became clear that many of the causative agents of disease were social in nature, social medicine embraced not only what is usually called *preventive medicine*—that is, advice on the prevention of illness provided to individuals and families within medical practice—but also what is usually called *public health*—efforts to prevent disease in whole communities. For health and disease, an interface was seen to exist between society and medicine, not just between the doctor and a patient. The family itself, the home, the workplace, the environment, and various other social conditions played a part in whether or not people became sick, how long they remained sick, whether they recovered, and even whether medical care and other healthcare services were available.

Social medicine ranges from the doctor's use of social factors in making a better diagnosis or offering better treatment (that is, an approach to clinical problems) as well as providing preventive medicine, to helping the medical profession recognize social factors that are *pathological* or

therapeutic in society (that is, an approach to public health). In its contemporary interpretation, social medicine also means influencing the doctor's frame of mind as a professional, so he or she will recognize the need to modify social factors (in effect, an approach to social reform).

Social medicine therefore includes four components:

1. *medical care*: treatment of the individual patient (or family) to provide comfort and hope, ease symptoms, and, when possible, prolong satisfying and productive life or even "cure" the disease;
2. *preventive medicine*: guidance for the individual patient (or family) in promoting health and preventing disease;
3. *public health*: advocacy and action for health promotion and disease prevention in the community; and
4. *social well-being* (as used in the definition of "health" in the Constitution of the World Health Organization), including amelioration of hunger, homelessness, unemployment, poverty, and hopelessness.

Social medicine in action attempts to

1. ensure equitable access to an effective and efficient medical-care system;
2. encourage preventive medicine by, for example, educating practitioners;
3. support extensive public-health activities; and
4. increase resources and services to improve social well-being.

Social Medicine as an Ethical Model

Physicians engaged in the field of social medicine must concern themselves with a wide variety of problems, disciplines, and factors that encompass what are conventionally understood to be outside the proper concerns of the medical profession. Once the physician recognizes a person as a social creature, the whole range of a patient's needs becomes relevant. Traditionally, physicians have rarely seen themselves as responsible for intervention to correct a social situation outside the family that might be contributing to the patient's illness or obstructing recovery. A socially-oriented medical profession may need to take vigorous action in its patients' interest to promote improved housing, nutrition, and educational opportunities or to combat racism, discriminatory practices, or the inequities and inadequacies of the medical delivery system and its distribution or availability.

Social medicine holds that the physician has an ethical responsibility to take steps to change pathogenic situations to protect society, of which the particular patient for whom he or she bears responsibility is a part. In such circumstances, the practice of social medicine may place a physician in serious opposition to many powerful forces in society, not excluding the majority membership of his or her own profession. A physician may thereby incur social and professional opprobrium. This was the fate of playwright Henrik Ibsen's Dr. Stockmann, described by his community as an "enemy of the people" because he questioned the safety of the town's springs, the source of its prosperity (Ibsen).

Even in milder efforts, physicians who undertake the practice of social medicine may face resistance in utilizing their professional role to ameliorate pathogenic social situations such as inadequate nutrition or malnutrition; accidents and disease that befall those who live in inadequate housing; unsafe working conditions; environmental hazards or decayed neighborhoods; and polluted air and water. Again, since many of these factors are the result of neglect commonly visited upon the poor, the physician who seeks to modify such situations may find it necessary to engage in social movements that attempt to mitigate or eliminate poverty and to encourage poor people to take action on their own. The physician may be forced to take a political position, even initiate political action, in pursuing this end, just as those who do not act or who oppose such actions are taking political positions.

The remainder of this article will cover specific aspects of social medicine. These aspects—environmental and occupational health, medical-care systems, responsibility of the profession, and medical education—illustrate the range of the field and its relevance to current issues.

Environmental and Occupational Health

When a physician, as a responsible practitioner of social medicine, recognizes the potent and often baleful influence of industry on the health not only of its workers but of the community in which it is located, community education and further action may be indicated. There is increasing recognition of the environmental origins of cancer, for example, including the role of carcinogens in the workplace. Some workplaces are hazardous by the nature of the job; in others, accidents—commonly the result of inadequate safety measures or careless disregard for safety standards—result in thousands of deaths and millions of injuries. Further, in an unfortunately large number of instances, the effluent of factories poisons rivers, lakes, and air, contributing to chronic morbidity and increased mortality among the workers and in the community.

The physician with social concern may find both political action and educational efforts unwelcome in a

community torn between its need for the jobs provided by the industrial presence and fear of the industry's lethal qualities. In some communities, the answer has been to keep the lethal factory rather than accept unemployment, poverty, and starvation without it. Doctors and communities must begin to deal with a novel ethical conflict: How to modify the paradox of democratic capitalism—the need to restrain the profit motive in order to protect the community from destructive exploitation.

These actions include something more than professional response. The requirements for social change and political action (e.g., nutrition for the children of the poor or occupational safety measures) also demand that the physician act as citizen. In some situations the physician may very well be torn between social concern and his or her livelihood. The physician who works for an industry whose work processes are unsafe or pathogenic may jeopardize his or her job by taking a stand against the employer or the industry of which the employer is a part. Yet failing to take a stand makes him or her complicit and endangers the lives of countless others. A physician cannot be expected ethically to remain silent when the work situation is likely to produce trauma or disease.

Some employed physicians are expected to minimize reports of injury or disease in order to reduce the employer's financial commitment. That is the "job," as the employer sees it, for which the physician was hired. But is the physician's job to put first the interests of the employer who pays his or her salary, or the interests of the patient?

The dilemma of dual responsibility is most vividly apparent in wartime. In addition to the medical oath the physician may have taken at the completion of medical school, on entering military service the physician, like all military officers, must agree to obey military orders. These orders, for example, usually require the military physician to return wounded military personnel to action as quickly as possible. The decision as to which patient to treat first may therefore be determined by which one can be returned to duty most quickly rather than by the urgency of each patient's individual need for medical care. In an extreme case, the military physician would be expected to let a seriously wounded soldier die in order to save the life of one less seriously wounded who was able to return more quickly to battle. And if there were enemy wounded who were more urgently in need of care, when would their turn be?

Medical-Care Systems

In its scholarly manifestation, social medicine initiates studies on a nation's economic and social systems' influence on the structure and function of its healthcare system. Studies and procedures of healthcare in individual countries and cross-national comparisons are an important part of the analytic work of social medicine (Allende; Cochrane; Navarro; Roemer; Sidel and Sidel, 1982, 1983; Waitzkin).

The ethical imperative that arises from this work invites agitation for change and improvement in the structure of the medical-care system to improve its functioning. To that end the results of social medicine studies may generate promotion of the values and methods observed in other national systems, toward better access and improved quality in meeting the needs of the poor and the geographically isolated, and of marginally self-supporting workers. At the turn of the twenty-first century, for example, the inflation of medical costs resulting from disorganization and inequities bankrupted many families and barred adequate access to medical care for many others. What is the physician's role in this situation?

If access to medical care is dependent upon ability to pay, and many people are unable to obtain care for lack of funds, is the physician ethically obliged to oppose ability to pay as a condition for service? Of whom, if anyone, should the physician ethically demand payment? Should physicians demand that medical care be free to everyone at the time of service? When ability to pay interferes with access to medical care, does not the profit motive operate against the best interests of the patient and the ethical principles of the physician?

Newspaper reports and medical journal articles offer accounts of unequal medical treatment by race or gender. Blacks receive fewer advanced technological studies than whites for the same conditions (Kahn, Pearson, Harrison, et al.; Kjellstrand; Wenneker and Epstein); women receive less intensive studies and procedures for heart disease than men (Ayanian and Epstein; Kjellstrand). Ethical principles require reversal of such situations, and social medicine studies and principles guide physicians in taking action (Perkins; Hurowitz).

Evidence accumulates that, with the increase of managed care as a method of cost control in medicine, physicians are urged to limit expenditures by reducing services or narrowing access to expensive studies, hospitalization, or medications. Physicians in medical groups under managed-care controls are offered incentives to conform with such regulations or may be punished financially for not complying.

Official reports as well as media accounts about the scandalous treatment of elderly people confined to nursing homes is another example in point. The profit motive too often leads not only to cutting corners on services and

allowing short weights in food or supplies, but to making substitutions of less qualified staff, eliminating necessary services, and waiving safety and protective measures for the helpless inhabitants. Aside from the corrupt financial dealings it encourages in such cases, profit-making often prevents and obstructs both the best care and the provision of alternatives to institutional care. Physicians cannot insulate themselves morally from the mistreatment of elderly people in nursing homes nor from the exploitation of patients through the entrepreneurial mechanics of the pharmaceutical drug industry.

Is it part of the ethics of social medicine to condemn investment in drug industry stocks, in private proprietary hospitals, and in a variety of entrepreneurial enterprises such as laboratories, radiological centers, and other diagnostic and treatment modalities to which they refer their patients? The U.S. Congress and the American Medical Association have strongly condemned "self-dealing" of this nature.

Responsibility of the Profession

In addition to the question of the individual physician's ethics in financial dealings that may compromise patients' best interests, there is the associated question of the physician's responsibility for taking action when he or she observes any unethical or unprofessional behavior on the part of a colleague. If a physician knows first-hand about the poor quality of a particular nursing home, even if his or her particular patient is not affected by it, is the physician required to take steps to correct the situation? Legal steps? Professional steps? Or, more narrowly, if the physician knows of colleagues who do not or cannot adequately carry out their obligations as physicians because of incompetence or because of lack of training, illness, or addiction, what should be done about it? Social medicine holds that there is an ethical responsibility to call attention to these facts even if they do not cause risk to the physician's particular patients.

The physician as social medicine practitioner is asked to make a difficult choice, as a citizen and as a doctor. Social medicine as an ethical model imposes an obligation on the physician to serve his or her individual patient by serving all patients. And, as a member of a profession, the physician must act not only as an individual but as representative of that profession, adopting an advocacy role for the groups in society that require special attention and care. The profession is being asked to act toward society as the individual physician is asked in traditional ethical statements to act toward an individual patient.

Finally, the ethical physician has a responsibility to inform and educate the community on the social nature of health and illness. An educated and knowledgeable constituency is required to provide the necessary support for the political social action. Discussing the dangers of smoking, for example, is hardly enough. Physicians ought also to discuss the economics of the tobacco industry and suggest that steps need be taken to cushion workers from unemployment if the tobacco industry is diminished or eliminated. Moreover, if there is an industrial hazard that needs correction, physicians ought to advise not only on the danger but on means for correcting it.

It is clear, nonetheless, that for physicians to discharge social medical responsibilities in complex areas, they need to see themselves as part of a group larger than the medical profession alone. In 1956, Theodore Fox described the "Greater Medical Profession" and urged "converting the medical empire into a commonwealth" (Fox). To respond ethically to social needs is to recognize the contribution of all health workers and to act in concert with others in the health field and outside it. In doing this the physician may wish to join with others in professionally oriented groups—such as the American Public Health Association, the International Physicians for the Prevention of Nuclear War, Physicians for Human Rights, and Physicians for Social Responsibility.

Social Medicine in Medical Education

Medical education should include not only the technical, laboratory, and clinical models of what a physician can do, must know, and be able to deal with; it should also give the future physician the tools to recognize the social circumstances—industrial, neighborhood, legislative, administrative—that play a part in the production of disease or that influence medical care. Exposure to social medicine as an important component of medical education, along with the example of role models and the fact that faculty members have such interests, will influence students' and later practicing physicians' ideas as to what their responsibilities are and how these responsibilities can be discharged (Silver, 1973).

Although departments of social medicine had long existed in medical schools and hospitals in other countries, it was not until the 1950s that Ephraim Bluestone and Martin Cherkasky organized the first department of social medicine in a U.S. medical institution, Montefiore Medical Center in New York City (Levenson). Other institutions such as Harvard Medical School, the University of North Carolina College of Medicine, and the Albert Einstein College of Medicine later adopted the term in department names or titles of professorships, but the pace of this development in the United States has languished.

Conclusion

Early medical ethics was largely restricted to the concept of a physician–patient dyad. Social relationships of pathogenic factors were unknown or ignored. By the beginning of the twenty-first century, it had become clear that the social aspects of the prevention, causation, maintenance, or cure of disease cannot be adequately dealt with solely in the one-to-one relationship. Expanded notions of the physician's responsibility based on social factors ought to be included in modern medical ethics statements. The physician should learn to recognize and articulate social demands for change in situations that are harmful to patients and to the community, and not simply deal with problems as they arise in his or her patients.

To this end, physicians must know more about the social situations in which disease occurs or which contribute to disease; they must adopt an advocacy role in pursuing change, and join with other health workers in ensuring appropriate social action for correction. In addition to oaths and declarations in which physicians bind themselves to serve individual patients honorably and ethically, service to society must also be required of physicians. Social medicine deserves an integral place within a more traditional medical ethics. Unfortunately, issues of social medicine are often assigned low priority in medical education and in medical practice.

SOCIAL WORK IN HEALTHCARE

• • •

Social workers have played a vital role in healthcare settings since the early twentieth century. Social work was introduced to medical settings in the United States by Dr. Richard C. Cabot in 1905. Cabot, a professor of both clinical medicine and social ethics at Harvard University, was instrumental in adding social workers to his clinic staff at Massachusetts General Hospital. Under the direction of their first department head, Ida Cannon, these social workers helped patients and their families cope with illness, disease, disability, and hospitalization by focusing particularly on their psychosocial needs, including their emotional reaction and adaptation (Rossen).

Over time, social work's function and influence in healthcare settings have expanded significantly (Miller and Rehr). In addition to assisting hospitalized patients and their families, social workers provide genetic counseling, hospice services, psychotherapy and counseling in mental-health agencies, and treatment of people with eating disorders and substance abuse problems. These opportunities exist in hospitals, neighborhood health and family planning clinics, psychiatric institutions, community mental-health centers, nursing homes, rehabilitation centers, and other long-term care facilities. Social workers' specialized role is to help patients and their families cope with illness and disability.

Many social workers in healthcare settings provide patients and their families with counseling, and information about and referral to needed resources (e.g., home healthcare, financial assistance, nursing home placement). Social workers are also skilled in organizing and facilitating support groups for various populations, such as cancer patients, rape victims, and parents of seriously impaired infants. They work to enhance the availability of community-based resources (e.g., healthcare clinics in low-income neighborhoods or residential programs for children with AIDS), advocate on behalf of individual patients who are in need of services, and advocate to ensure that important public policy issues related to healthcare are addressed (e.g., funding for lead screening or guidelines concerning involuntary commitment of mentally ill individuals to psychiatric hospitals).

Social workers typically function as part of an interdisciplinary team, which may include physicians, nurses, nutritionists, rehabilitation staff, clergy, and healthcare administrators. On occasion, they facilitate the process through which healthcare professionals negotiate differences of opinion or conflict among themselves concerning specific ethical issues. Social workers' skilled use of mediation techniques can help to resolve disagreements that sometimes arise in healthcare settings. Their sensitivity to ethnic and cultural diversity can be particularly helpful when there is a clash between patients' and families' ethnically or culturally based values and prevailing ethical norms, policies, and healthcare practices (e.g., concerning the use of mood-altering medication, autopsy, or blood transfusion).

Bioethical issues in healthcare settings present social workers with complex challenges (Reamer, 1985, 1987). Some of these ethical issues pertain to specific medical conditions. Examples include ethical dilemmas related to a family's decision about withdrawal of a patient's life support, abortion following a rape, organ transplantation, the use of restraints with a noncompliant psychiatric patient, or a patient's decision to refuse neuroleptic medication. When such issues arise, social workers often serve as important intermediaries in relationships among patients, their families, and healthcare professionals. In these instances, social workers help patients and their families make difficult personal decisions, facilitate communication among members of the healthcare team, advocate on a patient's or family's behalf, or raise policy issues that need to be addressed by a hospital, nursing home, or rehabilitation center.

Other bioethical issues concern the nature of relationships and transactions between social workers and patients or their families. For example, social workers in healthcare settings must be familiar with privacy and confidentiality norms that govern relationships with patients and families. They must also be sensitive to complex ethical issues involving patients' right to self-determination, informed consent

procedures, truth telling, professional paternalism, and whistleblowing (Loewenberg and Dolgoff; Reamer, 1990).

In particular, social workers can clarify differences among the ethical obligations that guide various professions. For example, social workers in a healthcare setting can help clarify the ethical responsibilities of various professionals when staff suspect child abuse or that a patient with AIDS poses a threat to a third party.

Healthcare social workers are also involved in discussion and formulation of the ethical aspects of healthcare policy and administration. This may take several forms. Social workers may participate as members of institutional ethics committees (IECs) that discuss ethically complex cases and policies. They may have a particularly valuable perspective because of their extensive contact with patients and their families and can, therefore, contribute to discussions about, for example, resuscitation guidelines, patients' right to refuse treatment, advance directives, organ transplantation, treatment of severely impaired infants, and the privacy rights of AIDS patients. Similarly, social workers are active participants on institutional review boards (IRBs) that examine a variety of ethical issues in research on human subjects.

In addition, social workers may be involved in discussions about the ethical aspects of healthcare financing mechanisms and cost-containment measures. They may also propose ways to advocate on patients' behalf or to advocate for policy reform that may provide a more just allocation of scarce healthcare resources at the local, national, or international level. An example is social workers' participation on a hospital committee to assess the pressure to limit care provided to, and hasten discharge of, psychiatric patients covered under *managed care* programs operated by private insurers. In these instances, social workers may help identify the psychosocial consequences of various strategies to allocate limited healthcare resources.

As a profession, social work has its formal origins in nineteenth-century concern about the poor, and is an outgrowth of the pioneering work of charity organization societies and settlement houses, primarily in England and the United States (Brieland; Leiby). Thus, social workers are inclined to be attentive to the needs of low-income, culturally diverse, and oppressed patients and families.

Although contemporary social workers provide services to individuals and families at all points on the socioeconomic spectrum, the profession continues to have an abiding concern for the disadvantaged. As a result, social workers in healthcare settings are alert to ethical issues that involve such populations as low-income patients, abused children and elders, women, refugees and immigrants, substance abusers, ethnic minorities, and gay or lesbian individuals. Concern about such vulnerable groups—for example, with respect to their access to healthcare, their privacy rights, or discrimination against them by healthcare providers—is one of social work's principal hallmarks. Social workers may advocate for individual patients and families whose rights are threatened or who are victims of institutional abuse or discrimination. They also may advocate for public policy that will enhance protection of the rights of these populations.

Like all healthcare professionals, in order to participate fully in discussions of bioethical issues and dilemmas, social workers need specialized knowledge and training. First, they need to be familiar with the history, language, concepts, and theories of bioethics, particularly as they have evolved since the early 1970s. Second, social workers should be knowledgeable about formal mechanisms that can help healthcare professionals monitor and address bioethical issues. These include phenomena such as IECs, IRBs, utilization review and quality assurance committees, informed consent procedures, and advance directives. It is also useful for social workers to be acquainted with relevant codes of ethics and legal considerations (statutes and case law) related to patients' rights and healthcare professionals' obligations.

Finally, social workers should be familiar with the various schools of thought that pertain to ethical decision making and ethical theory. This can be particularly useful when social workers are involved in discussion of cases with professional ethicists, for example, when a decision must be made about when and how to tell a fragile, terminally ill patient the truth about his or her diagnosis, or to disclose confidential information, against a patient's wishes, in order to protect a third party. This training may be offered as part of agency-based in-service education, professional conferences, or undergraduate and graduate social work education.

Especially since the early 1970s, social workers have been aware of the diverse and complex bioethical issues involved in healthcare, whether it involves acute or chronic, inpatient or outpatient, or medical, rehabilitative, nursing, or psychiatric care. Social workers' growing awareness of, and enhanced expertise in addressing, bioethical issues helps to ensure the protection of patients' and families' rights and the soundness of ethical decisions made in healthcare settings.

SPORTS, BIOETHICS OF

• • •

The use of banned substances (doping), genetic enhancement, and gender issues are three topics central to the discussion of bioethics in sports.

Doping in Sport

Prior to the inception of the World Anti-Doping Agency (WADA) in 1999 and the World Anti-Doping Code (2003), banned substances and practices in organized sport were identified by the International Olympic Comittee (IOC). In its *International Olympic Charter against Doping in Sport* (1990), the IOC declared that "the use of doping agents in sport is both unhealthy and contrary to the ethics of sport, and that it is necessary to protect the physical and spiritual health of athletes, the values of fair play and of competition, the integrity and unity of sport, and the rights of those who take part in it at whatever level." This charter contains a list of substances and practices that are banned from the Olympic Games. The use of these banned substances and practices is referred to as *doping.* However, the IOC lacked a clear ethical framework that could justify the banning of these items by showing them to be relevantly different from permitted substances and practices.

Each of the IOC's reasons for banning certain substances and practices can be found in more developed forms in the literature of the philosophy and ethics in sport. These include arguments against cheating, unfair advantage, and harm,as well as the ideas that doping perverts the nature of sport and that doping is dehumanizing. The basis for a potential coherent and enforceable ban on doping in sport derives from a view of the intrinsic goods of sport.

THE INADQUACY OF CURRENT ARGUMENTS TO SUPPORT BANS. There are four arguments that are generally proposed to justify banning drugs in sport. All of them have some merit, though none of them provide a sufficient justification for banning doping.

Cheating and unfairness. The argument that doping amounts to cheating was used by Justice Charles Dubin of the Canadian Royal Commission, which was established by the Canadian Federal Government after the Ben Johnson

scandal during the 1988 Seoul Olympics. The *Dubin Report* states that the most vigorous opponents of cheating in sport are those who insist that sports must be conducted in accordance with the rules. The moral disapprobation of doping is thus seen as coming from the fact that doping is cheating.

The major problem with this position is that an activity only becomes cheating once there is a rule prohibiting it. So while the fact that doping is cheating may well provide a reason for enforcing the rules against doping, and while the fact that doping is cheating may give other athletes a reason to have an extremely negative attitude towards those who dope, there is not yet a clearly argued reason for creating the rule banning doping in the first place.

There are alternative interpretations of this argument. One is that there is something in the concept of *cheating* that implies a notion of *unfair advantage* of one competitor over another. The use of certain substances and practices falls into this category. However, for this view to justify banning a substance, the notion of unfair advantage must be independent of the rules of sport (unlike cheating). In other words, if *unfair advantage* turns out to be just rule-breaking, then it cannot do the work that the concept of "cheating as rule-breaking" could not do. This raises a variety of philosophically interesting questions: What is cheating? Why is cheating wrong? And, independent of the answer to these questions, *Why should doping been banned?* From a bioethics perspective, it will not do to say simply that one should not dope because it is banned. What is significant is the justification for banning it in the first place.

The argument that doping is unfair suffers from a similar weakness. The simplest idea of fairness is one connected to adherence to the rules: an action is unfair if it is against the rules. An alternative notion of fairness is independent of the rules of sport. But this notion would have to show how doping was inherently unfair, even if the contestants agreed that all could do it, and even if the rules of the game permitted it. Thus, the concept of unfair advantage is no better justification for banning a substance than cheating is.

The concepts of cheating and unfair advantage would have to exist independently outside of sport in order to be brought to bear to evaluate sport. For example, the concepts of cruelty or brutality, which are moral evaluations, have been used to ban sports such as bare-knuckle boxing. It may well have been the case that bare-knuckle bouts were free of cheating and quite fair, they were, however, brutal and cruel, and on these grounds they were banned. Unless the concepts of cheating and unfair advantage can similarly be grounded outside of sport, they will be unavailable to justify or criticise the rules of sport.

Harm to the athlete. The second most commonly cited argument used to justify the ban on doping is that it is harmful. Doping is viewed as being: (1) harmful to users, (2) harmful to other athletes, (3) harmful to society, and (4) harmful to the sports community. However, these arguments cannot be expected to provide a general justification for prohibiting doping, but must be addressed sport by sport and substance by substance.

The argument that a ban is justified because doping is harmful to the user assumes that a particular substance or pracice is harmful, and that potential users need to be protected from the substance or practice. Anabolic steroids provide a good example of such a substance. The assertion that medically supervised steroid use harms the user is, at the turn of the twenty-first century, scientifically unproven. Much of the evidence concerning harm is derived from anecdotal testimony of athletes using very high doses in uncontrolled conditions, and the medical evidence from controlled low-dose studies tends to show minimal harm. Society's abhorrence of the practice has prevented the gathering of hard scientific evidence, because such research has yet to be approved by ethics committees. Autologous blood-doping has not been shown to have adverse side-effects at all.

There are two elements to the charge of harm to the user of a substance: the bad effects of the substance, and the causal linkage of these effects to doping. It has not been scientifically proven just what the "bad effects" from doping are. For the sake of argument, however, one can grant that steroids do indeed harm their users (not an implausible assumption). It would then be necessary to address each particular steroid on its own merits, rather than formulated a general argument against doping.

It can also be argued that the desire to protect competent adults from the consequences of their own actions is paternalistic. Paternalism has both acceptable and unacceptable forms. For example, some would argue that banning doping for minors is acceptable, but that banning doping for adults is unacceptable.There are, however, instances where certain practices are banned for adults, such as banning driving without seatbelts. The question thus becomes whether banning steroids, and other substances and practices, is acceptable paternalism?

Much of the thrust of modern bioethics has been directed against medical paternalism. It may be argued that to ban steroids solely to protect competent adults is to treat those adults athletes as children who are unable to make choices that directly impact their lives. This position is generally inconsistent with the nature of high-performance sport, in which athletes are constantly pushing their limits.

Some would argue that it is inconsistent, and even hypocritical, for the governing bodies of sports to attempt to justify a ban by appealing to the athlete's well-being. There are many training practices, and indeed many sports, that carry a far greater likelihood of harm to the athlete than does the controlled use of steroids. If the reason for banning doping in sport really were a concern for the health and well-being of athletes, then many other practices (and many sports) should also be banned.

One might argue that the risks incurred by the nature of the sport (e.g., brain damage from having one's head pummelled in boxing) are different from the risks that are incurred from practices that have nothing to do with competition in the sport per se (e.g., liver damage from steroid use). The basis of this argument might be tied to a distinction between the *external good* and the *internal good* that are derived from participation in a sport. Internal goods (skill, strategy, self-fulfillment, etc.) are gained from participation in the activity itself, while external goods (fame, prestige, money, etc.) are gained from societal recognition of success. Some might argue that the only way one can gain these internal goods is to take the risks involved in participation. However, this distinction is invalid if the justification for the ban is that a substance harms the user, because the athlete can be harmed in either case (i.e., both brain damage and liver damage are harmful).

There is little evidence to suggest that banning doping will protect athletes. As long as a subculture exists that believes that doping brings benefits—and that it is an occupational hazard of highlevel competitive sport—athletes will continue to use these substances in clandestine, unsanitary, and uncontrolled ways. Only a change in values will end such use, and this will only happen after a logically consistent position for the ban has been put forward (presumably, a ban would be intended as part of a larger process aimed at producing just such a change in values).

Harm to other athletes. It is also argued that steroids should be banned because of the harm their use causes to other athletes. ("Others" are usually deemed to be "clean," or nondoping, athletes.) This is called the *coercion* argument, and it is more difficult to dismiss quickly. The same liberal tradition that prohibits paternalistic interventions permits interventions designed to prevent harm to others. What must be determined is how great the harm is to other athletes, and how severe the limitation on personal action is.

In order to assess this argument one needs to consider whether or not the potential coercion of clean athletes outweighs the infringement on the liberties of athletes caused when a substance or practice is banned. Clean athletes are harmed, so the argument goes, because the dopers "up the ante." If some competitors are using steroids, then all competitors who wish to compete at their level will need to take steroids or other substances to keep up. This argument has some merits, but it is still incomplete, for elite-level sport is already highly coercive. If full-time training, altitude training, or diet control are shown to produce better results, then everyone is forced to adopt these measures to keep up. The feeling that somehow steroid use is worse than longer or more specialized training just raises the question of *why* it is worse. Why can't an athlete accept two "raises of the ante" but not accept a third, or even an unlimited number?

The answer to this question relies on a demand for consistency. There must be some reason why a particular practice is banned, and that reason cannot be merely that it raises the ante too high. This is a qualitative question, not a quantitative one, that necessarily requires an explanation for banning a substance on its own merits.

On the other hand, the coercion argument has merit if it can be shown that doping is irrelevant to a particular view of what is important to sport. If sports and sporting contests are about testing skills, then it can be argued that the improved performance that comes with doping is irrelevant to that test of skill (especially when one bears in mind that if some athletes dope, others will be forced to dope in order to keep up, thus obviating the original advantage that came with doping). If doping is irrelevant to sport, the athletes can shun it as being unnecessarily coercive.

Harm to society. This position says that doping harms others in society, especially children who see athletes as role models. If children see athletes having no respect for the rules of the games they play, there will be an undermining of respect for rules, and for law in general. This argument only works if doping is against the rules, however, and so cannot function as a justification for banning doping in the first place.

Athletic drug use is also seen as part of a wider social problem of drug use. The argument here is that if children see athletes using drugs to attain sporting success, then other drugs may be seen as a viable means to other ends. The limitation of this argument is that there are many things that are considered appropriate for adults but not for children. Alcohol and cigarettes are obvious examples, as is sex, but, in North America at least, these substances or activities are not banned for adults simply because they would be bad for children.

A further response to the suggestion that athletes should be role models—and, in particular, *moral* role models—is to ask why. People expect widely varying things of their public figures. No one seriously expects musicians or actors and

actresses to be moral role models, so why should athletes be singled out for special treatment? Why should more be expected from athletes than from other public figures?

Some philosophers have argued that sport is one of the very first areas young people experience, and one of the first in which they hope to gain excellence. From a societal perspective, if the heros and heroines of young people are morally despicable, then they will exert a negative influence. Young people will not separate the athletic abilities of their heroes or heroines from the quality of their personal lives, especially when fame and glamour surround such persons. The achievement of excellence in athletics comes prior to, and will greatly influence, the achievement of excellence in adult arenas such as business, academia, and politics. Perhaps for these reasons people are more concerned about the moral image of athletes than of other public figures.

What is it about drug use in sport that people find morally repugnant? No one else is prevented from using cold remedies, even if they drive public transportation, or from using caffeine as a stimulant to work harder. So it is not even the case that athletes are asked to meet the standards every one else meets, but rather, at least in regard to substance use, they must meet more rigorous standards.

Harm to the sport community. One other group that is potentially harmed is the sports-watching public. These people will be harmed, the argument goes, if they are being cheated—if they expect to see dope-free athletes battling it out in fair competition and are denied this form of entertainment. This harm can be removed in other ways than through banning steroid use, however. One could, for example, remove the expectation that athletes be dope-free. The feeling of being cheated is dependent on the idea that what was expected was a particular type of competition. However, this means asking people to settle for less than what they really want. They might, therefore, suffer other harms, such as the loss of the chance to watch doping-free competition. Of course, this does not address the question of why people value doping-free competition.

HARM CAUSED BY BANS. Because any bans that are imposed need to be enforced, there are potential harms caused by the bans themselves. Enforcement of bans on substances or practices designed to help one train, rather than improve one's performance on the day of competition, requires year-round, random, unannounced, out-of-competition testing. This is an intrusion into the private lives of athletes. Thus, athletes are harmed by being required to consent to such testing procedures (and to give out constant updated information on their whereabouts) in order to be eligible for competition.

One aspect of the harm caused by bans is abstract. Any time one's choices are restricted, one has been harmed. One could argue that the athlete is harmed when deprived of the chance to dope in order to improve performance. On the other hand, the spectator is harmed when deprived of the chance to watch doping-free sport. There is, however, a more direct harm. If one bans drugs or practices, one must necessarily take steps to enforce that ban. Despite the number of positive tests during a competition, the only effective way to test for banned substances is to introduce random, unannounced, out-of-competition testing. This is because some substances, such as anabolic steroids, can be discontinued before competition, and still retain their effects and also because of the prevalence of masking agents and urine substitution using catheters. The demand that athletes be prepared to submit to urine (or blood) testing at any time is considered by some to be a serious breach of their civil and human rights. It could also be argued, however, that such interference is just part of the price of being in sports—no one is forced to become an athlete, let alone an elite athlete.

Many who discuss this topic suggest that "sport is different," that it is not "real life," but "only a game." They argue that, because of this difference, the limitations imposed by the requirements of consent do not apply. The suggestion is that participation in high-performance sport is a privilege, not a right. Therefore, athletes are not deprived of their rights if they are deemed ineligible because they will not submit to a drug test, because they do not have a right to participate in the first place. The serious consequences of this argument is that it would allow the imposition of any rules, no matter how absurd.

Further, this argument is unclear. It may mean that no person has the right to be selected for a national team or for financial support. This is certainly true, but it is also true that there is some obligation to select the best available people for national teams and, barring income tests, for financial support as well. It could then be argued that the "best available person" means the best person available who abides by the rules of the game. However the rules of sport are not arbitrary, and they are open to moral scrutiny. If the format of the drug test is unacceptable on the moral grounds that it invades privacy, then it is also unacceptable for there to be a rule of eligibility that requires it. Sport may well be different, but nothing is so special or different that it can escape all moral scrutiny.

Perversion of sport. The concepts of cheating and unfairness and of harm are moral concepts. Cheating and unfairness presuppose a set of rules, so logically these concepts cannot be used to justify a rule. The concepts of cheating and unfairness are are thus *inside* sport. The

arguments related to harm utilize a principle found outside of sport and applied to it, thus working from the outside in.

In contrast, arguments related to the perversion of sport do not operate from moral principles, but from metaphysical ones. What the arguments seek to show is that there is some feature of sport, which, if properly understood, would be demonstrably incompatible with doping. Thus, doping should be banned because it is somehow antithetical to the true nature of sport.

Part of the problem when dealing with this question is that sport is socially constructed, and there is no obvious reason why it could not be constructed to include doping. A view of sport which places at its center the testing of sporting skills, with sporting skills defined by the nature of the game concerned, suggests that doping is not so much antithetical to sport, but rather irrelevant to it (Schneider and Butcher, 1994). Doping is irrelevant to sport because it does not improve skill, but merely provides a competitive advantage over those who do not dope. But a prerequisite for this justification is that it must come from the athletes themselves, not from sport administrators.

Unnaturalness and dehumanization. It is also argued that doping should be banned because it is either unnatural or dehumanizing. The unnaturalness argument does not get very far for two reasons. The first is that it is not clear what would count as *unnatural.* The second is that it is inconsistent. Some things designated unnatural are permitted (e.g., spiked shoes) while certain natural substances (e.g., testosterone) are banned.

The dehumanization argument is interesting but incomplete. There is no agreed upon conception of what it is to be human. Without this it is difficult to see why some practices should count as dehumanizing. We also have a problem with consistency. Some practices, such as psychodoping (the mental manipulation of athletes using the techniques of operant conditioning) are not banned, whereas the re-injection of one's own blood is banned.

An Alternative Approach

A two-tiered approach has been proposed that could justifiably prohibit doping in sport. This approach tries to show: (1) why athletes should not want to dope, and (2) why the community should support doping-free sport.

WHY ATHLETES SHOULD NOT WANT TO DOPE. Sports are practices that provide the opportunity for individuals to acquire and demonstrate skills. A well-executed back-hand volley is a demonstration of skill because of the kinds of things that are necessary to win at tennis. The shot is difficult and effective, and it is just this sort of manifestation of skill that makes participating in sport so worthwhile. The joy of sport comes from acquiring the goods that are internal to sport, the goods that come with the mastery and demonstration of skill. If this joy is the primary reason for participation in sport, then doping is irrelevant to the internal goods of sport.

Every sport is a sort of game, a game where obstacles have been artificially created to prevent one from readily achieving the object of the game. Skill is demonstrated in the overcoming of those obstacles, within the limits provided by the rules of the game. What makes sport interesting and worthwhile is the mastery of skill, and its demonstration in a fair contest with equally skilled opponents. Doping does not help one to acquire sporting skills, but simply provides a competitive advantage over those who do not dope.

Further, as long as one's competitors do not dope, there is no reason for any athlete to dope, even if the risks are minimal and the probabilities of harm are small. Because there is no game-productive reason for doping, athletes would be wise to avoid it as an unnecessary risk.

Finally, the coercive effect of doping is such that if athletes believe that a good number of their opponents dope, they will feel compelled to dope in order to keep up. But this has the effect of removing the competitive advantage that those who first doped soughtto gain. Doping is only an advantage—in terms of *winning*—if you dope and your opponent does not. That advantage is lost if everyone dopes.

These arguments point the way to a method of avoiding the invasion of privacy caused by the enforcement of bans. If athletes want doping-free sport, they will also want to be assured that the competition is fair. Athletes, then, would be in the position to request the enforcement of the rules of self-limitation that they themselves have rationally and prudently chosen.

WHY THE COMMUNITY SHOULD SUPPORT DOPING-FREE SPORT. The sporting community, both participants and fans, is in a position to defend a view of human excellence that can put limits on the pursuit of performance excellence in sport. Given that in most countries amateur sport is publicly funded, the community can promote a view of sporting excellence that places it within the context of a complete, and excellent, human life. So, despite the fact that excellence in certain sports (i.e. boxing and downhill skiing) requires running dreadful risks, society is in a position to limit those risks because it does not want to promote downhill speed over long and healthy lives. The message

from those who support sport should be that an athlete's sporting life is only a part of his or her entire life. While excellence in sport is a worthy pursuit, it should not be pursued at the expense of one's health and well-being. Because amateur sport is publicly funded, the community is in a position to put limits on its support, limits that come from the desire to promote human excellence across a complete lifetime.

Genetic Enhancement in Sport and Bioethics

Gene transfer technology will revolutionize the way people view illness and health, and it will also transform the way we diseases are treated and prevented. While this work is still in the research phase, the most imminent applications of gene transfer research to sport performance include muscle growth factors and oxygen transport and utilization.

CONCEPTUAL ISSUES. The primary challenge in gene transfer technology is in drawing the line between therapy and enhancement. The standard approach in sport has been that therapy (repair to bring one back to *normal*) has been permitted, but enhancement (going beyond *normal*) has been banned. This approach does not fit neatly with current medical practice and thinking. For example, in many forms of prevention, the body's normal responses to disease are enhanced to enable a person to avoid infection or illness. Some muscle-repair therapies may have the effect of making the muscle stronger than it was before the injury, thus enhancing performance.

The wording used in a particular ban or regulatory list needs careful consideration. It is easy to be either too specific (thus missing a significant new development) or too general (thus encompassing a variety of acceptable uses of technology). Because of the relation of sport to society, the language used in the World Anti-Doping Code attempts to deal with the development of genetic technology. This code addresses the use and impact of gene transfer technology in sport, while acknowledging that sport operates in a social context. In regard to genetic enhancement, even if sport organizations decided that enhancements should not be permitted, if it became standard medical and social practice to enhance memory and mental acuity, or to enhance muscle growth and strength in the elderly, it would be extremely difficult for sport to stand apart in opposition. There are many areas where enhancement is not only accepted, but encouraged, valued, and highly rewarded (e.g., cosmetic surgery) and even sport—some drug use is permissible in baseball in North America, for instance. If it is socially acceptable in some settings, why not in sport?

The World Anti-Doping Agency (WADA) attempted to initiate discussion on the development of some core agreements by hosting a conference on genetic enhancement and sport at the Banbury Centre in New York in February 2002. WADA has the opportunity to influence and shape the discussion, and to define and direct policy, before gene transfer technologies become available for general use.

OBJECTIONS TO GENE TRANSFER TECHNOLOGY FOR PERFORMANCE ENHANCEMENT. Despite a lack of clarity in exactly what is meant by *treatment* and *enhancement,* it is generally agreed that enhancement for sport purposes is unacceptable. However, within medicine and science this is a very complicated issue, partly because the technology is in the early stages of development. It is difficult for medical scientists to state, in the abstract, that enhancement for sport is unacceptable. This position is thus far more appropriate as a statement from the sport community. Scientifically, it would certainly be unacceptable when the technology is in this immature state.

There is strong agreement that action is required on this issue, and that this action will be complex and multifaceted. It should include: (1) ongoing cooperation between the research and sport community, (2) communication between the sport community and regulatory bodies for review and regulation of research and biotechnology, (3) inclusion of wording covering gene transfer technology in the World Anti-Doping Code, (4) research into detection mechanisms, (5) ongoing discussions between the sport community and the medical and scientific communities concerning standards of practice, (6) ongoing discussions between the sport community and the biotech and pharmaceutical industries, (7) education of athletes, the professions (especially medicine), industry, governments, and the public.

UNDISCOVERED COUNTRY. A number of themes and issues related to genetic therapy and genetic information have yet to be discussed in the sport context. The first of these is *genetic design,* which involves "designing" babies for specific (athletic) traits. The second of these issues is *germ-line,* or heritable, therapy. Other uses of genetic technology include *in vitro* genetic screening, which, in principle, makes it possible to screen embryos for genetic characteristics, and then implant into the womb only those with the "desirable" genetic makeup. It is not known if it will be possible to do this for genes associated with traits that predispose to greater athletic performance, but such a possibility raises numerous ethical questions.

There is also the possibility of genetic screening *in vivo,* where genetic screening techniques could be used (as a form

of potential aptitude testing) to determine which children or young people were most likely to benefit from specialized sport training. There has been no comprehensive discussions of the acceptability of these procedures for sport purposes, nor of the privacy issues associated with this genetic information.

REGULATION AND REVIEW. Research on the human applications of gene transfer technology is highly regulated and reviewed at local and national levels in the United States, and, to some extent, by similar mechanisms in other nations. However, review and regulation vary by jurisdiction and nation. The research is currently highly sophisticated and expensive.

There are gaps in regulation in regard to sport applications. For example, a study would not be likely to be described as having the purpose of exploring the enhancement of sport performance, though it could have that effect. The prospective regulation of gene transfer technology for sport purposes must be multifaceted and include: (1) regulation of research, (2) regulation of professional medical practice, and (3) regulation of athletes and support staff.

TESTING. There is general agreement in the sport community that the possibility of testing requires the development of more efficient methods for detection of genetic modification or of the physiological effects of genetic modification. Testing may well be difficult, and it may raise additional ethical issues, but it involves technical issues that are soluble by improved research and technology development. Testing could be aimed at both the primary genetic modification and at secondary indicators. The incorporation of *markers,* or tags, into foreign therapeutic genes to make them more readily detectable may help in detection programs, though this would be contrary to best principles of drug design, in which only therapeutic efficacy should be relevant.

RESEARCH AND EDUCATION. There needs to be increased research and development in the areas of *in vivo* gene and vector detection and the identification of the physiological effects of genetic modification, along with careful and constant ethical review. General education, as part of social change, is viewed as essential. Education should be values-based and target-specific. Researchers need to be educated on the potential uses of their research for sport enhancement purposes—and why this would be harmful to sport and athletes. Biotech companies need to be educated on the potential uses of their products and processes, and on their role (and self-interest) in avoiding misuse. The professions (particularly medicine) need to be educated on standards of professional practice and distinctions between therapy and enhancement. Finally, athletes need to be educated on the values of sport and the side effects and hazards of gene transfer technology.

Bioethics, Sport, and Gender

Many elite-level sports require pushing human limits, and thus present high risks of injuries. Generally speaking, elite-level training can produce fit, but not necessarily healthy, athletes. The results of the pressure to can be different for men and women, however. Three issues in particular—disordered eating, amenorrhea, and osteoporosis—are commonly referred to as *the female athlete-triad.* These problems surface most often in sports such as gymnastics, where victory is the result of judging. In such cases, the physical requirements and resulting risks are directly caused by decisions about what counts as excellent sport. The judging criteria for these sports need to be tailored so as to minimize the health risks they impose on the athletes.

Women athletes have a much higher prevalence of disordered eating than men. Women athletes have, at various times, faced different body-type ideals, but the greatest tension is that between the traditional ideal athlete and the traditional ideal woman. This reflects the higher level of eating disorders among women in the general population, a result of unattainable ideals among many women regarding their bodies. Thus, this problem is partly cultural, and medical control may not be the best, and is certainly not the only, way of addressing the issue.

Historically, some medical authorities have viewed menstruation, pregnancy, menopause, body size, and some feminine behaviors as diseases. For the female athlete the situation becomes even more complicated, because she can be classified as even more abnormal when reproductive changes are evaluated in the context of the traditional male sports arena. If a normal healthy woman is considered unhealthy because the model of the ideal healthy adult is based on being male, then the female athlete starts out as an unhealthy adult simply because she is a woman. If the female athlete then shows signs of becoming masculine through excellence in sports, this only increases her "abnormality." Following this kind of medical classification, when a woman bleeds, she is ill, yet if she does not bleed she is also ill. Pregnancy, then, theoretically constituting a state of health for the traditional ideal woman, should not be treated as disease.

Serious charges of irresponsibility can occur when the relationship between women athletes and their fetuses are characterised as adversarial. Some countries (e.g., Canada,

the United States, Australia) have begun to imprison women for endangering their fetuses (Sherwin). Most pregnant women athletes face, at the very least, moral pressure based on the view that simultaneously being pregnant and participating in sport is socially unacceptable. However, genuine harm to the fetus may occur with participation in sport (e.g., through oxygen deprivation). This is a problem best dealt with through education, however, not through prohibition and criminal penalties.

The classification of the reproductive aspects of women's lives as illnesses has led to wide-scale paternalistic medical management of women under claims of beneficence (Sherwin). In sport, these so-called illnesses have been part of the basis for excluding women. Certainly, serious complications requiring medical interventions can occur with any aspect of a female athlete's reproductive life or life-cycle changes. The physical and emotional pain experienced by older women athletes during menopause has always been a fact. Sport physicians, however, who are predominately male, had to learn to take their female patients seriously before they could recognize that this pain was real, and not just "in their heads." There are instances where the label of illness or disease is appropriate, but it is important that this does not lead to harming women athletes from a policy perspective (e.g., banning them from participation, rather than educating them about coping with their illness and participating in sport).

The Logic of Gender Verification and Transsexualism

Having entirely separate sports for men and women inevitably leads to the question of the logic of gender verification. If there are to be separate sporting events for women, it must be possible to exclude any men that may wish, for whatever reason, to compete in these events. This means that there must be a rule of eligibility that excludes men. (Conversely, if there is such a rule, the question arises of whether there should also be such a rule excluding women from men's events, even if the women believed they would inevitably lose.) This requires a test of gender that can be applied fairly to any potential participant. There are at least three methods of applying any such test. The first would be to test all contestants, the second would be to test random contestants, and the third would be to test targeted individuals.

It is not beyond the realm of imagination, however, that a money-hungry promoter might decide to enter men in a women's event. A male may even, with good intentions, choose to enter a women's event (such as synchronized swimming) as a form of protest against gender discrimination. Without a test to decide just who is eligible, women's events could be forced to accept participants who were quite obviously and unashamedly male, but who professed to be female.

There is a great deal of debate about how sex roles and gender are established. One school of thought takes the position that *sex* refers to biological characteristics and *gender* to socially learned characteristics. The standard practice in the Olympic Games has been to have medical experts verify gender. But, by delegating gender verification to medical experts, the sport community (and society in general) has given great power to medical experts on an issue that is in dispute by researchers.

One famous case that illustrates the conceptual and moral issues of gender verification is that of Renée Richards. Richards was previously a male elite-level tennis player who underwent what is commonly termed a "sex-change operation." The U.S. Women's Tennis Federation wanted to exclude a player who was genetically male, and they therefore introduced the requirement that players take a chromosomal test known as the Barr Test. Richards refused, and went to court to demand the right to participate in women's events. In court she was deemed to be female on the basis of the medical evidence. In the media, this story played as an example of a courageous individual fighting for personal rights against an intransigent and uncaring system, though there are, of course, other ways of viewing the story.

What makes a woman a woman? Is it chromosomes, genitalia, a way of life or set of roles, or a medical record? It is not clear why medical evidence of surgery and psychology should outweigh chromosomal evidence, nor is it clear why any one answer should be taken as categorically overriding any other. Some women argue that any gender or sex test is demeaning (especially visual confirmation of the "correct" genitalia) and discriminatory if it is not also applied to men. Clearly the use of any test, given the complexity of human sex and gender, may lead to anomalies and surprises. Yet many women wish to have sporting competitions that exclude men. One thing that does seem to become clear when faced with the complexity of this issue is that women athletes themselves should be the guardians and decision makers concerning women's sport. The best result will be one that arises through discussion, debate, and consensus.

STUDENTS AS RESEARCH SUBJECTS

• • •

Why does it matter if research subjects are students? Three answers surface immediately: first, students might be children; second, students might be in school; and third, students might be engaged in learning. None of these answers is always true, but they are true often enough to deserve consideration in research plans involving students as research subjects. Research involving students, be they minors or adults, should be conducted in accord with ethical principles and applicable regulations to protect students from potential coercion and harm. Paradoxically, these

regulations and ethical codes send conflicting signals: The regulations carve out certain kinds of education research as being exempt from the umbrella of regulatory protection, while various ethical statements, disciplinary codes, and guidance—most notably from the American Educational Research Association—single out students as deserving careful treatment (Office for Human Research Protections; Strike, Anderson, Curren, et al.; American Psychological Association; American Sociological Association).

Primary and Secondary Education Students

The vast majority of students in primary and secondary schools have yet to reach adult maturity, legally and developmentally. Given the ethical principle of respect for persons, from which arises the practice of informed consent, research involving young students raises the question of students' abilities to make voluntary, competent and informed decisions about whether or not to participate in proposed research. Human development and experience affect the level of student understanding of research participation. Language and literacy skills affect students' ability to receive and interpret relevant information, much less appreciate the implications of what the consequences of participation could be. Children are generally less familiar than adults with key concepts relevant to research participation and risk, such as confidentiality, experimental trials, or the estimated probability of a particular outcome. Such cognitive tools are essential to grasping a specific research activity and the involvement of research subjects. As they develop and learn, students gradually become more like adults in their capacity to truly understand what involvement in research entails (Bruzzese and Fisher). Some education systems set standards regarding what students should know and be able to do in science at various grade levels, as illustrated by the American Association for the Advancement of Science and the National Research Council. Such standards may provide useful guidance regarding what prospective young research subjects should be expected to understand about participation in research.

Young students also vary significantly from adults in their perceptions and assessments of risks and benefits. Their abilities to make practical judgments are less well developed than those of adults. They may attach very different values to specific harms and benefits, and most concern themselves with short-term consequences. A typical sixth grader views the sacrifice involved in giving up math class to participate in research differently from how an adult would understand it. Children and adolescents also have their own views about common forms of research compensation such as money or material goods. Young people's faculties of moral judgment, including the reasons they use to justify practical decisions, also vary from adults in patterned ways (Bebeau, Rest, and Narvaez).

Students' voluntary decision-making is also shaped by various influences. Very young children are strongly affected by their parents and other significant adults, while adolescents become more susceptible to their friends' and peers' value orientations and pressures as adult influences wane (Steinberg, Brown, and Dornbusch) These influences obviously bear upon how researchers should construct the circumstances in which students are asked to participate in research.

Parents, Guardians, and School Officials

These developmental considerations lead ethicists and some federal agency regulations to view the agreeable young person as providing *assent,* that is, an affirmative expression of willingness to participate voluntarily in research. U. S. federal regulations generally require assent from minors and supplement that requirement with the *permission* of a parent or guardian. Requirements are less rigidly established in other countries, and practices vary widely. Permission is construed according to standard criteria for informed consent with respect to the parent or guardian's decision on behalf of the student.

Permission generally provides an appropriate mechanism for protecting the autonomy, interests and welfare of the young student, but it may also present challenges. If permission comes from the parents, the research team needs twice the number of affirmative responses to its request for participation. Parents often are not as easy to contact as students, and research suggests that some parents do not give permission for their children to participate in research not because they object, but simply because they don't get around to signing and returning a consent form (Singer). Other parents have reservations about a research team's overtures that are unrelated to any concerns about their children's welfare; they may be embarrassed to reveal their lack of literacy skills, or believe that signing a form reflects a legal concession, or even fear that their signature somehow puts them in jeopardy. Some parents have interests contrary to the students whose welfare they are expected to protect; they may worry that their child's responses to a research survey may embarrass or incriminate the parents. On the other side, students' hesitation about participation may stem from apprehensions about what their parents may find out about sensitive survey questions or how they answered them.

Other adults have a role in protecting prospective student research subjects, which may lead to tension over

who has authority to permit student participation in research. School officials are responsible for students' welfare and directly supervise students' school day activities. Since proposed research activities may disrupt normal school life, researchers are generally obliged to obtain school officials' permission to carry out research with students as research subjects. Researchers might also view school officials as appropriate sources for permission to involve students in research. This view is contestable, however, as conflicts arise about parents having control over, or at least a say in, what happens to their children in schools. In the United States, federal laws—most notably the *Family Educational Rights and Privacy Act* and the *Protection of Pupil Rights Amendment*—and state and local laws and policies reflect efforts to prescribe when parents must be consulted before researchers may collect data about students through school records, surveys, or other means. Since federal regulations do allow for waiver or alteration of elements of consent or documentation of consent under certain conditions, researchers sometimes request such waivers, particularly for large scale surveys where the researchers point to the low level of risk involved and the difficulties of securing adequate unbiased samples if active parental permission is required. For some parents, however, it is the sensitivity of survey topics and the potential invasion of privacy that concerns them, not the degree of risk involved.

The School Site

The question of who has authority over what happens to students in schools also raises the issue of the convenience of conducting research with students in schools. Most primary and secondary schooling is compulsory in affluent countries; consequently, researchers can expect to find in schools large and fairly representative samples of young people, neatly segregated by age, under adult supervision, engaged in activities not of their own choosing, and legally required to stay. The opportunities for relatively inexpensive and efficient data collection are obvious. Thus some research efforts seek to involve populations of students as research subjects not because the research objective is focused on understanding education or the lives of students per se, but rather because students in schools offer a convenient way to study a wide variety of phenomena concerning youth. This approach may be viewed by some as a form of exploitation that could be unwelcome and disruptive to the educational process. Frequently students are surveyed about their health and development, extracurricular activities, and perceptions of themselves and society, for reasons unrelated to their educations. Research studies focused on areas outside of education may detract from the school's pursuit of its educational mission, and may pose risks for students by asking for sensitive information about criminal, antisocial, or private behavior.

Education Research and Practice

Education research involves students for the specific purpose of studying the formal and informal processes of learning. Such research projects raise their own set of important ethical concerns, particularly when they involve educational practice and practitioners. Some of these concerns resemble those raised in clinical trials of therapeutic medical interventions.

Education research may involve the educational equivalent of the *therapeutic misconception*: the mistaken belief that the nature of the subject's involvement in research in designed to improve that subject's welfare, rather than in developing generalizable knowledge (Appelbaum, Roth, Lidz, et al.). Students, parents, and researchers may all fall prey to the *educational misconception,* especially in the context of educational practice.

Education researchers often involve teachers or other practitioners in data collection or as co-researchers, and the dual roles of researcher and practitioner sometimes conflict (Hammack), as they do in biomedical research (Koski). What should a practitioner/investigator do in a classroom situation where pursuing a research question comes at the expense of delivering an important lesson? What if one uncovers sensitive information about the students that an educator would not otherwise have known? If a practitioner/investigator discovers that a student cheated on a test, should he or she, as an educator, discipline the student and alter the grade, or, as a researcher, protect the research subject from harm? Note that in such circumstances the protective research device of confidentiality is rendered useless, because the person who collects the information is the selfsame person as the one from whom the potentially harmful information is supposed to be kept.

Education research also raises issues of justice or fairness with regard to the selection of research objectives and selected student populations. Should the focus be on research that will benefit the largest possible number of students, with current level of success in the middle range? Or should the focus be on those students who possess the potential to improve the most from better educational interventions, even if they are already doing relatively well? And what of those students who are currently doing relatively poorly in the current educational system, whose level of achievement may be the most difficult to improve? Do students of one ethnic or linguistic minority deserve more attention than students of another, because their numbers in

the education system are larger? Such questions of beneficence and justice are reflected in any research project proposing a selective sample of students, and are framed by deeply held cultural beliefs about the importance of education as a vehicle for equality of opportunity and social mobility.

Education research frequently involves the evaluation of interventions delivered at a collective level in classrooms and schools. Reducing class size, changing teacher behavior, altering curricula, attaching high stakes to test performance, and reforming school culture are all educational interventions that can only be accomplished and studied at a group level. In a study where classrooms or schools are randomly assigned to an innovative approach (treatment) or to the standard educational practice (control), by the time the results are available, students may have outgrown the opportunity to benefit from the more effective intervention if they did not receive it during the study. Individual students and their guardians may be able to decline to have the data about them collected or included in research analyses, and sometimes accommodations such as classroom re-assignment can be made to enable students to opt out of a research study. In many cases, though, if a student or guardian wants to avoid the student's participation in a research evaluation of an educational practice at a participating school, the options may be severely constrained or costly. Such collective decisions about the involvement of students as research subjects must face the challenge of striking a reasonable balance between majority will and minority freedoms (Oakes)

The use of qualitative methods and the involvement of practitioners in many education research studies significantly transform the relations and ethical orientations among researchers, practitioners, and students. Qualitative research strategies in education characteristically intertwine the prescriptive and descriptive dimensions, place research activities in specific moral and political frameworks, and recognize the essential contributions of the "insider" subjects' perspectives, abandoning disinterested stances in favor of "advocacy" positions (Howe and Moses). Likewise, practitioner/investigators often find themselves sharing control over the nature, objectives, and credit for research projects with their colleagues and students, making the relationships among the participants more egalitarian, changeable, and complex (Zeni). In such cases the ethical responsibilities shift accordingly.

Tertiary Education Students

Undergraduate and graduate students generally have the background knowledge, literacy skills, and abilities to appreciate potential harms and benefits at a level resembling those of adults. Indeed, nearly all are adults, removing the need for parental permission for the vast majority of tertiary education students. The typical college student also has relatively good health, more flexible schedule commitments, few or no dependents, limited financial resources, considerable disposable time, and openness to new experiences. More than fifteen million students attend degree-granting tertiary education institutions in the United States, where they are easily accessible to academic researchers. Tertiary education students are prime candidates for research involvement.

DEPARTMENTAL SUBJECT POOLS. Academic researchers, most notably psychologists, have capitalized on the ready availability of students, often their own students. The vast majority of findings in human studies by psychologists come from research involving students as research subjects (Chastain and Landrum). In order to avoid the coercive situation of faculty asking their students to participate in their own research, many institutions set up departmental subject pools (DSPs) through which they arrange for students to participate in faculty research projects.

The practical arrangements of DSPs vary. Some are entirely voluntary, while others are attached to course selection—usually introductory psychology or other lower-division social science courses—and are either required of students or award extra credit for the course. Most DSPs allow students other options, such as writing a paper, as an alternative to participation in research. The ethical rationale generally put forward for this practice is that the DSP arrangements for research participation provide an educational benefit to the research subjects while efficiently supplying sufficient numbers of research subjects to enable faculty to carry out a more robust research agenda of valuable studies.

Some DSPs are ethically better than others, depending on specific features of the DSP, including the following:

- Clear, timely information is provided to prospective students.
- Investigators demonstrate respect for research subjects through their conduct.
- Student participation in the system is efficient and non-punitive.
- Students choose from a variety of research studies.
- Research studies are appropriate for a sample population of college students.
- Research studies are generally low in risk.
- Subject participation is structured to provide educational consent and debriefing experiences.
- A variety of alternatives to participation in research are offered, involving comparable

educational value, time commitment, and enjoyment (Sieber).

The 2002 revision of the American Psychological Association's ethical code reaffirms its previous position on students as research subjects, allowing DSPs if students have alternative options: "8.04 Client/Patient, Student, and Subordinate Research Participants (b) when research participation is a course requirement or an opportunity for extra credit, the prospective participant is given the choice of equitable alternative activities" (American Psychological Association).

There are reasons for skepticism about whether DSPs are ethical at all, unless they are entirely voluntary. Given the imbalances in power, authority, and autonomy inherent in the relationship between teacher and student, complete voluntariness may not be possible. Whatever degree of latitude DSPs permit in student choice of research projects or alternatives, required participation still reflects researchers' use of their control over students' educational choices to induce them to participate.

The claim that DSP participation represents a genuinely beneficial and authentic educational experience is open to objection. DSPs present students with consent situations that do not reflect the ideal of voluntary participation: Outside of DSPs, research subjects are either volunteers or are offered compensation in forms they value. Extraordinary briefing or debriefing experiences may provide students with better understanding of the substance of a particular research project, but to the extent that they succeed in this regard they also provide a distorted picture of the educational benefits of the typical non-DSP research subject's experience. It is also difficult to accept the idea that well-designed debriefing exercises will overcome the inherent differences in the educational potential of the research subject's actual experience of participation in a given research study. If the goal throughout is really supposed to be educational, it seems a more effective approach would be for faculty to involve their students in mock research activities specifically designed to demonstrate key features of research subject participation connected to the rest of the course's curricular content. In sum, the rationale for DSPs may be said to represent the institutionalization of the educational misconception. What is especially intriguing in this regard is the fact that the educational value of research subject participation in DSPs is seldom even assessed, and few if any rigorous research studies have been conducted comparing the educational effectiveness of research participation to the frequently utilized alternative educational options. Some educational institutions have taken steps to eliminate DSPs or impose additional oversight procedures to ensure that when and if they are permitted, they are closely scrutinized. For some, recruitment of students through broad-based appeals to the general public is considered preferable both ethically and scientifically, as a less selected population of subjects may enhance the generalizability of study results.

STUDENTS IN GRADUATE OR PROFESSIONAL TRAINING. Outside of DSPs, students sometimes participate in research studies related to their field of study, some of which focus on their regular education and training. These studies present challenges resembling those discussed above with regard to primary and secondary school practitioner researchers, with respect to the general issues of possible coercion, the educational misconception, and the inherent limits of confidentiality protections. What is different, however, is that the researcher/subject relationship has grown in some ways: The student research subject is now an adult, and the researcher is now someone whose authority over the student has taken on a different shade. For example, graduate or medical students may view the investigator as an important mentor and career influence, in addition to whatever control the investigator might possess over students' grades, recommendations, teaching or research assignments, and opportunities for postdoctoral work or residency programs. Even if the researcher wishes the students to view a decision to participate as a research subject as entirely voluntary, the students may see themselves as having no choice.

At the same time, academic faculty may view participation in research as an obligation students should accept as a function of their having chosen to pursue a profession in which research plays an integral part. Where faculty are doing research to evaluate the effectiveness of their educational practices, they may feel that students have an obligation to contribute to improving those practices, because the students are benefiting from lessons drawn from studying previous students' experiences (Dubois). At the same time, faculty may be conscious of the importance of providing role models of researchers who treat their subjects with the utmost respect, and must therefore solicit their voluntary consent (Henry and Wright). Hans Jonas argued that those persons who are most knowledgeable, committed, and autonomous should be the first to participate as research subjects, which presumably implies that graduate and medical students should be the first to volunteer for such studies, after the faculty themselves. This argument construes the idea of autonomy more broadly, in the sense that while the student may feel pressured to volunteer for a study at the given moment, the student has chosen to pursue a highly-rewarded profession in which research—with its incumbent risks and sacrifices for human subjects such as themselves—plays an important role. To the extent that a student's

autonomy is limited by the personal and professional circumstances of their participation, Jonas's presumption may not be true.

Conclusion

Students' decisions to participate in research may be affected by various influences, incentives, rewards, or compensation, and yet the pressure of these factors does not always rise to the level of undue influence or coercion. Students occupy a wide range of locations along the spectrum of opportunities for participation in research, ranging from invitation to attraction to enticement to pressure to force. Some influences may be altered, while others are endemic to the student's natural condition. As long as investigators and institutions are cognizant of and responsive in the design and execution of their studies to the special situations that arise in research involving students, they can reduce the likelihood that additional social and regulatory limits to their work will be imposed. Unless society is willing to forego all research in which students are the research subjects, the challenges of enlisting students as research subjects under circumstances of mixed voluntariness will continue.

SUICIDE

• • •

Philosophical issues concerning suicide arise in a wide range of contemporary end-of-life dilemmas: the withdrawal or withholding of medical treatment; involuntary treatment; high-risk, experimental, and unconventional treatment; euthanasia, assistance, and physician assistance in suicide; requests for maximal treatment; and many others. Although suicide is often popularly understood in a narrower sense of active, pathological self-killing, traditionally abhorred, the underlying issue most broadly conceived concerns the role that individuals may play in bringing about their own deaths.

Two focal issues concerning suicide are evident in these broader dilemmas. First, should suicide be recognized as a right, and if so, under what conditions? On this first question rest the foundations for various applications of the "right to die," as well as a variety of other issues in high-risk and self-sacrificial behavior.

Second, what should the role of other persons be toward those intending suicide? On this second question rest practical, legal, and public-policy issues in suicide prevention and suicide assistance. Both focal issues concerning suicide raise larger questions about the nature of choices to die and the relevance of mental illness, about the role of the state, about conceptual issues in determining what actions are to be counted as suicide, about the role of religious belief concerning suicide, about the possibility of an autonomous choice of suicide, and about the moral status of suicide.

The Incidence of Suicide

The United States exhibits a rate of reported suicide—10.7 per 100,000 year (year 2000 figures)—that falls approximately midway between societies in which reported suicide rates are extremely low, such as the Islamic countries, and those in which reported rates are extremely high, for example, Hungary. In the United States, there are almost 30,000 reported suicides per year and twenty-five times that many reported attempts; it is the eleventh highest cause of death for the U.S. population as a whole, ahead of homicide, the fourteenth highest. This means that, as John L. McIntosh points out, more Americans kill themselves than are killed by others.

Suicide rates are approximately equivalent across socioeconomic groups. Suicide rates are four times higher for males than females, but attempted suicide rates are four times higher for females than males. Attempt rates for whites and blacks are equivalent; rates of death by suicide are twice as high for whites. Suicide is the third leading cause of death for fifteen- to twenty-four-year-olds. For white males, suicide rates increase with age, rising to a peak of 61.7 per 100,000 in the age range eighty-four to eighty-nine; for women, suicide rates peak in midlife and decline thereafter; and elderly black women have the lowest rate of all adult groups, with those eighty-five and above showing the lowest risk (0.04 per 100,000, a rate based on such a low number of deaths that it is considered unreliable). In the United States, suicide rates declined throughout the 1990s and early 2000s—possibly due, among other factors, to the increased availability of antidepressant medications. Nevertheless, the number of deaths remains high. On average, one person commits suicide in the United States every eighteen minutes.

There are no reliable estimates of the number of unreported suicides, particularly those in medical situations involving terminal illness, the very cases that raise the most pressing current ethical issues. Suicide statistics, including those just cited, primarily reflect suicide in the narrower sense of active, pathological self-killing, whereas deaths brought about by refusal of treatment, by self-sacrifice or voluntary martyrdom, by high-risk behavior, or by self-deliverance in terminal illness are rarely described or reported as suicides. Rates of physician-assisted suicide where legal are quite low: In the Netherlands, where both voluntary active euthanasia and physician-assisted suicide are legal, the former comprises approximately 2.4 percent of the total annual mortality and the latter approximately 0.2 percent, figures fairly constant over the sixteen-year period, 1985 to 2001, for which reliable data is available. In Oregon, where physician-assisted suicide has been legal since 1997 under Measure 16, the Oregon Death with Dignity Act, 125 patients used lethal prescriptions provided legally by their physicians during the first five years of the act, representing less than 0.1 percent of the total annual deaths in the state.

Scientific Models of Suicide

Contemporary scientific understandings of the nature of suicide, primarily in the narrower sense, tend to fall into

three groups: the "medical" model; the "cry-for-help," "suicidal career," or "strategic" model; and the "sociogenic" model.

THE MEDICAL MODEL. This model, heavily influential throughout most of the twentieth century, has understood suicide in terms of *disease:* If suicide is not itself a disease, then it is the product of disease, usually mental illness. Suicide is understood as largely involuntary and nondeliberative, the outcome of factors over which the individual has little or no control; it is something that "happens" to the victim. Studies of the incidence of mental illness in suicide often tacitly appeal to this model by attempting to show that mental illness—usually depression, less frequently other mental disorders—is always or almost always present in suicide. This invites the inference that the mental illness or depression "caused" the suicide.

More recent work presupposing the medical model has focused on biological factors associated with suicide, exploring among other findings decreases of serotonin in spinal fluid; drug challenges with fenfluramine; twin studies and other avenues of detecting heritable genetic patterns in families with multiple suicides; and environmental and disease exposures during pregnancy. While work to date remains provisional and in any case establishes correlations rather than causes, it nevertheless points to biological factors that may play a role in suicide.

THE CRY-FOR-HELP MODEL. A second model, developed in the pioneering work of Edwin S. Shneidman and Norman L. Farberow in the 1950s, understands suicide as a communicative strategy: It is a cry for help, an attempt to seek aid in altering one's social environment. Thus it is primarily *dyadic,* making reference to some second person (or less frequently, an institution or other entity) central in the suicidal person's life. In this view, it is the suicidal gesture that is clinically central; the completed suicide is an attempt that is (often unintentionally) fatal. While the cry for help is manipulative in character, it is also often quite effective in mobilizing family, community, or medical resources to assist in helping change the circumstances of the attempter's life, at least temporarily. Later theorists have developed related models that also interpret suicide attempts as strategic: The concept of *suicidal careers* interprets an individual's repeated suicide threats and attempts as a method of negotiating the world, though—as for the American poet Sylvia Plath (1932–1963)—an attempt in such a "career" may prove fatal.

THE SOCIOGENIC MODEL. Originally developed by the French sociologist Émile Durkheim (1858–1917) in his landmark work *Suicide* (1897), the sociogenic model sees suicide as the product of social forces varying with the type of social organization within which the individual lives. "It is not mere metaphor," Durkheim wrote, "to say of each human society that it has a greater or lesser aptitude for suicide, … a collective inclination for the act, quite its own, and the source of all individual inclination, rather than their result" (p. 299). In societies in which individuals are very highly integrated into the society and their behavior is rigorously governed by social codes and customs, suicide tends to occur primarily when it is institutionalized and required by the society (as, for example, in the Hindu practice of *sati,* or voluntary widow-burning); this is termed *altruistic* suicide. In societies in which individuals are very loosely integrated into the society, suicide is *egoistic,* almost entirely self-referential. In still other societies, Durkheim claimed, individuals are neither over- nor underintegrated, but the society itself fails to provide adequate regulation of its members; this situation results in *anomic* suicide, typical of modern industrial society. In Western societies of this sort, institutionalized suicide has been extremely rare but not unknown, confining itself to highly structured situations: the sea captain who was expected to "go down with his ship" and the Prussian army officer who was expected to kill himself if he was unable to pay his gambling debts.

Like the medical model, the sociogenic model considers suicide to be "caused," but it identifies the causes as social forces rather than individual psychopathology. Like the cry-for-help model, the sociogenic model sees suicide as a responsive strategy, but the responses are not so much matters of individual communication as conformity to social structures and reaction to the social roles a society creates.

Prediction and Prevention

Two principal strategies are employed to recognize the prospective suicide *before* the attempt: the identification of verbal and behavioral clues and the description of social, psychological, and other variables associated with suicide. Suicide prevention includes alerting families, professionals (especially those likely to have contact with suicidal individuals, such as schoolteachers), and the public generally to the symptoms of an approaching suicide attempt. They are trained to recognize and take seriously both direct warnings (e.g., "I feel like killing myself") and indirect warnings (e.g., "I probably won't be seeing you anymore") and behavior (e.g., giving away one's favorite possessions). They are also encouraged to be especially sensitive to these symptoms in those at highest risk, especially in males, those who are older, live alone, are alcoholic, have negative interactions with important others, are isolated, have poor or rigid coping

skills, are less willing to seek professional help, have low religiosity, and have a history of previous suicide attempts—the last of these being a particularly at-risk group. Prevention strategies take a vast range of forms, from the *befriending* techniques developed by the Samaritans in England and the crisis *hot lines* widely used in the United States to involuntary commitment to a mental institution. Prevention strategies also include *postvention,* or post-occurrence intervention, for the survivors—spouse, parents, children, or important others—of a person whose suicide attempt was fatal, because such survivors are themselves at much higher risk of suicide, especially during the first year following the death.

These models of suicide and the associated forms of prediction and prevention are ubiquitous in contemporary medical and psychiatric practice. Yet although suicide has been treated largely as a medical or psychiatric matter, the conceptual, epistemological, and ethical problems it raises have reemerged in two central contexts: that of right-to-die issues in terminal illness and that of political phenomena such as self-sacrifice and suicide terrorism.

Conceptual Issues

The term *suicide* carries extremely negative connotations. There is little agreement, however, on a formal definition. Some authors count all cases of voluntary, intentional self-killing as suicide; others include only cases in which the individual's primary intention is to end his or her life. Still others recognize that much of what is usually termed suicide neither is wholly voluntary nor involves a genuine intention to die, such as suicides associated with depression or other mental illness. Many writers exclude cases of self-inflicted death that, while voluntary and intentional, appear aimed to benefit others or to serve some purpose or principle—for instance, the Greek philosopher Socrates (c. 470–399 B.C.E.), who drank the hemlock; Captain Lawrence Oates (1880–1912), thean English explorer who, after falling ill during the return trip from an expedition to the South Pole, deliberately walked out into a blizzard to allow his fellow explorers to continue without him; or the Buddhist monk Thich Quang Duc, who immolated himself in the streets of Saigon in June 1963 to protest the Diem regime during the Vietnam war. These cases are usually not called suicide, but *self-sacrifice* or *martyrdom,* terms with strongly positive connotations.

However, attempts to differentiate these positive cases from negative ones often seem to reflect moral judgments, not genuine conceptual differences. Conceptual and linguistic framing of a practice plays a substantial role in social policies; for example, supporters of physician-assisted suicide often use the term *aid-in-dying* as well as earlier euphemisms such as *self-deliverance* to avoid the negative connotations of *suicide,* while opponents insist on the more negative term *suicide.* The term suicide is not used in Oregon's Death with Dignity Act to describe the practice it makes legal, and indeed the statute stipulates: "Actions taken in accordance with this Act shall not, for any purpose, constitute suicide, assisted suicide, mercy killing or homicide, under the law" (Section 3.14). In contrast, the U.S. Supreme Court cases *Washington v. Glucksberg* and *Vacco v. Quill* (decided jointly in 1997) expressly considered the issue as one involving "suicide." Similarly, Palestinian militants attacking Israeli civilians have been called *suicide bombers* by their targets and by the Western press, but they are called *martyrs* by their supporters and those who recruit them for this role.

Cases of death from self-caused accident, self-neglect, chronic self-destructive behavior, victim-precipitated homicide, high-risk adventure, refusal of lifesaving medical treatment, and self-administered euthanasia—all of which share many features with suicide but are not usually termed such—cause still further conceptual difficulty. Consequently, some authors claim that it is not possible to reach a rigorous formal definition of suicide, and prefer a *criterial* or operational approach to characterizing the term, noting its varied, shifting, and often inconsistent range of uses. Nevertheless, conceptual issues surrounding the definition of suicide are of considerable practical importance in policy formation, affecting, for instance, coroners' practices in identifying causes of death, insurance disclaimers, psychiatric protocols, religious prohibitions, codes of medical ethics, and laws prohibiting or permitting assistance in suicide.

Suicide in the Western Tradition

Much of the extremely diverse discussion of suicide in the history of Western thought has been directed to ethical issues. The Greek philosopher Plato (c. 428–c. 348 B.C.E.) acknowledged Athenian burial restrictions—the suicide was to be buried apart from other citizens, with the hand severed and buried separately—and in the *Phaedo,* he also reported the Pythagorean view that suicide is categorically wrong. But Plato also accepted suicide under various conditions, including shame, extreme distress, poverty, unavoidable misfortune, and "external compulsions" of the sort that had been imposed on his teacher Socrates by the Athenian court when it condemned him to drink the hemlock. In the *Republic* and the *Laws,* respectively, Plato obliquely insisted that the person suffering from chronic, incapacitating illness or uncontrollable criminal impulses ought to allow his life to end or cause it to do so. Plato's pupil, the Greek philosopher

Aristotle (384–322 B.C.E.) held more generally that suicide is wrong, claiming that it is "cowardly" and "treats the state unjustly." The Greek and Roman Stoics, in contrast, recommended suicide as the responsible, appropriate act of the wise man, not to be undertaken in emotional distress, but as an expression of principle, duty, or responsible control of the end of one's own life, as exemplified by Cato the Younger (95–46 B.C.E.), Lucretia (sixth century B.C.E.), and Seneca (c. 4 B.C.E.–65 C.E.).

Although Old Testament texts describe individual cases of suicide (Abimilech, Samson, Saul and his armor-bearer, Ahithophel, and Zimri), nowhere do they express general disapproval of suicide. The Greek-influenced Jewish general Josephus (c. 37–c. 100 C.E.), however, rejected it as an option for his defeated army, and clear prohibitions of suicide appear in Judaism by the time of the Talmud during the first several centuries C.E., often appealing to Genesis 9:5, "For your lifeblood I will demand satisfaction." The New Testament does not specifically condemn suicide, and mentions only one case: the self-hanging of Judas Iscariot after the betrayal of Jesus. There is evident disagreement among the early church fathers about the permissibility of suicide, especially in one specific circumstance: Eusebius of Caesarea (c. 260–c. 339), Ambrose (339–397), Jerome (c. 347–c. 419), and others all considered whether a virgin may kill herself in order to avoid violation.

While Christian values clearly include patience, endurance, hope, and submission to the sovereignty of God, values that militate against suicide, they also stress willingness to sacrifice one's life, especially in martyrdom, and absence of the fear of death. Some early Christians (e.g., the Circumcellions, a subsect of the rigorist Donatists) apparently practiced suicide as an act of religious zeal. Suicide committed immediately after confession and absolution, they believed, permitted earlier entrance to heaven. Rejecting such reasoning, Augustine (354–430) asserted that suicide violates the commandment "Thou shalt not kill" and is a greater sin than any that could be avoided by suicide. Whether he was simply clarifying earlier elements of Christian faith or articulating a new position remains a matter of contemporary dispute. In any case, it is clear that with this assertion the Christian opposition to suicide became unanimous and absolute.

This view of suicide as morally and religiously wrong intensified during the Christian Middle Ages. Thomas Aquinas (c. 1225–1274) argued that suicide is contrary to the natural law of self-preservation, injures the community, and usurps God's judgment "over the passage from this life to a more blessed one" (*Summa theologiae* 2a 2ae q64 a5). By the High Middle Ages the suicide of Judas, often viewed earlier as appropriate atonement for the betrayal of Jesus, was seen as a sin worse than the betrayal itself. Enlightenment writers began to question these views. The English statesman Thomas More (1478–1535) incorporated euthanatic suicide in his *Utopia* (1516). In his *Biathanatos* (1608, published posthumously in 1647), the English poet John Donne (1572–1631) treated suicide as morally praiseworthy when done for the glory of God—as he claimed was the case for Christ. The Scottish philosopher and historian David Hume (1711–1776) mocked the medieval arguments, justifying suicide on autonomist, consequentialist, and beneficent grounds.

Later thinkers such as the French writer Madame de Staël (Anne-Louise-Germaine, née Necker, the baroness Staël-Holstein, 1766–1817) and the German philosopher Arthur Schopenhauer (1788–1860) construed suicide as a matter of human right—although Mme. De Staë subsequently reversed her position. Throughout this period, other thinkers insisted that suicide was morally, legally, and religiously wrong: Among them, the English evangelist and founder of methodism John Wesley (1703–1791) said that suicide attempters should be hanged, and the English jurist William Blackstone (1723–1780) described suicide as an offense against both God and the King. The German philosopher Immanuel Kant (1724–1804) used the wrongness of suicide as a specimen of the moral conclusions the categorical imperative could demonstrate. In contrast, the Romantics tended to glorify suicide, and the German philosopher Friedrich Nietzsche (1844–1900) insisted that "suicide is man's right and privilege" (Nietzsche, p. 210).

Although religious moralists have continued to assert that divine commandment categorically prohibits suicide, that suicide repudiates God's gift of life, that suicide ruptures covenantal relationships with other persons, and that suicide defeats the believer's obligation to endure suffering in the image of Christ, the volatile discussion of the moral issues in suicide among more secular thinkers ended fairly abruptly at the close of the nineteenth century. This was due in part to Émile Durkheim's insistence (1897) that suicide is a function of social organization, and also to the views of psychological and psychiatric theorists, developing from the French physician Jean Esquirol (1772–1840) to the Austrian neurologist Sigmund Freud (1856–1939), that suicide is a product of mental illness. These new "scientific" views reinterpreted suicide as the product of involuntary conditions for which the individual could not be held morally responsible. The ethical issues, which presuppose choice, reemerged only in the later part of the twentieth century, stimulated primarily by discussions in bioethics of terminal illness and other dilemmas at the end of life.

Suicide and Martyrdom in Religious Traditions

The major monotheisms, Judaism, Christianity, and Islam, all repudiate suicide, though in each martyrdom is recognized and venerated. Judaism rejects suicide but venerates the suicides at Masada, where in May of the year 73 C.E. some 960 Jews trapped in a fortress built on a high rock plateau killed themselves rather than be taken prisoner by the Romans, and accepts *kiddush hashem,* self-destruction to avoid spiritual defilement. At least since the time of Augustine, Christianity has clearly rejected suicide but accepts and venerates martyrdom to avoid apostasy and to testify to one's faith. Islam also categorically prohibits suicide but at the same time defends and expects martyrdom to defend the faith. Yet whether the distinction between suicide and martyrdom falls in the same place for Judaism, Christianity, and Islam is not clear. Judaism appears to accept self-killing to avoid defilement or apostasy; Christianity teaches passive submission to death when the faith is threatened but also celebrates the voluntary embrace of death in such circumstances; some Islamic fundamentalists support the political use of *suicide bombing,* viewing it as consistent with Islam and its teachings of jihad, or *holy war,* though others view this as a corruption of Islamic doctrine. Thus while all three traditions revere those who die for the faith as martyrs and all three traditions formally repudiate suicide, at least by that name, the practices they accept may be quite different: Christians would not accept the mass suicide at Masada; Jews do not use the suicide-bombing techniques of their Islamic neighbors in Palestine; and Muslims do not extol the passive submission to death of the Christian martyrs, appealing on Koranic grounds to a more active self-sacrificial defense of the faith.

Non-Western Religious and Cultural Views of Suicide

Many other world religions hold the view that suicide is prima facie wrong, but that there are certain exceptions. Still others encourage or require suicide in specific circumstances. Known as *institutionalized suicide,* such practices have included the *sati* of a Hindu widow, who was expected to immolate herself on her husband's funeral pyre; the seppuku or hara-kiri (suicide by disembowelment) of traditional Japanese nobility out of loyalty to a leader or because of infractions of honor; and, in traditional cultures from South America to Africa to China, the apparently voluntary submission to sacrifice by a king's retainers at the time of his funeral in order to accompany him into the next world. Eskimo, Native American, and some traditional Japanese cultures have practiced voluntary abandonment of the elderly, a practice closely related to suicide, in which the elderly are left to die, with their consent, on ice floes, on mountaintops, or beside trails.

In addition, some religious cultures have held comparatively positive views of suicide, at least in certain circumstances. The Vikings recognized violent death, including suicide, as guaranteeing entrance to Valhalla (the central hall of the afterlife). Some Pacific Islands cultures regarded suicide as favorably as death in battle and preferable to death by other means. The Jains, and perhaps other groups within traditional Hinduism, honored deliberate self-starvation as the ultimate asceticism and also recognized religiously motivated suicide by throwing oneself off a cliff. On Mangareva, members of a traditional Pacific Islands culture also practiced suicide by throwing themselves from a cliff, but in this culture not only was the practice largely restricted to women, but a special location on the cliff was reserved for noble women and a different location assigned to commoners. The Maya held that a special place in heaven was reserved for those who killed themselves by hanging (though other methods of suicide were considered disgraceful), and they recognized a goddess of suicide, Ixtab. Many other pre-Columbian peoples in the western hemisphere engaged in apparently voluntary ritual self-sacrifice, notably the Aztec practice of heart sacrifice, which was generally characterized at least during some historical periods by enhanced status and social approval. The view that suicide is intrinsically and without exception wrong is associated most strongly with post-Augustinian Christianity of the medieval period, surviving into the present; this absolutist view is not by and large characteristic of other cultures.

Contemporary Ethical Issues

Is suicide *morally* wrong? Both historical and contemporary discussions in the Western tradition exhibit certain central features. Consequentialist arguments tend to focus on the damaging effects a person's suicide can have on family, friends, coworkers, or society as a whole. But, as a few earlier thinkers saw, such consequentialist views would also recommend or require suicide when the interests of the individual or others would be served by suicide. Deontological theorists in the Western tradition have tended to treat suicide as intrinsically wrong, but, except for Kant, are typically unable to produce support for such claims that is independent of religious assumptions. Contemporary ethical argument has focused on such issues as whether hedonic calculus of self-interest—weighing pleasures and pains, or benefits against harms—in which others are not affected, provides an adequate basis for an individual's choice about suicide; whether

life has intrinsic value sufficient to preclude choices of suicide; and whether any ethical theory can show that it would be wrong, rather than merely imprudent, for the ordinary, nonsuicidal person, not driven by circumstances or acting on principle, to end her life.

Epistemological Issues

Closely tied to conceptual issues, the central epistemological issues raised by suicide involve the kinds of knowledge available to those who contemplate killing themselves. The issue of what, if anything, can be known to occur after death has, in the West, generally been regarded as a religious issue, answerable only as a matter of faith; few philosophical writers have discussed it directly, despite its clear relation to theory of mind. Some writers have argued that because we cannot have antecedent knowledge of what death involves, we cannot knowingly and voluntarily choose our own deaths; suicide is therefore always irrational. Others, rejecting this argument, instead attempt to establish conditions for the rationality of suicide. Others consider whether death is always an evil for the person involved, and whether death is appropriately conceptualized as the cessation of life. Still other writers examine psychological and situational constraints on decision making concerning suicide. For instance, the depressed, suicidal individual is described as seeing only a narrowed range of possible future outcomes in the current dilemma, the victim of a kind of *tunnel vision* constricted by depression. The possibility of preemptive suicide in the face of deteriorative mental conditions such as Alzheimer's disease is characterized as a problem of having to use the very mind that may already be deteriorating to decide whether to bear deterioration or die to avoid it.

Public-Policy Issues

It is often, though uncritically, assumed that if a person's suicide is *rational,* it ought not to be interfered with or prohibited. This assumption, however, raises policy issues about the role of the state and other institutions in the prevention of suicide.

RIGHTS AND THE PREVENTION OF SUICIDE. In the West, both church and state have historically assumed roles in the control of suicide. In most European countries, ecclesiastical and civil law imposed burial restrictions on the suicide as well as additional penalties, including forfeiture of property, on the suicide's family. European attitudes and legal sanctions concerning suicide were translated into colonial societies as well, for example in India, Africa, and various Pacific Islands. In England, suicide remained a felony until 1961, and in Canada until 1971. Suicide has been decriminalized in most of the United States and in England, primarily to facilitate psychiatric treatment of suicide attempters and to mitigate the impact on surviving family members; in most U.S. states, however, assisting another person's suicide is a violation of statutory law, case law, or recognized common law. In Germany assisting a suicide is not illegal, provided the person whose death it will be is competent and acting voluntarily; in the Netherlands, physician-assisted suicide is legal under the same guidelines as voluntary active euthanasia: In Switzerland, assisted suicide is legal if it is done without self-interest on the part of the assister; and in Belgium, physician-performed voluntary active euthanasia is legal but physician-assisted suicide is not. Ongoing ferment characterizes the legal status of physician-assisted suicide in many countries.

Building on Shneidman and Farberow's early work, suicide-prevention strategies have been enhanced by considerable advances in the epidemiological study of suicide, in the identification of risk factors, and in forms of clinical treatment. Suicide-prevention professionals welcome increased funding for education and prevention measures targeted at youth and other populations at high risk of suicide. Nevertheless, philosophers are increasingly alert to the more general theoretical issues these strategies raise, for example, the effect of high false-positive rates on the right to avoid unjustified coercion. Restrictions to prevent suicide—such as involuntary incarceration in a mental hospital or suicide precautions in an institutional setting—typically limit liberty, but because the predictive measures of suicide risk that are available are neither perfectly reliable nor perfectly sensitive, they identify some fraction of persons as potential suicides who would not in fact kill themselves and fail to identify others who actually will. There are two distinct issues here. First, how great an infringement of the liberty of those erroneously identified is to be permitted in the interests of preventing suicide by those correctly identified? Second and more generally, can restrictive measures for preventing suicide be justified at all, even for those who will actually go on to commit suicide? Civil rights theorists are generally disturbed by the first of these problems, libertarians by the second.

Although U.S. law does not prohibit suicide, suicide has not been recognized as a right. There has been considerable pressure from right-to-die groups in favor of recognizing a broad right to self-determination in terminal illness not only by refusal of life-prolonging treatment but also by bringing about one's own death. In the *Washington v. Glucksberg* and *Vacco v. Quill* cases, the U.S. Supreme Court ruled unanimously that there was no constitutional right to assisted suicide, though the Court's ruling did not prohibit

states from establishing laws that would legalize it. Cases such as these, however, tend to conflate the notion of a negative right to assistance in suicide, which would prohibit interference when a willing physician wished to provide assistance to a patient, with the far more controversial notion of a positive right to assistance in suicide—something that would give patients a claim to be provided with help from physicians when they sought it.

Other rights issues raised by suicide include, for example, freedom of expression. When Hemlock Society president Derek Humphry's *Final Exit*—a book addressed to the terminally ill that provided explicit instructions on how to commit suicide, including lethal drug dosages—was published in the United States in 1991 and sold over half a million copies, its publication was protected on the grounds of freedom of expression; yet in several other countries, including France and Australia, *Final Exit* was banned. More recent controversy surrounds web sites that provide explicit how-to information about suicide, including how to do so using readily available materials, and internet chat rooms that encourage or dare visitors to kill themselves.

PHYSICIAN-ASSISTED SUICIDE. Although issues of the permissibility of suicide generally have been the focus of sustained historical discussion, contemporary public-policy debate tends to focus on a narrower, specific issue: that of physician-assisted suicide, usually coupled with the question of voluntary active euthanasia. There are two principal arguments advanced for the legalization of these practices. First, claims about autonomy appeal to a conception of individuals as entitled to control as much as possible the course of their own dying. To restrict the right to die to the mere right to refuse unwanted medical treatment and so be *allowed* to die, this argument holds, is an indefensible truncation of the more basic right to choose one's death in accordance with one's own values. Thus, advance directives, such as living wills and durable powers of attorney, "do not resuscitate" (DNR) orders, and other mechanisms for withholding or withdrawing treatment, are inadequate to protect fundamental rights. Second, arguments for the legalization of physician-assisted suicide, usually together with arguments for voluntary euthanasia, involve an appeal to what is variously understood as mercy or nonmaleficence. Because not all terminal pain can be controlled and because suffering encompasses an even broader, less controllable range than pain, it is argued, it is defensible for a person who is in irremediable pain or suffering to choose death if there is no other way to avoid it.

Two principal arguments form the basis of the opposition to legalization of these practices. The first is that killing (in both suicide and euthanasia) is simply morally wrong, and hence wrong for doctors to facilitate or perform. The second argument is that legalization would invite a "slippery slope" leading to involuntary killing. The slippery slope argument contends, among other things, that permitting assistance in suicide or the performance of euthanasia would make killing "too easy," so that doctors would turn to it for reasons of bias, greed, impatience, or frustration with a patient who was not doing well; that it would set a dangerous model for disturbed younger persons who were not terminally ill; and that, in a society marked by prejudice against the elderly, the disabled, racial minorities, and many others, and motivated by cost considerations in a system that does not guarantee equitable care, "choices" of death that were not really voluntary would be imposed on vulnerable persons. Suicide in these circumstances would become a matter of social expectation or imperative. The counterargument for legalization replies that more open attitudes toward suicide would reduce psychopathology by allowing more effective counseling, and that by bringing practices that have always gone on in secrecy out into the open—and hence under adequate control—legalization would provide the most substantial protection for genuine patient choice.

Data from the Netherlands, where physician-assisted suicide and voluntary active euthanasia have been legally tolerated since the mid-1980s and are now legal, and from Oregon, where physician-assisted suicide became legal in 1997, do not support claims about a slippery slope, though full legalization is comparatively recent in both. In both only a very small fraction of patients who die actually die with physician assistance. Most are patients with cancer: 75 percent in the Netherlands, 79 percent in Oregon. Even so, of patients with cancer, the vast majority of those who die in either the Netherlands or Oregon do not die with this form of assistance. There is no evidence of disparate impact on groups of patients understood as vulnerable—the elderly, the poor, people with disabilities or with developmental delays, and others, although prior to the development of the protease inhibitors, was high for people with AIDS. Pain has not been the central issue; rather, most patients who have elected physician assistance in dying have done so, according to family members, physicians, and hospice caregivers, to avoid deterioration and loss of control over their circumstances. In Oregon, for example, the most frequently reported concerns by patients who died in 2001 included loss of autonomy (94%), decreasing ability to participate in activities that make life enjoyable (76%), and loss of control of bodily functions (53%); inadequate pain control and the financial implications of treatment were mentioned by just 6 percent each.

Particularly relevant to public-policy discussions is the contention of some contemporary writers that suicide will

become "the preferred way of death" because it allows control over the time, place, and circumstances of dying. Others claim that as pain control in terminal illness improves, interest in physician-assisted euthanatic suicide will disappear. These may seem to be mere predictive claims. But in the technologically developed nations, where the epidemiologic transition in causes of death now means that the majority of the population will not die of parasitic and infectious disease, as was the case in all societies until the middle of the nineteenth century and is still the case in many less developed nations, but will die of late-life degenerative diseases with prolonged downhill courses, these claims may seem to harbor quite different normative visions of the roles people may—and should—play in their own deaths. One now faces a death that is comparatively predictable and prolonged, often perceived as burdensome to oneself and to those one loves.

Several particularly contentious issues have been raised in view of these facts. One concerns the question of whether a person can have a "duty to die." Some theorists have argued that as the burdens and costs of terminal care increase, both to the patient and to the family, a person becomes obligated to end his life; other commentators find this claim repugnant, an example of the kind of thinking that would fuel a slide down the slippery slope. Resolution of this issue rests on whether an individual's preferences and personal sense of concern for and obligation to family or others can be disentangled from social expectations about costs and savings.

Another issue of growing philosophical concern is that of suicide in old age, for reasons of old age alone rather than illness that accompanies old age. Despite extensive discussion among the Stoics of this matter—they held it to be a reasonable choice—and despite the prospects of vastly extended life expectancies of people in advanced industrial societies, such matters as preemptive suicide to avoid the deterioration of old age have been very little discussed.

Nor has the issue of altruistic suicide, not only in order to spare healthcare costs or other burdens for family members or others, but also in situations such as political protest and military strategy, received adequate philosophical analysis. In situations in which individuals committing suicide believe themselves to be acting for the common good, even at extreme personal sacrifice, is suicide—though it might be labeled with such euphemisms as martyrdom or heroism—morally acceptable or even praiseworthy? Such issues will form the basis for some of the many ethical challenges concerning suicide to be faced in future years.

SURROGATE DECISION-MAKING

• • •

It is well established in medical ethics, practice, and law that the informed consent of competent patients must be secured before treatment. However, patients frequently are unable to participate in decision making about their treatment because of the effects of the illness, treatment, or underlying condition. This is especially common when patients are critically ill or near death, but it can happen at any time in the course of treatment. More specifically, patients who cannot make their own decisions are those who have been found to be incompetent to make a particular treatment choice; the determination of competence sorts patients into those whose treatment choices must be respected even if others disagree with them and those for whom decision-making authority will be transferred to another person.

When someone else must make decisions for a patient, a possible alternative is for their physicians to do that; when decisions are routine and uncontroversial, this is often what

happens. However, when decisions have significant consequences for the patient, it is common practice to seek a surrogate or proxy to take the patient's place in decision making with the patient's physician.

The practice of and requirement for informed consent with competent patients are based on two central moral values: self-determination and patient well-being. Self-determination is the interest of ordinary persons in making important decisions about their lives for themselves and according to their own values; informed consent respects patients' self-determination. Patients' well-being is served by informed consent because the consent process allows a patient to decide which alternative treatment, including the alternative of no treatment, will best serve his or her values and life plans; the practice of informed consent usually, though not always, results in decisions that serve the patient's well-being. These two values can support the practice of surrogate decision making when a patient is not able to take part in decision making. The surrogate can be the person the patient authorized or would authorize to decide for him or her and can reflect the patient's values and life plans.

This entry examines in more detail how surrogate decision making can serve a patient's self-determination and well-being by considering two central issues: Who should be selected to be a patient's surrogate? and By what standards should a surrogate make decisions about a patient's care? (Buchanan and Brock). The entry then briefly considers some controversies about surrogate decision-making.

Selection of a Surrogate

Who should be selected to be a patient's surrogate? If the goal is to serve a patient's self-determination when that patient is unable to take part in decision making, it is appropriate to select the person whom the patient wanted or would want to act as a surrogate. If the goal is to serve the patient's well-being, it is appropriate to select a person who will be well positioned to represent the patient's interests and values. Sometimes the patient will have authorized another individual explicitly to act as his or her surrogate through an advance directive. In most states in the United States a durable power of attorney for healthcare (DPAHC) allows a patient to legally designate a surrogate to make healthcare decisions for him or her in the case of the patient's incompetence. Many other countries also have procedures for designating a surrogate. Ethically, there is a strong presumption that the surrogate should be the person whom the patient selected.

Most patients who become incompetent, however, do not have an advance directive to select a surrogate. In that case the surrogate should be the person whom the patient would have wanted to serve as a surrogate. In most cases it will be clear who that is: either a close family member or a friend who cares about the patient and knows the patient's values and wishes (Brock). When it is clear who the patient would have wanted to be the surrogate, there is a strong presumption that that is who should be selected. In the absence of a DPAHC or guardianship, many states in the United States have statutes authorizing a family member to make healthcare decisions for an incompetent patient; these statutes often list the order of the family members in terms of their relationship to the patient who should be selected. This presumption that a close family member should be the surrogate when the patient has not chosen one explicitly is justified by the fact that a close family member is the person whom most patients would want to be the surrogate. A close family member also usually will be most concerned to secure what is best for the patient and usually will know the patient best and thus be in the best position to represent the patient's wishes and values in decision making.

In cases where it is clear that the patient would have wanted someone besides the closest family member to be the surrogate, however—for example, because of conflict with or estrangement from that family member—that other person should be selected. In other cases there may be conflict between family members over who should serve as the surrogate. In either case it often is possible to resolve the question of who should be surrogate informally with the healthcare team or within the family. If those attempts fail, the healthcare team can have the responsibility to utilize the courts to attempt to obtain an appropriate surrogate for the patient.

In some cases there is no appropriate person available and willing to serve as the patient's surrogate. This typically occurs when no family members or friends can be located, or located in time, to make the necessary decisions. Different healthcare institutions have different procedures and practices for these cases. Relatively routine and uncontroversial decisions often are made by the healthcare team. For more consequential or controversial decisions, such as the patient's resuscitation status or the withdrawing or withholding of life-sustaining treatment, practice varies. Some institutions allow such decisions to be made by the healthcare team after consultation with others, such as the chief of service or an ethics committee. Others go to court to have a legally authorized surrogate appointed for the patient. It is important that healthcare institutions have clear procedures to follow when patients lack a natural surrogate so that decision making is not paralyzed but can proceed appropriately.

Standards for Surrogate Decision Making

What standards should surrogates employ in making decisions for incompetent patients? As in the selection of a surrogate, the standards for surrogate decision making should support the values of patient self-determination and well-being that underlie all treatment decision making. Viewed from this perspective, there are three ordered principles to guide surrogate decision-making. They are ordered in the sense that the first should be applied when possible; if that cannot be done, the second should be used, and if the second cannot be applied, the third should be used. This ordering means that the three principles should be understood as applying in different circumstances rather than as competing for application in the same circumstances.

The first principle is the advance directives principle, according to which decisions should be made in accordance with the patient's advance directive when one exists with instructions that relate to the decision at hand. The advance directive might be either a so-called treatment directive such as a living will with specific instructions about treatment the patient does or does not want in specific circumstances (whereas advance directives typically are used to decline treatment, they also can be used to indicate what treatment the patient wants) or a DPAHC that names a surrogate but also includes instructions about the patient's treatment wishes for the surrogate. Despite great efforts at the end of the twentieth century to increase the use of advance directives, most patients do not have one when they are incompetent to make their own decisions. Moreover, the instructions in advance directives are often so vague—for example, "if I am terminally ill no extraordinary measures should be applied"—that it is unclear what their implications are for the specific treatment decision at hand. As a result there usually will not be an advance directive available that clearly and decisively states the patient's wishes regarding the treatment choice in question.

When the advance directives principle cannot be applied for these or other reasons, the substituted judgment principle should be used. This instructs the surrogate to attempt to make the decision the patient would have made if he or she had been competent in the circumstances that obtain. More informally, it tells the surrogate to use his or her knowledge of the patient and the patient's values, wishes, and concerns to try to determine what the patient would have wanted. Even in the absence of explicit instructions from the patient, a surrogate often will know the patient well enough to have considerable evidence about what the patient would have wanted. However, some caution is needed when there has not been a prior explicit discussion between the patient and the surrogate about treatment because a number of studies have shown that family members frequently are mistaken in their judgments about patients' wishes, and physicians tend to do even less well in predicting patients' wishes in the absence of explicit prior discussions (Seckler et al.).

One of the most important functions of the substituted judgment principle is to emphasize that surrogates' role is not to determine what they would want in the circumstances if they were the patient or what they want for the patient but what the patient would want for himself or herself. An important responsibility of healthcare providers in working with surrogates is to help them understand their appropriate role however much what they might want for themselves differs from what the patient would want.

When there is no surrogate available who knows the patient well or, more specifically, has knowledge of the patient bearing on the treatment choice at hand, the best interests principle should be employed. That principle instructs the surrogate to attempt to make the choice that best serves the patient's interests. In practice this generally entails making the choice that most reasonable persons would make in the circumstances. This standard is justified because in the cases in which it is used the surrogate does not have knowledge about how the patient might differ from most reasonable persons in respects that are relevant to the decision to be made.

In actual practice decision-making circumstances cannot be characterized as neatly as they have been in this discussion of these three principles. For example, sometimes an advance directive may give some, but not decisive, guidance, and so the surrogate must interpret it by using substituted judgment reasoning. In other cases, there may be no advance directive and a surrogate may have only incomplete knowledge of the patient's likely wishes; in this case substituted judgment reasoning must be supplemented by best interests reasoning to arrive at a treatment choice. The relative weight that should be given in these cases to advance directives versus substituted judgment reasoning or to substituted judgment versus best interests depends on the particular circumstances of the case and how decisive or indeterminate the prior principle is for the choice and thus to the extent to which the subordinate principle must be used to supplement it.

Controversies about Surrogate Decision Making

One of the main controversies in surrogate decision making concerns the degree of discretion surrogates should have in making decisions for incompetent patients. It is not possible to be precise about this and there will be disagreement in

particular cases, but the standards for surrogate choice make it clear that surrogate discretion should not be unlimited. More specifically, surrogates should make decisions that are reasonably in accordance with the appropriate principle or standard for decision; "reasonable accord," however, does not mean that others, such as the healthcare providers, must always be convinced that a surrogate is making the best choice. The important point is that it is a mistake for healthcare providers to believe that they must do whatever the surrogate wants no matter how unreasonable that choice appears to be. The law reflects such limits as well; for example, DPAHCs typically do not give surrogates the authority to make choices that conflict with the patient's known wishes or fundamental interests.

A second controversy concerns conflicts between advance directives or substituted judgment standards and the best interests standard (Dworkin). Defenders of the best interests standard (Dresser) argue that an incompetent patient's prior wishes, especially when the patient is no longer aware of or identifies with them, should not be followed when they are in conflict with the current interests of the patient. An example would be a patient with pneumonia who needs antibiotics, is demented, and can no longer recognize friends or family members but enjoys his or her existence watching television and previously said that he or she would want no life-sustaining treatment in those circumstances. Here the patient's previous wishes expressed when the patient was competent appear to be in conflict with the patient's current interests. There is no consensus about how these conflicts should be resolved, although they are probably relatively uncommon.

A third controversy concerns whether and to what extent the interests of others justifiably can override the wishes or interests of the patient (Hardwig). Especially when patients are very near death, decisions about treatment may have little impact on their interests but a considerable impact on others, such as family members. Some have argued that in this case the standard patient-centered model for decision making should be set aside to recognize the needs and interests of family members.

SUSTAINABLE DEVELOPMENT

• • •

The idea of sustainable development dominates late-twentieth-century discussions of environment and development policy. It is a key term in international treaties, covenants, and programs and is being written into the constitutions of nation-states. An immense literature has gathered around it (Marien). Even those who reject the term must define their views in reference to it. In spite of this influence, serious empirical, conceptual, and normative problems must be addressed if the term is to serve as a comprehensive framework for efforts to sustain the biosphere and advance human fulfillment, economic security, and social justice throughout the world.

The Appeal of Sustainable Development

If the peoples of the world are to cooperate in solving their economic, social, and environmental problems, they must share a common understanding of the relationships among these problems and a common vision of a sustainable and just future. The economic expansion that began in the West several centuries ago has spread to embrace the world,

transforming all societies in its wake and creating a global economic system and attendant monoculture with powerful human and environmental impacts. Given the dominance of this system, there needs to be a comprehensive policy framework to guide it—even if the framework adopted is critical of the system itself and seeks to redirect or even dismantle it.

Sustainable development is an appealing candidate for this office. "The key element of sustainable development is the recognition that economic and environmental goals are inextricably linked" (National Commission on the Environment, p. 2). This premise, bolstered by empirical claims that poverty and environmental degradation feed one another and that conservation need not constrain development nor development result in environmental degradation, has obvious political advantages. It allows persons with conflicting positions in the environment-development debate to search for common ground without appearing to compromise their positions. New coalitions of nongovernmental organizations (NGOs) concerned for justice, population, environment, and development issues have formed under the flag of sustainable development. Business leaders have come forward to propose new business-to-business and business-to-government partnerships in the name of sustainable development (International Chamber of Commerce; Schmidheiny). In addition, sustainable development has broad moral appeal among those motivated by concern for present as well as future generations, since it purports to be the name for a process and a future state in which everyone and the environment as a whole will benefit.

"Sustainable" qualifies the idea of development. After World War II it was widely assumed that economic development would lead to greater freedom, justice, and security for the world's peoples. When environmental issues first appeared on the international agenda at the Stockholm Conference on the Human Environment in 1972, the debate was whether—and how—concerns for environment and equity could be reconciled with economic development. In succeeding years, as economic development strategies failed to close the gap between rich and poor, within or between nations, and studies showed growth in world population and consumption approaching Earth's biophysical limits, questions were raised about whether the theory of development could serve either human or environmental needs and whether it did not need to be modified to include ecological, political, social, cultural, and spiritual considerations.

By 1992, for most participants at the World Conference on Environment and Development (UNCED) held at Rio de Janeiro, these issues appeared settled. The principal agreement of the conference, *Agenda 21,* affirms that "integration of environment and development … will lead to the fulfillment of basic needs, improved living standards for all, better protected and managed ecosystems and a safer, more prosperous future. No nation can achieve this on its own; but together we can—in a global partnership for sustainable development" (United Nations, p. 15).

This entry analyzes why the concept of sustainable development occupies the center of thought on development and environment policy, how it is being defined, what criticisms are being raised about it, and what kind of work is needed if the concept truly is to meet the needs of the planet.

Sustainable development nicely expresses the progressive evolutionary worldview that emerged in the West in the late nineteenth century, with all the presumed objective support of the natural sciences, and the positive attitude toward social change often associated with it (Esteva). This progressivist ideology recognizes the problems posed by the interactions of population growth, resource use, and environmental degradation but is guardedly optimistic about the capacities of modern societies to solve those problems, given public understanding, technological and structural improvements in keeping with sound scientific research, and strong political leadership. As the Stockholm Declaration affirmed: "[T]he capability of man to improve the environment increases with each passing day" (Weston et al., p. 344).

The discourse of sustainable development thus occupies a middle-of-the-road position between those perspectives that take an uncritically optimistic attitude toward growth and technological change and those that predict the inevitability of global collapse. It also confirms the liberal insistence that the meaning of the goal of human development, fulfillment, or quality of life be stated in purely formal terms so that individuals and groups have the opportunity to define it for themselves (Kidd).

The Meaning of Sustainable Development

Mainstream thinking on sustainable development views it as a form of societal change that adds the objective or constraint of resource sustainability to the traditional development objective of meeting basic human needs (Lélé). "Mainstream thinking" refers to those ideological frameworks typical of international environmental agencies such as the United Nations Environment Programme (UNEP); international development agencies, including the World Bank; research organizations such as the International Institute for Environment and Development; and NGOs such as the Washington-based Global Tomorrow Coalition.

The concept of resource sustainability originated in the late nineteenth century in the context of renewable resources such as forests or fisheries, where it informed such ideas as

maximum sustainable yield. When the language of *sustainable development* came into international usage with the publication by the International Union for the Conservation of Nature and Natural Resources (IUCN), UNEP, and the World Wildlife Fund (WWF) of the *World Conservation Strategy* in 1980, this original meaning was retained but broadened to include the maintenance of ecosystem *carrying capacity* and the management and conservation of all living resources as a necessary prerequisite to development. Thus a clear line of intellectual (and often institutional and professional) descent runs from Gifford Pinchot, the first director of the U.S. Forest Service, and other turn-of-the-century advocates of the *resource conservation ethic* in Europe and the United States, to contemporary mainstream thought on sustainable development. Pinchot's utilitarian notion that "conservation … stands for development … the use of natural resources … for the greatest number for the longest time" remains at the root of contemporary thinking on sustainable development (Pinchot, pp. 42–48).

It is possible to interpret *sustainable development* literally to mean sustaining indefinitely the process of economic growth, change, or development. But this viewpoint is not representative of the U.N. World Commission on Environment and Development, chaired by Gro Harlem Brundtland, prime minister of Norway, the group most responsible for marshaling the data, argument, and political influence necessary to put the term on the agenda of international debate. In the commission's view, although a new era of more efficient technological and economic growth is needed in order to break the link of poverty and environmental degradation, "ultimate limits [to usable resources] exist" and indefinite economic expansion is therefore impossible (World Commission on Environment and Development, pp. 8–9).

Nonetheless, like the goal of equity, the prerequisite of ecological sustainability is often either downplayed or presumed, as in the classic definition offered by the World Commission on Environment and Development: "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (World Commission on Environment and Development, p. 43). Ecological sustainability is more likely to be mentioned in a list of *requirements* of sustainable development, such as those composed by the organizers of the Ottawa Conference on Conservation and Development in 1986 (Jacobs and Munro):

- integration of conservation and development
- satisfaction of basic human needs
- achievement of equity and social justice
- provision for social self-determination and cultural diversity
- maintenance of ecological integrity

Issues of Sustainable Development

For many critics, sustainable development lacks clarity of definition, including criteria for and examples of successful achievement (Yanarella and Levine). As early as 1984, UNEP Executive Director Mostafa K. Tolba lamented that sustainable development had become "an article of faith, a shibboleth; often used, but little explained" (Lélé, p. 607). A recent survey of the literature on sustainable development found that "case studies are surprisingly few and often hard to come by" (Slocombe et al.). It is notable that the second version of the *World Conservation Strategy, Caring for the Earth,* acknowledges the ambiguity of the term, and places its emphasis on "building a sustainable society" (IUCN, UNEP, WWF, 1991).

For other critics, the concept of sustainable development is all too clear and fundamentally mistaken. Negative critiques of sustainable development cluster around its (1) empirical accuracy; (2) idea of justice; (3) idea of sustainability; (4) economic assumptions; (5) view of science; and (6) metaphorical and spiritual assumptions.

EMPIRICAL ACCURACY. The empirical basis of sustainable development thinking is criticized both for its analysis of the problems of poverty and environmental degradation and for its proposed solutions to them. Thijs de la Court and Richard B. Norgaard (1988a), among others, argue that mainstream thinking typically ignores the two major factors responsible for both of these problems—the shift of local economies to production of exports for the world market and the adoption by traditional societies of the values of Western urban and capitalist society. Thus global free trade, the solution often offered by sustainable development proponents as the way to greater integration of the local community into the world economic system, will only intensify the problems, lending support to massive, hierarchically managed, capital-intensive industrial projects—dams, plantations, factories, urban settlements—that destroy the diversity and integrity of human communities and environments alike (Sachs). Nor will most of the other policies typically promoted in the name of sustainable development be of much help: more scientific data, more efficient technology, improved managerial capabilities, and more effective environmental education. Much more fundamental and difficult actions are necessary, such as community control of the economy, land reform, changes in cultural values, and reductions in the consumption of industrial commodities and in birthrates (Lélé).

SOCIAL JUSTICE. Most pronouncements on sustainable development hold that social justice, especially in the form of equity between wealthy and poor nations, is essential to the process. Critics contend that these ideas are seldom explicated in any detail, however. The issue of population stabilization is generally avoided, conflicting claims of intragenerational versus intergenerational equity are not addressed, and fundamental civil and political rights are seldom mentioned. In keeping with traditional development theory, there is abstract emphasis on meeting *basic human needs* and, in recent years, *participation of all stakeholders,* but it is seldom clear what these needs are, which ones should have priority, what kind of participation is required, or how sustainable development will result in greater justice or environmental protection.

These questions have become especially acute in the sphere of gender. One of the primary challenges to mainstream thinking on sustainable development has come from the international women's movement through organizations such as INSTRAW (United Nations International Research and Training Institute for the Advancement of Women) and ecofeminist theoretical perspectives, such as those of Vandana Shiva and Maria Mies (Braidotti et al.). Within the women's movement there is widespread recognition of the deep-seated patriarchal assumptions in development discourse and the connections between the destruction of nature and the exploitation of women and other marginal groups in the development process. Mainstream sustainable development theory does little to change this. *Agenda 21,* the blueprint for sustainable development adopted by the United Nations Conference on Environment and Development in 1992, retains a patriarchal orientation, evident in its failure to recognize the special role of "subdominants"—women, people of color, children, native and indigenous people—in each of its seven major themes (Warren). In order to address this problem, the Women's Environmental and Development Organization (WEDO) and other organizations have argued for the need for women to gain control over natural resources and the benefits that are derived from them and for recognition of women's special knowledge and skills in environmental care.

IDEA OF SUSTAINABILITY. Environmental ethicists and scientific ecologists are critical of the idea of sustainable development because of its reductionist approach to environmental values. Discussions of sustainable development typically assume that what needs to be sustained is human use, especially human agricultural use and industrial production. Yet instrumental value is only one of the many environmental values that need to be sustained in the complex interplay of human enjoyment, respect, use, and care of nature, and there is empirical evidence that single-minded pursuit of instrumental value through such policies, for example, as "maximum sustainable yield" seldom succeeds (Ludwig et al.). *Agenda 21* is criticized for its exclusive concentration on the need to sustain the environment for human use. Chapter 15, for example, argues that the primary reason for preserving biodiversity is that it provides a potential source of genetic materials for biotechnological development (Sagoff). This emphasis reflects a strong anthropocentric value orientation, explicit in Principle 1 of the Rio Declaration on Environment and Development: "Human beings are at the centre of concerns for sustainable development" (United Nations, p. 9).

In an unprecedented policy decision in 1991, the Ecological Society of America challenged the widely held assumption that what ought to be sustained is human use of the biosphere. It set the goal of a "sustainable biosphere" as its priority for research in ecology in the closing decade of the twentieth century, thus implying that the biosphere has value in and for itself and that above all else this is the value that must be sustained (Risser et al.).

Failure to recognize that nature has value of its own (as well as for the sake of humans) has serious practical consequences. Not only does it inhibit acceptance of the idea of sustainable development by many environmental and religious groups whose traditions embrace a more generous understanding of nature's values, but it eliminates consideration of those meanings of sustainability having to do with the way life nourishes life—with sustenance. Certain methods of subsistence agriculture, for example, built up over many generations, especially by women, simultaneously nourish human communities and the soil, yet fail to receive public recognition and support (Shiva).

ECONOMIC ASSUMPTIONS. Criticisms of the economic analysis and prescriptions of sustainable development thinking have been suggested above and may be summarized under two primary headings. First, and most generally, are those criticisms that find in the idea of sustainable development only another example of the triumph of *homo economicus* in modern society. There is a prevalent assumption that sustainable development is equivalent to sustainable *economic* development. Thus economists at the International Institute for Environment and Development argue in circular fashion that their "sustainability paradigm," a version of the "conventional economic paradigm, illustrated by utilitarian benefit-cost analysis," if modified to allow for the concept of intergenerational equity, is preferable to the "bioethics paradigm" that recognizes intrinsic values in

nature, because, among other things, the latter "inhibits [economic] development" (Turner and Pearce, p. 2).

The second sort of criticism concentrates on the failure of sustainable development thinking to challenge the assumption that economic growth can break the link between poverty and environmental degradation. Although the Brundtland commission recognized "ultimate limits," it nonetheless recommended a five- to tenfold increase in global economic productivity to reduce poverty and provide the resources for environmental protection (World Commission on Environment and Development). Ecological economists such as Herman Daly point out the biophysical impossibility of such growth and the need to arrest, or even reduce, the total "throughput" or flow of matter-energy, from natural sources, through the human economy, and back to nature's sinks. They believe that a strict distinction should be made between *growth,* defined as "quantitative expansion in the scale of the physical dimensions of the economic system," which cannot be sustained indefinitely, and *development,* defined as the "qualitative change of a physically nongrowing economic system in dynamic equilibrium with the environment," which can be so sustained (Daly and Cobb, p. 71). In their view, limited progress can be made in arresting economic growth by enforcing accepted maxims of sound economics, for example, increased resource efficiency and environmental accounting to show how income is actually a drawdown of natural capital or stock resources. Such measures alone, however, will be insufficient without redistribution of wealth and income between nations and classes, as well as population stabilization.

VIEW OF SCIENCE. Mainstream sustainable development thinking is dominated by the policy languages of science, economics, and law. Typical of such discourse is the view that science can provide a value-neutral definition of sustainability acceptable to persons with widely differing value perspectives (Brooks). But critics point to hidden norms in scientific methodology that support the status quo and are inconsistent with the personal and political transformations needed for justice and care of Earth. Moreover, only a very narrow range of considerations can be scientifically determined, thereby effectively eliminating challenges to established value judgments. In addition, the use of *risk analysis* focuses on involuntary costs that ecological changes may impose on society rather than on what should be the most important concern: the altering of ecosystems that risk-free business-as-usual will effectuate (Sagoff). Donald Ludwig, Ray Hilborn, and Carl Walters (1993) argue that the history of resource exploitation teaches the necessity of action before scientific consensus is achieved and that while science can help recognize problems, it cannot provide solutions. They caution that spending money on more scientific research is often a way to avoid addressing problems of population growth and excessive use of resources.

METAPHORICAL AND SPIRITUAL ASSUMPTIONS. Some critics consider the concept of *development* a dangerous mystification of history and do not believe adding the adjective *sustainable* appreciably alters the difficulty. Biologically speaking, *development* means progress from earlier to later, or from simpler to more complex, stages in the growth of an organism. In post-World War II development discourse, it was used as a metaphor for the transition of traditional societies into modern industrial societies (leading to distinctions between "underdeveloped," "developing," and "developed" societies). Used in this way, the metaphor implies a step forward in a linear progression, a natural, organic flowering, rather than a deliberate, culturally specific invention. It also implies that the most modern nations, such as the United States, are the most civilized and therefore models to imitate. Adding *sustainable* to *development* only confirms these biological connotations and hence strengthens its potential to obscure differences among cultures and the drawbacks of modernization.

But more than a misplaced analogy is at issue. *Development* is a powerful secular religion, in the words of Peter Berger, "the focus of redemptive hopes and expectations" (Berger, p. 17). Viewed in these terms, *development* means more than an improvement in material living standards. Development as religion means that human fulfillment is to be found in activities that improve material living conditions, for oneself and for others. Development as religion is a messianic mission to bring the fruits of material progress to the world, and it is questionable whether the idea of *sustainable development* substantially changes this. To depart from the religion of development would require defining the ends of development in terms of qualitative, as well as quantitative, goods—goods such as truth, beauty, freedom, friendship, humility, simplicity. Not only are such moral and spiritual goods the most worthy ends of human life; they may be the only way to empower persons to reduce their consumption, limit their procreation, and live sustainable lives (Goulet, 1990).

The Future of Sustainable Development

Given the value placed upon unthrottled economic growth in industrial and nonindustrial societies alike, acceptance of the goal of sustainable development, even in a weak sense, is a remarkable and positive step (Marien). Moreover, acceptance of the idea of sustainable development in international

circles and by the government, business, and NGO leadership of many nations, north and south, means that there now exists an opportunity for dialogue and new social compacts between diverse political constituencies. It is possible to argue, therefore, that the idea of sustainable development offers a realistic way of effecting a potentially radical transformation in global environment and development policy. The question is whether (1) these diverse constituencies can be engaged in a process of mutual inquiry, criticism, and discussion that will lead, step by step, toward improvements in the empirical, conceptual, and normative adequacy of the idea and in meaningful attempts to embody it in practice; and (2) an international political constituency, uniting mainstream and marginal groups and actors, can be mobilized to challenge the entrenched powers that will inevitably be threatened by changes in policy. There is also the question of whether these things can happen quickly enough, before disillusionment sets in and a fragile consensus is shattered. There are several ways of advancing this kind of agenda over the next decade. Empirical understanding of sustainable development will improve with a more issue-driven and democratically structured scientific approach that recognizes the uncertainty of facts, conflicts in values, and the urgency of decisions. Such an approach needs to be transdisciplinary and practically focused on the dynamics responsible for poverty, injustice, and environmental degradation and on how these dynamics may be changed without economic growth through resource depletion. It requires analyses of factors such as human motivation and ownership patterns, neglected in most studies to date. Studies of alternative development policies in the Indian state of Kerala present good examples (Franke and Chasin).

Empirical adequacy also will improve through initiatives such as those now underway to design quantitative "indicators" of sustainability (Trzyna), especially those indexes that can challenge, and eventually replace, the Gross National Product (GNP) as the measure of economic and social well-being. For example, Daly and Cobb (1989) propose an Index of Sustainable Economic Welfare that measures not only levels of consumption but also income distribution, natural resource depletion, and environmental damage. Macroeconomic criteria and indicators of sustainability have been proposed in areas such as population stability, greenhouse gases, soil degradation, and preservation of natural ecosystems (Ayres). Specific moral and material incentives to meet these criteria are also being developed (Goulet, 1989).

The conceptual and normative adequacy of the idea of sustainable development will improve as it is expanded to include the full range of moral and public policy criteria necessary to sustain the biosphere and advance human fulfillment, economic security, and social justice throughout the world (Corson). Such a redefinition of the goals of sustainable development will need to include (1) development conceived primarily as improvement in the quality of human life; (2) sustainability conceived as the sustainability of Earth's biosphere, with protection and restoration of ecosystems and biodiversity and sustainable use of renewable resources contributing to that end; (3) the transition to a steady-state global economy by reducing consumption among affluent classes while at the same time promoting economic growth in poor communities to meet basic human needs and provide the resources necessary for environmental protection; (4) redistribution of wealth and income between rich and poor nations; (5) population stabilization and eventual reduction to more optimal levels; (6) guarantees of basic human rights, including environmental rights, to all persons, with special attention to the empowerment of women and children; (7) new nondominating and nonreductionsitic ways of producing and transmitting knowledge of the environment and sustainable livelihood; and (8) freedom for local cultures, Western and non-Western, to pursue a variety of alternative visions and strategies of sustainable development.

The philosophy of sustainable development will also improve as discussion moves beyond the confines of economics and resource management into larger multidisciplinary and public arenas. Most mainstream thought on sustainable development has taken place without the benefit of philosophy, theology, the arts, or humanities and with only limited benefit from scientific ecology. Yet intellectual leaders in these fields, from diverse cultures and faiths throughout the world, have been trying to understand the meaning of just, participatory, and sustainable ways of life for several decades (Engel and Engel). Citizens also have substantial contributions to make to an enlarged understanding of sustainable development, as the peoples' alternative treaties signed at the NGO-led Global Forum at Rio de Janiero demonstrate (Rome et al.).

Nowhere is the challenge to mainstream sustainable development thinking more difficult—or more fateful—than in the area of comprehensive spiritual values and morals. In 1987 the U.N. Commission on Environment and Development concluded that "human survival and well-being could depend on success in elevating sustainable development to a global ethic" (World Commission on Environment and Development, p. 308). Faced with the prospect that the mainstream interpretation of sustainable development might well become a global ethic, critics argue for what they believe to be more adequate understandings of human nature and destiny, calling instead for "authentic development," "just, participatory ecodevelopment," or simply "good life." Sustainable development need not be anthropocentric or androcentric; it may be theocentric or

coevolutionary (Norgaard, 1988b), a human activity that nourishes and perpetuates the historical fulfillment of the whole community of life on Earth.

T

TEAMS, HEALTHCARE

• • •

A healthcare team is two or more health professionals (and, when appropriate, other lay or professional people) who apply their complementary professional skills to accomplish an agreed-upon goal. Coordinated, comprehensive patient care is the primary goal of most teams. Other goals may include education of health professionals, patients, or families; community outreach; advocacy; abuse prevention; family support; institutional planning; networking; and utilization review in hospitals. The team approach to patient care has been viewed as a means of building and maintaining staff morale, improving the status of a given profession (for example, nurses and allied health professionals may become team collaborators with the physician rather than working under the physician), or improving institutional efficiency.

Some teams are ongoing, such as a psychiatric care team, home visit team, ventilator patient care team, child development team, or rehabilitation team. Such teams may be responsible for following the person throughout the entire process of healthcare interventions, including diagnosis, goal setting and planning, implementation, evaluation, follow-up, and modification of goals for the patient. Other teams form around an event (for example, a disaster plan team or organ transplant team), or focus on a single function, such as discharge planning or the initiation of renal dialysis. Some teams are undisciplinary; others are multidisciplinary, and may include lay people.

Though taken for granted today, a team approach to healthcare has appeared only recently in many places where Western medicine is practiced. The development of team approaches in the United States reflects the history of that development in North America and Europe as well. In the first period, between World War I and World War II, a multiprofessional approach appeared that later developed into the team model. Major sources of impetus included the proliferation of medical specialties, an increase in expensive, complex technological interventions, and the ensuing challenge of providing a coordinated and comprehensive approach to patient care management. A second period of development occurred between the 1950s and the 1980s, when teamwork became the norm: healthcare became increasingly hospital-based, enabling a large corps of health professionals in one place to minister to the patient. In addition, new professional groups were generated in the belief that healthcare should be attentive to patients' social as well as physical well-being. The third period, which continues to the present, has focused on the appropriate goals and functions of the healthcare team and evaluation of the team's effectiveness (Brown).

Ethical issues regarding teams arise in four major areas: challenges arising from the team metaphor itself; the locus of authority for team decisions; the role of the patient as team member; and mechanisms for fostering morally supportable team decisions.

The Team Metaphor

It is generally agreed that the healthcare team idea and rhetoric arose from assumptions about sports teams and military teams (Nagi; Erde). This metaphor is not completely fitting because the healthcare team is not in competition with another team. However, it is fitting insofar as members experience their affiliation as entailing *team loyalty,* a moral obligation to other members and to the team itself. They may believe that they have voluntarily committed

themselves to a type of social contract requiring a member not only to perform maximally but also to protect team secrets, thereby promoting a tendency for cover-ups or protection of weaker members. In the military team, obedience to and trust in the leader is an absolute.

A troubling ethical conflict arises when the member's moral obligation of faithfulness to other team members or "captain" does battle with moral obligations to the patient. This may manifest itself in questions of whether to cover up negligence or a serious mistake by some or all of the team. Overall, holding peers morally accountable for incompetence or unethical behavior may be made more difficult by the team ideal. Therefore, teams must foster rules that require and reward faithfulness to patient well-being, and balance and value of team membership with that of maintaining high ethical standards.

Feminist analyses of bureaucratic structures and bioethical issues highlight a related ethical challenge. The team metaphor entails assumptions about relationships, rules, and "plays" that often exclude women from full participation because their childhood and later socialization did not prepare them for this "game" and its insiders' rhetoric. Noteworthy is the sports or military team ethos of ignoring the personal characteristics of fellow team members (within limits), provided each person is technically well suited to carry out assigned functions. Many women find it almost impossible to function effectively with team members whom they judge as morally deplorable, no matter the latter's technical skills; for such women, the relationships among and integrity of team members is as important as the external goal (Harragan).

Sometimes a further breakdown of communication and effectiveness accrues because of the team leader's allegiance to scientific rigor and specificity at the expense of subjective attentiveness to caring. Since many team leaders are physicians, on multidisciplinary teams the problems may become interpreted as pointing to serious differences in orientation between physicians and other healthcare professionals (addressed in the next section). Whatever its cause, marginalization of some team members results in team dysfunction.

Locus of Authority for Decision Making

Roles involve ongoing features and conduct appropriate to a situation, and create expectations in the self and others regarding that conduct. Each role has an identity and boundaries, giving rise to the question of whose role carries the authority for team decision making (Rothberg). The challenge applies to both unidisciplinary and multidisciplinary teams but is highlighted in multidisciplinary ones, particularly those involving physicians and other health professionals. Traditionally the physician was the person in authority by virtue of his or her office. The team metaphor reinforces the nonmovable locus of authority vested in one who holds such office (for example, *captain*).

At the same time, the team metaphor created expectations of more equality among members based on competence to provide input. Each member becomes an authority on the basis of professional expertise instead of office, and should be in a position to provide leadership at such time as expertise indicates it. In ethical decisions regarding patient care, the question of authority must be viewed in terms of who should have the morally authoritative voice. Technical expertise does not automatically entail ethical expertise. In both types of decision-making situations, the locus of authority is movable.

Clarification of role identity and boundaries helps to create reasonable expectations and mitigate this type of conflict regarding locus of authority (and concomitant locus of accountability) regarding team decisions (Green). A further complication arises, however, because teams usually have several members. A critical question regarding such collective decision making is whether team decisions are the sum of individual members, with accountability allocated only to the individuals, or whether a team itself can be regarded as a moral agent (Pellegrino). Lively debate continues regarding this topic (Abramson; Newton; Green).

Sometimes teams have difficulty coming to consensus about the appropriate course of action. The moral responsibility of the team members is to assure that further role clarification, further attempts at consensus building, and other collective decision-making mechanisms are instrumental only to maximizing patient well-being (or any other appropriate goal of teamwork). Negotiation strategies must be built into the team process so that the authority of any one or several members, or even the team as a whole, does not govern at the cost of the competent, compassionate decision geared to the appropriate ends of that team's activities.

The Patient as Team Member

There is much discussion about whether and in what respect patients/clients and their families are members of healthcare teams. The doctrine of informed consent and its underlying legal and ethical underpinnings dictate that patients and families should have input into decisions affecting themselves and their loved ones. At the same time, much of the team's work proceeds without direct involvement of patients

and families. Some have argued that a primary care orientation places the patient as focus and arbiter of the care, and that present team practices fall short of that essential condition (Smith and Churchill). Others argue that conceptually a primary care approach is consistent with the goals of good teamwork (Barnard).

Moral Education for Teams

The team ideal provides a widely used model for effective and efficient patient care. Ethical issues are an inherent part of clinical decision making. In preparation for facing ethical issues the team can (1) develop a common moral language for discussion of the issues; (2) engage in cognitive and practical training in how to articulate feelings about pertinent ethical issues; (3) clarify values to uncover key interests among team members; (4) participate in common experiences upon which to base workable policies; and (5) refine a decision-making method for the team to use (Thomasma).

It appears that team approaches to a wide variety of healthcare issues and events will continue to develop and grow. The emergence of ethics committees as a type of team approach focusing explicitly on ethical decisions should help further in these deliberations.

TECHNOLOGY

• • •

I. HISTORY OF MEDICAL TECHNOLOGY

Medical technologies are objects, directed by procedures, that are applied against the hazards of illness. The object is

the tangible dimension of technology. The procedure is the focused and standardized plan that guides the use of the object according to defined purposes.

Some medical technologies are more object-embedded. In them the tangible portion is the principal functional component. The X ray, artificial kidney, and penicillin are examples. Others technologies are more procedure-embedded. Their main function is to organize facts, individuals, and/or other technologies. Examples are the medical record, hospital, and surgical procedures. Indeed, the common synonym for the surgical procedure, the operation, connotes actions that are related as parts in a series.

It is important to distinguish technologies from another medium through which actions are taken in medicine—techniques. Medical techniques are procedures mediated through the human senses rather than through objects. Examples are percussion, pulse-feeling, and psychoanalysis. This perspective on medical technology will be used in this entry.

Technology, Nature, and Ethics

The works of the Hippocratic corpus, a group of essays on medical theory and therapy written between the fifth and third centuries B.C.E., analyze the relation between nature and the agents of the medical art, from the viewpoints of effectiveness and ethics.

The ancient Greek concepts of health and illness were based on a theory postulating four humors or basic elements of the body: blood, phlegm, yellow bile, and black bile. In health, these were in a stable equilibrium. Illness occurred when one or more of these humors increased or decreased and thus changed their proportional relation. This change caused an instability of the equilibrium state synonymous with health, and the breakdown produced illness. Nature—the force that inclined the humors toward remaining in or returning to the proportional relations of the healthful state—was viewed as the most powerful agent of healing. The purpose of the medical art was to assist nature to reestablish the proportional relationship of health among the humors.

Works in the Hippocratic corpus cautioned physicians against misapplying medical means. Such behavior constituted an offense that could harm both the patient and the reputation of medicine. In the essay "The Art," the following observation is made:

> For in cases where we may have the mastery through the means afforded by a natural constitution or by an art, there we may be craftsmen, but nowhere else. Whenever therefore a man suffers from an ill which is too strong for the means at the disposal of medicine, he surely must not even expect that it can be overcome by medicine. (Hippocrates, 1923a, p. 203)

To exceed the rational limits of the means of medicine was to commit the sin of hubris.

The technology of Greek doctors was relatively simple. They used ointments, compresses, bandages, surgical instruments, simple and compound drugs, and bloodletting in moderation. They used the techniques of history taking, visual observation, and palpation to learn the circumstances of illness, and prescribed diets, bathing, and exercise to maintain health and combat illness.

The Greeks also recognized that the manner in which physicians dressed, approached the bedside, and discussed illness with a patient could influence their success at healing by producing help and avoiding harm, and thus had an ethical meaning. Accordingly, attention to the effects of the physician as a person on the patient as a person became a significant aspect of Greek medical practice. The physician is told "to have at his command a certain ready wit, as dourness is repulsive both to the healthy and the sick." When coming into the sickroom, doctors should consider their "manner of sitting, reserve, arrangement of dress, decisive utterance, brevity of speech." The doctor was to perform all duties "calmly and adroitly, concealing most things from the patient while you are attending him," lest such revelations cause the patient to take "a turn for the worse" (Hippocrates, 1923b, pp. 291–299).

The Hippocratic Greek physicians recognized that appropriate applications of technology required a searching analysis of its capabilities, of the ethical canons that should guide its use, and of the relation between technology and nature in treating patients. Consideration of these three factors was the significant contribution of Greek civilization to the use of medical technology.

Anatomy and Specialization

The content of the technologies used in medical practice did not change appreciably for two thousand years. Indeed, the Hippocratic works and other Greek texts, in Latin translations, formed the core of medical learning in Europe through the Middle Ages.

As the sixteenth century began, however, a growing interest in firsthand exploration of nature, and learning and questioning the authority of tradition, created what we call the Renaissance, generating a perspective that would eventually exert a profound influence on the development and use

of technology in medicine. Although the study of the structural composition of the body through anatomic dissection was thwarted by cultural, social, and religious constraints against dismemberment, Renaissance scientific and artistic interest in the body's physical makeup overcame these restrictions and encouraged its exploration.

The leading figure in this movement was Andreas Vesalius, a physician and professor at Padua, who in 1543 published *De humani corporis fabrica.* In it the structure of the body was analyzed in detail and portrayed through illustrations that were far in advance of any previous work. Its illustrations, the work of a still unknown Renaissance artist, were startling in their beauty and detail. In contrast, the typical anatomical illustrations of the day were inaccurate and crude outlines, with organs drawn in more as symbols than as representations. Vesalius corrected over two hundred errors in the work that had been the standard, authoritative text in use for almost fifteen hundred years. Written by the Greek doctor Galen in the second century, it reflected typical restrictions on human dissection, for its content was based on animal dissection (mainly pigs and apes) extrapolated to human structure.

Vesalius' book, devoted to the normal anatomy of the body, fostered within medicine an interest in bodily structure, particularly in the changes it underwent when attacked by illness. During the next two hundred years, physicians examined bodies and wrote texts commenting on the pathological transformation of anatomic structure. These efforts were brought together in a 1761 text by the Italian physician Giovanni Battista Morgagni, *The Seats and Causes of Diseases Investigated by Anatomy.* The work's principal objective was to demonstrate that the symptoms of illness in the living were determined by the structural changes produced within the body by disease. Morgagni demonstrated this relation through a tripartite analysis of cases. Typically, he began by reporting on the clinical course of an illness experienced by a patient who eventually died. This was followed by the autopsy findings. Then came a synthetic commentary in which he connected clinical and autopsy results.

Morgagni asserted that through anatomic examination, particular diseases could be recognized by their telltale footprints on the landscape of the body. As the title of Morgagni's work suggests, the author believed that diseases had "seats" in the body, and that they were expressed through characteristic disruptions of the body's fabric in discernible sites. This perspective ran directly counter to that prevailing under the humoral theory of illness, dominant since Hippocratic times.

Anatomy, beginning in the sixteenth century, when it departed from this whole-body perspective, focused the doctor's vision on the search for sites in the body where a change in structure had occurred. The leading question for anatomists and the physicians who adopted their outlook was *Where is the disease?* This question and viewpoint paved the way for the modern specialization of medicine, beginning in the nineteenth century and undergirded by a new technology. It justified a retreat by the doctor from patients as individuals to aspects of their anatomy, giving rise to the practice of having different physicians for the eyes, heart, kidneys, and other organs and organ systems.

Technology and the Nineteenth Century

With the anatomic ideology firmly established, the nineteenth century became one of the great centuries for medicine, a time of significant advance and change fueled largely by technologic innovation.

The transformation of diagnosis by technology was one of the century's most important features. The symbol and initiator of this change was a simple instrument used to enhance the conduction of sound, the stethoscope. Its transforming effect was as much caused by the new relationship it generated between physicians and patients as by the new information it provided. Before the stethoscope, the evidence that physicians acquired about illness came mostly from two sources: the visual inspection of the motions and surface of the body, and the story told by the patient of the events, sensations, and feelings that accompanied the illness. It was this encounter with the life of the patient that was at once enlightening, troubling, and engaging for physicians.

The patient's story provided significant diagnostic evidence that often determined the doctor's judgment. But physicians expressed concern about the authenticity of this evidence, which usually could not be confirmed. Who could know if a patient really heard a buzzing in the ears? Diagnosis was prone to the distortions of memory and whim. For all of its evidentiary faults, however, the narrative of the patient's journey through illness connected the doctor with the life of the patient.

The stethoscope challenged the place of the narrative of illness. It was introduced into practice through 1819 treatise (*De l'auscultation médiate*), written by the inventor of the stethoscope, the French physician René Laennec. Laennec claimed that physicians who placed their ear to one end of the foot-long wooden tube that was the first stethoscope and the other end to the chest of a patient, would hear sounds generated by the heart and lungs indicative of health or disease within them. He demonstrated through autopsy evidence that a particular sound perceived in the chest

corresponded to a particular lesion within its anatomic structure. He asserted that his technology enabled physicians to diagnose illness not only precisely but often without the help of other symptoms. Doctors need depend on no one else. They could be scientifically self-reliant. The findings of their own senses, extended by a simple instrument, were adequate to reach diagnostic judgments.

This technological advance reduced the significance of the patient's narrative. Why should physicians painstakingly acquire this story and its subjective and unverifiable verbal evidence, if they could use more objective sonic evidence they gathered themselves? With the stethoscope, physicians stepped back from the lives of patients. They began to engage patients through the anatomic and physiologic signs detected by their instruments.

Other simple technologies to extend the doctor's senses into the body, such as the ophthalmoscope (1850), the clinical thermometer (1867), and the sphygmomanometer (1896), were introduced during the nineteenth century. By the century's end physicians had become skillful diagnosticians, seekers of physical clues they used to deduce the source of their patients' troubles. The doctor's black bag contained the technologies to explore the body physically and to obtain evidence that greatly improved diagnostic accuracy. It was, in fact, through witnessing great skill in the analysis of physical evidence by one of his instructors, Joseph Bell, that a physician-in-training, Arthur Conan Doyle, was led to create the fictional character Sherlock Holmes.

Still, therapy remained limited. In the 1860 address to the Massachusetts Medical Society, Oliver Wendell Holmes, Harvard professor of anatomy, proclaimed: "I firmly believe that if the whole materia medica, *as now used,* could be sunk to the bottom of the sea, it would be all the better for mankind,—and all the worse for the fishes" (Holmes, p. 203).

The only major bright spot to emerge in the nineteenth century on the therapeutic side of medicine was in surgery. Radical change in the ability of surgeons to perform the dangerous and delicate work of cutting into the body occurred through two separate innovations, one introduced in 1846 and the other in 1867. At the beginning of the nineteenth century, pain had become so inseparably linked with surgical incision that several reports of an anesthetic effect produced by nitrous oxide and ether were disregarded by practitioners. Surgical pain was dealt with by efforts to shorten its presence. Techniques of rapid surgery were developed, with some surgeons capable of detaching a limb in minutes. The conclusive demonstration (in a surgical procedure for a tumor of the neck) at the Massachusetts General Hospital in 1846 of the ability to control operative pain through use of ether, was made by the American Dentist William Morton, who administered the ether. It ameliorated the trauma of surgery for patient and surgeon alike, but cutting into the cavity of the body still was limited by infection.

To control infection, insight was needed into the causal role of bacteria. Joseph Lister, a British surgeon, wrote a paper in 1867 in which he described eleven operations on compound fractures of the limbs in which nine patients recovered without amputation, one required it, and one died. These startling results were made possible by treating the operating space—wound, instruments, surgeon's hands, and air—with the antiseptic carbolic acid. In 1882, the German scientist Robert Koch published a paper that proved through rigorous experiments the causal link between the tubercle bacillus and tuberculosis—a disease that at the time was responsible for about one out of seven deaths in Europe. This essay established the pivotal role played by bacteria in infection. It not only gave further impetus to the practice of antiseptic surgery and liberated surgeons, no longer thwarted by pain or infection, to perform extensive operations within the body cavity. It also produced a new workshop for surgery and all of medicine—the hospital.

The Technologies of Twentieth-Century Medicine

The origins of the hospital reside in military hospitals put up by Roman soldiers on their routes of march, and hospices established early in the history of Christianity to care for the homeless, travelers, orphans, the hungry, and the sick. These multiple activities gradually became divided among separate institutions, one of which was the hospital. It flourished greatly through the medieval period but began a decline afterward, due to diminished church support of its activities.

By the nineteenth century the hospital's medical role was restricted. It was a place for those who could not afford either to call a physician or surgeon to the house for treatment or to employ servants to administer needed bedside care at home. There were two kinds of medicine: home care for the well-to-do and hospital care for the indigent. Hospitals were dangerous places. Infections could rage through them, killing large numbers of patients and making work there dangerous for staff. Hospitals were also feared for the moral dangers said to be posed to women and children by the rough patients they housed.

New technologies transformed the hospital medically and socially. Surgery could no longer be done on kitchen tables at home: it required an antiseptic environment,

sterilized instruments, and a staff of skilled nurses for the aftercare of patients undergoing more extensive procedures than were possible in the past.

As the twentieth century dawned, diagnosis and therapy of nonsurgical disease could not be readily done in the home with technology carried in a doctor's bag. diagnostic technology now entered a new phase of development. The simple instruments to extend the senses of the physicians were being replaced by sensing machines too large and expensive to be housed anywhere but in hospitals.

This new technology automatically recorded the data of illness, leaving the reading of its results to the doctor. The X ray, discovered in 1895; the ward laboratory, with its microscopes and chemical tests of the body fluids, which came together as a hospital space in the early 1900s; and the electrocardiograph, introduced in 1906, all converted medical diagnosis from a personal act to a scientific event. The physician leaning over the bedside, at least physically connected to the patient through the stethoscope and similar technologies, became an increasingly anachronistic image as the twentieth century wore on. The physician holding an X ray up to light, studying it, was more in keeping with physicians' growing self-image as scientists. Where was the patient? There was less need for personal medical encounters; the best evidence available to medicine was increasingly not what the patient said, nor what the physician sensed, but what the pictorial or graphic image reported.

As it entered this new technologic phase, medicine required a location within which patients, the increasingly specialized medical staff, and technology could be brought together. The hospital became that place. Its success was dramatic. While there were about four hundred hospitals in the United States in 1875, by 1909 the number grew to over four thousand, and by 1929 surpassed six thousand. No longer shunned but sought by communities, the hospital became the workshop of medicine. By the mid-twentieth century not only patients and technology but also doctors' offices were placed in hospitals. Home care and the house call, no longer adequate as means to apply new medical knowledge, were disappearing as the hospital, perhaps the quintessential technology of the twentieth century to organize medical care, enfolded medicine.

Several other innovations critical to the functions of hospitals and medicine were in place by the mid-twentieth century. One—having integrative influence like the hospital—was the technology of organizing the data of medicine—the medical record. It was fundamentally reformed in the 1920s by the work of the American College of Surgeons (Reiser, 1991). In an era of growing specialization, not only among physicians but also among nurses and the technical experts needed to run the hospital and its machines (there were over two hundred separate healthcare specializations by the mid 1970s), communication was of great importance. How to learn what each had done? Through the record, which was the main agent of synthesis in medicine. In its pages the thoughts and actions of a diverse staff were recorded.

But for all its integrative significance, the medical record remains a problem. It shows the results of the information explosion. These data literally burst the confines of the chart. Hundred-page records abound. They contain the details of medical care, but their order often makes following the course of an illness, or locating a particular bit of information, difficult and frustrating. Innovations such as the unit record (having all hospital encounters of a patient recorded in a single place rather than dispersed through separate charts in each clinic); the problem-oriented record (ordering medical data problems—physical, psychologic, or social—rather than by data source, such as putting laboratory data in one place, X-ray data in another); and the computerized record have yet to solve the problem of what to do with the avalanche of technologic evidence.

Another critical innovation available by mid-century was antibiotics. The mass production of penicillin in 1944 (it had been discovered by Alexander Fleming in 1928) inaugurated the antibiotic era in medicine. Antibiotic drugs flowed from the laboratories of the pharmaceutical industry, finally breaking the hold of bacterial illness. Penicillin was called a wonder drug when it was introduced. Given the drug, a patient gravely ill with meningitis or pneumonia would be up and about and home in a week. Not only was it fast-acting and fully curative, but it was safe and cheap. It was commonly thought that penicillin would be the first innovation of a pharmaceutical revolution to produce not only antibacterial drugs but also drugs to deal as effectively with other human ailments. However, the symbol of medicine in the second half of the twentieth century would not be penicillin but a machine that made its debut in the mid-1950s.

The artificial respirator had a long history, dating back to the mid-nineteenth century, when rudimentary forerunners were fashioned to deal mainly with the respiratory crisis of drowning. A tank respirator introduced by Philip Drinker and Charles McKhann in 1929, which used negative-pressure techniques to secure respiration, became the "iron lung" that sustained victims of poliomyelitis. Its effectiveness was variable, and its use was complicated. But by the mid-1950s, using new machines based on positive-pressure technology, clinicians had a far better means of dealing with diseases and accidents that threatened lives through respiratory failure.

Initially, this machine was intended to assist critically ill persons by temporarily sustaining a vital physiologic function and giving them time to recover. For the first time in medical history, physicians acquired a technology that, allied to other advances in nursing, monitoring, and drug therapy, and all brought together by an integrative technique of care embodied in the intensive care unit (ICU), permitted the long-term sustenance of desperately ill people who had no chance of recovery. Now families and medical staff waited by ICU beds, where the main signs of life were not manifest in the expressions or movements of the patient but in the mechanical sounds, motions, and readouts of the new machinery of rescue.

Ethical Issues in Applying Medical Technologies

As families and medical staff assimilated the consequences of the life-support technology represented by the artificial respirator that could prolong dying or life without cognition, they reached out to the ethical traditions of religion, medicine, and society for help (Pius XII, pp. 501–504). Physicians particularly began to see that the ethical problems to be solved in these crises were as great as or greater than the technical problems of treatment. How to decide whether in a hopeless case to remove the technology that maintained the person's life? On what values should this judgment be based, and who should decide?

Other machines developed in this period posed a similar mix of ethical and technical issues. The artificial kidney was created as a device for acute, intermittent dialysis by Willem Kolff in The Netherlands in 1944. However, it was introduced as a clinically usable machine in the early 1960s in Seattle, Washington, by Belding Schribner. He added an arteriovenous shunt that allowed long-term access to it and made continuing hemodialysis possible. The limited number of machines and personnel to run them led to moral agonizing over developing criteria for selection. Someone had to choose which of the thousands of individuals in the United States having chronic renal failure and able to benefit from dialysis would gain access to a technology that could save their lives. Thirteen years after the machine's introduction, American society decided how to resolve this crisis. In 1973, U.S. congressional legislation provided funds to provide dialysis to all who required it.

Technologies such as the artificial kidney and the respirator have been criticized as offering expensive but partial solutions to fundamental problems of biologic breakdown. The American physician Lewis Thomas calls them "halfway technologies," because they represent only a partial (halfway) understanding of a biologic puzzle that, once solved, will do away with the expense and the disadvantages of such therapies (Thomas, p. 37).

The extraordinary and growing expense of the healthcare system that followed the development of such technologies may be reduced when biomedical research produces comprehensive biologic answers to problems such as organ failure. But in the twentieth century, we have acquired few such complete technologies. One group, already mentioned, is penicillin and other antibiotics, which offer total solutions, that also are inexpensive and rapidly acting, to the problems of bacterial infection. A second generic complete technology is the vaccine. Those invented to prevent smallpox (first introduced in the eighteenth century) and poliomyelitis (developed in the mid-1950s) have in the twentieth century eradicated the first disease and almost wholly contained the second.

The emerging field of genetic research promises fundamental solutions to a host of disorders, with the prospect of their early detection and correction. Finally, the growing ability to visualize the basic structures of the body through endoscopes and computer-driven imaging machines such as the MRI and PET scans provides diagnostic knowledge facilitating the use of therapeutic technologies that promise complete cures. Indeed, genetic and imaging technologies have taken the anatomic concept of illness to its ultimate terminus. To the question "Where is the disease?" the answer now can be "In this particular gene!"

Conclusion

Technologies, history shows, can be imperative: We may be impelled to use the capacities they provide us without adequate reflection on whether they will lead to the humane goals of medical care. The ancient Greeks understood this issue. They recognized that technologic means must be used in consonance with articulated, ethically informed ends. Their example remains worth following.

II. PHILOSOPHY OF MEDICAL TECHNOLOGY

Philosophy of technology aspires to comprehensive reflection on the making and using of artifacts. Medicine is increasingly defined not just by the character of its human interactions (physician—patient relationships) or professional expertise (knowledge of illness and related therapies) or its end (health), but also by the type and character of its instruments (from stethoscope to high-tech imaging devices) and the construction of special human-artifact interactions (synthetic drugs, prosthetic devices). Indeed, the physician-patient relationship, medical knowledge, and the concept of health are all affected by technological change. There is even debate about whether the term *artifact* should include nonmaterial as well as material human constructions, in which case all of the above might well be interpreted as technologies. From either perspective, medicine and the issues of bioethics fall within the purview of the philosophy of technology.

Historical Development

Philosophy of technology as a distinct discipline originated with the publication of Ernst Kapp's *Grundlinien einer Philosophie der Technik* (1877), the first book to be entitled a "philosophy of technology." A left-wing Hegelian contemporary of Karl Marx, whose thought includes important analyses of human-machine systems, Kapp left Germany in the mid-1800s to become a pioneer and "hydrotherapist" on the central Texas frontier. Returning to Europe two decades later, he elaborated a general theory of technology as "organ projection"—from the hammer as extension of the fist to railway and telegraph as extensions of the circulatory and nervous systems—thereby promoting analysis of the philosophical-anthropological foundations of technology.

Another major formative figure was Friedrich Dessauer, whose *Philosophie der Technik* (1927) and *Streit um die Technik* (1956) reflect his experience as the inventor of deep penetration X-ray therapy. For Dessauer the philosophical core of technology is the act of invention, for which he sought to provide a Kantian analysis of transcendental preconditions. Dessauer's argument that the fact inventions work shows how inventors depend on insight into a supernatural realm of "pre-established solutions" to technical problems raises basic epistemological and metaphysical issues.

José Ortega y Gasset and Martin Heidegger, two major philosophers of the twentieth century, also contributed texts

dedicated to the theme of technology. Ortega's "Meditación de la técnica" (1939) presents technical activity as a means for realizing some supernatural human self-conception, and modern technology as generalized knowledge of how to create such means. Ortega thus pushes anthropological reflection to new depths. Heidegger's "Die Frage nach der Technik" (1954) argues that both traditional technics or craft and modern technology are forms of truth, revealing different aspects of Being. Modern technology in particular is a "challenging" and "setting-upon" that reveals Being as "resource"—that is, the world as a reservoir of materials subject to indefinite human manipulations. In this argument Heidegger likewise carries epistemological and metaphysical reflection well beyond Kantian terms.

Lewis Mumford, Jacques Ellul, Herbert Marcuse, Jürgen Habermas, and Michel Foucault have made further contributions to the development of philosophy of technology from the perspective of social theory. Mumford (1934) focuses attention on technological materials and processes as major elements in the historical development of modern civilization. Ellul (1954) argues that the pursuit of technical efficiency is the defining characteristic of the contemporary world, which constitutes a milieu distinct from the natural and social milieus that preceded it. For Ellul, just as the Hebrew-Christian tradition once demythologized the two earlier milieus, now it called upon to demythologize technology.

Marcuse (1964) and Habermas (1968) have debated the character of technology as ideology. Foucault (1988) views all technologies and sciences as masking power manipulations, and develops a special analysis of technologies as historical transformations and determinations of the self. Such ideas exercise continuing influence in debates over the extent to which technology is properly conceived as an autonomous determinant of human affairs (see Winner, 1986) or as a social construction (see Feenberg). Such debates in turn influence fundamental orientations with regard to practical questions about the assessment and control of technology that find expression in such applied fields as medical ethics, environmental ethics, engineering ethics, and computer ethics.

Ortega and Heidegger are leading figures in the Continental or phenomenological tradition in the philosophy of technology. Further analyses of phenomenological inspiration can be found in the work of Don Ihde (1979) on human-technics interactions and of Albert Borgmann (1984) on the political-cultural implications of contemporary technological formations.

A different, equally strong tradition in the philosophy of technology is constituted by Anglo-American analytic reflection on artificial intelligence (AI). Here questions center on the extent to which brains are computers and thinking processes can be modeled (see, e.g., Simon; Dreyfus). In contrast to the phenomenological tradition, the Anglo-American analysis of AI exhibits considerable interactions with biomedical theory of neurological processes and, to a lesser extent, with biomedical practice.

Theoretical Perspectives

Throughout its diverse strands, philosophy of technology, like philosophy generally, includes theoretical and practical issues, from epistemology and metaphysics to ethics and politics, all of which can helpfully inform bioethics. Comprehensive understanding nevertheless grows out of partial understandings. The making and using of artifacts involve not only the artifacts themselves but also technological knowledge, technological activity, and technological volition. Theoretical analyses can thus conveniently be described by referencing tendencies to interpret technology in one of four primary forms.

TECHNOLOGY AS OBJECT. The theory that identifies technology with particular artifacts, such as tools, machines, electronic devices, or consumer products, is the commonsense view. Initially it involves a classification of artifacts into different types, according to their own internal structures, different kinds of human engagement, impacts on the environment, or other factors. Mumford, for instance, distinguishes utilities (roads, electric power networks), tools (artifacts under immediate human power and guidance), machines (nonhuman power with immediate human guidance), and automatons (nonhuman power and no immediate human guidance).

Taking a different tack, Borgmann argues a distinction between things and devices. An example of a thing, in Borgmann's special sense, is a traditional fireplace, which engages a variety of human activities ranging from cutting wood to cooking food, functions in a clearly understandable manner, and is an explicit center of daily life. By contrast, a device, such as a heat pump, simply makes available some commodity (hot and cold air) by nonobvious processes and disappears into a background of quotidian activities. The device is a special instance of what Heidegger called a "resource."

Ihde, in a different but equally provocative manner, distinguishes embodiment and hermeneutic relations between humans and their instruments. Embodiment relations experience the world through instruments, as exemplified by eyeglasses, which disappear into and become an unconscious part of the experience of seeing. In hermeneutic

relations, by contrast, the instrument itself—for instance, a camera—becomes part of the world with which one engages; a user consciously focuses on the operation and interpretation of this instrument. Both Borgmann's and Ihde's distinctions obviously provide frameworks within which to interpret the myriad tools and instruments of high-technology medicine.

TECHNOLOGY AS KNOWLEDGE. Etymologically, however, the word *technology* implies not objects but "knowledge of techne," or craft skill. Epistemological analyses of such knowledge distinguish between knowing how (intuitive skill) and knowing that (propositional knowledge). The transition from premodern technics to modern technology can thus be argued as defined by the development of propositional knowledge about techne through the unification of technics and science.

This theory of modern technology as applied science is particularly influential among scientists and engineers, and has been given detailed philosophical exposition by Mario Bunge (1967). For Bunge, modern technology develops when the rules of prescientific crafts, originally discovered by trial-and-error methods, are replaced by the "grounded rules" or technological theories. Technological theories can be formulated by applying either the content or the method of science to technical practices. The former application takes preexisting scientific knowledge (e.g., fluid dynamics) and adapts it under certain boundary conditions to formulate an engineering science (aerodynamics). The latter uses the methods of science to formulate distinctive engineering analyses of human-machine interactions, such as operations research and decision theory.

Medicine can readily be incorporated within such an epistemological analysis. Prior to the nineteenth century, most medical practice relied on rule-of-thumb experience. But twentieth-century medicine has involved the progressive grounding of medical practice in the sciences of anatomy and physiology as well as the development of such distinctive fields as epidemiology and biomedical engineering. Indeed, José Sanmartín (1987), for instance, analyzes genetic engineering exactly as an embedding of techniques in scientific theory.

TECHNOLOGY AS ACTIVITY. The transformation of some technics (such as medicine) into an applied science is not, however, simply an epistemic event. As Foucault (1963) argues, for example, modern medicine "is made possible as a form of knowledge" by the reorganization of hospitals and new kinds of medical practices. This emphasis on technology as activity or a complex of activities is characteristic of social theory. Ellul's "characterology of technique" and analysis of the central role played by the rational pursuit of technical efficiency in the economy, the state, and what he terms "human techniques" (ranging from education to medicine) is another case in point, as are the Marxist and neo-Marxist analyses of Marcuse, Habermas, and Andrew Feenberg.

The emphasis on technology as activity has roots in Max Weber's observation that there are techniques of every conceivable human activity—from artistic production and performance to mass manufacturing and bureaucratic organization—even education, politics, and religion. One classic problem for social theorists is to explain the character and limits of *technicalization*—that is, the movement from traditional societies, in which techniques are situated within and delimited by nontechnical values, to modern societies, in which techniques are increasingly evaluated solely in technical terms. In traditional societies, for example, animals can be eaten only if butchered in a ritually prescribed manner; in modern societies animal slaughter is largely subject to calculations of efficiency.

Efficiency can also be conceived in economic terms and applied at micro or macro levels. The former is typical of analyses internal to business corporations (including hospitals and clinics); the latter, of social assessments of technology. In regard to technology assessments especially, there arise questions of the limits of technicalization and possible alternative forms of technical institutions (see Feenberg), as well as of responsible agency and risk.

TECHNOLOGY AS VOLITION. A fourth element in the interrelationship of knowledge, object, and activity is that of volition. The human activity of making and using artifacts depends not only on knowledge but also on volition. Indeed, it can be argued that volition is even more important in this respect than knowledge, that is, that human action can be ignorant but not unwilled.

The philosophical analysis of volition distinguishes between volition in the weaker senses of wishing, hoping, longing, and desiring, and the stronger or more decisive intending and affirming. Volition in the second or stronger senses is constituted by self-reflective identification with some particular wish, hope, or desire that takes on the character of a project. Ortega, Mumford, and Frederick Ferré (1988) argue that technology is essentially a matter of volition in one or more of these senses. According to Ferré, for instance, technology is grounded in "the urge to live and to thrive." For Ortega, technology is based in the willed attempt at a worldly realization of some specific self-image. For Mumford, technology in a distinctive sense emerges when human beings subordinate their traditional

polytechnical activities of craft, religious ritual, and poetry to the monotechnical pursuit of physical power—something that first happened about five thousand years ago in Egypt, with the construction of the pyramids by means of large, rigid, hierarchical social organizations that he terms "megamachines."

Defining technology in terms of volition makes possible the perception of broad historical continuities more than does a focus on the elements of knowledge or object or even activity. It is inherently more believable that the *will* to fly was coeval with human existence than that technical knowledge of how to fly, flying machines, or the human performance of flying or flying-like actions have existed from time immemorial. Such an approach once again has immediate implications for the interpretation of medicine. If medicine is interpreted primarily as grounded in volition, then it is inherently more believable that there exists a fundamental continuity between premodern and modern medicines.

Nevertheless, one of the most sustained critiques of modern medicine is precisely that as volition, it is fundamentally different from all previous kinds of medicine. Ivan Illich's *Medical Nemesis* (1976) argues that modern medicine arises from a basic "social commitment to provide all citizens with almost unlimited outputs." Indeed, the nemesis of rising iatrogenic disease is a direct result of "our contemporary hygienic hubris," which can be reversed only "through a recovery of the will to self-care." In the 1990s, however, Illich becomes critical of the idea of self-care when it serves as an ideological support for what has been termed "health fascism."

Practical Perspectives

Not theoretical analysis, however, but ethical and political concerns predominate in philosophy of technology. Ethics has from its beginnings in the West involved at least marginal considerations of technology. Aristotle's *Nicomachean Ethics,* for instance, in passing identifies *techne* as an intellectual virtue. More than two thousand years later Immanuel Kant distinguished moral and technical imperatives. But in line with such marginal attention, from Plato and Aristotle to the Renaissance, technology was widely accepted as properly subject to ethical constraints. From the Renaissance to the Enlightenment, by contrast, traditional restraints were effectively replaced with an ethical commitment to the unfettered pursuit of technology for what Francis Bacon called "the relief of man's estate." It is precisely this modern commitment, along with its subsequent questioning in response to a series of increasingly prominent problems, that frames the contemporary prominence of ethical issues in the philosophy of technology.

ALIENATION. Historically, the first problem of modern technology involved the industrial revolution and alienation. At the basis of modern technological making lies a belief that the world as it is given does not provide a suitable home for human beings; humanity must construct a home for itself. The problem is that human beings do not immediately find themselves at home in the worlds they technologically create. The resulting alienation is especially problematic to the extent that it is grounded in attempts to overcome alienation.

The two most extensive critiques of technological alienation are Romanticism and socialism. The Romantic critique, an early version of which appears in Jean-Jacques Rousseau's *Discourse on the Sciences and the Arts* (1750), focuses on how technology alienates the individual from feelings and sentiments, as manifested in relationships with nature, the past, or other human beings. This is caused, according to the Romantic argument, by a one-sided development of rationality. Romanticism thus perceives technology as an extension of reason and proposes to enclose it within a larger affective life.

By contrast, in the socialist critique of alienation, Marx, like Kapp, explicitly conceives technology as a human organ projection. Marx thus focuses on the separation of human beings from control over the tools and products of their labor, as manifested in an economy based on money and the "fetishism of commodities." In response, socialism argues for a comprehensive restructuring of society to promote worker control of the means of production.

In biomedical practice the use of technological instruments and rationalized systems of diagnosis raises the issue of alienation in the form of questions about the depersonalization of healthcare techniques and organizations. Responses can exhibit characteristically Romantic or socialist features. Exemplifying Romanticism are proposals to situate diagnostic techniques within a more humanistic framework, perhaps one of beautiful buildings and a pleasant environment. Exemplifying a socialist response might be arguments for the promotion of patient autonomy by granting patients more direct control over their own healthcare institutions.

WARFARE. A second ethical problem has centered on technology and war. There are two basic theories about the relationship between war and technology: First, technological weapons make war so horrible that it becomes unthinkable; rational self-interest leads to deterrence of their use. Second, human beings will always tend to miscalculate their self-interests and go to war; weapons production must therefore be limited, and a higher ideal of global human unity promoted.

Prior to World War I, naive versions of the first theory largely supported the pursuit of technology. The trauma of the war contributed to pessimistic criticisms of technological civilization and led to emphasis on the second theory. This pessimistic critique, coupled with idealist attempts at world government, failed to avoid World War II and a technological practice of genocide, the invention and use of the atomic bomb, and a subsequent Cold War spread of nuclear weapons. As a result, much more sophisticated versions of deterrence policy were developed in alliance with management and decision theories. Advanced technological weapons development projects also stimulated science and technology policy and management studies, while the practice of nuclear deterrence was subject to extended moral criticism. One of the more idealistic criticisms argues that human unity and peace, which in the past could remain as moral exhortations, have now become necessities, lest human beings obliterate themselves from the face of the planet. In this argument the rational self-interest of the first theory appears to merge with the idealism of the second.

Prospects for social and genetic engineering call forth similar arguments between pragmatic deterrence management and idealistic delimination. The progressive refinements of conditioning techniques and sophisticated drug therapies create behavior-control technologies of immense potential power. Developments in recombinant DNA technology and the Human Genome Project offer opportunities to extend this power to the biological creation of human life. As Sanmartín has pointed out, this attack on the vagaries of human nature can be seen as developing new technologies for the prevention of "social diseases" such as war.

TECHNOLOGY AND SOCIAL CHANGE. Concerns about the relatively specific issues of alienation and warfare have been complemented by more general analyses of the causal relations and patterns of interaction that obtain between technology and social change. Such analyses include bottom-up case studies of changes related to bureaucracy, urbanization, work (from mass production to automation to customized production), leisure and mobility, secularization, communications (from telephone and radio to television and computer), and medical technologies, as well as top-down theoretical reflections on the same dimensions of social life and on the social order as a whole. Within both approaches it is common to find descriptions of disorder between technology and society brought about by technological change along with arguments for addressing such disorder by means of some intellectual and/or volitional adaptations.

In the period between the two world wars, for instance, William F. Ogburn's *Social Change* (1922) described a "cultural lag" between technological development and social adaptation across a variety of indicators, and argued for a more intelligent appropriation of technology. A decade later Henri Bergson's *Two Sources of Morality and Religion* (1932) argued that the vices of industrial civilization as a whole could be corrected only by what he termed a "supplement of soul" that is at once ascetic (against luxuries) and charitable (for eliminating inequalities).

To stress the need for intellectual or rational adaptations is no doubt more characteristic of advanced industrial society, with its concomitant large-scale educational institutions and activities. The kind of piecemeal social engineering advocated by John Dewey and Karl Popper, and the many theories of economic rationality from Pareto efficiency to risk-benefit analysis, and of postindustrial organization from Daniel Bell to Habermas, likewise advocate effective increases in the rational control of modern technology. By contrast, a follower of Bergson such as Ellul argues that technology has become a kind of totalitarian milieu that requires comprehensive demythologizing. Others suggest the need for expansions of affective sensibility. Some theories of postmodern culture exhibit certain affinities with this approach.

With regard to increasing rationality, Kristin Shrader-Frechette (1991) has drawn an explicit parallel between the requirements of informed consent in the practice of medically risky procedures and the general societal adaptation to technological change. With regard to affective responses to technological change, the work of Illich is illustrative.

POLLUTION AND THE ENVIRONMENTAL CRISIS. Perhaps even more demanding of attention than warfare, and adding a new dimension to analyses of technological change, are problems associated with environmental pollution and global climate transformation. The environmental crisis has obvious and fundamental impacts on human health and safety, and thereby on biomedicine. Indeed, outside medical ethics, perhaps the single most intensively explored area of applied philosophy is that of environmental ethics.

Beyond intensified self-interest, environmental change has engendered the new science of ecology and extended ethical concern both temporally (for future generations) and ontologically (for nonhuman entities). As analyzed by Hans Jonas (1979), this extension is grounded in "the altered nature of human action" brought about by the "novel powers" of modern technology. Although all human life requires some technical activity, not until the advent of modern scientific technology did the technical power to create become so explosive as to be capable of fundamentally transforming nature and the future of the human condition. On the basis of this power there arises what Jonas terms an "imperative of responsibility" to "ensure a future."

Jonas explicitly argues the application of this principle of responsibility in the field of bioethics. Applications might also be adumbrated for other discussions in environmental ethics, such as those that distinguish shallow versus deep ecology movements and argue the rights of nature understood as wilderness. Could one not, for instance, distinguish a shallow versus a deep bioethics? Would it not be possible to argue, against excessive medical intervention, a defense of wildness in biology?

ENGINEERING ETHICS. A second well-developed field of applied ethics with potential implications for the medical dimensions of bioethics is that of engineering ethics (see Martin and Schinzinger). Here a basic shift has taken place in the interpretation of the primary responsibility of the professional engineer—from loyalty to a company or client (patterned after the ethics of the medical and legal professions) to responsibility to public health, safety, and welfare. Could this shift, resting on a recognition of engineering as social experimentation, have implications for new understandings of professional medical obligation? Is it not the case that technological medicine is, as much as the treatment of individual patients, to some extent a social experiment? If so, then the engineering ethics defense of the rights and role of the whistle-blower might well have analogous applications in the biomedical field.

COMPUTERS AND INFORMATION TECHNOLOGY. A third well-developed area of applied ethics deals with computers. One defining book in this field was written by a computer scientist (see Weizenbaum) and based on Mumford's philosophical anthropology of the human as a polyvalent being for whom calculating is only a very small part of thinking and a limited dimension of technics. Key issues in the philosophical analysis of computers concern the degree to which human thinking can be modeled by computers and the extent to which human beings should properly rely on computer programs, especially in areas such as weapons. Subsequent development, as summarized by Deborah Johnson (1985), has emphasized issues of individual privacy and corporate security, the formulation of ethical codes for computer professionals, and liabilities for the malfunctioning of computer programs. The computerization of medical practice calls for the application of such reflection to many aspects of high-tech medical diagnosis and treatment.

DEVELOPMENT AND DIVERSITY. The ambiguities of technology in developing countries, together with reassessments of the impacts of advanced technological transformations in relation to women and ethnic minorities, especially in the United States and Europe, raise new issues regarding the abilities of scientific technology to accommodate true diversity. On the one side, there are questions of equity. In advanced technological countries, technological power and affluence are not equally shared between men and women and among different ethnic communities. Nor does there appear to be equality of opportunity among advanced and developing countries. On the other side, technological development tends to set up national and international economic orders that homogenize personal and world cultures. Distinctions among markets and ways of life are subsumed within the financial structures of transnational corporations and global communications systems. This paradox of inequity and homogenization poses a fundamental challenge to both reflection and action.

Attempts to address this challenge can be found in the alternative technology movement, arguments regarding the ethics and politics of development, and in diverse feminist contributions to the philosophy of technology (as collected, for instance, in Rothschild). Feminist critiques of technology, for instance, emphasize both the need for equity and the threats of homogenization. Technologies of the workplace are to a large extent sexually differentiated; those of the home are designed and used in ways that confirm masculine and feminine roles. But technological culture creates images of androgynous liberation while medical procedures diminish the experiences of gendered bodies. In the face of this paradox, what some feminists argue is the need for a new theory and practice of technology itself, a truly alternative technology, one that transforms both its masculine biases and its characteristically modern commitments. The ideals and pursuit of alternative medicines can be interpreted as concrete attempts to achieve such a goal.

Conclusion

Successive technological problems have provoked a series of ethical analyses and moral responses. Reflections on these problems and their emerging responses, because they have been focused on a particular technology, have tended to remain isolated from each other and untested by generalization. Philosophies of technology that have attempted to bridge such particularities, and that include a substantial role for bioethics, can be found in the work of Jonas, Sanmartín, Gilbert Hottois (1990), and Friedrich Rapp (1990).

Complementing such work, problems addressed by the varied discussions of practice have been approached from within a variety of ethical frameworks, among which are natural-law theory, deontologism, and consequentialism. With natural-law theory, one tends to assess technological

change in terms of its harmony with some given lawful order perceived in nature. With deontological theory the emphasis is on evaluating the rightfulness and wrongfulness of technological change in accord with some inner criteria of the action. With consequentialism there is an effort to look to the goodness or badness of future results that flow from some particular technology. Each such ethical framework can exhibit selective affinities with different basic theoretical conceptions of technology.

Environmental ethics, for instance, tends to be distinguished by criticisms of technologies that do not harmonize with preexisting natural order. The emphasis here is easily placed on human activity, with nonhuman realities taking on special moral significance. Computer ethics, by contrast, tends to put forth deontological principles about the wrongness, for instance, of the invasion of privacy. Such an ethics emphasizes human intention or volition with respect to technology. Finally, technology policy studies are likely to stress the evaluation of technologies in terms of results, and thus to call attention to the physical consequences of technological decisions. Here the issue of risk becomes a special challenge to the accepted cost-benefit calculus typical of consequentialist analysis.

The suggestive character of such relationships points toward the need for a more systematic pursuit of the philosophy of technology in ways that integrate epistemological, metaphysical, ethical, and political analyses. They also indicate the opportunities for more extended interactions between general philosophies of technology and the issues of biomedical ethics, interactions that have the potential for deepening and increasing the fruitfulness of both.

TISSUE BANKING AND TRANSPLANTATION, ETHICAL ISSUES IN

• • •

Although the transplantation of solid organs such as kidneys and hearts is familiar to the general public, knowledge about transplants of tissues such as bone, skin, veins, and heart valves is only beginning to be disseminated broadly. In the first decade of the twenty-first century the tissue transplant industry grew rapidly as tissue transplantation became a standard treatment option for thousands of patients. Spurred by technological developments and new clinical applications, the transplantation of human tissue grew from a $20 million industry in the early 1990s to one that was approaching $1 billion. In 1994 an estimated 6,000 persons were tissue donors upon death; by 1999 that number had grown to 20,000, more than tripling.

The great majority of cadaveric organs come from brain-dead, heart-beating donors who are maintained on ventilators, of whom there are an estimated 10,000 to 20,000 each year. The pool of potential tissue donors is in the hundreds of thousands because tissue can be retrieved up to 24 hours after death, assuming that the donor is medically suitable and meets generally applied age criteria. With tissue from one donor going to as many as 50 to 100 recipients, the number of tissue transplants dwarfs that of organ transplants. It is estimated that there were more than 850,000 tissue transplants in 2002. The immunological properties of most tissue are reduced greatly or eliminated in the processing of tissue. Therefore, unlike recipients of solid organs, tissue recipients are not required to take antirejection drugs for the rest of their lives.

With this growth in transplantation have come changes in organization, financing, and regulation, and those changes have led to unique ethical concerns. Those concerns arise in great measure from the stark contrast between the selfless gift of human tissue by donor families and the commercial forces at play as tissue passes down a complex chain of distribution from donor to recipients.

This entry describes the history, organization, technological developments, clinical applications, and regulation of the tissue industry and then dicusses the ethical issues that have emerged. It is concerned solely with the transplantation of tissues that come as gifts from families whose members have died recently. Other human tissues also may be used for medical and research purposes, including gametes (sperm and eggs), tissue discarded during surgery, blood and blood products, and cell lines grown in laboratories. The collection, distribution, financial implications, regulation, and ethical issues raised by those tissues are different from those which apply to tissues transplanted from newly dead donors to recipients.

History

Although many human tissues can be transplanted, including corneas, heart valves, veins, and skin, the most common type of transplant by far involves musculoskeletal tissue. Legend has it that Saints Cosmos and Damian performed the first transplant (a leg) in 287 C.E., but the first documented successful transplantation of musculoskeletal tissue was performed by the Scottish surgeon William Macewan in 1881. In 1908 the U.S. surgeon Eric Lexer reported transplanting an entire knee joint. Although Inclan established a surgical bone bank (storing bone from living patients) in Cuba in 1942, the U.S. Navy Tissue Bank in Bethesda, Maryland, established in 1949, was the first modern tissue bank. The Navy Tissue Bank recovered and preserved tissues to treat injured servicemen and servicewomen and advanced the science of tissue banking through research programs.

Tissue banks have always attempted to provide tissues needed by surgeons in the form in which they can be used best. The organization and operation of tissue banks have changed in response to changes in practice and demand. In the 1960s and 1970s many hospitals maintained their own surgical discard bone banks, storing primarily femoral heads that were removed during hip replacement surgery. Advances in orthopedic surgery, especially the treatment of primary large bone (e.g., femur, humerus) cancers by replacing entire bones with those obtained from cadavers, increased the need for more sophisticated tissue banking. In the 1980s, local tissue banks began to proliferate and a few regional tissue banks were established. Over time banks began to distribute outside their traditional service areas. Currently, many U.S.

tissue banks have allocation systems that return high-demand tissue to the area that provided the donation and distribute other tissue throughout the country. Some tissue banks distribute tissue to other countries.

Clinical and Organizational Developments

As the proportion of older patients in the United States has grown, there has been a dramatic increase in the types of tissues used for joint replacement surgery, which often requires transplanted bone in combination with a metallic prosthesis. There also has been a major increase in spinal fusion surgery. Some reports estimate that more than 200,000 patients in the United States have received cadaveric bone for spinal surgery. Enhanced techniques for limb salvage surgery in cancer patients have increased the demand for large tissue grafts. Sports medicine uses increasing amounts of *soft tissues,* primarily patellar and Achilles tendons, to repair damaged knee ligaments.

The 1990s saw the development of proprietary processing technologies, patented tissue configurations, and advanced processing systems that result in tissue grafts with very specific dimensions and shapes designed by biomechanical engineers that are used primarily in spinal fusion surgery and sports medicine. These and other developments have resulted in the need to hire new and different kinds of personnel, the move by tissue banks to affiliate with traditional competitors to gain access to new technologies, the elimination of smaller tissue banks, and the consolidation of tissue banks. They also have facilitated the entry into the field of for-profit companies. In 1992 Grafton® demineralized bone matrix (DBM) was introduced by the for-profit company Osteotech. Grafton® and similar DBM products are made from demineralized cortical bone combined with various types of carriers that are designed to function as defect fillers or as adjuncts to traditional bone-grafting techniques to promote bone healing. This type of tissue originally was designed for use in dental and periodontic applications but now is being used broadly in orthopedics and neurosurgery. By 2000 at least five other DBM products were on the market, usually codeveloped and promoted by a nonprofit tissue bank and a for-profit device partner.

Another development that has spawned controversy has been the use of tissue for enhancement purposes. Deep layers of skin can be processed into an acellular form that can be used by plastic surgeons to reconstruct deep dermal defects and scars as well as to smooth out wrinkles and temporarily "puff up" lips. Despite the debate that this use of donated tissue has generated, the industry reports that this type of surgery accounts for only a minuscule proportion of tissue transplants.

By the 1990s larger tissue banks, most of which are nonprofit organizations, were moving toward a more traditional medical device–pharmaceutical sales and marketing system, using professionally trained sales representatives or agents to promote their tissue and services, developing advertisements and brochures, and implementing controversial market-driven practices such as consignment, discounting, and bundling. Nonprofit tissue banks also have entered into relationships with orthopedic and medical device companies, sometimes allowing a device company to process, package, market, and sell the tissue. These activities and relationships have blurred the line between an altruisitic gift and the distribution of a medical device and created ethical challenges relating to the handling of the gift. In 1996 the American Association of Tissue Banks (AATB) adopted a set of principles intended to provide guidance in the growing commercialization of tissue, Ethical Guidelines for Commercial Advertising and Activities.

Regulation and Safety

Although tissue safety is not the only medical and ethical issue in which regulation may come into play, it is a crucial one. The avoidance of potential infection has always been of paramount importance. This is not a simple task because transplant tissue is removed from a dead body that may have been exposed to bacteria, viruses, and other pathogens before death or during the decomposition process. Until the late 1980s processing techniques primarily entailed sterilization, which was felt by many to be mandatory despite concerns that sterilization techniques damage the biological and/or biomechanical properties of tissue.

In the late 1980s the construction of pharmaceutical-grade processing facilities allowed *aseptic processing,* which eliminated the need for sterilization of tissues while maintaining the biomechanical and biological properties of tissue. *Clean room* technology provides an environment with 10 to 100 microorganisms per cubic foot of air. In comparison, a standard operating room, normally the "cleanest" place any patient will enter, provides an environment with 1,000 to 10,000 microorganisms per cubic foot. As tissue transplantation becomes an increasingly integral part of modern medical treatment, processors must strike a balance between the goals of maximal tissue safety and viability.

Regulation of organ transplantation began in the mid-1980s with the passage of the National Organ Transplantation Act and other legislation that initiated federal influence on and regulation of organ procurement and transplantation policy and practice. A national Organ Procurement and Transplantation Network (OPTN) was created at government expense to set organ transplantation policy and gather

data on organ transplantation events. The transplant community formed the United Network of Organ Sharing (UNOS), which obtained the OPTN contract. None of this authority, however, has been extended to tissue transplant practices. In addition, organ procurement organizations (OPOs) were given the authority to operate within a designated territory by the Health Care Financing Administration (HCFA, now the Centers for Medicare and Medicaid Services, or CMS), which also provided for financial reimbursement for the costs associated with kidney transplantation. Tissue banks, in contrast, were not and still are not compensated directly by the federal government for their operations, and there are no governmental regulations or guidelines that govern the organization of tissue banks.

Despite their safety risks, tissue banks were subject to very little federal regulation until the 1990s. In 1976 the AATB was founded as scientific nonprofit peer group organization to address issues of donor criteria and recovery and processing systems with an eye toward maintaining quality and safety. In the mid-1980s it established standards for acceptable norms of technical and ethical performance, including a program of inspection and accreditation. However, the AATB is strictly voluntary. In 2002 it listed 73 accredited banks among the estimated 100-plus banks in the United States. Among the unaccredited banks are some of the largest tissue processors. Only a handful of states have any type of tissue bank regulation.

A seminal event occurred in 1991 with the report of the transmission of human immunodeficiency virus (HIV) from an organ and tissue donor who had tested negatively for the antibody to HIV. This focused the public's attention on the potential for disease transmission, especially the need for more rigorous donor screening. In 2001 safety issues resurfaced. The Federal Drug Administration (FDA) and the Centers for Disease Control (CDC) reported several cases of infection, possibly caused by donor tissue in recipients, including one that resulted in the death of the patient. In 2002 the CDC issued a report documenting fifty-four tissue infections that had occurred over several years, noting, however, that out of an estimated 650,000 annual tissue transplants, bacterial infection was a rare complication. Later in 2002 there were reports involving six organ and tissue recipients who contracted hepatitis C from an organ and tissue donor, and several organ recipients who were infected with West Nile virus, including a number who died. Creutzfeldt-Jakob disease, the human variant of mad cow disease, looms as a potential hazard, and new testing regimens to screen out potential donors with these diseases are awaited by the tissue banking and surgical communities.

FDA regulation of tissue banking began in earnest in 1993 with the Interim Rule for Banked Human Tissue, which was intended to require infectious disease testing, donor screening, and record keeping. Among the things required were extensive interviews about a potential donor's sexual history, use of illegal drugs, and other exposure to infectious diseases. This rule was finalized in 1997 and resulted in in-depth training of tissue bank and hospital staff and a lengthy interview (between thirty and sixty minutes) with a grieving family member. During that time the FDA also began routinely inspecting tissue banks, suggesting changes, and conducting mandatory recalls at large tissue banks that remained out of compliance. It is anticipated that additional FDA regulations for good tissue banking practices will be issued in 2004.

In 1997 the Centers for Medicare and Medicaid Services (CMS) established regulations that changed the system of organ and tissue donation dramatically. The Conditions of Participation (CoP) required that all hospital deaths be reported to the OPO that serves the hospital and that all those deaths be evaluated as potential donors. The results of the CoPs were most notable among tissue banks, which often experienced an increase of over 50 percent in their tissue donors.

Ethical Issues

As tissue transplantation has gained visibility, it has attracted the attention of critics. In April 2000 the *Orange Country Register* ran a series of articles titled "The Body Brokers." With provocative headlines such as "Assembly Line" and "Skin Merchants," the newspaper raised concern that the tissue industry was commodifying the human body, making outrageous profits, and irresponsibly allocating skin for "cosmetic" purposes. According to those and other allegations, the industry was violating the trust of grieving families that altruistically had donated tissue. The tissue industry replied that those allegations were inflammatory and inaccurate. However, press coverage brought the the industry to public attention. Several senators approached the secretary of the U.S. Department of Health and Human Services (DHHS), Donna Shalala, who asked the DHHS's inspector general to investigate. Out of that investigation came two thorough 2001 reports, *Oversight of Tissue Banking* and *Informed Consent in Tissue Donation: Expectations and Realities.*

As was mentioned above, the ethical issues of tissue banking arise largely from the apparent contrast between the way society views the source of human tissue and the industrial and commercial aspects of tissue processing and distribution. Like organs, tissue comes as an altruistic gift from grieving families. The notion of altruistic donation has been the bedrock of the ways in which organs and tissues are obtained. The National Organ Transplant Act specifically

prohibited the sale of human organs and tissues, allowing only reasonable charges for the costs of retrieval, processing, and the like. Whereas some would argue that financial incentives and even outright payment should be allowed to increase the supply of organs, the law continues to recognize only altruistic donation.

Commerce is not absent from organ transplantation, however. Surgeons, hospitals, OPOs, and pharmaceutical companies, among others, make money from their participation in the transplantation process. However, with tissue transplantation, commodification and commercialization are much more evident. Unlike organs, which remain identifiable as organs in their relatively brief journey from donor to recipient, many tissue forms are highly processed and machined into forms that no longer resemble the bones or skin from which they were derived. Tissue forms are packaged much like pharmaceutical products and medical devices and can be stored for distribution years later. As they pass down the chain of distribution from donor to recipients, for-profit companies enter into the process. Many of those companies have invested capital to develop new processes for which they hold patents.

Unlike organs, tissue is rarely lifesaving, with skin for severe burn victims being the major exception. Instead, tissues are used to treat medical and surgical illnesses that are debilitating but not necessarily life-threatening. Sometimes tissue products are employed for cosmetic or enhancement purposes.

In summary, the chain of distribution of tissue from donor to recipient involves multiple players, including organ procurement organizations, nonprofit and for-profit tissue banks, and publicly held companies that process and distribute tissue. Tissue often is changed from its original form into packaged grafts that may sit on shelves to be distributed months or years later. Value is thus added to tissue as it passes along the chain of distribution. Sometimes donated tissue can be used for enhancement rather than saving lives or the treatment of serious medical and surgical conditions.

These characteristics make the commodification and commercialization of tissue much more evident than those of solid organs and, most important, present a stark contrast to the altruistic gifts of grieving families that make the entire enterprise possible. This contrast forms the basis for much of the criticism of the tissue industry. For example, if the families that selflessly donate do not make money, why should others? Another criticism is that families would not want their gifts used for cosmetic purposes.

Two potential solutions to these problems are not acceptable in the current legal and cultural context. On the one hand, society could abandon altruism and allow families to sell tissue at its fair market value. On the other hand, financial incentives could be eliminated from the processing and distribution of tissue. The first solution would eliminate the traditional basis of organ and tissue procurement: the gift. The second would bring an increasingly successful and desired clinical intervention to a halt.

Informed Consent

As a more realistic alternative many have suggested a rigorous informed consent process. If families were informed about the commodification and commercial aspects of their gifts, they would have the freedom not to give them. This would avoid the abandonment of both altruism and the market forces that have allowed the tissue industry to flourish. Although this suggestion has great merit, it also has several limitations.

First, the informed consent model does not fit the situation perfectly. People think of informed consent as the principle governing the decision of patients to consent to treatment or that of research subjects to consent to research. With tissue donation, the patient is dead and no treatment or research is involved. The decision to donate generally is made by a family member. Second, the request is made under less than ideal conditions: The family is in the middle of a crisis, and the request most often is made by a stranger, frequently over the telephone. In these circumstances the ability and willingness of the family to receive and process large amounts of information are limited. Third, issues involving the financial aspects of donation are complicated and to some extent dependent on the political views of the requestor and the family member. Is it possible, for example, to give a robust description of the structure and function of the tissue transplant industry in the context in which the request is made? Even if one attempted to do that, what words and tone should be used? Should the difference between for-profit and not-for-profit organizations be explained? Should the realities of the market economy be presented? Should those realities be praised or criticized, and in what balance? Words such as *for profit* and *making money* used out of context can be provocative and even manipulative. However, avoiding a discussion of these issues might allow people to naïvely imagine that their gifts of tissue make their way to grateful recipients without money changing hands or acting as an incentive.

Some things are known about what families want to be told. In 2000 the University of Florida Tissue Bank released the results of two telephone surveys of 507 persons who had been offered the option of tissue donation at the death of a family member. Among those who donated, 86 percent said they had enough time to make a decision, whereas 73

percent of nondonors said they did not. Twenty-eight percent of donors and 36 percent of nondonors said they did not receive enough information. Thirty-five percent of donors and 43 percent of nondonors said it would have been helpful to know that recovered tissue is "sent to companies" and in that group10 percent of donors said that knowing would have made a difference in their decisions. Forty-one percent of donors and 49 percent of nondonors said they would have wanted to know costs are associated with recovery, preparation, distribution, and surgery, including salaries, materials, shipping, and administration. Nineteen percent of donors said that knowing those facts would have made a difference in their decisions. Forty-eight percent of donors and 24 percent of nondonors said that profits should be permitted.

Donor families that have written on the subject point out that not all donor families think alike and acknowledge their ambivalence about their right to information versus their ability to process information in the middle of a tragedy.

After interviewing 30 organizations involved in tissue recovery and receiving more than 50 responses to a questionnaire from donor families, the inspector general of the DHHS concluded that the expectations of altruistic motives among donor families are the foundation of tissue banking. The report, *Informed Consent in Tissue Banking: Expectations and Realities,* said that, among other things:

- Large-scale financial operations may overshadow the underlying altruistic nature of tissue donation.
- After processing, tissue and products containing tissue often are marketed and sold as a medical supply rather than as a donation.
- Some tissues, particularly skin, may be processed into products that are used for cosmetic puposes.

The inspector general concluded that the special nature of tissue and the way in which it is made available call for steps beyond those which apply to most other businesses and philanthropic enterprises. He called for the HHS Division of Transplantation to identify principles and guidelines that should underpin consent requests; make suggestions about the type, format, and content of written information that should be shared with families; make recommendations about training tissue bank staff and external requestors; and make recommendations about ways to evaluate the effectiveness of requestors. He also called on the tissue industry to give written materials to families at the time of a request or in the days immediately afterward, including a copy of the consent form, a full description of the uses to which donated tissue may be put, and a list of other companies and entities with which the bank has relationships, and to indicate clearly on all tissue packaging and marketing materials that the contents are derived from donated human tissue. Finally, the report called for the tissue banking industry to explore a process for public disclosure of tissue banks' financing and research into what types and how much financial information would be useful for families and to consider the impact of that disclosure on the rate of donation.

The report also asked the tissue banking industry to work with groups representing the interests of donor families. The most prominent of those groups is the National Donor Family Council of the National Kidney Foundation. The council is an organization of over 8,000 donor families whose mission is to nurture and protect the interests of donor families as well as to promote donation. In 2000 the Donor Family Council issued a report titled *Informed Consent Policy for Tissue Donation* that called for full disclosure of the facts, including the ways in which tissue is recovered, processed, stored, and distributed. The report also said that families should have the right to restrict use of the tissue they donate. It did not mention financial issues.

In response to those suggestions the transplant community has begun to strengthen the process of informed consent. Many tissue banks now offer informational brochures to donor families that more clearly outline the specifics of donation, including the fact that tissue may be processed into many forms and sizes and may be stored for extended periods and the fact that for-profit companies may be involved in the processing. Education for tissue requestors also has been expanded. Tissue banks routinely offer donor families follow-up information, including copies of the consent form. The AATB, the Association of Organ Procurement Organizations (AOPO), and the Eye Bank Association of America (EBAA) established guidelines for obtaining informed consent on tissue donation that formed the basis of many recovery agencies' consent policies. In addition, the AOPO established suggested guidelines for its members to use in selecting a tissue processor or tissue banking partner.

Many commentators think that the inherent limitations of those recommendations call for other mechanisms to protect potential donors and the integrity of the industry. One of those mechanisms is public education. If the general public better understood the way tissue is altered and the financial realities of tissue processing and distribution, there would be less need to place the burden for sharing that information only at the moment of the actual request. The inspector general, for example, recommended that the tissue banking industry work with groups representing donor

families to explore a process for disclosure of tissue banks' financing, including knowledge about the sources of tissue banks' funding and other entities with which tissue banks have financial arrangements. Proposed legislation in California would mandate that families be given information about the involvement of for-profit companies and the possibility of cosmetic uses of tissue and be given the option to "opt out" of those scenarios.

Many states have passed laws that may further change the landscape as it relates to obtaining consent. Known as designated donation or first person consent, those laws give individuals an opportunity to declare their intention (or consent) to donate upon death and do not allow the next of kin to override that declaration. These laws present an entirely new set of challenges for OPOs, tissue banks, and eye banks: If an individual has declared his or her desire to "be an organ donor," does that necessarily refer to any body part that can be transplanted? Did that person receive full information about tissue donation so that the decision to donate was fully informed? What if the family objects strongly? Should the recovery agency move forward without regard for their feelings?

Good Stewardship

In the essay "The Gift and the Market" Courtney Campbell argues against the industrial perception of tissue banking, emphasizing instead that the tissue industry should "act in accordance with a model of 'stewardship of the gift'" (Campbell, p. 207). The acceptance of the gift of tissue, he writes, involves harmony between donor and recipient in regard to the meaning of the gift, the intention for its use, and the relationship of giver and recipient. Others also have emphasized this point. For example, Helen Leslie and Scott Bottenfield from LifeNet, one of the United States' leading tissue banks, in the essay "Donation, Banking and Transplantation of Allograft Tissues" note that "it is only through the humanitarian actions of donors and donor families—people helping people, the noblest of principles—that tissue transplantation is made possible" (Leslie and Bottomfield, p. 281). Stewardship mediates the relationship of the donor to the recipient. It provides a moral connection between the gift and the use of the gift and establishes a framework for enhancing the value of the gift as long as the intent of the donor is respected and the benefits of the gift are directed toward the larger community, not claimed solely as proprietary interests by tissue bankers, processors, and distributors.

Good stewardship in the context of human tissue for transplantation means that the industry should take collective responsibility by doing the following:

- Minimizing commodification by insisting that all packaged tissue prominently reveal its origin as an altruistic gift;
- Adopting nationwide rules for the just allocation and distribution of tissues, for example, making sure that purely cosmetic uses of tissue occur only after more worthy needs are met;
- Working to make tissue as safe as possible;
- Making sure that all tissue recovery is done by nonprofit organizations whose finances are publicly known;
- Maintaining a publicly accessible national database against which potential problems can be assessed rationally; and
- Providing a public forum for discussion and debate of controversial issues.

Although the industry has begun to adopt some of these aspects of good stewardship, there is much room for improvement and it remains to be seen how active a role the federal government will assume in pushing for these important moral and social goals.

TRANSHUMANISM AND POSTHUMANISM

• • •

At one time or another, most people have dreamed of having the ability to fly (without technological assistance), of never having to have to age or die, or of having bodies and minds that transcend human limitations. Yet in the end people move on with their lives, trying to learn to deal with the realities of finitude and mortality. This is necessary, given the lack of means to significantly alter biological constraints. Yet new technologies may soon begin to enable people to transcend such limitations. With such technologies, however, come questions about the appropriateness of actually pursuing and employing them to experience greatly extended longevity—perhaps even some form of physical immortality—and to re-engineer the human body to expand its functional capacity. Transhumanism and posthumanism are worldviews, or philosophies, that strongly favor an affirmative reply to these questions and that look forward to the day when *homo sapiens* have been replaced by biologically and technologically superior beings.

Transhumanism has been defined as "the intellectual and cultural movement that affirms the possibility and desirability of fundamentally improving the human condition through applied reason, especially by using technology to eliminate aging and greatly enhance human intellectual, physical, and psychological capacities" (Bostrum, 1999). A posthuman would no longer be a human being, having been so significantly altered as to no longer represent the human species. Underlying this worldview is a core belief that the human species in its current form does not represent the end of our development, but rather its beginning (Bostrom, 1999).

The tools transhumanists would use to achieve their ends include genetic manipulation, nanotechnology, cybernetics, pharmacological enhancement, and computer simulation. The most ambitious—and controversial—transhumanist vision involves the concept of *mind uploading.* According to proponents, advances in computing and neurotechnologies will, within several decades, enable individuals to completely read the synaptic connections of the human brain, enabling an exact replica of the brain to exist and function inside a computer. This simulation could then "live" in whatever mechanical body-form it desired (Kurzweil). In his book *The Enchanted Loom* (1981), Richard Jastrow speculated about this future time: "At last, the human brain, ensconced in a computer, has been liberated from the weakness of the mortal flesh.… It is in control of its own destiny.… Housed in indestructible lattices of silicon, and no longer constrained in its span of years, … such a life could live forever" (p.166–167).

Origins of Transhumanism

While the terms *transhumanism* and *posthumanism* are very recent in creation, the ideas they represent are anything but new. The underlying philosophical ideals are fully those of the Enlightenment, imbued with a healthy dose of postmodern relativism. From the Enlightenment comes a fully reductionistic view of human life characteristic of that movement's materialistic empiricism. In *L'Homme Machine (Man a Machine),* written in 1748, the French physician and philosopher Julien Offray de la Mettrie wrote that humans "are, at bottom only animals and machines," while the Marquis de Condorcet, another French Enlightenment philosopher, wrote in 1794 that "no bounds have been fixed to the improvement of faculties … the perfectibility of man is unlimited." These eighteenth century ideas could be easily

updated to recent transhumanist writings, such as Bart Kosko's *The Fuzzy Future* (1999), in which he proclaims: "Biology is not destiny. It was never more than tendency. It was just nature's first quick and dirty way to compute with meat. Chips are destiny" (p. 256). Consider also Kevin Warwick's declaration, written in 2000, "I was born human. But this was an accident of fate—a condition merely of time and place. I believe it's something we have the power to change" (p. 145). Derived from other Enlightenment ideals is a fierce libertarianism, supported by a postmodern moral skepticism, that proclaims that each individual is the final arbiter of what is right and appropriate for his or her life or body. One also sees a precedent for transhumanist thinking in Frederick Nietzche's thoughts on the will to power and the *ubermensche* (superman), particularly in *Thus Spake Zarathustra,* "man is something to be overcome"(p. 12).

As a named movement, transhumanism started in the 1980s with the writings of a futurist known as FM-2030, with the term *transhuman* being a shorthand for *transitional human* (Bostrom, 1999). Transhumans were "the earliest manifestation of new evolutionary beings, on their way to becoming posthumans" (FM-2030). Within the first years of the 1990s, a whole series of groups emerged embracing transhumanist ideology, including the Extropians, the Transtopians, and the Singularitarians, the latter group anticipating and working to bring about the technological "Singularity" predicted by Vernor Vinge. Writing in 1993, Vinge predicted that the exponential increase in scientific and technical knowledge, coupled with feedback loops from artificial intelligence systems, would soon lead to a massive destabilization and transformation of all social structures, technical devices, and human beings, who would be transformed into superior beings. While the Singularity is the most extreme of the transhumanist visions, the idea that humankind should engineer the next phase of its own evolution, and that human beings should be augmented and altered, even to the point of losing their humanity, has captured the thinking of numerous faculty and leaders in the engineering and scientific establishment. This can no better be illustrated than the National Science Foundation's (NSF) proposed plan for converging several technologies, including nanotechnology, biotechnologies, information technologies, and cognitive technologies (such as cybernetics and neurotechnologies) for the expressed purpose of improving human performance (Roco and Bainbridge).

Fundamentals of Transhumanism and Posthumanism

The first assertion of transhumanist thinking is a rejection of the assumption that human nature is a constant (Bostrom, 1999). There is nothing sacrosanct about *nature* in general, or about *human nature* in particular. Criticisms of attempts to modify nature as "playing God" or as the ultimate human hubris are therefore rejected as inappropriate.

Katherine Hayles, in her book *How We Became Posthuman* (1999), describes four characteristic posthuman, or transhuman, assumptions. First, information patterns are more important or essential to the nature of being than any "material instantiation, so that embodiment in a biological substrate is seen as an accident of history rather than an inevitability of life" (p. 2). Second, consciousness is an epiphenomenon. There is no immaterial soul. Third, the body is simply a prosthesis, albeit the first one we learn to use and manipulate. Consequently, replacing or enhancing human function with other prostheses is only a natural extension of our fundamental relationship with our begotten bodies. Lastly, the posthuman views the human being as capable of being "seamlessly articulated with intelligent machines. In the posthuman, there are no essential differences or absolute demarcations between bodily existence and computer simulation, cybernetic mechanism and biological organism, robot technology and human goals" (p. 3).

Ethical Issues

One of the first significant ethical issues relating to transhumanism and posthumanism is the question of enhancement or augmentation: should human beings augment or enhance themselves and future generations? This is not a simple question to answer, though humans have made a practice of augmenting and enhancing themselves throughout recorded history. This is the nature and explicit goal of all tool use and education. Yet there are some implicit boundaries that transhumanist modifications challenge.

As an example, consider correction of vision. The use of glasses or contact lenses to correct vision is an example of a commonly employed augmentation. Yet this intervention is only correcting a deficiency, returning the individuals function to species-normal levels. It is thus a healing intervention more than an enhancement. What becomes problematic for some is when the augmentation or enhancement in question potentially exceeds the function that could be achieved by the finest specimens of *homo sapiens* trained in the most rigorous fashion. People accept the use of some enhancing technologies, such as telescopy or microscopy, which may be used for a time, and for a specific purpose, but cannot become a permanent fixture of the human being. They remain tools, rather than becoming attributes. Thus it is acceptable to use a computer or personal digital assistant (PDA), which can be separated from the user, but permanently enhancing the brain with cybernetic connections or

brain implants seems to many to cross a boundary that should not be violated. Why is this so?

Two criticisms of such permanent enhancements are that: (1) they are unnatural; and (2) they engage people in activities that should be the sole purview of the deity—"Playing God" is a frequent aspersion thrown at enhancement technologies. While these are both legitimate concerns, the rhetoric used in the critique typically misses the point, which is a concern about the appropriateness, personal and social consequences, and wisdom of pursuing the proposed modifications and are thus generally dismissed as irrelevant by transhumanists (without addressing the genuine issues).

Transhumanists dismiss the claim of *unnatural* because most of what human beings do with any technology is *unnatural,* yet these uses are accepted as benefits, not harms. As to the second argument, many, if not most, transhumanists are agnostic or atheists, and thus engaging in a supposed Promethean rebellion against the gods is not to them a legitimate concern. The issue is one of great concern to theists, however, though the way the argument is commonly expressed comes close to violating their own basic theological tenants. Can God be so easily dethroned? Can the creature really act outside the permissive will of the creator? Further, many theologians assert that part of the *Imago Dei,* the "image of God," that humankind is said to bear, is the creative impulse.

The real issue of concern to those who object to or are wary of transhumanist goals is that human beings are engaging in activities that may have a profound impact on the individuals involved, as well as on the surrounding environment, without balancing forces or divine wisdom that might minimize possible negative consequences of such activities. From the environmental, or naturalist, perspective, the changes are occurring too swiftly and too dramatically for ecosystems or individual creatures to evolve appropriate safeguards or counterbalances. From the more theistic perspective, these changes are occurring without proper understanding and respect for God's initial designs and plan, and certainly without God's foresight or wisdom. In the end, both arguments are expressing concern for the great harm that these interventions could potentially induce, calling into question activities that presuppose a significant degree of knowledge, foresight, and wisdom that may, and most likely will, be lacking. Hubris, therefore, not ingenuity or even a passion for change, is the fundamental problem.

For others, however, even if such enhancements would not be tried until there was careful prospective evaluation for, and protections against, undesirable consequences, any intervention intended to move function beyond species-normal levels would be rejected. This leads to the next series of concerns: the social consequences of transhumanism. The pursuit of transhumanist goals could lead to individuals and communities possessing significant differences in the type and extent of biotechnological modifications. One consequence of these disparities will be the likelihood of discrimination—against both the enhanced and the unenhanced, as each community may feel threatened by the other. Claims of unfair competitive advantage are probable, potentially leading to attempts at restrictive legislation. Yet it is doubtful such restrictions would find sufficient consensus to be passed, let alone prevent the enhancements from taking place. According to Freeman Dyson, a British physicist and educator, "the artificial improvement of human beings will come, one way or another, whether we like it or not, as soon as the progress of biological understanding makes it possible. When people are offered technical means to improve themselves and their children, no matter what they conceive improvement to mean, the offer will be accepted.… The technology of improvement may be hindered or delayed by regulation, but it cannot be permanently suppressed.… It will be seen by millions of citizens as liberation from past constraints and injustices. Their freedom to choose cannot be permanently denied" (p. 205–206). Particularly powerful—especially in the United States, which is predicated upon the right to life, liberty, and the pursuit of happiness—is the argument posed by the transhumanist Anders Sandberg that freedom to pursue enhancing technologies is a fundamental matter of the right to life.

One likely consequence of this is that multiple communities will develop that adhere to certain values and agreed-upon levels of technological modification. But as some groups may choose lesser degrees of enhancement they may run the risk of becoming ghettoized or restricted from other goods of the larger society that they may still desire. While some transhumanists are quite clear that they do not wish to force their desires for enhancement onto others (Bostrom, 1999), as a group, or even as individual scholars, they have not satisfactorily resolved how tolerance will be maintained both within and outside their communities of choice. In fact, some transhumanists already display belligerent attitudes against skeptics and dissenters (Dvorsky; Smith; Shropshire).

This fact itself acknowledges one of the fundamental flaws of transhumanist, or any other, utopian thinking: the failure to understand the darkness, the fears, and the unpredictability of each human heart. The lesson of the twentieth century, such as the experience with eugenics, fascism, and communism, should have been to beware the power of utopian dreams to enslave, destroy, and demean, rather than

provide the promised justice, freedom, and human flourishing. Now the transhumanists offer yet another form of human contrivance to provide salvation for all. This time the faustian bargain is with technology—what John McDermott, a professor emeritus in labor studies at the State University of New York at Old Westbury, has referred to as "the opiate of the intellectuals"—rather than with economic or political systems.

Technology is not inherently evil, and has in fact been the source of much good (as well as harm). It is but a tool, and as a tool must be carefully examined and carefully used. Transforming ourselves into our tools in the hopes of achieving immortality is an illusion. Decay cannot be forestalled indefinitely. If one must change the underlying substrate of the body to "live," then it is really something else that exists, not the original being, and death will still need to be confronted. Extended life may be achieved, but at what social cost? How will people deal with greatly enhanced life spans? What will be the impact on economic structures, the workforce, and reproduction? These questions are all, as yet, unanswered by the transhumanists and the Converging Technologies project of the NSF. While it is doubtful that consensus could ever be reached on enhancing or augmenting technologies, humankind must engage prospectively in a full and open dialogue concerning the coming technologies and their implications.

TRIAGE

• • •

Triage is the medical assessment of patients to establish their priority for treatment. When medical resources are limited

and immediate treatment of all patients is impossible, patients are *sorted* in order to use the resources most effectively. The process of triage was first developed and refined in military medicine, and later extended to disaster and emergency medicine.

In recent years, it has become common to use the term *triage* in a wide variety of contexts where decisions are made about allocating scarce medical resources. However, triage should not be confused with more general expressions such as *allocation* or *rationing* (Childress). Triage is a process of screening patients on the basis of their immediate medical needs and the likelihood of medical success in treating those needs. Unlike the everyday practice of allocating medical resources, triage usually takes place in urgent circumstances, requiring quick decisions about the critical care of a pool of patients. Generally, these decisions are controlled by a mixture of utilitarian and egalitarian considerations.

History

Baron Dominique Jean Larrey, Napoleon's chief medical officer, is credited with organizing the first deliberate plan for classifying military casualties (Hinds, 1975). Larrey was proud of his success in treating battle casualties despite severe scarcity of medical resources. He insisted that those who were most seriously wounded be treated first, regardless of rank (Larrey). Although there is no record of Larrey's using the term *triage,* his plan for sorting casualties significantly influenced later military medicine.

The practice of systematically sorting battle casualties first became common during World War I. It was also at this time that the term *triage* entered British and U.S. military medicine from the French (Lynch, Ford, and Weed). Originally, *triage* (from the French verb *trier,* "to sort") referred to the process of sorting agricultural products such as wool and coffee. In military medicine, *triage* was first used both for the process of prioritizing casualty treatment and for the place where such screening occurred. At the *poste de triage* (casualty clearing station), casualties were assessed for the severity of their wounds and the need for rapid evacuation to hospitals in the rear. The emphasis was on determining need for immediate treatment and the feasibility of transport.

The following triage categories have become standard, even though terminology may vary:

1. *Minimal.* Those whose injuries are slight and require little or no professional care.
2. *Immediate.* Those whose injuries, such as airway obstruction or hemorrhaging, require immediate medical treatment for survival.
3. *Delayed.* Those whose injuries, such as burns or closed fractures of bones, require significant professional attention that can be delayed for some period of time without significant increase in the likelihood of death or disability.
4. *Expectant.* Those whose injuries are so extensive that there is little or no hope of survival, given the available medical resources.

First priority is given to those in the immediate group. Next, as time and resources permit, care is given to the delayed group. Little, beyond minimal efforts to provide comfort care, is given to those in the expectant category. Active euthanasia for expectant casualties has been considered but is almost never mentioned in triage proposals (British Medical Association, 1988). Those in the minimal group are sent to more distant treatment facilities or left to take care of themselves until all other medical needs are met.

From the beginning, the expressed reasons for such sorting were a blend of utilitarian and egalitarian considerations. Larrey stressed equality of care for casualties sorted into the same categories. On the other hand, one early text on military medicine advised, "The greatest good of the greatest number must be the rule" (Keen, p. 13). Over the years, it also became clear that the utilitarian principle could be interpreted in different ways. The most obvious meaning was that of limited medical utility: The good to be sought was saving the greatest number of casualties' lives.

But the principle could also be construed to mean doing the greatest good for the military effort. When interpreted this way, triage could produce very different priorities. For example, it was sometimes proposed that priority be given to the least injured in order to return them quickly to battle (Lee). An oft-cited example of the second use of the utilitarian principle for triage occurred during World War II (Beecher). Commanders of U.S. forces in North Africa had to decide how to use their extremely limited supply of penicillin. The choice was between battle casualties with infected wounds and soldiers with gonorrhea. The decision was made to give priority to those with venereal disease, on the grounds that they could most quickly be returned to battle preparedness. A similar decision was made in Great Britain to favor members of bomber crews who had contracted venereal disease, because they were deemed most valuable to the continuation of the war effort (Hinds, 1975).

As military triage has evolved during the twentieth century, the goal of maintaining fighting strength has increasingly become the dominant, stated goal. In the words of surgeons Gilbert W. Beebe and Michael E. DeBakey, "Traditionally, the military value of surgery lies in the salvage of battle casualties. This is not merely a matter of saving life; it

is primarily one of returning the wounded to duty, and the earlier the better" (p. 216).

The nuclear weapons used at the end of World War II introduced unprecedented destructive power. In the nuclear age, triage plans have had to include the possibility of overwhelming numbers of hopelessly injured civilians. In earlier days, it was not uncommon to plan for 1,000 or 2,000 casualties from a single battle. Now, triage planners must consider the likelihood that a single nuclear weapon could produce a hundred times as many casualties or more. At the same time a single blast could destroy much of a community's medical capacity. Such probabilities have led some analysts to wonder if triage would be a realistic expectation following a nuclear attack (British Medical Association, 1983).

Triage has moved from military into civilian medicine in two prominent areas: the care of disaster victims and the operation of hospital emergency departments. In both areas, the categories and many of the strategies of military medicine have been adopted.

The necessity of triage in hospital emergency departments is due, in part, to the fact that a number of patients needing immediate emergency care may arrive almost simultaneously and temporarily overwhelm the hospital's emergency resources (Kipnis). More often, however, the need for triage in hospital emergency departments stems from the fact that the majority of patients are waiting for routine care and do not have emergent conditions. Thus, screening patients to determine which ones need immediate treatment has become increasingly important. Emergency-department triage is often conducted by specially-educated nurses using elaborate methods of scoring for severity of injury or illness (Purnell; Wiebe and Rosen; Grossman).

Ethical Issues

The traditional ethic of medicine obligates healthcare professionals to protect the interests of patients as individuals and to treat people equally on the basis of their medical needs. These same commitments to fidelity and equality have, at times, been prescribed for the treatment of war casualties. For example, the Geneva Conventions call for medical treatment of all casualties of war strictly on the basis of medical criteria, without regard for any other considerations (International Committee of the Red Cross; Baker and Strosberg). However, this principle of equal treatment based solely on medical needs and the likelihood of medical success has competed with utilitarian considerations in military medicine. In such triage, healthcare professionals have sometimes thought of patients as aggregates and given priority to goals such as preserving military strength; loyalty to the individual patient has, at times, been set aside in order to accomplish the most good or prevent the most harm. The good that might have been accomplished for one has been weighed against what the same amount of effort and resources could do for others. The tension between keeping faith with the individual patient and the utilitarian goal of seeking the greatest good for the greatest number is the primary ethical issue arising from triage.

Triage generates a number of additional ethical questions. To what extent are the utilitarian goals of military or disaster triage appropriate in the more common circumstances of allocating everyday medical care, such as beds in an intensive care unit? If some casualties of war or disaster are categorized as hopeless, what care, if any, should they be accorded? Should their care include active euthanasia? Should healthcare professionals join in the triage planning for nuclear war if they are morally opposed to the policies that include the possibility of such war (Leaning, 1988)? What new issues arise for triage in a time of global terrorism (Kipnis)?

Triage is a permanent feature of contemporary medical care in military, disaster, and emergency settings. As medical research continues to produce new and costly therapies, it will continue to be tempting to import the widely accepted principles of triage for decisions about who gets what care. Indeed, whenever conditions of scarcity necessitate difficult decisions about the distribution of burdens and benefits, the language and tenets of medical triage may present an apparently attractive model. This is true for issues as far from medical care as world hunger and population control (Hardin; Hinds, 1976). The moral wisdom of appropriating the lessons of medical triage for such diverse social problems is doubtful and should be carefully questioned. Otherwise, utilitarian considerations often associated with triage may dominate issues better addressed in terms of loyalty, personal autonomy, or distributive justice (Baker and Strosberg).

TRUST

• • •

Trust Between Patients and Providers

Trust between patients and providers is a central topic for bioethics. Consider the trust (or distrust) involved when someone contemplates major surgery: First of all, there is the relation between the surgeon and patient. The patient needs from the physician both a high level of competence (both judgment and skill) and a concern for the patient's well-being. For healthcare professionals to behave in a responsible or trustworthy way requires both technical competence and moral concern—specifically, a concern to achieve a good outcome in the matter covered, which is sometimes called "fiduciary responsibility," the responsibility of a person who has been entrusted in some way. The moral and technical components of professional responsibility have led sociologist Bernard Barber to speak of these as two "senses" of trust. However, if the patient trusts the surgeon, it is not in two senses; the patient trusts the surgeon simply to provide a good, or perhaps the best, outcome for the patient. To fulfill that trust, the surgeon needs to be both morally concerned for the patient's well-being (or at least health outcome) and technically competent.

Because the exercise of professional responsibility characteristically draws on a body of specialized knowledge that is brought to bear on the promotion or preservation of

another's welfare, to trust someone to fulfill a professional responsibility is to trust that person to perform in a way that someone outside that profession cannot entirely specify, predict, or often even recognize. In drawing attention to this point, Trudy Govier says that trust is "open-ended." The point is not captured in the frequent suggestion that trust is necessary because the trusting party cannot control or monitor the trusted party's performance. It would do the patient little good to have full prescience of all the events in the operation, or even the ability to guide the surgeon's hand, unless the patient also happened to be a surgeon. Although a typical patient might be able to recognize some acts of gross malpractice, such as being stitched up with foreign bodies left inside, the patient would not know the implications of most of what he or she saw and would have no idea of how to improve the surgeon's performance. For this reason, from the point of view of the patient, there are no good alternatives to having trustworthy professionals. There are no good alternatives in these circumstances because the patient must rely on the discretion of the practitioner.

Philosophers like John Ladd and legal theorists like Joel Handler have drawn attention to the role of discretion in many areas of professional practice. They have argued that because of the role of discretion, the criteria for morally responsible practice cannot be specified in terms of rules or rights alone. The centrality of discretion makes it all the more difficult to separate competence (having adequate knowledge and skill) and moral elements (exercising sufficient concern for the client's well-being) in the professional's behavior.

The provider—in this case the surgeon—also must trust the patient. At a minimum, the surgeon depends on the patient to disclose all information relevant to the case so as to minimize the risks of unexpected events in the operating room. If the patient disappoints the surgeon and does not disclose all relevant information, the negative consequence for the surgeon is, at most, to impair the surgeon's professional performance. The disappointment does not carry a risk of death or disability for the surgeon. The difference in the severity of risk is one of the many aspects of a trust relationship that is counted as a difference of power in that relationship. The lesser severity of consequence for the provider—in this case the surgeon—can obscure the mutuality of trust in the patient-provider relationship.

When the provider is a nurse or physical therapist rather than a surgeon, the provider's central tasks often require an understanding of the patient's experiences, hopes, and fears. Although some nursing, such as the work of the surgical nurse who assists in the operating room, does not depend on an understanding of the patient's experience, most nursing does. Postsurgical nursing care is a good example. This care typically includes motivating the patient to do things such as coughing and breathing deeply in order to reduce the risk of postoperative lung infection. These acts are often quite uncomfortable. Such nursing requires an understanding of the individual patient's state of mind and the ability to motivate the patient—the ability to inspire confidence and hope in patients.

CHANGING THE STANDARDS OF THE PATIENT-PROVIDER RELATIONSHIP. When sociologist Talcott Parsons put forward his influential theory that professionals function as trustees, or in a "fiduciary" capacity, the standard for the so-called fiduciary aspects of the relationship between patients and physicians was that the provider furthered the patient's well-being by being entrusted to make medical decisions in the best interests of that patient.

The doctrine of informed consent for medical procedures was adopted only gradually over the next two decades as a check on provider discretion. This doctrine has been implemented to require informed consent only for a very circumscribed set of procedures. To treat competent persons against their will is considered battery, in legal terms. Therefore, there is a foundation in law for the prohibition of forced or nonconsensual treatment of all types. In practice, however, information is often given only for major procedures, and practitioners tend to assume consent for lesser interventions, including most medical tests. Although patient-oriented practitioners will offer an explanation of why they are ordering a particular test, others will explain only when explicitly asked. For procedures other than surgery, formal requests for consent are rare unless there is a significant risk of death or severe disability from the procedure.

Furthermore, most patients are well informed only about the risk of death or significant permanent injury in circumstances in which informed consent is legally or institutionally mandated. Significant risk—such as becoming temporarily psychotic as a result of the trauma of open-heart surgery, as a result of intensive-care procedures, or from the sleep deprivation that often results from those procedures—is rarely disclosed to patients. The rationale for not telling a patient about to have bypass surgery or enter intensive care is that the risk will seem so shocking that the patient will refuse needed care.

Although the standard of informed consent is enforced by law and institutional practice only for certain risks of major procedures, the U.S. President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (President's Commission) has urged that the informed-consent standard be replaced by another,

more comprehensive standard, the standard of *shared decision making.*

The President's Commission's 1982 report, *Making Health Care Decisions,* advocated such a shift, which would presumably apply to most significant healthcare decisions. The rule of informed consent requires only the recognition of the patient's right of veto over the alternatives that the provider has presented to the patient. In contrast, shared decision making requires participation of the patient in setting the goals and methods of care and, therefore, in formulating the alternatives to be considered. This participation requires that patients and practitioners engage in complex communication, which the practitioners have a fiduciary responsibility to foster. This new standard is particularly appropriate for a pluralistic society, in which the responsible provider may have an idea of the patient's good that is significantly different from the patient's own idea.

The responsibility to foster shared decision making requires significant skill on the part of medical professionals in understanding patients of diverse backgrounds and in fostering communication with them in difficult circumstances—circumstances in which their communication may be compromised by fear and pain as well as by a lack of medical knowledge. Although some physicians, notably primary-care providers, have sought the skills to fulfill the responsibility to foster such communication, this responsibility is not one that medical education prepares physicians to accept.

IMPLEMENTING THE FIDUCIARY STANDARD. Ironically, although the fiduciary responsibility in healthcare has often been viewed primarily as the responsibility of physicians, as was noted above, it is other classes of providers, especially nurses, who are educated in a way that prepares them to understand patients' experience. Although there is much to recommend the new fiduciary standard in healthcare, its realization requires either a major change in medical education or a change in the relations among members of the healthcare team, so that those who are prepared to oversee and foster shared decision making have the authority to do so. Without such changes, the trust that one's healthcare will be shaped by one's own priorities and concerns is not well founded.

In many cases, distrust of either individual providers or medical institutions has been warranted, especially for women, people of color, and the poor, whose experience has often been discounted or who have been viewed as less rational or less competent than white males. Annette Dula argues that historical events, from the Tuskegee syphilis study to the experience with screening for sickle-cell carrier trait, confirm that trust of the healthcare system on the part of African-Americans is often not warranted (Dula, 1992). The problem is one of the need not only for assurance but also for evidence that the former conditions no longer prevail.

Many poor or uninsured people have not even had a significant patient-provider relationship; when they are able to obtain healthcare, it is often with a provider whom they see in only a single clinical encounter. It is therefore impossible to establish a trusting relationship that would serve the patient's health interest. If society is obliged to provide decent healthcare for its citizens, this failure of the healthcare system is a betrayal of trust not by individual providers but by society and its healthcare institutions.

Trust and Family Members

Trust among family members is at least as important an issue for healthcare as is trust in the provider-patient relationship. The trustworthiness of parents and guardians to decide the care of children and other dependent family members is widely discussed, and trust among family members is beginning to receive more attention in connection with the writing of living wills and health proxy statements. The issues of the competence of family members to give various forms of care or to make technical decisions, and the sufficiency of their concern for the patient's well-being, parallel those issues for providers. The matter is further complicated by the phenomenon of psychological denial that interferes with decision making about the healthcare of a person who is important in one's own life. Denial, as well as incompetence or lack of commitment to the patient's welfare, may compromise a person's decisions or care when the health or life of a close friend or relative is gravely threatened. Therefore, warranted trust in family members to provide or decide one's care requires confidence not only in their competence and in their concern for one's well-being but also in their psychological ability to come to terms with the situation.

Other Areas of Trust in Healthcare

There is also the question of the public's trust in a class of professionals, which is distinct from the question of the public's concern that, should they become clients of these professionals, their interests will be well served. For example, Sissela Bok (1978) has examined the concern about the trustworthiness of lawyers, not by their clients but by the public. Of particular concern is lawyers' commitment to keep the crimes of their clients confidential, even certain ongoing or planned crimes. The public believes that lawyers should not violate usual ethical norms for the sake of their

clients' interests. The corresponding issue in healthcare is the fear that providers will, in protecting patient confidentiality, put the public health or the safety of individuals at undue risk. The question of ethical criteria for breaking confidentiality is regularly discussed, especially in the case of a sexually transmitted disease or a patient intent on harming another person. However, there is no widespread public concern that healthcare providers may be going so far in protecting patient confidentiality that they are derelict in protecting the public.

In addition to the public's trust of providers, the trust or distrust of medical technology is often a significant factor. The risk is particularly salient in the case of artificial organs, joints, and other body parts. In place of the components of competence and concern of a trusted provider, the qualities required of a technology to warrant trust are its performance (it performs the function it was designed to perform) and its relative safety (it is relatively unlikely to cause accidents or to have other injurious side effects). Of course, with such life-critical technologies as artificial organs, the performance issue is itself a safety issue.

There are many aspects of the healthcare system on which patients rely but which most rarely consider. Many people become fully aware of their trust only when that trust is disappointed. A case in point is the discovery that research misconduct occurred in a major breast cancer study. The belated revelation of misconduct made patients aware of their trust in medical research.

The Morality of Trust

Although Sissela Bok has discussed trust as a moral resource since the 1970s, the question of the morality of trust relationships—the question of the circumstances under which, from a moral point of view, one ought to trust—was not explicitly discussed until Annette Baier's 1986 essay, "Trust and Anti-Trust." Two earlier essays were important in laying the foundation for this major turn in the discussion. In 1984, Ian Hacking provided a devastating assessment of the use of game theory to understand moral questions, such as the Prisoner's Dilemma, which will be discussed below. Baier herself argued in 1985 for broadening the focus in ethics from obligations and moral rules to the subject of who ought, as a moral matter, to be trusted and when. As Kathryn Addelson points out, Baier's change of focus establishes a general perspective on ethical legitimacy that is shared by all—both the powerful and those whom society labels *deviant*—rather than privileging the perspective of those who make, instill, and enforce moral rules.

Baier's general account of the morality of trust illuminates the strong relation between the trustworthy and the true. A trust relationship, according to Baier, is decent to the extent that it stands the test of disclosure of the premises of each party's trust (Baier, 1986). For example, if one party trusts the other to perform as needed only because the truster believes the trusted is too timid or unimaginative to do otherwise, disclosure of these premises will tend to insult the trusted party and give him or her an incentive to prove the truster wrong. Similarly, if the trusted party fulfills the truster's expectations only through fear of detection and punishment, disclosure of these premises may lead the truster to suspect that the trusted would betray the trust, given an anonymous opportunity to do so.

Although explicit discussion of moral trustworthiness is relatively recent, both professional ethics and the philosophy of technology have given considerable attention to the concept of responsibility. Since being trustworthy is key to acting responsibly in a professional capacity, or to being a responsible person if one considers responsibility a virtue, the literature on responsibility provides at least an implicit discussion of many aspects of the morality of trust, much of which is relevant to the subject of trust in healthcare.

Conceptual Relationships

Trust involves both confidence and reliance. Annette Baier (1986) argues that if we lack other options, we may continue to rely on something even when we no longer trust it. Similarly, we may have confidence in something, or confidence in our expectations concerning it, without relying on it. To rely only on what we can trust is a fortunate circumstance.

Niklas Luhmann (1988) urges a different distinction between confidence and trust, suggesting that *trust* be used only when the truster has considered the alternatives to trusting. Such use is incompatible with unconscious trust, a phenomenon to which Baier draws attention. Luhmann's discussion of the distinction between trust and confidence highlights the element of risk in trusting. Risk or vulnerability does characterize situations in which trust is necessary, in contrast to situations in which one's control of the outcome makes trust unnecessary. However, the element of risk taking in trust is captured in the notion of reliance when trust is understood as confident reliance. Being vulnerable in one's reliance does not require that one have considered the alternatives, if any, to such reliance.

Although one often trusts people, their intentions and goodwill, there is also trust in mere circumstances or events: One may trust that a taxi will come along shortly, even if no taxi has been ordered, without believing anything about another person's reliability in providing a taxi.

The risk taken in trusting does leave the truster liable to disappointment (or worse), whether that trust is of persons or events. But only when trust is in other people, and not merely in the events involving them, can one be let down by them. Suppose that a person is awakened every weekday by another person's calling for a neighbor. If the first person has come to rely on being awakened, but one day the other person does not come for the neighbor or does so quietly, the first person's expectations will be disappointed. But the person will not have been disappointed or let down by the one who usually picks up the neighbor. To be disappointed by another person, that person must at least be aware of doing or not doing the act in question. Here the person doing the calling for the neighbor is not aware of waking up the first party, much less of being trusted to do it. As Baier mentions (1986), it is possible for there to be trust of which the trusted person is unaware, and so one might let down another without being aware of letting that person down.

Niklas Luhmann (1979) has shown how trust simplifies human life by endowing some expectations with assurance. To consider all possible disappointments, defections, and betrayals by those on whom we rely, the possible consequences of those disappointments, and any actions that one might take to prevent those disappointments or change their effect is prohibitively costly in terms of time and energy. Trust reduces that burden.

The Literature on Trust

Sociologists like Bernard Barber and Luhmann (1979, 1988) have written on many facets of the notion of trust, and legal theorists have reflected on the distinct, though related, notion of a legal trust. Until the 1980s, however, the explicit attention given to the common notion of trust, or confident reliance, in Anglo-American philosophy was largely in relation to such questions as how the "prisoners" in the so-called Prisoner's Dilemma might solve their problem of assurance with regard to one another's behavior so as to cooperate in achieving a mutually beneficial outcome. (In the Prisoner's Dilemma, each of two prisoners will receive a light sentence if neither confesses to a crime, and a more severe sentence if both confess; but if one confesses and the other does not, the latter will be freed, but the former will receive the most severe sentence of all. Without assurance about each other's behavior, and in spite of knowing that both would be better off if neither confesses, both are likely to confess and be less well off.)

Recent literature on trust has examined trust in a variety of different social circumstances, involving a wide range of objects and systems, persons in a wide variety of roles, and matters in which they might be trusted or distrusted. For example, some writers focus on cases of the breakdown of trust in war, under the influence of the Mafia, or in some other extreme situation. Differences in the domain of application of the notion of trust lead to an unusually wide range of estimates of its character and importance. They also lead to disparate distinctions between trust and such notions as reliance, faith, vulnerability, and confidence, as well as to different conclusions about the moral value and the moral risks associated with trust.

Those who write about trust in a market context often take economic rationality—according to which each person simply seeks to maximize his or her goals by the most efficient means—as their model. They then often regard trust as a way of coping with *imperfect rationality,* understood as uncertainty about the facts or about one another's behavior, and how to estimate the consequences for the achievement of one's goals. The economic model of rationality is not readily applicable in considerations of ethics because it was designed to avoid consideration of values other than efficiency, and it treats moral considerations as nonobjective *personal preferences.* Where a market context is assumed, the relatively minor risk of being a "sucker" is likely to be mentioned as a barrier to trust. (See, for example, Dasgupta.) In discussions of trust among family members or between nations (Bok, 1990a), much more is recognized to be at stake.

Feminists like Trudy Govier argue that attention to trust relationships will bring attention to other relationships, such as those between parents and children, that have been neglected when contracts are the focus of attention. Such relationships, however, together with the features of trust that are prominent in them, continue to be ignored in much of the literature on trust. For example, Geoffrey Hawthorn mentions a parent's nonegotistic motives toward his or her child, only to turn immediately to "more ordinary" instances of nonegoistic motives.

Bernard Williams, who begins his own essay with a discussion of the Prisoner's Dilemma, argues that the problem of how nonegoistic motivation is to be encouraged and legitimated does not have a general solution. He argues that the problem of trust or cooperation is not one that can be solved in a general way at the level of decision theory, social psychology, or the general theory of social institutions. To ensure cooperation in a given situation requires an understanding of the ways in which the people in that situation are motivated. Williams believes that solutions to the problem of cooperation are found only for particular historically shaped societies, rather than for society in general. He argues that investigating the sorts of combinations of motivations that make sense in that society might lead to a general perspective on the problems of cooperation in such a society.

However, as he says, "there is no one problem of cooperation: the problem is always how a given set of people cooperate" (p. 13). Those whose cooperation is of the greatest interest in bioethics are patients, their families, the healthcare providers, and the policymakers who shape the healthcare system.

UTILITARIANISM AND BIOETHICS

• • •

In bioethics the influence of utilitarianism as an applied ethical theory is widely felt, both positively and negatively. On almost all substantive issues in the area, utilitarianism anchors one of the contending positions. Yet, it is the object of fierce criticism, nearly always to do with the challenges it poses to ordinary or conventional morality, especially in cases involving the taking of life, and to the distinctions that are supposed to carry the weight of that morality.

Classical Utilitarianism

Classical or act-utilitarianism is the view that an act is right if its consequences are at least as good as those of any alternative. In this form the view is consequentialist, welfarist, aggregative, maximizing, and impersonal, and the principle of utility that it endorses what might be called the utilitarian goal.

The view is consequentialist, in that it holds that acts are right or wrong solely in virtue of the goodness or badness of their actual consequences. This view is sometimes called act-consequentialism, or, here, for reasons of brevity, simply consequentialism. It is matters to do with consequentialism, and the conflicts that consequentialist thinking is supposed to engender with ordinary morality in bioethics (and elsewhere), that has made the present topic one of note in contemporary bioethics. The view is welfarist, in that rightness is made a function of goodness, and goodness is understood as referring certainly to human welfare but also, perhaps, to animal welfare as well. The view is impersonal and aggregative, in that rightness is determined by considering, impersonally, the increases and diminutions in well-being of all those affected by the act and summing those increases and diminutions across persons. The view is a maximizing one: One concrete formulation of the principle of utility, framed in the light of welfarist considerations is "Always maximize net desire-satisfaction."

The act-utilitarian goal, understood in the light of the above characterization, then, is to maximize (human) welfare. The crucial question to which this goal gives rise is how best to go about achieving it, and some contemporary act-utilitarians have come to think that the best way of going about maximizing (human) welfare overall may be to forego trying to maximize it on each occasion. It is this insight, in some form or other, that has spurred the most important developments in act-utilitarianism today—developments, however, that have not for the most part featured in bioethics, where the utilitarianism discussed and criticized remains classical or act-utilitarianism, with its embedded consequentialism.

Act-Utilitarianism v. Moral Intuition: The Opposition View

What has driven and continues to drive much of the opposition to act-utilitarianism has been the thought that some alternative view can better account for a number of our moral intuitions. Our moral intuitions, it is said, frown upon murdering or torturing someone, upon enslaving people or using them as means, upon acting in certain contexts and so using people in certain ways for mere marginal increases in utility, all of which act-utilitarianism is supposed to license. It is supposed to license these things because of its constituent consequentialism: If such acts were

to have better consequences than the actual consequences of any alternative, then the act-utilitarian would be compelled to call such acts right. And this, allegedly, conflicts with our moral intuitions or ordinary moral convictions or what some people think of as commonsense morality.

This is familiar territory in past debates over utilitarianism generally, though it is no more settled for all that, and it raises directly the question of whether our moral intuitions have probative force in ethics. This is an important issue in its own right, separate from the fate of any form of utilitarianism, but far too broad and complex an issue to be gone into in any detail here. For those inclined to the view that moral intuitions do have probative force in ethics and utilitarianism can be rejected if it produces clashes with those intuitions, the problem has been to make it appear that certain of our intuitions are more secure than others—so secure, in fact, that we believe them to be more *correct* or *true* than any normative ethical theory that contended otherwise could be. Obviously those who adopt this line need to identify which these crucial intuitions are, and various ways of doing this have been suggested. Today reflective equilibrium methodologies are perhaps the preferred way, though some relatively straightforward intuitionists still survive, as do some who seek for the preferred intuitions or convictions in their religion. Even with the back and forth movement between intuition and principle that reflective equilibrium methodologies involve, however, it is clear that some intuitions survive and remain intact. Thus, in *A Theory of Justice,* Rawls appears to think that, if a moral/political theory gave the result that slavery was justified, that would be enough to demand from us amendment and/or abandonment of the theory. His intuition on this score needs no revision. Other writers privilege other of their moral intuitions either about particular acts or classes of acts. Of course the more people that are found, whether in our own or another culture, to differ over these crucial intuitions, the more difficulty there is in selecting just which the crucial ones are. Thus reflective equilibrium methodologists on the one hand and straightforward intuitionists on the other seek ways to discount variation in these crucial intuitions, or, at the very least, to reduce the scope and depth of variations.

The Taking of Life: A Prime Example

Whatever the scope and depth of variations, however, the assumption that certain intuitions survive critical scrutiny has been the springboard from which assaults upon act-utilitarianism have nearly always begun. In cases involving the taking of life, this has been especially true, so that, for example, the topics of abortion, infanticide, euthanasia, suicide, and physician-assisted suicide have become battlegrounds for the playing out of certain kinds of consequentialist reasoning over intending and causing or bringing about death. Of course, other issues in bioethics have been contentious between consequentialists and their opponents, and those involving genetic engineering and therapeutic cloning promise to become intense in the near future; but it is the cases of taking life that have pressed upon the opponents of consequentialism. Four points may be used to illustrate the clash:

(1) Can a genuine distinction be drawn between intending death and merely foreseeing death as a side-effect of one's act and, if such a distinction can be drawn, whether it can be used to mark off moral differences between cases? This issue haunts the taking-life cases; it has been one of the main bones of contention over the viability of the doctrine of double effect; and it is, when allied with a whole array of concerns having to do with whether the act/omission, acting/refraining, and active/passive distinctions are morally significant ones, part of the killing/letting die debate. On the whole, consequentialists attack the moral significance of these distinctions. Thus with a patient who has required ever larger doses of a pain-killer, a physician now proposes to administer the minimum dosage necessary to relieve pain, in the knowledge, however, that the drug at that dosage will prove fatal or at least hasten death. Is the doctor's act permissible? According to some it is permissible, since the physician intends the relief of pain, not death, and only foresees as a side effect of the act that death will ensue or be hastened. Were the doctor to intend the death, either as end or as means, the act would be, not tantamount to, but in fact murder. In this way, then, some want to distinguish morally between the doctor's intentionally killing the patient and his knowingly bringing about the patient's death. Consequentialists, on the whole, have doubts that any such moral distinction can be drawn on this basis: In both cases, the patient ends up dead as the result of causal steps that the doctor takes. Suppose the doctor chooses to administer the drug and knowingly brings about the patient's death: What is one to say about this *bringing about*? One cannot say that it was the result of negligence or recklessness or of accident or mistake. In fact the death is in part the result of choice or decision on the part of the doctor, and it is an integral part of the case that the doctor is a causal agent in the patient's death. Certainly the choice or decision by the doctor to administer the drug cannot be ignored in describing what happened in the patient's case, since that choice or decision in part determines what happened to the patient. This

is true, moreover, even if it is true that the patient's death forms no part of the doctor's intention. It is simply false that the only way morality can be injected into the doctor's case is through what is intended; for that fails to take account of the fact that the patient's death is brought about by the doctor, in the sense described. Unplugging ventilators and turning off machines, among other acts, are all things that the doctor does, in the course of bringing about the patient's death. (The causal account requires complication in a case involving an omission; but the injection of morphine is not an omission.)

(2) In this regard, withdrawing treatment or food and hydration is something the doctor does as well. It is sometimes held that a doctor may not permissibly supply the means of death to a competent, informed patient who is terminally ill, who has voluntarily requested the doctor's assistance in dying, and whose request has survived depression therapy. Yet the very same doctor, it is held, may withdraw food and hydration if, for example, the patient makes a valid refusal of further treatment. Not all withdrawal cases take this form, since things other than food and hydration can be withdrawn from a patient's treatment; but consequentialists on the whole have difficulty in seeing what the morally relevant differences are between these cases. The doctor can supply a pill and produce death, he can withdraw feeding tubes and produce death; how can one be permissible and the other impermissible? Causally he appears to be a factor in the patient's death in both cases. Nor will the consequentialist allow the case to be made out to be one in which, by his valid refusal of further treatment, the patient is to be regarded as the sole actor present, as if the doctor who will withdraw feeding tubes were not there and did not act. The patient's autonomous, voluntary decision to forego further treatment is not the only morally or causally relevant fact to the situation: Death is only produced if the doctor withdraws feeding tubes. Notice, importantly, that the case cannot be reduced to one in which it is claimed that the patient is *permitted* or *allowed* by the doctor to die and that it is the underlying disease which kills him, which is what is usually claimed in the cases of omissions; for in the withdrawal of feeding tubes, it is starvation, not the patient's underlying condition, that kills him. What one causes in the world is relevant to the issue of one's moral responsibility. One may want the doctor to take seriously the autonomous, voluntary decision of the patient to refuse further treatment, but this does not settle the issue of whether withdrawing feeding tubes helped cause death by starvation. Withdrawal of feeding tubes is not an alternative to physician-assisted suicide, so far as causality is concerned: In both cases, the doctor takes an essential step in the production of death.

(3) In the withdrawal case, if the doctor does not withdraw feeding tubes, then he fails to honor the patient's right to refuse treatment, but if he fails to provide the pill, there is no violation of the patient's right to refuse further treatment. Nor does a right to refuse treatment entail a right to be provided with the means of death. So why is there not a moral difference between the withdrawal and pill cases, in that not prescribing the pill does not violate the patient's rights, whereas not withdrawing the feeding tubes does. But this lands the opponent of consequentialism with another problem: While to insist upon one's right to refuse treatment is one way of committing suicide, taking the pill is another way of committing suicide. Why, if suicide is permissible, is one way of committing suicide, the doctor withdrawing feeding tubes, more acceptable than another way of committing suicide, the doctor supplying a pill that the patient takes? It is necessary to identify some reason to think that, if suicide is morally permissible for terminally ill patients, having a doctor withdraw feeding tubes is acceptable but having the doctor provide a pill is not, when both are seen by the patient and by the rest of society as means of committing suicide. If one refuses to allow that suicide is permissible in such cases, then there will be no moral difference between the withdrawal and the pill cases and so the one cannot be used by way of contrast to the other. Of course, in the withdrawal case, those who want to find a difference between it and the pill case may point to the fact that the law allows the doctor to withdraw feeding tubes but not, for example, the patient's son to withdraw those tubes. But it would be a mistake to treat this as if it were identical with the claim that, if the son withdraws the tubes, the withdrawal causes death, whereas if the doctor withdraws them, the withdrawal *does not cause* death. In either case the cause of death is starvation through the removal of feeding tubes; it is just that the law frowns upon the son's act in a way that it does not the doctor's act, in the relevant circumstances.

(4) There is an issue that intersects this discussion of alleged moral differences between cases that turns the debate in another direction. Consequentialists on the whole accept a quality of life view of the value of a life. The value of a life is a function of its quality, and quality of life is a function of a life's content. In this regard, some lives lack the scope and capacities for richness of life that confer on other lives untold blessings, and this regard for content can reach the desperate levels involved in the cases of anencephalic infants and those in a

permanently vegetative state, where even the very capacities for having a rich life are impaired or missing. The result is that such lives are judged on a quality of life view to be deficient in quality, with the result that their value is less than the lives of ordinary humans. This view enrages some people, for whom the thought that all lives are equally valuable, whatever their quality, is a stance or intuition or principle that is paramount and to remain unchallenged. This view is difficult in some ways to credit; for there are some lives so deficient in quality that one would not wish to live them and would not wish those lives on even enemies. To be fully in the progressive grip of amyotrophic lateral sclerosis is to have a life the quality of which seems progressively to plummet; indeed, some of those condemned to such lives often ask for relief from them through the earlier discussed examples of physician-assisted suicide. It is not society who is judging their lives adversely that prompts them to seek help; they themselves so judge their lives. It seems hard, therefore, to think of such lives on all fours with ordinary ones, and the quality of life view of the value of life reflects this fact.

It doubtless strikes some as repugnant and offensive to think of human lives as of different values. The old view would have been that all human lives were equally valuable in the eyes of God, but today this view cannot be assumed to be prevalent in all medical contexts, even when it could be agreed that people ought to base value claims about lives on the assumption of God's existence, religious tenets, or the like. So what is to replace God in this claim about lives? One can make assumptions about, say, equal worth being apart from value, but are these more than assumptions? And does society not use quality of life judgments about lives all the time in hospitals and medical settings, to decide all kinds of issues, from who gets what resource to how much of it they get? And there all the while, of course, is the plain fact that the content of some lives inspires an overwhelming sense of tragedy, of what lives once were or could have been but of what they have become. How can this sense of tragedy and dire outcome represent equal value?

Of course, in many lives, say, where certain physical handicaps are present, there does not exist this sense of overwhelming tragedy, and people cope very well with misfortune. But where a life begins to plummet disastrously in quality, equal value appears harder to defend. Unequal value, however, implies that some are at greater risk than others: If one could save either a life of very high quality or a life of very low quality; if in hospitals medical intervention is likely to produce in one case a life of ordinary dimensions and in another a life of radically reduced dimensions, and a doctor can only make one such intervention; which life should be choosen?

V

VALUE AND HEALTHCARE

Bioethics is concerned with values insofar as they are identical to universal or objective goods (benefits) and evils (harms). There is a use of *value* such that it refers to whatever any person happens to value, but this sense of value has no normative implications. What *value* refers to in this sense is completely determined by empirical research; it is a purely descriptive sense. There is a related sense of *value* such that it refers to what a large number of people value. This is the sense that seems to be important in economics. Economically speaking, something has value or is valuable if there are many people who value it, it can be transferred from one person to another, and there is not enough of it for all of the people who value it. How valuable something is on this understanding is also a completely empirical matter with no normative implications. However, there is another sense of *valuable* where what is valuable is what leads to less harms being suffered or more benefits gained, regardless of whether or not people are aware of this. This is an instrumental sense of *valuable,* and is objective. Modern healthcare, as a whole, is valuable in this sense, but some kinds of healthcare are not valuable, even though misinformed people value them.

Basic Values

Whether something has instrumental value is determined by whether it leads to a decrease in universal or objective evils or an increase in universal or objective goods. These goods and evils are the basic values because all other values in a normative sense are derived from them. Positive basic values have been called intrinsic goods, and negative basic values, intrinsic evils, but the phrases *intrinsic goods* and *intrinsic evils* are misleading, as they suggest that whether something is an intrinsic good or evil is independent of the attitudes of rational persons. However, an account of basic values that does not relate them to the attitudes of rational persons cannot explain why all rational persons avoid evils and do not avoid goods.

The following definition of basic evils (harms) and basic goods (benefits) acknowledges the necessary connection between basic values and rationality. "In the absence of reasons, evils or harms are what all rational persons avoid, and goods or benefits are what no rational person gives up or avoids" (Gert, 1998, ch. 4, p. 92). On this account of the basic values, there are five basic evils: death (permanent loss of consciousness), pain (including mental pains and other unpleasant feelings), disability (including loss of physical, mental, or volitional abilities), loss of freedom (including loss of freedom from being acted on as well as the freedom to act), and loss of pleasure (including loss of sources of pleasure). There are four basic goods: consciousness, ability, freedom, and pleasure.

These basic values are central to healthcare. Healthcare is primarily concerned with the prevention and cure of maladies, and with the relief of the symptoms of maladies that cannot be cured. Maladies, which include both diseases and injuries, have as an essential feature, that a person with a malady is suffering one of the basic harms, or has a significantly increased risk of suffering one of them (Gert, 1997, ch. 5). It is almost a truism that healthcare is primarily concerned with preventing, as far as possible, death, pain, and disability. Although not mentioned quite so commonly, healthcare is also concerned with treating those conditions of persons that would result in their suffering a loss of freedom or pleasure. Those in healthcare might rank the basic values differently from people outside of healthcare;

physicians generally rank preventing evils as more important than promoting goods, and view death as the worst evil. However, no one in healthcare would challenge any of the items on the list of basic goods and evils, that is, the basic values.

Values and Rationality

Given that the definition of good and evils is based on the actions of rational persons, it may seem as if, without empirical research, nothing could be said about what counts as evils or harms, or what counts as goods or benefits. However, such research is impossible to carry out, for it requires examining what *all* rational persons avoid and do not avoid. A list of the basic goods and basic evils has already been provided, however, so there is a seeming inconsistency. It is important to clarify the definition so as to remove this problem. To say "In the absence of reasons, evils or harms are what all rational persons avoid, and goods or benefits are what no rational person gives up or avoids," means "In the absence of reasons, evils or harms are what all rational persons, *insofar as they are acting rationally,* avoid, and goods or benefits are what no rational person, *insofar as he is acting rationally,* gives up or avoids." Almost all rational persons sometimes act irrationally. This happens when they are in a very frightening situation or are overcome by some other strong emotion. What they happen to avoid or not avoid at these times is not relevant to the account of objective values.

Making clear that basic values are determined only by the behavior of rational persons insofar as they are acting rationally introduces a new problem. How is it determined that a person is acting rationally? This is a crucial question. Most philosophers, as well as most economists and political scientists, answer this question by providing a formal answer, one that has no universal or objective content. With various modifications, the standard answer to the question "What is it to act rationally?" is "It is to act in a way that maximizes the overall satisfaction of your desires." On the formal account of rationality under consideration, persons are acting rationally if and only if their actions are consistent with maximizing the satisfaction of their desires, regardless of the content of those desires.

On this account of rationality, there is no particular kind of thing that all rational persons act to avoid and not avoid, and thus there are no basic values or objective goods and evils. There are only values in a sense that has no normative implications. It might be thought that, at least, pleasure and pain would remain as goods and evils, but this is not so. The formal answer cannot restrict itself to persons who are not suffering from mental disorders. When people with serious mental disorders are included, it is not true that all persons acting rationally, defined as acting in a way that maximizes the overall satisfaction of their desires, act to avoid pain and act so as not to avoid pleasure, even in the absence of reasons. The maximizing satisfaction account of rationality results in values being defined as whatever people value. So defined, values have no normative implications. People determine for themselves what is good or evil and so pain and disabilities can be goods to some people, and pleasure and abilities, evils to them.

The Inadequacy of Formal Accounts of Rationality

Many attempts have been made to handle this problem, none of them satisfactory. Insofar as rationality is defined in purely formal terms with no limit on content, it loses its normative implications. It will always be possible to come up with an example that will categorize someone as acting rationally when no one would ever recommend that any person for whom they are concerned act in that way. For example, suppose a person's desire to kill himself in the most painful possible way is stronger than all of his other desires put altogether, even after full consideration. On the maximum satisfaction of desire view, he would be acting rationally to consult *Consumer Reports,* read biology books, etc., in order to achieve his goal. Once this consequence of the maximum satisfaction of desire view is made explicit, it is clear that this account of rationality has no normative force. Given this sense of rationality, it makes perfectly good sense to ask, "Why should I act rationally?" Many people would respond that on some occasions you should not act rationally.

In the normative sense of rationality, the one with which philosophers are properly concerned, no persons who are regarded as a moral agents, i.e., who are held responsible for their actions, would ever recommend to anyone for whom they were concerned, including themselves, that they ever act irrationally. They would never seriously ask, "Why shouldn't I act irrationally?" If it makes perfectly good sense to ask, "Why shouldn't I act irrationally?" then it is not important to determine whether rationality supports morality or anything else. The normative sense of rationality, like the normative sense of values, evils (harms) and goods (benefits), requires that there be universal agreement among moral agents on what kinds of things are harms and what kinds are benefits. All persons who are regarded as responsible for their behavior agree that they would always recommend to anyone for whom they were concerned, including themselves, that they act rationally and they would never recommend acting irrationally.

This agreement is what allows for clear counter-examples to all of the formal definitions of rationality. Everyone agrees

that death, pain, disability, loss of freedom and loss of pleasure are evils. In the absence of reasons, all of us would recommend to anyone for whom we are concerned that he act in such a way as to avoid these harms. Likewise, in the absence of reasons, all of us would recommend to anyone for whom we are concerned that she not act so as to avoid the goods of consciousness, ability, freedom, or pleasure. Indeed, if, in the absence of reasons, persons do not act so as to avoid any of these harms or act to avoid any of these goods, they are regarded as acting irrationally. If they act in these ways for an extended period of time, they would be classified by the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM IV*) as suffering from a mental disorder. Having objective values (objective goods and evils), and having an account of rationality with content necessarily go together. Healthcare presupposes these objective values. Medicine aims at avoiding and relieving the basic evils that are the result of a condition of the person being treated.

Reasons

As pointed out in the previous paragraph, people are regarded as acting irrationally if, in the absence of reasons, they do not avoid the evils and do avoid the goods. This correctly suggests that the primary function of a reason is to make some otherwise irrational action rational. Since irrational actions are those in which, in the absence of reasons, a person does not act to avoid an evil or acts to avoid a good, reasons must be facts about avoiding evils or gaining goods. Only such facts can make it rational not to avoid an evil or to avoid a good. It is rational to amputate my right arm if that is necessary to avoid the spread of a cancer that will kill me. It is not rational to amputate my right arm simply because I want to do so, or because I correctly believe that doing so will make me asymmetrical. If desires are taken as reasons that can make an otherwise irrational action rational, then it could be perfectly rational not to avoid an evil or to avoid a good simply because of a desire to do so.

All reasons must involve one or more of these basic goods or evils that are involved in the account of an irrational action. Of course, not all reasons will be adequate to make all otherwise irrational actions rational. An adequate reason must be one that involves a good or an evil that is viewed by a significant number of otherwise rational persons as compensating for the evil suffered. Otherwise rational persons are persons who, in the absence of reasons, avoid evils and do not avoid goods. Rational people can, within limits, differ in their rankings of the goods and evils. What one person regards as an adequate reason for not avoiding a given evil, another person might not. But there are limits. It is irrational to commit suicide to avoid going to the dentist. However, it is not irrational to commit suicide when suffering from an incurable illness that is sufficiently painful or disabling. Although rational persons can, within limits, differ on which good counts as better and which evil counts as worse, they do not disagree on what counts as an evil or as a good. There is complete agreement on the basic values even though there is limited disagreement concerning their ranking.

Healthcare and Values

Healthcare is primarily concerned with preventing or treating those conditions of persons that cause or significantly increase the risk of death, pain, and disability and, to a lesser extent, the loss of freedom and pleasure. Healthcare is less involved with gaining any of the goods, but still has some concern with these matters. Those in healthcare might have a unique ranking of values, with the avoidance of death, pain, and disability, being ranked higher than they might be by people not in healthcare. However, English philosopher Thomas Hobbes (1588–1679), who was primarily concerned with politics, not with healthcare, also took death, pain, and disability to be of primary importance. Indeed, like many doctors, Hobbes seemed to view death as the worst of the evils. When the rankings of individual healthcare practitioners are not the same as the rankings of their patients, patients need not accept the rankings of their healthcare practitioners. On the contrary, healthcare practitioners must accept the rational rankings of their patients, for it is the patients that will actually be suffering the evils.

In addition to the basic values, there are also moral values. Moral values are the moral virtues, such as kindness, fairness, trustworthiness, and honesty. Moral values, like the basic goods and evils, are objective values. Kindness, fairness, trustworthiness, and honesty, are traits of character that all impartial rational persons want everyone to have because having these traits of character increase the probability that less harm will be suffered by all people affected. Indeed, a trait of character counts as a moral virtue only if its general practice increases the probability that less harm will be suffered than its not being generally practiced. There are other virtues of character such as courage, prudence, and temperance that all rational persons want for themselves because they increase the probability that the person himself, or those he cares for, will suffer less harm and gain greater benefits. These are personal virtues and although they are necessary in order to have the moral virtues, they are, as Hobbes and German philosopher Immanuel Kant (1724–1804) pointed out, traits of character that make immoral persons even more dangerous.

It should now be clear that there are no unique values in healthcare, either unique basic values or unique moral values. Since the moral values in healthcare cannot conflict with the moral values in the rest of life, it is not even plausible that there are any unique moral values in healthcare. There are duties that are unique to those in health case, but there are duties that are unique to those in every profession. But none of these duties exempt those in healthcare from the requirements of common morality. As in any profession, a physician may have duties that are in conflict with some other moral rule, but in all of these cases they must be willing for everyone to know that everyone is allowed to violate this other moral rule in circumstances with the same morally relevant features.

Although it may seem that some values such as kindness take on more importance in healthcare, there is no unique ranking of moral values. There are no moral values that are unique to healthcare. The importance of recognizing that there are no values, including moral values, that are unique to healthcare is that it makes clear that, as long as two persons know the facts of a situation equally well, it makes no difference to the validity of their judgments whether or not one is a practitioner of healthcare and the other not. Of course, those involved in healthcare usually know more of the relevant facts better than someone not involved in healthcare. However, the relevant facts should be made available to people outside the field as well as to those within. The advantages in moral evaluation and moral decision making about healthcare matters that those in healthcare have over those not in healthcare, in addition to greater knowledge of the facts, is greater experience and practice. These are not insignificant advantages.

Ethical Relativism

Anthropologists investigating a society previously unknown to them are very wary of criticizing any aspect of that society, even when that aspect involves a harmful practice. At one time, this reluctance to criticize was based upon a kind of naïve ethical relativism. They believed that each society had its own morality, but they believed that their own morality required tolerance, which they took to require that they not judge any practice in another society on the basis of their own moral standards. They did not even care whether the harmful practice was based on false beliefs about the empirical world. That the people of that society, or more commonly the dominant group in that society, accepted a certain practice, was all that was important. For various reasons, these views changed. Partly this was due to a great increase in the number of women anthropologists, and the widespread practice of female circumcision or genital mutilation in many societies being studied by anthropologists. However, even though many anthropologists now consider the practice of female circumcision to be immoral, they do not thereby immediately criticize that practice and try to get the society to stop practicing it. The reason for this is that they realize that this practice is tied into many other beliefs and practices, so that it is not clear how this practice can be changed or eliminated without doing greater harm to the people of that society.

Realization that objective evaluation of a society's practices is legitimate should lead to a more careful examination of the complex interrelationships between the practices in that society. It is not appropriate to criticize a practice and attempt to change or eliminate it until reasonably sure that changing or eliminating that practice will not result in even worse consequences. Caution is in order before trying to get a society to change or eliminate any of its practices. This is true not only of the practices of other societies, but also of a person's own society. Nonetheless, when encountering a harmful practice, it is now recognized that it is morally acceptable to try to find out what can be done to lessen the amount of harm, without causing even greater harm. A harmful practice should always give rise to an investigation about what can be done to change or eliminate that practice without resulting in greater harms. Anthropologists came to realize that the basic harms were universal. They also understood that a practice could be recognized as harmful even though it might not yet be known how to eliminate that harm without causing even greater harms.

Relativism and Unique Values in Healthcare

If healthcare is thought to have unique values, then people outside of healthcare, e.g., philosophers, might be in a position like those anthropologists who held ethical relativism. Evaluation by outsiders who did not share these unique values would be inappropriate. However, if healthcare shares the same values as all other areas of life, then all that outsiders need to know is what the facts are. However, similar to the situations of anthropologists, knowing all the facts is not an easy matter. Consider the following example; a philosopher claims, with some justification, that the process of providing information as practiced by the overwhelming number of doctors, is not adequate. On an ideal or philosophical level, a patient ought to be provided with all of the information that any rational person in that situation would want to know. This would include not only any significant risks and benefits of the proposed treatment, of alternative treatments, and of no treatment at all, it would also include

information about which hospitals and doctors are most successful in providing those treatments.

Everyone agrees that patients are deprived of some freedom to make rational decisions if they are not supplied with all of this information. Thus the current practice of not providing this information is a harmful practice. In the absence of adequate justification, it would seem that this failure to provide all of this information is not morally acceptable. However, it does not follow that this practice should be changed and that doctors should be required to provide all of this information. It might be that, unless many other practices are also changed, requiring doctors to provide all of that information will require so much time, with so little change in outcome, that the costs, human as well as financial, make it undesirable to require physicians to provide that information. Perhaps healthcare practitioners already know that. But if we know that a practice is harmful, we should be trying to see if something can be done to change that practice without thereby causing even more harm. There should be consideration of other methods of providing this kind of information to patients.

Summary

Healthcare accepts the same basic and moral values that are accepted by all rational persons. Death, pain, disability, loss of freedom and loss of pleasure, due to conditions of person, are the focus of healthcare. Those in health case might rank the basic values differently, they may even rank the moral values differently, but even if they do, it is quite likely not a uniform difference. It is only that more individuals in healthcare might rank avoiding death higher than avoiding pain than most people not in healthcare. Sometimes, however, as in end of life care, these differences in rankings can be very important. Although there are no unique values in healthcare, there is a unique experience. Those who are healthcare practitioners know more about what actually happens and how different practices are related to one another. Anyone not in healthcare who has not studied what actually goes on in healthcare should, like anthropologists confronting a new society, be very wary of suggesting changes in the way healthcare is practiced, even when confronted with what seem like clear cases of harmful practices. But those in healthcare should recognize that when all the facts are known and appreciated, the rankings of values by those in healthcare do not have any privileged status, rather the rankings of those who will suffer the evils carry the most weight.

VALUE AND VALUATION

• • •

Though values are integral to human experience, it is only in modern societies that they have gained an explicit place in ethics. In traditional societies, values generally operate as components of the common culture that are taken for granted. Their moral discourse focuses on the rules that define primary human obligations and on notions of moral excellence. Values first acquire ethical importance where individuals have wide choices about how they are to live their lives. These choices lead to a plurality of value perspectives whose competing claims may appear to express little more than subjective preferences. The challenge to ethics, then, is to devise ways of assessing values critically in relation to normative moral discourse.

In European civilizations, wide value choices were first opened up by the rise of capitalism and of liberal democratic

states. In this context, value considerations are never far removed from market dynamics or from basic principles of human liberty. Although class and status factors bar many from the benefits of these modern social formations, their impact on human life remains pervasive, compelling us for the sake of social order to accommodate various value orientations.

The Concept of Values

We take note of the realities in our world that matter to us. Values are concepts we use to explain how and why various realities matter. Values are not to be confused with concrete goods. They are ideas, images, notions. Values attract us. We aspire after the good they articulate. We expect to find our own good in relation to what they offer.

Because values are linked to realities we experience, they have an objective reference. They disclose features in our everyday world to which we attach special importance. Positive values are balanced by disvalues. Disvalues express what we consider undesirable, harmful, or unworthy about particular phenomena. They identify realities that we resist or strive to avoid. Virtually everything we experience has valuative significance: objects, states of affairs, activities, processes, performances, relational networks, and so on.

Values are linked to acts of valuation (Scheler). For every value that appears, there is a corresponding valuative orientation (Husserl). This orientation may not be fully self-conscious; still less is it an expression of critical judgment. It is, nonetheless, the subjective basis for the appearance of values. Without valuing subjects, there can be no such thing as values.

In an elemental sense, values are disclosed by feelings (Ricoeur). Explicit value language comes later, if at all. How do I know that health is good? I know because I feel good when I am healthy. The positive feeling signals the presence of value. How do I know that a performance of Shakespeare's *Hamlet* is good? Even an informed aesthetic judgment has an affective basis: I was moved by it. In being moved, I apprehend value. My primal awareness of value becomes explicit as I identify the features in a phenomenon that draw me to it. Human languages furnish a rich vocabulary for conversations about values.

The correlation between values and valuative acts does not imply that values are purely subjective or that they are merely secondary embellishments of empirical fact. On the contrary, the notion of an empirical reality devoid of all valuative meaning is itself an abstraction. As our perceptions disclose an object's reality, so our affections disclose its worth (Ricoeur). By means of perceptions and affections, we apprehend facets of the realities we encounter. Apart from corresponding acts of consciousness, however, nothing whatever can appear.

Values and Human Needs

Values are intimately related to human needs and desires (Niebuhr; Ogletree; Ricoeur). We value realities that satisfy basic needs and fulfill deeply felt aspirations. We associate disvalues with realities that threaten or diminish human well-being. Human well-being is only part of the story. With a growing environmental consciousness, value discussions embrace nonhuman life forms as well, perhaps creaturely well-being as a whole. Human life then gains its value within a natural world that has intrinsic worth. Religious communities honor a world-transcending center of values from which all lesser values derive their significance.

There are as many kinds of values as there are regions of experience where we distinguish good or bad, better or worse, beneficial or harmful: sensory values, organic values, personal values, interpersonal values, social values, cultural values, and spiritual values (Scheler). Social values can be differentiated into economic, political, legal, associational, and familial subsets. Cultural values embrace religious, moral, cognitive, and aesthetic interests (Parsons). The formal value types all contain values and disvalues. Notions of creaturely well-being are implied if not stated.

Value Issues in Biomedical Practice

Virtually all kinds of values figure in biomedical practice. Organic values are basic: life, health, vigor, bodily integrity. The purpose of medicine is to save lives and to promote healing. Yet the ill and injured are never merely "patients," organisms suffering treatable maladies; they are persons with dignity who have their own life plans (May, 1991; Ramsey). Personal values, therefore, qualify organic values. Patients as persons may in no case be subjected to medical procedures without informed consent. Ideally, they participate actively in their own healing.

Organic values are inherently problematic. Our impulses press us to strive for life, strength, and agility. Yet these strivings are limited by our vulnerability to illness, injury, disability, and, finally, certain death. Modern medicine inclines us to define the limits of organic life not as natural features of finitude but as problems to be solved. This tendency requires us to make value judgments about the boundaries of medical intervention. Medical practices inattentive to these boundaries can deprive the dying of the

personal space they need to achieve closure in their life pilgrimages.

At this point, organic values are qualified by more encompassing value commitments. Such commitments can help us to accept life's limits, acknowledge goods more noble than our own survival, and endure sufferings and disappointments with grace and wisdom. Life, death, health, and illness are never purely physiological; they are moral and spiritual as well. Healthcare must also have moral and spiritual as well as physiological dimensions (Cousins; May, 1991; Nelson and Rohricht).

Professional and economic values intersect medical practice in similar ways. Physicians have specialized knowledge that equips them to provide socially valued services. They enjoy social status as professionals who maintain standards for medical practice. In this role, they are public guarantors of prized social values (May, 1983). Physicians in the United States offer services for fees, primarily through third-party payments. Accordingly, medical practice is also a market transaction, and physicians are businesspeople with economic interests. The stake in economic values qualifies professional devotion to patient well-being.

The organization of healthcare profoundly conditions its operative values. Modern medicine requires sophisticated technologies affordable only to large medical centers. These institutions, usually constituted as corporations, dominate medical practice in the United States. The technologies they use are typically produced and supplied by global corporations. The income they receive derives largely from corporate employee-benefit plans and from insurance firms that service them. Health-related industries have become a major component of the economy, perhaps inappropriately overriding the legitimate claims of other social goods. Powerful economic and political interests support the continued growth of medical enterprises with little regard for wider social ramifications.

Because the desire for quality medical services is urgent, intense public debate surrounds federal policies that bear upon the organization, regulation, and funding of healthcare. The struggle is to determine appropriate government roles for the oversight and financing of biomedical activities. In this struggle, conflicting political values intersect healthcare practices as public actors respond to constituent interests. Similar sociocultural analyses could be directed to the roles played in the healthcare system by values resident in families, religious communities, research institutes, medical colleges, the legal system, the media, and the arts. Ethical studies of the intersection between biomedical practices and social processes uncover a volatile mix of conflict-laden value issues.

Fluidity of Values

Values are not only pervasive but also fluid. Any concrete experience harbors many values and disvalues, none of which is definitive or self-contained. Illness can be a physical malady, a ruthless disruption of personal plans, an economic disaster, an opportunity for self-discovery, a moment of human bonding, an occasion for medical virtuosity, or a case study in biomedical research (May, 1991). Each of these meanings captures some of the values that belong to a particular experience. As attention shifts, one set of values continually flows into another.

Our terminology for values is similarly fluid. The word *health* can be used descriptively; it also identifies an important value. *Justice* can designate a basic moral principle; it can refer equally to a value worthy of promotion in social arrangements. The term *objective* may characterize "value-free" inquiry, but it also designates a cognitive value.

Because of their fluidity, values resist schematic classification. Attempts to construct comprehensive value schemes do, however, have heuristic significance. They heighten awareness of the range of our valuative connections with our world, and they stimulate reflections on what belongs to human well-being (Hartmann; Perry; Scheler).

Moral Values

Within the value field, we can isolate a subset of moral values. Moral values cluster around personal identity, interpersonal relationships, and the makeup of groups, associations, social institutions, whole societies, and even the global community (Scheler). Numerous values—dignity, integrity, mutual respect, loyalty, friendship, social cohesion, fairness, stability, effectiveness, inclusiveness—are moral in import. Anthropocentric values are supplemented and corrected by the moral claims of animals and, more broadly, by the moral claims of the environment, a self-sustaining ecosystem. Even religious devotion to the divine life has moral dimensions, for the faithful are obliged to honor God as the final bearer of value.

Moral values enjoy precedence within the value field because they identify the basic loci of all valuing experience—that is, valuing subjects in relationship. Where moral values are secure, we can cultivate a wide array of values. Where moral values are in danger, all values are at risk.

Even so, in our responses to concrete cases we regularly rank some nonmoral values above specifically moral ones. Faced with a health emergency, our regard for life itself, an organic value, surpasses normal preoccupations with human dignity, a moral value. We do what we can to save a life! At

the same time, we know that life as such is but one value among many. Prolonging human life can never, therefore, be the primary goal.

Similarly, human beings can often best advance their own good through value commitments that transcend specifically moral considerations. Cognitive, aesthetic, and especially spiritual values finally stand *higher* than moral values in most value schemes because they bestow significance on existence in its travail and woe. Yet these values still require for their realization valuing subjects who are bearers of moral value.

We normally discuss moral values in terms of rights and duties. Rights identify claims that others properly make on us. These claims intersect our value-oriented projects and disclose our duties. A physician's professional judgment about a course of therapy is subject to the patient's informed consent. The abortion debate hinges on differing assessments of fetal rights against a pregnant woman's right to choose.

Duties consist of obligations and prohibitions. Obligations specify what we must do no matter what else we might also hope to accomplish. Hospital emergency rooms must treat seriously injured persons regardless of whether they can pay, offering such care as a part of normal operations. Prohibitions specify what we must not do regardless of larger objectives. We must not use human beings as research subjects without their consent no matter how important the research may be.

It is for the sake of moral values that basic rights and duties are binding. We may set such mandates aside only when extraordinary measures are required to safeguard the values they protect. For the sake of human dignity, physicians are normally obliged to do all they reasonably can to sustain the lives of their patients. Precisely for the sake of human dignity, however, this obligation loses its force when further medical interventions would only prolong the dying process.

Values and Human Action

Value awareness gains practical importance in terms of action (Ricoeur). We adopt courses of action that promise results favoring our prized values; we act to inhibit developments that endanger our values. Values guide decision making, disposing us to choose one course of action over another. We justify our decisions in terms of the values they are designed to promote.

Matters do not always turn out as we expect. We may lack the skill, the power, the influence, or the knowledge to achieve our objectives. In medical practice, few surprises follow the skilled application of routine therapies proven to be effective for treating particular ills. Physicians do not stay within safe territory, however. They regularly confront medical problems that they cannot diagnose with confidence and for which there are no known clinical responses with assured results. Medical outcomes frequently fall short of human hopes. They include side effects whose disvalues outweigh desired values. "Side effects" belong to action consequences even when they do not reflect our intentions.

When our actions affect the actions of others, uncertainty increases. Other people may not react as we expect. They may misunderstand our intentions or respond carelessly. We may misread their value commitments. Perhaps the relevant network of human interactions is so vast and complex that it surpasses what we can grasp. Here, too, the outcomes may not fit our values. Prediction is most reliable for highly routine actions with widely understood purposes. It is least reliable for novel initiatives, such as new directions in policy.

Because we cannot fully control or predict the consequences of our actions, the fit between actions and values is inexact. This inexactness carries over into value assessments. We may readily name the values that attach to desired outcomes. Before we can evaluate a course of action, however, we have to consider the uncertainties. We have to weigh the disvalues that could accompany significant miscalculations. Considerations of value differ from discussions of duty by virtue of the inexact fit between values and action. Duty refers not to the likely outcomes of actions but to actions as such, which are largely in our power. It specifies ground rules that order human activity. In general, we may pursue a larger vision of the good only within constraints set by these ground rules. In its early stages, biomedical ethics properly gave precedence to the delineation of basic moral duties.

The fit between values, action, and action consequences remains close enough, however, that values must figure in the ethical examination of action. I am accountable to myself and others not simply for the conformity of my actions to rules that define my duties but also for values and disvalues that reside in the results of my actions. In decision making, I project the likely outcomes of actions I am considering and I weigh probabilities that qualify my projections. I also bring into view risks of unpleasant surprises. Practical reflection on values depends on substantial knowledge of the social dynamics that structure action.

Values in Society and Culture

In traditional societies, the most crucial value issues are largely settled. To be viable, a society requires a shared set of

reasonably cohesive values. This shared value cluster composes the society's moral identity. It is expressed in many ways within the common culture: public rituals, speeches, novels, paintings, school textbooks, standard histories, and scholarly investigations.

Modern societies with market economies and liberal democracies are not able to sustain comprehensive value syntheses. At best, they promote what John Rawls calls a "thin" theory of the good—that is, elemental goods that all are presumed to need and want whatever else they might also desire (Rawls). Within the framework of basic goods, such societies host a multiplicity of concrete value orientations, reflecting the diverse priorities of individuals and groups within the society. Some question whether we can sustain even a "thin" theory of the good without a widely shared, substantive value synthesis fostered in basic social institutions (MacIntyre). The disintegration of traditional cultural values tends to undermine interest in the common good. Private preoccupations with individual advantage and "interest group" politics then displaces public discourse about the good of the society as a whole. Likewise, political battles are fought without the restraints of civility necessary to social order. Value theory becomes urgent when basic values are in dispute. Its task is not only to advance critical investigations of persistent value disputes but also to show how various value streams within a pluralistic society can contribute to the good of all.

Critical Reflection on Values

The scrutiny of values has four crucial layers: (1) the reflective identification of our operative values; (2) assessments of the fit between these operative values and considered judgments about creaturely well-being; (3) analyses of value relations in order to identify compatible and incompatible values sets; and (4) imaginative constructions of value syntheses capable of ordering life priorities in personal, communal, and social contexts.

The investigation of values begins with description. We seek to become self-conscious about the values we prize, taking note of value commitments ingrained in stable life patterns and ongoing institutional involvements. The descriptive task is informed by historical studies of normative traditions and of social developments leading to current practices. As we make our operative values explicit, we are often stimulated to reorder our priorities. We recognize that existing arrangements do not reflect our convictions about what matters most in life.

The relation that values have to basic human needs suggests a second step in value studies. British utilitarians and American pragmatists sought to test our presumptive values by empirical investigations (Bentham; Dewey). Their aim was to discover life practices and value attachments that truly accord with primary human needs. Much human-science research functions as value inquiry of this sort, shedding light on value patterns that tend to promote human well-being in contrast to those that finally prove dysfunctional. Historical, philosophical, and theological reflections can also inform such inquiry. For ethics, the challenge is to clarify the contributions empirical studies can make to the critical assessment of values and to incorporate those contributions into constructive philosophical and religious thought. The third step is an analysis of value relations. Not all values are compatible with one another, at least not in practical terms. We cannot both affirm free speech and shield people from all offensive public expressions. We cannot protect the environment without constraining market freedoms. Likewise, we cannot guarantee everyone healthcare that fully utilizes the most advanced medical technologies while also controlling aggregate healthcare costs. Critical thought examines values in terms of their fit with one another. It dramatizes the necessity of choices among different sets of values. We bypass some values and endure relative disvalues for the sake of value combinations that reflect considered priorities. The crucial step in the critical study of values is the imaginative construction of coherent value syntheses capable of guiding action. Because modern societies harbor a multiplicity of value perspectives, attempts to determine value priorities take place in several contexts.

Individuals develop a mature moral identity by clarifying the connections and priorities that order personally cherished values. Value syntheses are no less vital for families, special-interest associations, and religious bodies. These collectives gain moral, and perhaps religious, identity through shared value commitments. Organizations that give concrete form to economic, legal, political, and cultural institutions are themselves more effective when they make their defining values explicit.

Coherent sets of values are not easily achieved or sustained. They enjoy the greatest authority when they emerge as critical appropriations and transformations of normative value traditions within contemporary life settings. Because of the complexity of experience, value syntheses can never fully overcome areas of ambivalence or wholly resolve internal strains. Within limits, we can accommodate value conflicts that we acknowledge and honor. Such conflicts may even stimulate creativity. Within comprehensive value syntheses, value priorities normally run in two contrary directions. Elemental sensory, organic, and economic values enjoy priority over higher political, cultural, and

spiritual values in the sense that they furnish the conditions necessary to the appearance of the higher values. Political, cultural, and spiritual values enjoy priority over more basic sensory, organic, and economic values in the sense that they bestow meaning and significance on the more elemental values. Moral values play the mediating role because they identify the loci of value experience. These contrasting modes of priority can shed light on concrete values conflicts.

Public Value Syntheses

A basic value of modern societies is the protection of private spaces for people to pursue diverse visions of the good. Social cohesion rests, then, on minimal agreements that allow individuals and groups to live together in their diversity. In the United States, the prevailing value synthesis combines liberal democratic principles and principles of free-market capitalism. Enduring controversies concern the nature and extent of appropriate government intervention in market processes. Less clearly articulated are images of a greater national community embracing many races, cultures, and religions. The latter images are countered by persisting patterns of racism, ethnocentrism, and religious intolerance.

In biomedical ethics, the most urgent challenge is to form a public value synthesis that can guide healthcare reform. Though difficult disputes remain, there is considerable agreement that a good system will guarantee basic care for all, maintain acceptable standards of quality, foster an active partnership between patients and physicians, take account of the defining values of those who give and receive care, sustain advanced biomedical research, hold total costs to manageable levels, and protect contexts for personal preferences and individual initiatives in delivering and receiving care. These values—especially the contention that all people must have access to basic medical services—all have important moral dimensions.

Any workable system will include value trade-offs. It will require a reexamination of standards of quality care, a balance between healthcare needs and other social goods, and a workable mix of economic incentives and government regulations that maintains discipline within the system while allowing space for individual initiatives. Any system will also confront limits. Moral creativity requires imaginative responses to limits in the promotion of creaturely well-being.

Because of the subtleties involved, bioethics cannot easily incorporate notions of value and valuation into deliberations about basic human duties. Yet values pervade human experience. They even shape our perceptions of the obligations and prohibitions that set constraints on our actions. As we examine more comprehensively the moral issues that reside in biomedical practice, the more we will discover the necessity of systematic value assessments. Critical value studies will tend as well to force a shift in the dominant structure of moral reasoning, from the linear logic of the syllogism to the more nuanced process of weaving multiple value considerations together into an illuminating pattern of moral understanding. While the resulting judgments may appear less precise and decisive, they will probably be more true to life.

VETERINARY ETHICS

• • •

Veterinary medicine, as the distinctive medical discipline we know today, emerged during the nineteenth century as an adjunct to agriculture. Animals were valued for the food or fiber they provided or for the work they performed, and the veterinarian's role in society was to keep the animals healthy so they could serve people's needs. Even after anticruelty laws had become widespread by the late 1800s, and the horse doctor became the dog doctor with the growth of companion animal practice in the mid-twentieth century, the veterinarian's ethic remained unexamined and substantive ethical issues officially unacknowledged.

Unlike medical doctors, whose engaging of ethical issues can be traced back to Hippocrates, veterinarians did not have a historic tradition of professional ethics to draw on. Until the late 1970s, the field of veterinary ethics focused primarily on issues of business etiquette and professional relations. The Code of Ethics of the American Veterinary Medical Association (AVMA) addressed such areas as referrals to other veterinarians and whether it was "ethical" to have a large insert for one's practice in the Yellow Pages. Social changes, such as the emergence of the animal-welfare/rights movement and its impact on public consciousness, helped catalyze consideration of the complex of ethical concerns that face the veterinarian.

Two people acted as gadflies to the profession in this important period: Michael W. Fox, a veterinarian with the Humane Society of the United States, and Bernard E. Rollin, a philosopher at Colorado State University. Fox and Rollin published articles in influential journals (Fox, 1983b; Rollin, 1978, 1983) that pointed out the need for systematic examination of the ethical concerns of the veterinary profession. Fox also wrote letters to the *Journal of the AVMA* on this theme (Fox, 1983a). In 1978, Rollin inaugurated the first regular, required, full-term course in veterinary ethics at the Colorado State University College of Veterinary Medicine. Both Fox and Rollin wrote books on animal welfare and rights. Rollin, in addition, had taught and published in human medical ethics, and he was sensitive to the differences between the problems of human medical ethics and those of veterinary medical ethics. In particular, owing to his extensive work in the moral status of animals, Rollin was aware that veterinary medicine had not yet addressed its moral obligation to animals. By the end of the 1980s, veterinary interest in the ethics of the profession had developed enough to warrant publication of a textbook on the subject by Jerrold Tannenbaum of Tufts University (1989).

The Veterinary Oath and Its Moral Dilemmas

When the veterinarian graduates from veterinary school, he or she is administered the veterinarian's oath, which includes a promise "to use my scientific knowledge and skills for the benefit of society through the protection of animal health, the relief of animal suffering, the conservation of livestock resources, the promotion of public health, and the advancement of medical knowledge" (see the Appendix, Volume 5). The veterinarian is immediately faced with a fundamental ethical dilemma: to whom does he or she owe primary loyalty, the owner or the animal? In a 1978 article, Rollin used the examples of a pediatrician and a car mechanic to illustrate the two possible choices. When the repairs on a car are more costly than the car's value, the owner can simply tell the mechanic to "junk" it or not do the repairs; there is no such choice in a necessary surgery or treatment of a child (Rollin, 1978). The pediatrician is ethically (and legally) obligated to act as advocate of the child's well-being. On the other hand, the basic current legal status of animals is that they are property, although their sentient qualities have been the basis of limited protection provided by so-called welfare laws (in the United States, primarily local anticruelty ordinances and federal laboratory animal laws).

In addition to the responsibilities they have to the animal and the owner, veterinarians must weigh practice judgments in light of the needs of society in general ("public

health"), peers, and themselves as well. As the oath also states, "I will practice my profession conscientiously, with dignity, and in keeping with the principles of veterinary medical ethics. I accept as a lifelong obligation the continual improvement of my professional knowledge and competence" (Appendix, Volume 5). In the face of often conflicting interests of animal, owner, society, profession, and self, the individual veterinarian is often presented with situations that require complex ethical judgments (Rollin, 1988). The traditional minimalistic animal ethics proscribing cruelty, from which anticruelty laws derived, are not adequate to mid-twentieth-century uses of animals such as confinement agriculture or testing and research, which were not matters of cruelty yet caused significant suffering in pursuit of profit and scientific knowledge (Rollin, 1981). In seeking a new animal ethic, society began to apply the notion of rights, which protect human nature from being submerged for the sake of general welfare, to animals in order to protect their fundamental interests as dictated by their nature (or "telos"). The veterinarian came to be considered a natural animal advocate. As society elevated to the status of animals by applying a rights ethic, the status and effectualness of the veterinarian began to increase (Rollin, 1983).

Laboratory-Animal Legislation: Effect on the Profession

One area—laboratory-animal medicine—has had its ethical obligations to animals articulated by law because of societal concern for animal welfare. Before the 1985 Amendment to the Animal Welfare Act, which originated as a Colorado state bill written by Rollin and others, and the National Institutes of Health Reauthorization Act of 1985, which turned animal use "guidelines" into regulations, researchers enjoyed carte blanche in the use of animals. The pursuit of knowledge, or "advancement of medical knowledge," had completely trumped consideration of animal pain, suffering, or distress, and laboratory-animal veterinarians were relegated to the role of keeping animals in good enough shape to serve their research purposes. The legislation that was passed in 1985, as well as the original Animal Welfare Act of 1966 and other amendments to that act, was a direct result of societal response to well-publicized atrocities in research and testing activities and the correlative demand for assurance that animals' interests were protected.

Laboratory-animal veterinarians, because of animal-protective legislation, now fulfill the most unambiguous role of all veterinarians regarding animal well-being: They are obligated by law to act as animal advocates, to assure that pain and suffering do not occur or are minimized by proper medication, that proper animal care is provided, and that humane euthanasia is performed. The veterinarians are aided by Institutional Animal Care and Use Committees, which review research or testing protocols for humane considerations before studies may commence and provide regular monitoring of facilities.

Small-Animal-Practice Concerns

Although the role of the veterinarian has been defined by society in law for the laboratory-animal veterinarian, this has not occurred in other areas of veterinary medicine in which owner interest and animal interest may conflict. The small-animal veterinarian is often faced with ethical decisions based on these conflicts. Examples include cosmetic or behavior-altering surgery and orthodontic intervention for cosmetic reasons. In general, these procedures could be considered in the interests of the animal only if the animal were afflicted with a condition that was causing or was likely to cause it pain or distress. Dewclaw removal—dewclaws can catch and tear when dogs run through rough terrain—or repair of malocclusions like base-narrow lower canines, in which the offending tooth or teeth can drive into the upper palate, can easily be justified as in the animal's interest. Cosmetic surgery that causes the animal to conform to standards of style (e.g., ear cropping) or surgery that is used to curb "objectionable" behavior (e.g., declawing of cats, devocalizing of dogs) can be viewed as causing pain and distress to the animal for frivolous human reasons. Likewise, straightening teeth that are functional to provide a perfect bite for the show dog could be considered unnecessary.

Many veterinarians refuse to do purely cosmetic surgery, and consequently they lose clients. Other small-animal veterinarians believe they owe their major loyalty to the owner. They may argue that providing the service of cosmetic surgery enhances the animal's value, emotional as well as monetary, to the owner. Still other veterinarians will provide behavior-altering surgeries, such as declawing, after first pursuing, with an owner, honest attempts at retraining or other options. They may justify their actions by saying that the owner would otherwise get rid of the pet or that they are fostering the continuation of a rewarding relationship for both pet and owner.

Surgically neutering (spaying or castrating) dogs and cats to prevent sexual behaviors and overpopulation of pets is well accepted by North American society, but (especially for dogs) is largely rejected in other countries in favor of owner responsibility in administering contraceptives and controlling pets. Many small-animal veterinarians readily neuter

cats and dogs, assuming that the discomfort of the surgery is of less import than the enhancement of the desirability of the pet to the owner (the elimination of objectionable sexual behavior, for instance) and the elimination of the chance of unwanted pregnancies; in addition, there are health advantages to neutering.

Some Equine-Practice Concerns

The equine veterinarian is under similar tension, only more so. Lameness is the most frequent complaint of horse owners, as the horse's usefulness requires a smooth and efficient gait. The equine veterinarian is often pressured to provide painkilling medication or surgery to cut the nerves to the feet of race or performance horses because of lameness. In some respects this is a compassionate action, as the animal is rendered fully or relatively free of pain. However, there are cases in which eliminating painful sensations may cause the animal to use and seriously injure a limb. Pressures to administer performance-enhancing drugs, or to look the other way when objectionable training techniques may be used, may be severe for equine veterinarians. Veterinarians may also be called on to perform purely cosmetic surgery, such as tail docking or tail "breaking" for an artificially high tail carriage. Unfortunately, horses are generally of little entertainment or economic value if they do not "go sound," or conform to an ideal of beauty.

A Look at Food-Animal Medicine

Food-animal veterinarians have always been placed in a position of tension between the interests of animals and the interests of producers. In traditional agriculture, which prevailed as an "extensive" (as opposed to "intensive") endeavor until the mid-twentieth century, the tension was mitigated to some extent because producers generally did well economically only if they provided for the health and welfare of their individual animals. With the rise of confinement agriculture, however, new considerations have entered into the picture, and producers can prosper—in fact, may make the most profits—even if numerous individual animals suffer from poor health or die. For instance, feedlots may utilize diets that cause digestive and liver disease in a certain percentage of animals, but that loss will be more than compensated economically by the weight gain in the remaining animals. Furthermore, the use of antibiotics, vaccines, growth promoters, etc., have permitted selectivity in meeting animal needs and the separation of economic productivity from animal well-being. Animals can thus suffer in areas not related to economic productivity, yet producers can do well. Since the advent of intensive agriculture, veterinary concern for individual animals has tended to be replaced by a "herd health" philosophy to serve the livestock industry.

In confinement operations, a certain death loss is expected from the animals, whether from contagious or so-called production diseases, which are caused by handling, artificial environments, selective breeding, population density, or nutrition in the operation. Veterinary care in confinement operations usually covers only animals that are expected to recover without costing more in money and labor than the animals' market value. In sheep feedlots, a common daily chore is picking up dead or moribund animals. Discovering which animals are sick, separating them from their group, and treating or euthanizing them is often considered too expensive to support. In complete confinement houses for swine, animals are fed antibiotics because respiratory disease is so prevalent owing to high ammonia levels. To combat fighting in tight quarters among feeder pigs, their tails are amputated so the animals cannot wound each other by tail biting. Mastitis and footrot in dairy cattle are production diseases caused by the enforcement of high milk yields while the cattle are maintained on dirt lots. The average dairy cow is worn out and culled in four or five years, less than half of the expected useful lifetime fifty years ago.

Agrarian values of husbandry have been abandoned in much of present-day agriculture, affecting how the veterinarian may conduct his or her profession, because whereas a small farmer once maintained a modest lifestyle by caring for a few individual animals, a corporation now looks at profit margin only. Even in the more traditional agricultural activity of cattle ranching, economic considerations militate against veterinarians' controlling the pain of such activities as branding, dehorning, and castration. Thus the modern food-animal veterinarian faces a variety of conflicts arising out of tension between economic considerations on the one hand and animal health and welfare considerations on the other.

The Veterinarian and Euthanasia

Even if the veterinarian's inclination is to act as an animal advocate, he or she may be thwarted by the owner's wishes, because of the legal status of animals as chattel or property. Occasionally a veterinarian is faced with a situation in which a pet is suffering without hope of recovery, as in terminal cancer, but where euthanasia is not an option because an owner refuses to authorize it. Many veterinarians quietly

euthanize such animals as a humane act in spite of its illegality; but a more direct approach, utilized by veterinarians who often deal with death and the consequent grief of owners, is to discuss the inevitable with clients beforehand and exercise a humane ethic by requesting the clients to agree to euthanasia if certain clinical signs, like unremitting pain or inability to eat, arise.

A more common delay of euthanasia occurs when a food animal is kept alive despite suffering to maximize income. This scenario is most often seen in large, commercial operations, where, for instance, a sow with a fractured leg or a cow with a cancerous eye could be kept alive without expensive treatment until parturition or weaning of offspring. It is interesting to note that the laboratory-animal veterinarian is required by law to euthanize when faced with hopeless animal suffering, while the private practitioner is hamstrung by laws of private property in situations that do not constitute cruelty under the law.

The most obvious and rewarding use of euthanasia—killing without causing pain or distress—is to end an animal's suffering due to unremitting illness or fatal injury. However, there are other uses of euthanasia, such as end points for research, humane slaughter for meat, and humane killing of unwanted pets by pounds, shelters, or veterinarians. The AVMA Panel on Euthanasia periodically updates and publishes its report on euthanasia. The report examines methods of killing and labels as unacceptable those that cause animals to suffer. For instance, the report accepts an overdose of anesthetic, which causes an animal to become unconscious before dying, but condemns an overdose of paralytic drug, which causes motor and respiratory paralysis and suffocation in an alert animal.

Many small-animal veterinarians are confronted with requests for "convenience" euthanasia—euthanasia of healthy pets for owners who have rejected the implied contract of care they incurred when they acquired the pet. Some veterinarians avoid these ethical dilemmas by refusing categorically to perform any "convenience" euthanasia, even though they know that the owner may choose a nonhumane alternative, such as abandonment. Others accept such animals on the condition that they be allowed to find a home for the animal as an alternative to euthanasia; this route obviously requires time, effort, and probably expense on the part of the veterinarians but helps to satisfy their obligation to the animal.

Accepting an animal for euthanasia, and then not performing it, however, is a breach of contract and indefensible on legal grounds. One interesting dilemma that has challenged equine veterinarians is insurance companies' requirement that expensive horses be euthanized if they are rendered unfit by accident or illness for an insured purpose (e.g., racing, breeding, or showing) even if these animals are otherwise capable of a pain-free, or even useful, existence. When enormous sums of money are at stake, consideration of the animal's interests tends to disappear.

Veterinarians and Anticruelty Laws

Animal cruelty laws are notoriously lax. Most allow conviction only in cases of purposeful abuse, and in any case generally result in insignificant fines. However, the veterinarian may be able to make a difference in the lives of animals by reporting and testifying in animal abuse cases. Reporting a client for battering his dog or starving his horses or other stock, when all efforts at education and persuasion are exhausted, may be the only means of protecting animals. In taking a stand as an animal advocate, the veterinarian may experience a loss of clientele and income, thereby placing personal interest in conflict with animal and client interests.

The Veterinarian's Obligation to Society

The veterinarian's obligation to society can also be the occasion for conflicts relating to self or business interests. The most straightforward example may be the protection of society from contaminated animal-source foods. Hormonal and medicinal additives to feed, or treatments of individual animals with medications, can result in residues in meat and milk. These products, if allowed for food animals, have government-mandated withdrawal times before slaughter or milking. Sometimes products used in animal production are not approved for any food animal administration. Yet because of poor planning, inattention to withdrawal times, or attempt to defraud, producers may send contaminated animals or their products to market. The underlying motive is usually profit. If a veterinarian discovers that a producer is feeding an illegal additive, or if, for example, a heifer is sent to slaughter before the withdrawal time of the penicillin she was given, the food-animal veterinarian has a public-health obligation—an obligation to society—to report the client despite professional confidentiality concerns. The loss of one client may be the least of the financial impact of such an ethical choice; other potential or actual clients may avoid association with the veterinarian because of fear of also being turned in, as some illegal practices in the food-animal industry may be widespread, especially in a given region.

The laboratory-animal veterinarian's career can be seen as a service to society, in that he or she provides clinical

support or scientific information for the advancement of scientific knowledge. Despite his or her legal mandate as animal advocate, the veterinarian may experience personal conflict in areas of pain or disease research; for example, studies that involve the most animal suffering may also provide the most useful information for the betterment of humans and animals alike. The laboratory-animal veterinarian must also come to grips with the fact that virtually all of his or her patients will be killed at the end of a study.

The zoo or wildlife veterinarian serves societal interests in areas of animal conservation and wildlife management. Incarceration, as in a zoo, is not generally in individual animals' interests, but captive breeding programs may be needed to preserve a valued species. Similarly, situations may arise in which a disease is introduced into study animals to determine pathophysiology or treatment for that species or similar groups. The use of wild animals in research, especially when capture is a part of the research design, has been severely criticized by animal welfare and rights groups because of unacceptably high numbers of "stress" losses of animals used in the studies.

Policing the Profession: Obligations to Peers

The veterinarian, like practitioners in other professions, may have to take an ethical or legal stand regarding the practices of his or her peers—as, for example, when one gives testimony in a malpractice suit. Certainly a person's choice in business practices and commitment to medical standards indicate the quality of his or her moral fiber and loyalty to the profession. It is not unusual for veterinarians to sever professional or personal ties with other veterinarians over professional standards, although it is rare for them to make allegations of malpractice or business malfeasance of other veterinarians. This course is largely left to state boards of veterinary medicine, which respond to complaints by the public. Reluctance to speak out against professional misconduct by other veterinarians is not unique to this profession. A certain degree of prudence must be exercised by professionals to avoid unfairly slandering a colleague without knowing the entire story; for instance, a client's account of a veterinarian's actions may be biased and medically naïve. Many veterinarians also believe that exposing misconduct puts the entire profession in a bad light, even if the public would likely have a positive regard for "policing the ranks." Veterinarians, like other professionals, are allowed a fair amount of leeway in regulating themselves, since they are presumed to know the issues better than laypeople. Failure to self-police can result in loss of autonomy, with rules initiated and governed by people who know little about the profession, such as legislators.

The Veterinarian's Obligation to Self and Personal Values

The veterinarian's obligation to self is best fulfilled by examination of and adherence to his or her professional and personal values. Some veterinarians believe the veterinarian's only or major loyalty should be to the animal. Most veterinarians probably enter the profession with a desire to protect animal health and relieve animal suffering, without an understanding of competing interests. A fuzzy or unexamined ethic may lead to compromising professional decisions. Veterinary schools have responded to the need for ethical training in their curricula, with the understanding that veterinary students need intellectual tools to examine their own ethics throughout their professional lives.

Veterinary Ethics Today

The profession is by no means monolithic in its attitudes, but the AVMA and other veterinary organizations have gradually begun to take official positions on animal issues. A number of practitioners' organizations, including the American Society of Laboratory Animal Practitioners, the American Association of Bovine Practitioners, the American Association of Equine Practitioners, and some state veterinary organizations, have taken animal-welfare positions or have held symposia or meetings pertaining to issues of concern to them. Advocacy groups, such as the Association of Veterinarians for Animal Rights, have emerged. The Animal Welfare Committee of the AVMA has encouraged the association to take published positions on a variety of companion animal, exhibit and performance animal, research animal, and agricultural animal issues. Although some positions are weak and tentative (mainly on agricultural issues), many are specifically protective (e.g., condemning use of the steel-jawed trap and recommending to the American Kennel Club and breed associations that ear cropping be dropped from standards and that dogs with cropped ears be prohibited from showing). The AVMA also sponsors an annual Animal Welfare Forum, in which veterinary educators, animal advocates, philosophers, and others examine the need for animal-welfare reform within the profession.

Given that the formal articulation and organized study of veterinary ethical issues are new, the field has made a good deal of progress. In the future, we can expect the emergence

of more sophisticated treatments of many of the issues we have articulated. With society's expectations that the veterinarian serve as mandated animal advocate (as evidenced by the aforementioned laboratory-animal laws), veterinarians will doubtless be in the forefront of emerging social concerns about animal use and treatment.

VIRTUE AND CHARACTER

• • •

"Virtue" is the translation of the ancient Greek *arete*, which meant any kind of excellence. Inanimate objects could have *arete*, since they were assumed to have a *telos*, that is, a purpose. Thus, the *arete* of a knife would be its sharpness. Animals could also have *arete*; for example, the strength of an ox was seen as its virtue. Though an animal could possess *arete*, the Greeks assumed natural potentialities in men and women to be virtues requiring enhancement through habits of skill. Therefore, Aristotle defined virtue as "'a kind of second nature' that disposes us not only to do the right thing rightly but also to gain pleasure from what we do" (Aristotle, 1105b25–30).

Because there are many things that "our nature" as humans inclines us to do, Aristotle argues, there can be many human virtues. How particular virtues are constituted can vary with different understandings of "human nature" and the different social roles and their correlative skills. Yet the virtues, according to Aristotle, are distinguished from the arts, since in the latter excellence lies in results. In contrast, for the virtues it matters not only that an act itself is of a certain kind, but also that the agent "has certain characteristics as he performs it; first of all, he must know what he is doing; secondly, he must choose to act the way he does, and he must choose it for its own sake; and in the third place, the act must spring from a firm and unchangeable character" (Aristotle, 1105a25–30).

The word *hexis*, which Aristotle uses for "character," is the same word that denotes the habitual dispositions constitutive of the virtues. Character, therefore, indicates the stability that is necessary so that the various virtues are acquired in a lasting way. Character is not simply the sum of the individual virtues; rather, it names the pattern of thought and action that provides a continuity sufficient for humans to claim their lives as their own (Kupperman). However, the material form associated with character may vary from one society to another. Therefore any definition of virtue, the

virtues, and character can be misleading because it can conceal the differences between various accounts of the nature and kinds of virtues as well as character.

The Role of Virtue in Recent Moral Philosophy

Ancient philosophers as well as Christian theologians, though offering quite different accounts of the virtues, assumed that any account of the well-lived life had to take virtue into consideration. Modern moral philosophy, in contrast, treats virtues—if it treats them at all—as secondary to an ethics based on principles and rules. The attempt to secure an account of morality that is not as subject to variations as an ethics of virtue certainly contributed to this displacement of virtues. The first edition of the *Encyclopedia of Bioethics*, for example, had no entry on virtue or character.

In his widely used and influential introduction to philosophical ethics, William Frankena manifests the approach to ethics that simply assumed that considerations of virtue were secondary. According to Frankena, ethical theory should be concerned primarily with justifying moral terms and clarifying the differences between appeals to duty and consequences. The virtues, to the extent they were discussed by theorists such as Frankena, were understood as supplements to the determination of right and wrong action. The virtues in such a theory were seen more as the motivational component in more basic principles, such as benevolence and justice. As Frankena put it,

> We know that we should cultivate two virtues, a disposition to be beneficial (i.e., benevolence) and a disposition to treat people equally (justice as a trait). But the point of acquiring these virtues is not further guidance or instructions; the function of the virtues in an ethics of duty is not to tell us what to do, but to insure that we will do it willingly in whatever situation we may face. (Frankena, p. 67)

Frankena's understanding of the nature and role of the virtues drew on the commonsense view that in order to know what kind of person one ought to be, one needs to know what kind of behavior is good or bad. Unless one knows what constitutes acts of truth-telling or lying, one has no way to specify what the virtue of truthfulness or honesty might entail. Ethical theories were assumed to be aids to help people make good decisions on the basis of well-justified principles or rules. Virtues were secondary for that endeavor.

This account of ethics seemed particularly well suited to the emerging field of bioethics. It was assumed that the task of medical ethics was to help physicians and other healthcare providers make decisions about difficult cases created by the technological power of modern medicine. Whether a patient could be disconnected from a respirator was analyzed in terms of the difference between such basic rules as "do no harm" and "always act that the greatest good for the greatest number be done." The case orientation of medical decision making seemed ideally suited to the case orientation of ethical theory exemplified by Frankena.

In their influential book, *Principles of Biomedical Ethics*, Tom L. Beauchamp and James F. Childress retain the structure of ethics articulated by Frankena. Their account of biomedical ethics revolves around the normative alternatives of utilitarian and deontological theories and the principles of autonomy, nonmaleficence, beneficence, and justice. Each of these fundamental principles has correlative primary virtues—that is, respect for autonomy, nonmalevolence, benevolence, and justice—but these "virtues" play no central role. Beauchamp and Childress justify leaving an account of virtue to the last chapter by saying that there are no good arguments for "making judgments about persons independent of judgments about acts or … making virtue primary or sufficient for the moral life" (p. 265).

Both philosophers (Pincoffs) and theologians (Hauerwas) have challenged the assumption that ethics in general and biomedical ethics in particular should be focused primarily on decisions and principles. It is a mistake, they argue, to separate questions of the rightness or goodness of an action from the character of the agent. To relegate the virtues to the motivation for action mistakenly assumes that the description of an action can be abstracted from the character of the agent. To abstract actions from the agent's perspective fails to account for why the agent should confront this or that situation and under what description. Those who defended the importance of virtue for ethics argued, following Aristotle, that *how* one does *what* one does is as important as what one does.

The renewed interest in the nature and significance of virtue ethics has been stimulated by the work of Alasdair MacIntyre, in particular his book *After Virtue* (1984). MacIntyre's defense of an Aristotelian virtue theory was but a part of his challenge to the presuppositions of modern moral theory. MacIntyre attacked what he called "the Enlightenment project," the attempt to ground universal ethical principles in rationality qua rationality—for example, Kant's categorical imperative (Kant). MacIntyre agrees that principles and rules are important for ethics, but he rejects any attempt to justify those principles or rules that abstracts them from their rootedness in the historical particularities of concrete communities. The narratives that make such communities morally coherent focuses attention on the virtues correlative to those narratives. For the Greeks, for example, the *Odyssey* acted as the central moral text for the display of the heroic virtues. To separate ethics from its dependence on

such narratives is to lose the corresponding significance of the virtues.

MacIntyre's defense of an ethics of virtue is part of his challenge to the attempt to secure agreement among people who share nothing besides the necessity to cooperate in the interest of survival. Enlightenment theories of ethics, MacIntyre argues, falsely assume that an ahistorical ethics is possible; a historical approach tries to justify ethical principles from anyone's (that is, any rational individual's) point of view.

Renewed interest in the ethics of virtue has accompanied a renewed appreciation of the importance of community in ethics. Those commentators who emphasize the importance of community presume that morally worthy political societies are constituted by goods that shape the participants in those societies to want the right things rightly. Therefore ethics, particularly an ethics of virtue, cannot be separated from accounts of politics. Such a politics cannot be reduced to the struggle for power but, rather, is about the constitution of a community's habits for the production of a certain kind of people—that is, people who have the requisite virtues to sustain such a community.

Bioethics and the Ethics of Virtue

In the past the practice of medicine was thought to be part of the tradition of the virtues. As Gary Ferngren and Darrel Amundsen observe, "If health was, for most Greeks, the greatest of the virtues, it is not surprising that they devoted a great deal of attention to preserving it. As an essential component of *arete*, physical culture was an important part of the life of what the Greeks called *kalos kagathos*, the cultivated gentleman, who represented in classical times the ideal of the human personality" (p. 7). It should not be surprising, therefore, that not only was health seen as an analogue of virtue but medicine was understood as an activity that by its very nature was virtuous. In medical ethics, the "ethics of virtue" approach tends to focus on the doctor-patient relationship. The trust, care, and compassion that seem so essential to a therapeutic relationship are virtues intrinsic to medical care. Medicine requires attention to technical knowledge and skill, which are virtues in themselves; however, the physician must also have a capacity—compassion—to feel something of patients' experience of their illness and their perception of what is worthwhile (Pellegrino). Not only compassion but also honesty, fidelity, courage, justice, temperance, magnanimity, prudence, and wisdom are required of the physician.

> Not every one of these virtues is required in every decision. What we expect of the virtuous physician is that he will exhibit them when they are required and that he will be so habitually disposed to do so that we can depend upon it. He will place the good of the patient above his own and seek that good unless its pursuit imposes an injustice upon him, or his family, or requires a violation of his own conscience. (Pellegrino, p. 246)

The importance of virtue for medical ethics has been challenged most forcefully by Robert Veatch. According to Veatch, there is no uncontested virtue ethic. The Greeks had one set of virtues, the Christians another, the Stoics another; and there is no rational way to resolve the differences among them. This is a particularly acute problem because modern medicine must be practiced as "stranger medicine," that is,

> medicine that is practiced among people who are essentially strangers. It would include medicine that is practiced on an emergency basis in emergency rooms in large cities. It would also include care delivered in a clinic setting or in an HMO that does not have physician continuity, most medicine in student health services, VA Hospitals, care from consulting specialists, and the medicine in the military as well as care that is delivered by private practice general practitioners to patients who are mobile enough not to establish long-term relationships with their physicians. (Veatch, p. 338)

Virtue theory is not suited to such medicine, Veatch argues, because "there is no reasonable basis for assuming that the stranger with whom one is randomly paired in the emergency room will hold the same theory of virtue as one's self" (p. 339). The ethics of "stranger medicine" is best construed, Veatch contends, on the presumption that the relationship between doctor and patient is contractual. Such a relationship is best characterized by impersonal principles rather than in terms of virtue. The virtues make sense only within and to particular communities, and therefore only within a "sectarian" form of medicine.

Veatch's argument exemplifies what Alasdair MacIntyre calls the Enlightenment project. Yet MacIntyre would not dispute the descriptive power of Veatch's characterization of modern medicine. He thinks medicine is increasingly becoming a form of technological competence, bureaucratically institutionalized and governed by impersonal ethical norms. MacIntyre simply wishes to challenge the presumption that this is a moral advance. Put more strongly, MacIntyre challenges the presumption that such a medicine and the morality that underlies it can be justified in the terms Veatch offers. In particular, he asks, how can one account for the trust that seems a necessary component of the doctor-patient relationship without relying on an ethic of virtue?

Contrary to Veatch, James Drane and others argue that medicine does not exist within a relationship between

strangers, but in fact depends on trust and confidence, if not friendship, between doctor and patient. Ethics, they hold, is not based on principles external to medical care and then applied to medicine; rather, medicine is itself one of the essential practices characteristic of good societies. Medicine thus understood does not need so much to be supplemented by ethical considerations based on a lawlike paradigm of principles and rules; on the contrary, medical care becomes one of the last examples left in liberal cultures of what the practice of virtue actually looks like. Those who work from an ethics of virtue do not come to medicine with general principles justified in other contexts, to be applied now to "medical quandaries"; rather, they see medicine itself as an exemplification of virtuous practices. Here medicine is understood in the Aristotelian sense, as an activity—that is, as a form of behavior that produces a result intrinsic to the behavior itself (Aristotle). In MacIntyre's language, medicine is a practice in which the goods internal to the practice extend our powers in a manner that we are habituated in excellence (MacIntyre). Put simply, the practice of medicine is a form of cooperative human activity that makes us more than we otherwise could be.

MacIntyre's account of practice and Aristotle's account of activity remind us that the kinds of behavior that produce virtue are those done in and for themselves. Thus virtue is not acquired by a series of acts—even if such acts would be characterized as courageous, just, or patient—if they are done in a manner that does not render the person performing the actions just. As Aristotle says, "Acts are called just and self-controlled when they are the kinds of acts which a just and self-controlled man would perform; but the just and self-controlled man is not he who performs these acts, but he who also performs them in the way that the just and self-controlled men do" (1105B5–9).

There is an inherently circular character to this account of the virtues that cannot be avoided. We can become just only by imitating just people, but such "imitation" cannot be simply the copying of their external actions. Becoming virtuous requires apprenticeship to a master; in this way the virtues are acquired through the kind of training necessary to ensure that they will not easily be lost. How such masters are located depends on a social order that is morally coherent, so that such people exhibit what everyone knows to be good. Medicine, because it remains a craft that requires apprenticeship, exemplifies how virtue can and should be taught.

William F. May suggests that the very meaning of a profession implies that one who practices it is the kind of person who can be held accountable for the goods, and corresponding virtues, of that profession. Medicine as a profession functions well to the extent that medical training forms the character of those who are being initiated into that practice. This does not imply that those who have gone through medical training will be virtuous in other aspects of their lives; it does imply, however, that as physicians they will exhibit the virtues necessary to practice medicine.

In *Becoming a Good Doctor: The Place of Virtue and Character in Medical Ethics*, James Drane suggests that the character of the doctor is part of the therapeutic relationship, and that there is a structure to the doctor-patient relationship that is based on the patient's trust that the physician will do what is necessary to help the patient heal. The physician's task, Drane argues, is not to cure illness but to care for patients, and such care depends on the character of the physician. Drane, in contrast to Robert Veatch, argues that medicine must remain a virtuous practice if it is to be sustained in modern societies. Paul Ramsey's insistence that the focus of medicine is not the curing of illness but the care of patients "as persons," can be interpreted as an account of medicine commensurate with an emphasis on the virtues. The particular character of the judgments clinicians must make about each patient is not unlike Aristotle's description of practical wisdom, or *phronesis*. According to Aristotle, ethics deals with those matters that can be other; a virtuous person not only must act rightly but also must do so "at the right time, toward the right objects, toward the right people, for the right reasons, and in the right manner" (1106B20–23). Similarly, physicians must know when to qualify what is usually done in light of the differences a particular patient presents. From this perspective, medicine is the training of virtuous people so they are able to make skilled but fallible judgments under conditions of uncertainty. The increasing recognition of the narrative character of medical knowledge (Hunter) reinforces this emphasis on virtue and character. That the disease entities used for diagnosis are implicit narratives means medicine is an intrinsically interpretative practice that must always be practiced under conditions of uncertainty. Accordingly, patient and physician alike bring virtues (and vices) to their interaction that are necessary for sustaining therapeutic relationships.

Continuing Problems for an Ethics of Virtue

To construe medicine as a virtue tradition establishes an agenda of issues for investigation in medical ethics. How are the virtues differentiated? Are there some virtues peculiar to medicine? How are different virtues related to one another? How is the difference between being a person of virtue and character, and the possession of the individual virtues, to be understood? Can a person possess virtues necessary for the practice of medicine without being virtuous? Can a person be courageous without being just?

Such questions have been central to the discussion of the virtues in classical ethical theory. For example, Aristotle maintained that none of the individual virtues could be rightly acquired unless they were acquired in the way that the person of practical wisdom would acquire them. Yet one could not be a person of practical wisdom unless one possessed individual virtues such as courage and temperance. Aristotle did not think the circular character of his account was problematic because he assumed that the kind of habituation commensurate with being "well brought up" is the way we were initiated into the "circle."

Yet in what sense the virtues are habits remains a complex question that involves the question of how the virtues are individuated. For Aristotle some of the virtues are "qualities" that qualify the emotions, but not all the virtues are like courage and temperance in that respect. Aristotle's resort to the artificial device of the "mean" for locating the various virtues has caused more problems than it has resolved. These matters are made even more complex by the importance Aristotle gives to friendship in the *Nicomachean Ethics*, where it is treated as a virtue even though it is not a quality but a relation.

The Christian appropriation of the virtues did little to resolve these complex issues. For Saint Augustine the virtues of the pagans were only "splendid vices" insofar as they were divorced from the worship of God. In "Of the Morals of the Catholic Church," Augustine redescribed the fourfold division of the virtues as four forms of love:

> that temperance is love giving itself entirely to that which is loved; fortitude is love readily bearing all things for the loved object; justice is love serving only the loved object, and therefore ruling rightly; prudence is love distinguishing with sagacity between what hinders it and what helps it. The object of this love is not anything, but only God, the chief good, the highest wisdom, the perfect harmony. So we may express the definition thus, that temperance is love keeping itself entire and uncorrupt for God; fortitude is love bearing everything readily for the sake of God; justice is love serving God only, and therefore ruling well all else, as subject to man; prudence is love making a right distinction between what helps it toward God and what might hinder it. (p. 115)

Thomas Aquinas, influenced profoundly by Augustine and Aristotle, provided an extraordinary account of the virtues that in many ways remains unsurpassed. According to Aquinas, charity, understood as friendship with God, is the form of all the virtues. Therefore, like Augustine, he maintained that there can be no true virtue without charity (Aquinas). Unlike Augustine, however, Aquinas grounded the virtues in an Aristotelian account of human activity, habits, and passions. For Aquinas, therefore, the virtues are dispositions or skills necessary for human flourishing.

Aquinas's account of the virtues does present some difficulties, however. Even though he followed Augustine's (and Plato's) account of the four "cardinal" virtues—prudence, courage, temperance, and justice—neither he nor Augustine successfully argued why these four should be primary. (Aristotle does not single out these four as primary.) Indeed, it is clear from Aquinas's account that he thought of the cardinal virtues as general descriptions that required more specification through other virtues, such as truthfulness, gentleness, friendship, and magnanimity.

These issues obviously bear on medicine considered as part of the virtue tradition. Are there virtues peculiar to the practice of medicine that require particular cultivation by those who would be doctors? If the virtues are interdependent, can a bad person be a good doctor? Or, put more positively, do the virtues required to be a good doctor at least set one on the way to being a good person? If the Christian claim that the "natural virtues" must be formed by the theological virtues of faith, hope, and charity is correct, does that mean that medicine as a virtue requires theological warrant?

Some of these questions have not been explored with the kind of systematic rigor they deserve. MacIntyre, however, suggests some promising directions. For example, he has argued that practices are not sufficient in themselves to sustain a full account of the individual virtues, their interrelations, or their role in areas such as medicine. Practices must be understood within the context of those goods necessary for the display of a whole human life and within a tradition that makes the goods that shape that life intelligible (MacIntyre). Those initiated into the practice of medicine, for example, might well have their moral life distorted if medicine as a virtue was not located within a tradition that placed the goods that medicine serves within an overriding hierarchy of goods and corresponding virtues. Yet what such a hierarchy would actually consist of remains to be spelled out.

These matters are made more complex to the extent that those who stand in virtue traditions cannot draw on the distinction between the moral realm and the nonmoral realm so characteristic of Kantian inspired moral theory. Once distinctions between the moral and the nonmoral are questioned, strong distinctions between deontological ethics, consequential ethics, and the "ethics of virtue" are equally questionable. L. Gregory Jones and Richard Vance argue, for example, that to assume that the virtues are an alternative to an ethics of principles and rules simply reproduces the assumption that there is a distinct realm called

"ethics" that can be separated from the practices of particular communities. It was this assumption that led to the disappearance of virtue from modern moral theory.

For example, Aristotle thought that how a person laughed said much about his or her character. Therefore, what we consider matters of personal style and/or etiquette were considered morally significant by the ancients. For the virtues to encompass such matters as part of human character makes problematic the distinction so crucial to modernity—that is, the distinction between public and private morality. Thus, from such a perspective, what physicians do in their "private time" may well prove important for how they conduct themselves morally as physicians.

Equally troubling is the role *luck* plays in an ethics of virtue. For example, Aristotle thought that a lack of physical beauty made it difficult for a person to be happy: "For a man is scarcely happy if he is very ugly to look at, or of low-birth, or solitary and childless" (1099A35–37). Modern egalitarian sensibilities find it offensive to think that luck might play a role in our being virtuous (Card), yet the Greeks thought it unavoidable for any account of the virtuous and happy life. Indeed, as Martha Nussbaum has argued, the very strength the virtues provide create a "fragility" that cannot be avoided. Illness may well be considered part of a person's "luck" that limits the ability to live virtuously. Medicine may thus be understood as the practice that can help restore a person to virtue.

How medicine and an ethics of virtue are understood differs greatly from one historical period to another as well as from one community to another. To the extent that medicine can no longer be sustained as a guild, perhaps it should no longer be construed in the language of the virtues. As Mark Wartofsky asks, "How is benevolence, as a distinctively *medical* virtue, to be interpreted in those forms of the practice where the individual patient is literally seen not as a person but only through the mediation of the records, laboratory reports, or a monitoring of data in a computer network?" (p. 194).

Yet many continue to argue that any treatment of medicine that makes the virtues of both physician and patient secondary cannot be a medicine anyone should desire or morally support. Truthfulness, for example, is a virtue intrinsic to the care of patients; without it, whatever care is given, even if it is effective in the short run, cannot sustain a morally healthy relationship between patient and physician. Good medicine requires communication and participation by the patient that can be secured only by the physician's telling the patient the truth as well as the patient's demanding truthful speech. Without such truthful communication, the patient, as Plato argued, is reduced to the status of a slave (Drane). Ironically, in the name of freedom, the kind of medicine Veatch envisioned looks like a medicine fit for slaves—admittedly an odd conclusion since Veatch assumes that a contractual relation between physician and patient is the condition for a free exchange. Moreover, even Veatch continues to assume that truth-telling is a virtue necessary for medicine to survive as a practice between strangers.

For his part, Drane raises issues at the heart of any account of the virtues as well as of medicine as a virtue tradition. If it is true that truthfulness is a virtue intrinsic to the practice of medicine, can that virtue conflict with, for example, the virtue of benevolence? Plato and Aristotle assumed the unity of the virtues. Accordingly, the virtues would not conflict with one another if they were rightly oriented to a life of happiness. Aquinas held that the virtues might conflict during the time we are "wayfarers," but not in heaven. Drane resolves the possibility of such conflict by suggesting that medicine requires the truth to be spoken, but benevolently. One may doubt, however, whether this attractive suggestion resolves all questions about the conflict among the virtues, particularly in medical care.

If medicine is to be construed in the tradition of the virtues, the virtues and character of patients must be considered. The very term *patient* suggests a necessary virtue that is closely associated with Christian accounts of the virtues. If we must learn to live our lives patiently, then illness may appear in quite a different light than it does in those accounts of the moral life that have no patience with patience. For example, if suffering is thought to be an occasion to learn better how to be patient, then a medicine of care may be sustainable even when cure cannot be accomplished.

Karen Lebacqz suggests that the circumstances in which patients find themselves, especially the circumstance of pain and helplessness, can invite them to become accepting and obedient. These traits, which may appear virtuous, may just as likely be vices if they are not shaped by fortitude, prudence, and hope. Lebacqz suggests that these virtues are particularly relevant to the condition of being a "patient," because they provide the skills necessary to respond to illness in a "fitting" manner. No *one* way of expressing these virtues suits all patients; yet they do provide the conditions for our learning the tasks required in health and illness.

Questions of virtue also relate to issues of justice in the distribution of healthcare. For if the patient can ask medicine to supply any need abstracted from a community of virtue, then there seems no way to limit in a moral way the demands for medical care. In such a situation, those who have more economic and social power can command more than is due medically, since medicine seems committed to

meeting needs irrespective of the habits that created those needs. Liberal political theory has often tried to show how a just society is possible without just people; a "medicine of strangers" may result in a maldistributed medicine.

Conclusion

There is no consensus about the nature of virtue and/or the virtues that a good person should possess. That should not be surprising: the attempt to introduce the virtues into bioethics has gone hand in hand with an emphasis on the inevitable historical character of ethical reflection. If, as MacIntyre has argued, the virtues can be described only in relation to a particular tradition and narrative, then the very assumption that a universal account of ethics—and in particular, of medical ethics—is problematic. Yet the very character of medicine as a practice whose purpose is care for the ill remains one of the richest resources for those committed to an account of the moral life in the language of the virtues.

W

WARFARE

I. INTRODUCTION

In the immortal words of General William Tecumseh Sherman, one of its better known practitioners, "war is hell." Rather than diminishing with the cessation of the superpower rivalry that dominated the international scene for nearly half a century, the incidence of warfare is increasing. As the twenty-first century began over three dozen wars were being fought around the globe, like an insidious disease with no cure is in sight.

Types of War

Warfare is generally understood as armed conflict, often prolonged, between nations or parts of nations. Civil wars are fought between sections of the population within a nation. When an armed group engages in military action against its government, the war is an insurrection or a revolution, sometimes called a war of national liberation.

Despite its abhorrent character, nations routinely prepare for armed conflict, defensively, most claim. Some actively institute it for reasons their leaders deem necessary.

After the September 11, 2001, bombings of the World Trade Center and Pentagon, a new kind of war emerged, a war against terrorism. This turned out initially to be military action by the United States and its allies against the Taliban rulers of Afghanistan and against the international organization believed to be responsible for the September 11th attacks. It was followed shortly by Israeli forces invading Palestinian cities in an attempt to stop terrorist suicide bombings.

The point of all warfare, whether international, civil, revolutionary, or against terrorism, is to cause enough damage—human, physical, psychological, social, economic—that the other side gives up, surrenders, ceases to resist, or sometimes ceases to exist as a viable society. Throughout history the tactics of warfare have always included, sometimes reluctantly, sometimes not, but whenever deemed necessary, the deliberate targeting of enemy civilians. Contemporary military tactics emphasize creating severe damage to the enemy with as little loss of life on one's own side as possible.

Weapons of War

Over the centuries ever newer and more destructive means of waging war have been designed and produced. Contemporary wars are waged with highly sophisticated and lethal weapons by those societies that have sufficient technological and economic resources. The most deadly of these are the so-called weapons of mass destruction—nuclear, chemical, and biological weapons.

NUCLEAR WEAPONS. First used by the United States on the Japanese cities of Hiroshima and Nagasaki at the end of World War II, nuclear weapons can destroy an entire urban area in one blast. Thousands of them, capable of leveling cities of potentially hostile countries, are deployed by the United States, Russia, Great Britain, France, China, Israel,

India, and Pakistan. A one-megaton hydrogen bomb, a medium-sized nuclear weapon, would instantly destroy everything within a radius of a mile and a half of where it explodes. Every building in that radius would disintegrate, and all living creatures would die in a fraction of a second, and disappear. Within a three-mile radius, the heat would be so severe that anything exposed to it would burst into flames. As far as eight miles away people would suffer second-degree burns. As much as one-third of the population of a city of 1 million people would be killed or wounded by the blast and fire of such a bomb.

Smaller weapons, sometimes called mininukes or bunker busters, are designed to destroy underground targets. These bombs also create a huge crater above the target and spew radioactive dust for miles around the center. These smaller nuclear weapons are considered "usable" by military planners, by contrast with the larger city-destroying weapons whose value consists primarily in deterrence.

CHEMICAL AND BIOLOGICAL WEAPONS. Chemical weapons, first used by both sides in World War I in the form of poison gas, were later employed by Italy against Ethiopia in the 1930s, by the United States in South Vietnam in the 1960s, and by Iraq against Iran in the 1980s. In the twenty-first century the most advanced chemical warfare agent is binary nerve gas, which consists of two chemicals of relatively low toxicity that mix when their containing munition is fired. At that point they produce a lethal gas that is odorless and can be absorbed through the skin and eyes as well as by inhalation. The gas attacks the central nervous system, and those exposed to even low concentrations of it experience sweating and vomiting, followed by paralysis, respiratory failure, and then death.

Biological weapons spread viruses that cause diseases such as anthrax, botulism, plague, and smallpox, diseases that are usually accompanied by high fevers and deadly internal bleeding. Other viruses are designed to attack the lungs, brain, spinal cord, or heart. Once dispersed, these diseases can easily spread throughout a concentrated population, causing incurable illness, panic, and death.

Because it can also be used to manufacture benign agricultural and medicinal products, the equipment for manufacturing chemical or biological weapons is considered, in military terminology, "dual use." A pharmaceutical plant making civilian medical products might become a military target because it could also be used to make weapons for warfare.

The 1975 Biological Weapons Convention prohibited the development, production, and stockpiling of such weapons. But because they are relatively easy and cheap to produce—they have been called "a poor person's nuke"—less developed countries may consider them affordable weapons of mass destruction.

CONVENTIONAL WEAPONS. Conventional weapons include supersonic aircraft, swift ships and silent submarines, precision-guided munitions, remote-controlled pilot-less aircraft, rapid all-terrain vehicles for ground troops, land mines impervious to detection, visual aids for seeing in the dark, space-based sensors to pinpoint enemy targets, assault rifles that fire dozens of rounds a second, handheld grenade and rocket launchers, and shoulder-fired antiaircraft missile launchers.

SPACE-BASED WEAPONS. Space-based lasers and antimissile systems are being developed by the United States to give what military planners call full-spectrum dominance—control of land, sea, air, and outer space.

Ethical Frameworks

War involves the inflicting of pain and suffering, and the deliberate killing of other human beings, often on a large scale. It also inflicts serious emotional trauma on those who do the killing. Because warfare is so terrible, so contrary to the best inclinations of the human character, but because it is also a fact of national and international life, concerned persons through the ages have attempted to provide ethical frameworks with which to evaluate it.

Three such frameworks are traditionally presented, with a fourth added since the middle of the twentieth century. The first, often called the realist position, is the belief that a war must be prosecuted to a successful conclusion using all available means. The second, pacifism, maintains that all killing is wrong, that war is so inhumane that no one should take part in it. The third, and most widely held, is the just war theory, which maintains that, although war is regrettable, it is sometimes necessary and should be fought under specific ethical guidelines. The fourth, relatively new since Mohandas Gandhi (1869–1948) introduced it in waging India's war of national liberation against the British, involves active nonviolence as an effective alternative to the organized killing of warfare.

REALIST APPROACH. Realism is based on the belief that the end justifies the means, necessity knows no law, that if a war must be fought it should be fought totally. This meant, according to the nineteenth-century German theoretician Carl von Clausewitz in his influential book *On War* (1832), that an enemy's military power must be destroyed, and that the country must be conquered in such a way that it cannot

produce a new military power. Even the will of the enemy must be destroyed. Whatever means are necessary should be used to force the other side into submission.

The realist approach was epitomized in World War II when the Allies waged what came to be called "total war" against Germany and Japan, insisting on nothing short of unconditional surrender. Earlier President Franklin D. Roosevelt had decried the German bombing of the cities of Warsaw, Poland; Coventry and London, England; and Rotterdam, the Netherlands, calling these campaigns ruthless and shocking to the conscience of humanity. But in pursuit of the goal of unconditional surrender, the United States itself used saturation bombing on cities in Germany and Japan, culminating in the atomic bombing of Hiroshima and Nagasaki.

Those countries that possess nuclear weapons in the twenty-first century have steadily maintained their will to use them if their security is severely threatened, if deterrence fails, regardless of the consequences.

Contemporary warfare tends to absolutize one's country and the cause for which it is fighting: "My country, right or wrong"; "we're good, they're evil"; or, as President George W. Bush put it in launching the war on terrorism, "you're either with us or you're with the terrorists." Given the patriotic fervor that arises when a nation finds itself at war, the vast majority of a country's political, academic, and even religious leaders tend to support the war. Rare are the instances of religious officials questioning whether the war is right, rarer still those who put forward the great ideals of peace and common humanity as an alternative to fighting and killing.

PACIFISM. Pacifism, refusal to take part in war on religious or humanitarian grounds, is based on the belief that the deliberate taking of human life is wrong. The belief might be religious (e.g., "Thou shalt not kill," "Love your enemies"), or it could be a conviction that all human life is valuable, and that deliberately terminating it, even an enemy in warfare, violates the integrity of the human condition. A pacifist's refusal to take part in war is recognized by law in some countries as conscientious objection to military service. Where such refusal is not legal, pacifists suffer the consequences—often imprisonment, and sometimes even death.

JUST WAR THEORY. The just war position is based on the conviction that violence is sometimes necessary to stop aggression or to secure the legitimate goals of one's country. The phrase *just war* was coined by the Greek philosopher Aristotle in the fourth century B.C.E. to describe military action undertaken to enslave those designed by nature for servitude but who resisted their proper place in the social scale. The term's classical formulation in Western philosophy began, however, with the Christian theologian Augustine of Hippo in the fifth century C.E.

Augustine was convinced that humanity, corrupted by sin, was prone to violence. Although loving one's enemies was the Christian ideal and peace the goal, it was inevitable that human cruelty and desire for power would emerge. When this happened, Augustine maintained, force must be used to counteract it. But the intention must always be to restore peace.

The just war theory was later codified under two headings. The first, *jus ad bellum,* was the right to go to war. This could happen only when there was a just cause, and when going to war was a last resort. It also had to be ordered by the proper authority, responsible for the common good of the society. The damage to be inflicted must be proportionate to the good expected by taking up arms.

The second heading, *jus in bello,* concerned ethically proper conduct during a war. This involved two important restrictions: using only those military means that are sufficient to accomplish the goal (sometimes called the principal of proportionality) and a prohibition both on executing hostages and prisoners and on attacking nonmilitary targets (the principle of discrimination).

Governments in modern times have tended to reduce the *jus ad bellum* argument to having a just cause for war, expressed as a serious threat to national integrity or security. Although the Charter of the United Nations declares that all war is illegal, Article 51 allows nations to go to war in self-defense, with every nation free to define self-defense as it sees fit, including the maintenance of access to sufficient natural resources such as water or oil.

Modern weapons assure that some if not many noncombatants will be killed. The *jus in bello* part of the just war theory is increasingly focused not on avoiding such killing, but on preventing public revulsion over it. Political expediency demands that civilians not be considered as direct targets but, in military terminology, as collateral damage, regrettable side effects. Restricting the news media's access to areas of combat and limiting the media only to information derived from military briefings are ways of keeping civilian casualties from arousing negative public opinion.

ACTIVE NONVIOLENCE. Gandhi, leading the people of India in their struggle for independence against Great Britain in what would otherwise have been a war of revolution or national liberation, introduced a new tactic—active,

positive, organized nonviolent resistance. For the most part the Indian war of independence disavowed armed conflict in favor of a disciplined nonviolent movement by large numbers of Indian people. This new kind of war took several decades but resulted in freedom from the British and the creation of the modern nation of India.

Gandhi's tactics were taken up in the late 1950s and 1960s by the American clergyman Martin Luther King Jr. in the struggle for the civil rights of African Americans. It has also been used in other parts of the world, such as in the liberation of South Africa from the oppression of apartheid.

Gandhian nonviolence presents a whole other range of possibilities different from the pacifist refusal to take part in war. A determination to use nonviolent means to resolve international conflicts could involve a nonviolent defense force in which people would be trained in ways of resisting an aggressor through noncooperation and direct, unarmed confrontation. In his 1971 book, *The Politics of Nonviolent Action,* peace researcher Gene Sharp identified more than 146 specific techniques of nonviolent action, ranging from general strikes and boycotts to nonpayment of taxes.

Active nonviolence offers for many a fruitful alternative to the ethical positions of realism, pacifism, and the just war. It does not aim simply at achieving a more effective national defense, but also at establishing a system of human and international relationships that would eventually do away with the need for war altogether. Active nonviolence seeks to address the underlying causes of war by working for the establishment of social justice, environmental protection, and the defense of human rights.

Personal Responsibility

In the reality of the contemporary world, where warfare remains an ongoing possibility, each individual is involved in some way. Wars are made possible not only by political leaders who launch them and military personnel who fight them but also by those who design and produce the weapons, those who arouse citizen support, those who pay for war through their taxes, and those who form a chorus of patriotic approval.

Once a decision has been made for whatever reason to go to war, leaders try to mobilize popular support through communication verging on propaganda, by attempting to withhold negative information, and by discouraging public debate. It is hard to resist the groundswell of nationalistic fervor, hard to find the truth, and hard to see what is really going on, what are the causes, and where real justice lies. Hence the importance of looking at these issues ahead of time, getting information about international trouble spots and likely scenarios before hostilities break out, assessing it all according to what one knows and believes, and exploring realistic nonviolent alternatives.

Warfare is a troubling, vexing question. In the end, each person must make a decision about approving of, participating in, or supporting a war based on one's own personal integrity, which is to say, one's conscience.

II. MEDICINE AND WAR

Ethical conflicts occur whenever medicine and war intersect. This entry discusses four general types of ethical conflict: (1) conflict between the military obligation of physicians and other medical personnel to provide care to members of the military force in which they are serving and the medical obligation to serve others, such as members of opposing military forces and civilians, who need their care; (2) conflict

between the obligation of military medical personnel to "conserve the fighting strength" and the medical obligation to respond to the special needs or rights of individual military personnel under their care even if that response hinders the fighting strength; (3) conflict between the combatant and noncombatant roles of medical personnel; and (4) conflict between the national obligation to serve one's country through service in a military force and the international obligation to prevent war or prevent specific actions by the military force of one's country.

The history of physicians' involvement with military forces is a long one. Homer praised the efforts of the sons of Asclepios to provide surgical care before the gates of Troy, and Hippocrates, recognizing that the battleground was an important training ground for surgeons, urged that "he who would become a surgeon should join an army and follow it" (Vastyan, 1978, p. 1695).

However, physicians and other medical personnel had relatively little aid to offer to military casualties until the eighteenth century. Since that time developments in military weaponry and concurrent advances in medical technology and techniques for the evacuation of casualties have made the deployment of medical resources increasingly important to armies and their commanders. To the armies of the czar, for example, Peter the Great brought the *feldsher,* modeled after the *feldscherer* (field barber-surgeon) of the Prussian armies. In the New World deplorable medical care during the American Revolution caused political conflicts over the management of hospitals and healthcare for soldiers. The increase in the number of military casualties during the wars of the nineteenth century and the extraordinary increase in military and civilian casualties during those of the twentieth century, together with dramatic improvements in the ability to treat casualties successfully, led to changes in the types of ethical issues that arise in the context of war and an increase in their number.

Military Obligations Versus Medical Obligations

As a member of the military forces of a nation a military physician is charged with protecting the strength of that force. As a member of the medical profession, however, a physician generally is obligated to care for all the sick and wounded who need his or her services and to set priorities for providing those services on the basis of the urgency of medical need and the effectiveness of medical care.

Hippocrates, often called the father of medicine, apparently rejected the principle that physicians have an obligation in war to succor "enemies" as well as "friends." The evidence for this appears in Plutarch's *Lives* in a reference to "Hippocrates' reply when the Great King of Persia consulted him, with the promise of a fee of many talents, namely, that he would never put his skill at the service of Barbarians who were enemies of Greece" (Plutarch, p. 373).

Just before the start of the U.S. Civil War the American Medical Association (AMA) selected as the model for a commemorative stone carving for the Washington Monument, then being built in the District of Columbia, the painting *Hippocrates Refuses the Gifts of Artaxerxes,* portraying Hippocrates's dismissal of the emissaries of the king of Persia. The inscription the AMA selected was *Vincit Amor Patriae,* "Love of Country Prevails" (Stacey).

In a time of "unjustifiable and monstrous rebellion," a phrase used by one of its leaders, the AMA probably intended by its use of the painting and the inscription to applaud the refusal to provide medical services for enemies. Indeed, no evidence can be found that in the pre–Civil War United States there was a great deal of sympathy for even-handed medical care in time of war (Sidel, 1991b).

PHYSICIANS AS IMPARTIAL HEALERS. A physician's responsibility to treat those in medical need on both sides did not burn itself into public or medical consciousness until the late 1860s, in the aftermath of the Crimean War and the U.S. Civil War. Leadership in increasing the new consciousness was assumed by the nonphysicians Florence Nightingale, who served as a nurse in Turkey and the Crimea from 1854 to 1856, and Dorothea Dix, whose work in bringing humane care to mental patients in the United States led President Abraham Lincoln to invite her to organize the U.S. Army Nursing Corps and become the first superintendent of nurses in the U.S. Army.

Henri Dunant, a Swiss banker who was an eyewitness at the Battle of Solferino in 1859, organized medical services for the Austrian and French wounded. In 1864 he helped initiate an international conference in Geneva that led to the founding of the International Red Cross and its national affiliates. The conference adopted a Convention for the Amelioration of the Condition of the Wounded and Sick in Armed Forces in the Field. Fourteen signatory nations pledged to regard the sick and wounded, as well as personnel, facilities, and transportation for their care, as neutrals on the battlefield. For his efforts Dunant was awarded the first Nobel Peace Prize.

Two contemporaneous events in the United States influenced future codifications and applications of international law and their bearing on medicine. Francis Lieber, a German-born philosopher, lawyer, and historian, was commissioned by the Union forces to draft a code of conduct for

armies in the field. The resultant Lieber Code was promulgated in May 1863 as General Order No. 100 by the Union Army. Closely related to that development was the 1865 trial of Captain Henry Wirz, a physician who served as the commandant of the infamous Confederate prison at Andersonville, Georgia. Wirz was charged with a series of offenses involving inhumane treatment of the prisoners under his charge. His plea that "superior orders" mitigated the negligence of duty with which he was charged was disallowed, and Wirz was convicted and sentenced to be hanged.

During the eighty years after the first Geneva treaty on the treatment of war casualties three other related international agreements were negotiated in the Hague and in Geneva. The Convention for the Amelioration of the Wounded, Sick, and Shipwrecked Members of Armed Forces at Sea dealt with the care of casualties of naval warfare. The Convention Relative to the Treatment of Prisoners of War regulated the treatment and repatriation of prisoners. The Convention Relative to the Protection of Civilian Persons in Time of War prohibited deportation, the taking of hostages, torture, and discrimination in treatment. Those three agreements, along with the original Geneva accord, were codified in a single formal document in Geneva in 1949; together they are called the Geneva Conventions. Agreed to at that time by sixty nations, the 1949 conventions were declared binding on all nations according to "customary law, the usages established among civilized people … the laws of humanity, and the dictates of the public conscience" (Geneva Conventions of 1949).

Under the conventions medical personnel are singled out for certain specific protections by an explicit separation of the healing role from the wounding role. Medical personnel and treatment facilities are designated as immune from attack, and captured medical personnel are to be repatriated promptly. In return for that treatment, specific obligations are required of medical personnel:

1. Because they are regarded as noncombatants, medical personnel are forbidden to engage in or be parties to acts of war.
2. The wounded and sick—soldier and civilian, friend and foe—must be respected, protected, treated humanely, and cared for by the belligerents.
3. The wounded and sick must not be left without medical assistance, and only urgent medical reasons authorize any priority in the order of their treatment.
4. Medical aid must be dispensed solely on medical grounds, "without distinctions founded on sex, race, nationality, religion, political opinions, or any other similar criteria."
5. Medical personnel shall exercise no physical or moral coercion against protected persons (civilians), in particular to obtain information from them or from third parties.

Those duties are imposed clearly with no exceptions and are given priority over all other considerations. Thus, the Geneva Conventions formalized the recognition that although professional expertise merits special privileges, it incurs very specific legal as well as moral obligations (Vastyan, 1978). That special role of physicians has been incorporated in the public expectations and the ethical training of doctors in most societies. It also is embedded in the World Medical Association's Declaration of Geneva, which is administered as a "modern Hippocratic Oath" to graduating classes at many medical schools.

There is, however, evidence of deviation from those principles. An example of the erosion of the principle of equal medical care for "enemies" occurred in the United States during the Cold War. The medical society of Maryland and the AMA refused to criticize a Maryland psychiatrist who testified voluntarily before the Un-American Activities Committee of the U.S. House of Representatives in 1960 about information he had obtained while treating an employee of the National Security Agency (NSA). His patient, together with another NSA employee with whom the patient allegedly had had a sexual relationship, later defected to the Soviet Union. The psychiatrist, clearly without his patient's permission, provided to the committee information given to him by that patient, and the material was leaked to the press by the committee. In response to a petition by a group of Maryland psychiatrists and other physicians asking that the psychiatrist be censured, the medical society stated that "the interests of the nation transcend those of the individual" (Sidel, 1961).

Obligations to Enhance Military Strength Versus Personnel Needs

Military physicians must accept priorities different from those of their civilian colleagues (Vastyan, 1974). The primary role of a military physician is expressed in the motto of the U.S. Army Medical Department: "To conserve the fighting strength" (Bellamy). In describing that role, a faculty member of the Academy of Health Sciences at Fort Sam Houston in 1988 cited as "the clear objective of all health service support operations" the goal stated in 1866 by a veteran of the Army of the Potomac in the Civil War: "[to] strengthen the hands of the commanding general by keeping his Army in the most vigorous health, thus rendering it, in the highest degree, efficient for enduring fatigue and privitation [sic], and for fighting" (Rubenstein, p. 145).

Principles of triage that are unacceptable in civilian practice may be required in war, such as placing emphasis on patching up the lightly wounded so that they can be sent back to battle. For example, "overevacuation" (the presumed excessive transfer of personnel to a safe area rather than back to the military operation) is cited as "one of the cardinal sins of military medicine" (Bellamy). Violation of patient confidentiality, which is unacceptable in civilian practice, may be required. Medical personnel may be required to administer experimental drugs or immunizations to troops without their free and informed consent (Annas).

Combatant Versus Noncombatant Roles for Medical Personnel

Perhaps the most dramatic attempt to meld these conflicting obligations was made by the Knights Hospitallers of Saint John of Jerusalem, a religious order founded in the eleventh century. With a sworn fealty to "our Lords the Sick," the knights defended their hospitals against "enemies of the Faith," becoming the first organized military medical officers. They were "warring physicians who could strike the enemy mighty blows, and yet later bind up the wounds of that same enemy along with those of their own comrades" (Vastyan, 1978, pp. 1695–1696).

A more recent example of the erosion of the distinction between combatant and noncombatant roles was demonstrated in a U.S. Army exhibit at the 1967 AMA convention. It was titled "Medicine as a Weapon" and featured a photograph of a Green Beret (Special Forces) aidman handing medicine to a Vietnamese peasant (Liberman et al.). Dr. Peter Bourne, who had been an army physician working with the Special Forces in Vietnam, wrote that the primary task of Special Forces medics was "to seek and destroy the enemy and only incidentally to take care of the medical needs of others on the patrol" (Liberman et al., p. 303).

In 1967 Howard Levy, a dermatologist drafted into the U.S. Army Medical Department as a captain, refused to obey an order to train Special Forces aidmen in dermatological skills. He refused specifically on the grounds that the aidmen were being trained predominantly for a combat role and that cross-training in medical techniques would erode the distinction between combatants and noncombatants. Levy was charged with one of the most serious breaches of the Uniform Code of Military Justice: willfully disobeying a lawful order. Tried by a general court-martial in 1967, Levy admitted his disobedience, saying that he had acted in accordance with his ethical principles. The physicians who testified for the defense "argued that the political use of medicine by the Special Forces jeopardized the entire tradition of the noncombatant status of medicine" (Langer, p. 1349). They agreed with Levy that physicians are responsible for even the secondary ethical implications of their acts and that they must not only act ethically but also anticipate that those to whom they teach medicine will act ethically as well. Although Levy was a medical officer, the court-martial panel did not include a physician. Levy was given a dishonorable discharge and sentenced to three years of hard labor in a military prison. His appeals were not successful (Glasser; Langer).

Inside or outside the armed forces medical personnel may be involved in war-related research and development such as work on biological weapons or the radiation effects of nuclear weapons. In that work it is said to have been common practice to concentrate physicians into "principally or primarily defensive operations" (Rosebury). However, work on weapons and their effects can never be exclusively defensive, and at times the distinction is arbitrary. The question arises whether there is a special ethical duty for physicians, because of their medical obligation to "do no harm," to refuse to participate in such work or whether in non-patient-care situations physicians only share the ethical duties of all human beings (Sidel, 1991a).

The noncombatant role of a physician in military service is ambiguous even if frank combatant activities are eschewed. Military physicians, like all members of the armed forces, are limited by the threat of military discipline in the extent to which they can protest publicly against what they consider an unjust war. The issue of what is a just war has been debated for more than two millennia (Seabury and Codevilla; Walzer). It generally is thought that there are two elements in a just war: *jus ad bellum* (when is it just to go to war?) and *jus in bello* (what methods may be used in a just war?). Among the elements required for *jus ad bellum* are a just grievance and the exhaustion of all means short of war to settle that grievance. Among the elements required for *jus in bello* are the protection of noncombatants and the proportionality of force, including avoiding the use of weapons of mass destruction such as chemical, biological, and nuclear weapons and the massive bombing of cities. Membership in the armed forces, even in a noncombatant role, usually requires self-censorship of public doubts about the justness of a war in which the armed forces are engaged.

In 2003 the United States, with the support of the United Kingdom, initiated an attack on Iraq that those countries alleged was permissible under international law as a "preventive" or "preemptive" war. The action was not approved specifically by the Security Council of the United Nations. Many lawyers and physicians argued that because there had been no attack or imminent attack on the United States, the requirements for *jus ad bellum* had not been met

and the "collateral damage" to civilians caused by the attack exceeded the ethical test of *jus in bello.* Although there were protests from Physicians for Social Responsibility and other medical groups, U.S. service members, including medical personnel, evinced no public protest.

The U.S. military used depleted uranium as a casing for armor-piercing shells in the 1991 Gulf War, its actions in Kosovo and Afghanistan, and the 2003 Gulf War. Uranium is both toxic and radioactive, and its use is seen by many experts as a violation of the United Nations Charter, the Geneva Conventions, the Conventional Weapons Convention, and the Hague Conventions. There was no public protest by military physicians.

In addition, medical personnel, like other people, may consider themselves pacifists. "Absolute pacifism" opposes the use of any force against another human being even in self-defense against a direct personal attack. The argument underlying this position for many of its adherents is that the use of force can be ended only when all people refuse to use it and that acceptance of one's own injury or even death is preferable to the use of force against another person. More limited forms of pacifism, such as "nuclear pacifism," hold that the use of certain weapons of mass destruction in war is never justified no matter how great the provocation or how terrible the consequences of failure to use them. It has been suggested ("maternal pacifism") that because of their nurturing roles women have a special responsibility to oppose the use of force (Ruddick).

When a group is threatened with genocide, which the Nazis attempted in World War II, many who otherwise might adopt a pacifist or limited pacifist position believe that force may be justified. Their shift in position is based on the threat to the survival of the group, a threat that makes the pacifist argument that current failure to resist will lead to a future diminution in violence seem untenable.

There is considerable debate whether physicians, because of a special dedication to the preservation of life and health, have a special obligation to serve or to refuse to serve in a military effort. That position is made more complex by the physician's role as a military noncombatant. Many military forces permit physicians, like other military personnel, to claim conscientious objector status. In the United States conscientious objection is defined as "a firm, fixed, and sincere objection by reason of religious training and belief to: (1) participation in war in any form; or (2) the bearing of arms." Religious training and belief is defined as "belief in an external power or being or deeply held moral or ethical belief to which all else is subordinate and … which has the power or force to affect moral well-being" (U.S. Department of Defense). A person who claims conscientious objector status must convince a military hearing officer that the objection is sincere.

Obligations to Serve in War Versus Obligations to Prevent War

As wars kill an increasing percentage of civilians with so-called conventional weapons and as threats of the use of weapons of mass destruction continue, what form of service is appropriate for an ethical physician? One response was suggested in the late 1930s by John A. Ryle, then Regius Professor of Physic at the University of Cambridge:

> It is everywhere a recognized and humane principle that prevention should be preferred to cure. By withholding service from the Armed Forces before and during war, by declining to examine and inoculate recruits, by refusing sanitary advice and the training and command of ambulances, clearing stations, medical transport, and hospitals, the doctors could so cripple the efficiency of the staff and aggravate the difficulties of campaign and so damage the morale of the troops that war would become almost unthinkable (p. 8).

During the Vietnam War more than 300 American medical students and young physicians brought Ryle's vision a step closer to reality by signing the following pledge:

> In the name of freedom the U.S. is waging an unjustifiable war in Viet Nam and is causing incalculable suffering. It is the goal of the medical profession to prevent and relieve human suffering. My effort to pursue this goal is meaningless in the context of the war. Therefore, I refuse to serve in the Armed Forces in Viet Nam; and so that I may exercise my profession with conscience and dignity, I intend to seek means to serve my country which are compatible with the preservation and enrichment of life (Liberman et al., p. 306).

Ryle's vision is a variation on that of Aristophanes in his comedy *The Lysistrata,* which was written in 411 B.C.E., just before the probable time of Hippocrates's refusal to treat the Persians (circa 400 B.C.E.). The title character, an Athenian woman, ends the second Peloponnesian War by organizing the wives of the soldiers of both Athens and Sparta to refuse sexual intercourse with their husbands while the war lasts. The Athenians and Spartans make peace quickly and go home with their wives (Aristophanes).

Some physicians and other medical personnel have refused to support war by serving in the armed forces. In one of the most dramatic examples Yolanda Huet-Vaughn, a captain in the U.S. Army Medical Service Reserve, refused

active duty in the Persian Gulf. In her statement she explained her actions:

> I am refusing orders to be an accomplice in what I consider an immoral, inhumane and unconstitutional act, namely an offensive military mobilization in the Middle East. My oath as a citizen-soldier to defend the Constitution, my oath as a physician to preserve human life and prevent disease, and my responsibility as a human being to the preservation of this planet, would be violated if I cooperate (Sidel, 1991b, p. 102).

The reasons Huet-Vaughn gave for her action were quite different from the reasons given by Levy. Levy refused to obey an order that he believed required him to perform a specific act that would violate the Geneva Conventions; Huet-Vaughn refused to obey an order that she believed required her to support a particular war that she felt to be unjust and destructive to the goals of medicine and humanity.

One of the questions Huet-Vaughn's action raises is whether physicians have a special ethical responsibility, in view of their obligation to protect the health and lives of their patients and the people in their communities, to refuse to support a war they believe will cause major destruction to the health and environment of both combatants and noncombatants (Geiger; Sidel, 1991b). If a physician considers service in support of a particular war unethical on the grounds of sworn fealty to medical ethics, may—or must—that doctor refuse to serve even if that objection does not meet the criteria for formal conscientious objector status? Is there an ethical difference if the service is required by the society—as in a "doctor draft"—or if the service obligation has been entered into voluntarily in return for military support of medical training or for other reasons? Is military service a voluntary obligation if enlistment, as it is for many poor and minority people, is prodded by lack of educational or employment opportunities or, as for many doctors, by the cost of medical education or specialty training that in other societies is provided at public expense?

Although few physicians are willing or able to take an action such as that taken by Huet-Vaughn, other actions are available to oppose acts of war that are considered unjust, oppose a specific war, or oppose war in general. One is acceptance of a service alternative consistent with an ethical obligation to care for the wounded or maimed without simultaneously supporting a war effort. Opportunities for service in an international medical corps such as Médecins du Monde and Médecins sans Frontieres are limited, but U.S. physicians may wish to demand that their nation redirect some of the billions of dollars it spends annually on preparation for war to the United Nations or the World Health Organization to help fund an international medical service to treat the casualties of war.

Other physicians may work, as individuals and particularly in groups, to help prevent war by contributing to public and professional understanding of the nature of modern war, the risks of weapons of mass destruction, and the nature and effectiveness of alternatives to war. Among the groups organized for that purpose are the International Physicians for the Prevention of Nuclear War, whose U.S. affiliate is Physicians for Social Responsibility. If the world is to survive, physicians may need to consider new forms of national service and contribute in a broader sense to their nations and their planet (1986).

In the broader context of medical ethics it is widely accepted that opposition to war does not permit an ethical physician to refuse medical care to victims of war he or she is in a position to serve and that that care does not presume the physician's support of the war being fought. Ethical dilemmas arise when a physician actively supports the war effort through membership in a military medical service or by assigning priority to patient care on the basis of military demands rather than patient needs. These issues and those associated with the role of the physician in peacemaking and peacekeeping, which often are distorted by the fervor that may accompany war and preparation for war, require dispassionate analysis and action in times of peace.

III. PUBLIC HEALTH AND WAR

During the twentieth century, an estimated 110 million people lost their lives as a result of armed conflicts (WHO). If one includes the major episodes of "collective violence," such as the Stalinist terror of the 1930s and the famine associated with the Great Leap Forward in China (1958–1960), this figure reaches 191 million (Rummel), with approximately 60 percent of these deaths occurring among noncombatants.

Since the Second World War, approximately 190 armed conflicts have occurred affecting ninety-two countries (WHO; Federation of American Scientists). Most occurred in Asia, Africa, and Latin America; however, since 1990, four European conflicts—Chechnya, Azerbaijan, Georgia, and the former Yugoslavia—have caused more than 350,000 deaths. Some wars are still fought primarily between competing armies, such as the Iran-Iraq conflict (1980–1988), in which an estimated 450,000 military personnel died (Sivard), but the vast majority now take place within states.

Civilian populations have increasingly been the intentional targets of military actions, as can be seen in the shelling of urban centers during the conflicts in Bosnia and Herzegovina, Chechnya, Angola, Lebanon, and Somalia. In addition, modern weapons such as napalm, cluster bombs, and land mines do not discriminate between combatants and innocent civilians. In Mozambique the antigovernment forces killed approximately 100,000 civilians in 1986 and 1987 alone (Ugalde, Zwi, and Richards) and between 5 million and 6 million people were either internally displaced or fled to neighboring countries.

Since World War II there have been numerous episodes of massive human rights atrocities and genocide that defy the traditional characteristics of armed warfare. Examples include Pol Pot's killing fields in Cambodia; the Guatemalan government action against indigenous Mayan communities; the use of chemical and biological weapons against the Kurds in Halabja, Iraq; the genocide against Tutsis in Rwanda; and the civilian massacres following the referendum on independence in East Timor.

Public Health Impact of War

DIRECT IMPACT. The direct public health consequences of war include death, injury, sexual assault, disability, and psychological stress. Measuring the impact and hidden costs of conflict is complex for a variety of reasons. Even where huge numbers of people are involved, agreement on the magnitude of impact varies. Estimates of the number of victims of the Rwandan genocide are still imprecise and vary from 500,000 to one million (Murray, King, Lopez, et al.). Particularly high civilian death rates have been reported in Angola, Ethiopia, Liberia, Mozambique, Rwanda, Somalia,

Southern Sudan, El Salvador, Guatemala, Afghanistan, Cambodia, Tajikistan, and Bosnia and Herzegovina (Zwi and Ugalde; Toole, Galson, and Brady).

Rape is increasingly recognized as a feature of internal wars, and it has been present in many different types of conflicts. In some conflicts, rape has been used systematically as an attempt to undermine opposing groups. In the former Yugoslavia, for example, estimates of the number of rape survivors have ranged from 10,000 to 60,000 (Swiss and Giller).

Estimates of mine-related disabilities are also sobering: 36,000 in Cambodia (one in every 236 persons in that nation has lost at least one limb), 20,000 in Angola, 8,000 in Mozambique, and 15,000 in Uganda. The costs are both physical and social and affect all age groups. Between February 1991 and February 1992, approximately 75 percent of the land-mine injuries treated worldwide were in children five to fifteen years old (Toole, Waldman, and Zwi).

Immeasurable psychological trauma has been caused by widespread human-rights abuses, including detention, torture, and forced displacement (institutionalized in the former Yugoslavia as "ethnic cleansing"). The extent of mental health "trauma" experienced during and in the aftermath of war and conflict is controversial, with some analysts identifying significant proportions of affected populations suffering from post-traumatic stress disorder, while others argue that this term and the response to it medicalizes an essentially social phenomenon.

INDIRECT IMPACT. The indirect public health consequences of war have been mediated by hunger, mass migration, and collapsed health services, especially in impoverished developing countries where basic services and food reserves are already inadequate. The intentional use of food deprivation as a weapon has become increasingly common (MacCrae and Zwi). For example, armed factions on all sides have obstructed food-aid deliveries in southern Sudan, resulting in mass hunger and, during 1993, death rates up to fifteen times those reported in nonfamine times. In 1992 widespread looting and banditry deprived millions of Somalis of much-needed food aid.

At the end of 2002 there were more than 15 million refugees worldwide, and an additional 22 million people internally displaced in their own countries (U.S. Committee for Refugees). Crude death rates (the number of deaths per 1,000 population per month) among refugees and internally displaced persons have ranged between five and twenty-five times baseline rates. Most deaths have been caused by preventable conditions such as malnutrition, diarrhea, pneumonia, measles, and malaria (Toole, Waldman, and Zwi). High death rates reflect the prolonged period of deprivation suffered prior to displacement, the often inadequate response to humanitarian crises by the international community, and problems of gaining access to provide relief assistance to war-affected communities. More than 50,000 refugees from Rwanda died within one month of fleeing into eastern Zaire in 1994, representing a death rate more than 25 times higher than the baseline rate in Rwanda (Goma Epidemiology Group).

Health facilities have been intentionally destroyed by armed factions in Afghanistan, Angola, Bosnia, Mozambique, and other war-stricken countries. In addition, the high costs of both maintaining military forces and treating the wounded have often led to insufficient funding for basic health services. In the Bosnian province of Zenica, for example, the proportion of surgical cases related to war injuries rose from 22 percent to 78 percent between April and November 1993, resulting in the cessation of almost all preventive health services (Toole, Galson, and Brady).

Perhaps the most significant consequence of war on public health relates to the tremendous cost of preparing for war. Military budgets throughout both the industrialized and developing worlds have diverted precious resources from public health and other social development programs. For example, in April 2002 the U.S. Congress approved $85 billion to fund the initial stages of the war in Iraq. In comparison, the total global expenditure on the fight against HIV/AIDS in low- and middle-income countries was $1.5 billion in 2001. Moreover, the destruction of environmental resources, such as water sources, agricultural land, livestock, and housing has had a major impact on public health in numerous countries affected by war.

Ethical Issues

Modern warfare has increasingly involved flagrant violations of the Geneva Conventions related to the protection of civilian persons in time of war (ICRC). Ethnic cleansing, detention of civilians, summary executions, and torture are clearly illegal under international law. The unrestricted ability of combatants to target civilians is fostered by the officially sanctioned international arms trade. The International Committee of the Red Cross (ICRC), the custodian of the Geneva Conventions, has often been deprived of access to civilians in countries such as Somalia, Sudan, and Bosnia and Herzegovina. Further, providing humanitarian assistance has become more dangerous. Between 1985 and 1998, over 380 deaths occurred among humanitarian workers (Sheil et al.).

Although violations of human rights law and international humanitarian law are crimes, the legal systems for

punishing the perpetrators and compensating the victims are grossly inadequate. To date, international tribunals have been established to prosecute war criminals from the former Yugoslavia and from Rwanda. While these courts help to move the punishment of war criminals from theory to practice, they have been very slow to act and very expensive to implement. The establishment of an International Court of Justice is another step towards strengthening what has, in many respects, been a legal system without law enforcement capability.

International public opinion has increasingly supported the use of force by the United Nations to ensure delivery of humanitarian aid in situations either where governance has completely collapsed (e.g., Somalia and Liberia) or where governments consciously hinder access by relief agencies (e.g., Sudan and Bosnia and Herzegovina). However, there are no clear guidelines that might promote a consistent deployment of force to achieve humanitarian objectives (Dewey). The U.N. Charter prohibits interference in the affairs of a sovereign nation, thereby giving more weight to the rights of the state than to individual citizens.

Two contradictory examples from 1992 illustrate the ethical dilemmas inherent in the use of force to save lives from hunger and disease. In Bosnia and Herzegovina, European soldiers deployed to ensure the safe delivery of humanitarian supplies were powerless to prevent flagrant abuses of human rights committed in their presence (Jean). In contrast, the international armed contingent dispatched to Somalia in late 1992 to ensure the safe delivery of relief supplies eventually became a party to the internal conflict. This led to battles between U.N. troops and one local armed faction in heavily populated areas of the capital, Mogadishu, with high civilian casualty rates (Brauman). Thus, well-motivated intervention by the international community may inadvertently increase the risks to the intended beneficiaries.

Once access to an affected area is assured, health personnel have a critical role to play in accurately documenting the public health impact of war on civilian populations, thereby acting as effective advocates for a prompt and adequate response. Relief programs may pose a difficult choice for health workers: between the provision of individual curative care and the implementation of more effective, community-based programs such as childhood immunization.

Conclusions

Modern warfare has exacted a devastating toll on civilian populations. High mortality, morbidity, and disability rates have resulted directly from traumatic injuries and indirectly from hunger and mass displacement. Since the end of the Cold War, the potential for a more unified and coherent "international community" has emerged. The United Nations has a responsibility to carefully monitor the public health consequences of evolving conflicts and to apply aggressive diplomacy early to seek solutions. When conflicting parties obstruct access to civilians by relief agencies, the world needs to respond in a consistent and effective manner, and clearer guidelines on the use of force to deliver humanitarian aid in conflict settings need to be developed.

Relief programs will be more effective if they reflect the real needs of affected populations, rather than the availability of surplus commodities in donor countries. With a proper and timely scientific assessment of public health needs and careful monitoring of health and nutrition trends, those who are suffering are more likely to receive the aid they require. Primary prevention is the basic strategy of public health; consequently, in war settings, public health practitioners need to recognize that primary prevention means stopping the violence, as well as actively exploring methods for promoting sustainable peace.

IV. CHEMICAL AND BIOLOGICAL WEAPONS

The development, production, storage, transfer, use, and destruction (demilitarization) of chemical and biological weapons (CBW) pose a number of ethical issues. First, those weapons, like nuclear weapons, are largely indiscriminate in their effects and are generally more effective against vulnerable noncombatants than against combatants; they therefore are known as weapons of mass destruction, and their use generally is considered a violation of the proportionality principle of a just war. Second, CBW, also like nuclear weapons, are the subject of intensive international arms-control efforts involving problems of definition, verification, and enforcement. Third, biomedical scientists and physicians may be called on to participate in research and development on more effective CBW as well as on methods for defense against them and the treatment of their victims.

Chemical Weapons

Chemical weapons (CW), which have been known since antiquity, are designed to inflict direct chemical injury on their targets, in contrast to explosive or incendiary weapons, which produce their effects through blast or heat. In the siege of Plataea in 429 B.C.E., for example, the Spartans placed enormous cauldrons of pitch, sulfur, and burning charcoal outside the city walls to harass the defenders. Although nations that signed the 1899 Hague Declaration promised not to use CW, during World War I those weapons, including in descending order of use tear gas, chlorine gas, phosgene, and mustard gas, were employed. Overall, 125,000 tons of CW were used during World War I, resulting in 1.3 million casualties. One-quarter of all casualties in the American Expeditionary Force in France were caused by them (Harris and Paxman; Sidel and Goldwyn; Sidel, 1989; United Nations; World Health Organization).

In 1925 twenty-eight nations negotiated the Geneva Protocol for the "prohibition of the use in war of asphyxiating poisonous or other gases and of all analogous liquids, materials or devices and of bacteriological methods of warfare" (Wright, p. 368). In fact, however, the protocol prohibited only the use, not the development, production, testing, or stockpiling, of those weapons. Furthermore, many of the nations that ratified the protocol reserved the right to use those weapons in retaliation, and the protocol became in effect a "no first use" treaty with no verification or enforcement provisions. The United States was one of the initial signers, but the Senate did not ratify the treaty until 1975 (Sidel, 1989; Wright).

Despite the protocol, the use of CW continued. Italy used mustard gas during its invasion of Abyssinia (Ethiopia), and Japan used mustard and tear gases in its invasion of China. Germany, with its advanced dye and pesticide industries, developed acetylcholinesterase inhibitors known as nerve gases, and the United States and Britain stockpiled CW during World War II; transportation and storage accidents caused casualties (Infield), but there was no direct military use. After World War II CW were used by Egypt in Yemen, mustard and nerve gases were used in the Iran-Iraq war in the 1980s, and Iraq used CW against Kurdish villages in its territory. CW stockpiles and production facilities in Iraq were ordered destroyed by the United Nations after the 1991 Persian Gulf War. The United States and Russia are known to have maintained CW stockpiles, and a number of

other countries have stockpiles or facilities for rapid CW production (Harris and Paxman; Sidel, 1989).

Troops can be protected against those weapons for limited periods through the use of gas masks and impenetrable garments. That protective gear, however, reduces the efficiency of troops by as much as 50 percent and damages morale, and so the use or threat of use of CW may continue to be considered effective against troops. Civilian populations, in contrast, cannot be protected adequately. Israel, for example, provides every civilian with a gas mask and a self-injectable syringe filled with atropine, a temporary antidote to nerve gas. However, that protection is inadequate against weapons, such as mustard gas, that attack the skin and against longer-term exposure to nerve gas. Furthermore, poorly trained civilians are likely to injure themselves with equipment such as self-injectable syringes (Amitai et al.).

The production of CW has been associated with serious accidents to workers and high levels of pollution in the production sites and nearby communities. Tests of mustard gas, nerve agents, and psychochemicals, including lysergic acid diethylamide (LSD), during and after World War II involved thousands of military personnel, many of whom later claimed disabilities from the exposure. The records of participation and effects are so poor that only a small fraction of those who participated can be identified. Even the destruction of the weapons is dangerous because toxic ash is produced by their incineration (Sidel, 1993).

A Chemical Weapons Convention (CWC) that prohibits the development, production, storage, and transfer of those weapons and calls for their demilitarization was approved by the United Nations General Assembly in 1992. The Organization for the Prohibition of Chemical Weapons (OPCW), which is responsible for ensuring the implementation of the CWC, was established in the Hague after the entry into force of the CWC in 1997. By 2003 a total of 151 "states parties" (nations) had ratified or acceded to the BWC. The First Review Conference of the States Parties to the CWC was held in the Hague in April 2003, and Kofi Annan, secretary general of the United Nations, urged that "membership in the CWC be extended to all nations in the world and that enough funds be provided to accelerate complete chemical disarmament."

In the 1960s and 1970s the United States used both tear gas and herbicides in Vietnam. Although most nations that are parties to the Geneva Protocol considered tear gas and herbicides to be CW and thus prohibited under the provisions of the protocol, the United States until recently rejected that interpretation (Sidel and Goldwyn; Sidel, 1989). Many countries use tear gas to quell civil disorders (Hu et al.). The signatories to the CWC have agreed not to use riot-control agents or herbicides as weapons of war.

In 2002 Russia used derivatives of fentanyl, a potent opium-based narcotic, to subdue Chechen rebels who had occupied a theater in Moscow and taken 800 hostages. Although Russia formally considered the chemical agent "nonlethal" and its use permissible under the CWC, a total of 117 people died as a result of its use ("Russia Names Moscow Siege Gas").

In 1984 members of a cult in Oregon intentionally contaminated the salad bars in local restaurants with salmonella bacteria. More than 700 people became ill, but there were no reported deaths. In 2001, shortly after the attack on the World Trade Center, anthrax spores were disseminated through the U.S. mail. Approximately twenty people became ill, and five people died.

Biological Weapons

Biological weapons (BW) depend for their effects on the ability of microorganisms to infect and multiply in the attacked organism. In this regard they differ from toxins, which, as biological products used as chemicals, are covered under CW as well as BW treaties. BW are very hard to defend against and are not as controllable and predictable in their use as are CW (Harris and Paxman; Geissler, 1986; Sidel and Goldwyn; Sidel, 1989; United Nations; World Health Organization, 1970).

The effects of BW were characterized officially by a U.S. government agency in 1959: "Biological warfare is the intentional use of living organisms or their toxic products to cause death, disability, or damage in man, animals, or plants. The target is man, either by causing sickness or death or through limitation of his food supplies or other agricultural resources.… Biological warfare has been aptly described as public health in reverse" (U.S. Department of Health, Education, and Welfare).

BW have been known since antiquity. Persia, Greece, and Rome used diseased corpses to contaminate sources of drinking water. In 1347 Mongols besieging the walled city of Caffa (now called Feodosiya), a seaport on the east coast of the Crimea, began to die of the plague. The attackers threw the corpses into the besieged city; the defenders, who were Genoans, fled back to Genoa and carried the plague farther into Europe. During the French and Indian Wars Lord Jeffrey Amherst, commander of the British forces at Fort Pitt, gave tribal emissaries blankets in which smallpox victims had slept (Harris and Paxman; Geissler).

During World War I Germany is alleged to have used the equine disease glanders against the cavalries of eastern

European countries (Harris and Paxman, p. 74). According to testimony at the Nuremberg trials, prisoners in German concentration camps were infected during tests of BW. Great Britain and the United States, fearing that the Germans would use BW in World War II, developed their own BW. The British tested anthrax spores on Gruinard Island off the coast of Scotland; the island remained uninhabitable for decades. The United States developed anthrax spores, botulism toxin, and other agents as BW but did not use them (Bernstein).

In the 1930s Japanese troops dropped rice and wheat mixed with plague-carrying fleas from planes, resulting in plague in areas of China that previously had been free of it. During World War II Japanese laboratories conducted extensive experiments on prisoners of war, using a wide variety of organisms selected for possible use as BW, including anthrax, plague, gas gangrene, encephalitis, typhus, typhoid, hemorrhagic fever, cholera, smallpox, and tularemia (Wright). Unlike the Soviet Union, which in 1949 prosecuted twelve people who had been involved in that work, the United States never prosecuted any of the participants. Instead, U.S. researchers met with Japanese biological warfare experts in Tokyo and urged that the experts be "spared embarrassment" so that the United States could benefit from their knowledge (Powell; Williams and Wallace).

DIFFICULTIES OF SURVEILLANCE. After World War II the development of BW continued. None of the numerous allegations of BW use have been substantiated or even investigated fully, but it is known that extensive BW testing was done. In the 1950s and 1960s, for example, the University of Utah conducted secret large-scale field tests of BW, including tularemia, Rocky Mountain spotted fever, plague, and Q fever, at the U.S. Army Dugway Proving Ground. In 1950 U.S. Navy ships released as simulants (materials believed to be nonpathogenic that mimic the spread of BW) large quantities of bacteria in the San Francisco Bay area to test the efficiency of their dispersal. Some analysts attributed subsequent infections and deaths to one of those organisms. During the 1950s and 1960s the United States conducted 239 top-secret open-air disseminations of simulants, involving areas such as the New York City subways and Washington National Airport (Cole). The U.S. military developed a large infrastructure of laboratories, test facilities, and production plants related to BW. By the end of the 1960s the United States had stockpiles of at least ten biological and toxin weapons (Geissler). A 1979 outbreak of pulmonary anthrax in the Soviet Union is said to have been caused by accidental release from a Soviet BW factory. Recent disclosures by Russian scientists indicate extensive environmental contamination and medical problems caused by CW production ("Russian Experts Say Many Died Making Chemical Weapons").

In 1969 the Nixon administration, with the concurrence of the U.S. Defense Department, which declared that BW lacked "military usefulness," unconditionally renounced the development, production, stockpiling, and use of BW and announced that the United States would dismantle its BW program unilaterally. In 1972 the Soviet Union, which had urged a more comprehensive treaty that would include restrictions on CW, ended its opposition to a separate BW treaty. The United States, the Soviet Union, and other nations negotiated the Convention on the Prohibition of the Development, Prevention and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction (BWC). The BWC prohibits, except for "prophylactic, protective and other peaceful purposes," the development or acquisition of biological agents or toxins as well as weapons carrying them and means of their production, stockpiling, transfer, and delivery. The U.S. Senate ratified the BWC in 1975, the same year it ratified the Geneva Protocol of 1925. As of 1987, 110 nations had ratified the BWC and an additional 25 had signed but not yet ratified it (Wright).

Invoking the specter of new biological weapons and unproven allegations of aggressive BW programs in other countries, the Reagan administration initiated intensive efforts to conduct "defensive research," which is permitted under the BWC. The budget for the U.S. Army Biological Defense Research Program (BDRP), which sponsors programs in a wide variety of academic, commercial, and government laboratories, increased dramatically during the 1980s. Much of that research work is medical in nature, including the development of immunizations and treatments against organisms that might be used as BW (Piller and Yamamoto; Wright).

Although research on and the development of new BW are outlawed by the BWC, it is possible that they will occur in the future. Novel dangers lie in new genetic technologies that permit the development of genetically altered organisms that are not known in nature. Stable, tailor-made organisms used as BW could travel long distances and still be infectious, rapidly infiltrate a population, cause debilitating effects very quickly, and be resistant to antibiotic treatment (Piller and Yamamoto).

Ethical Issues for Biomedical Scientists

Biologists, chemists, biomedical scientists, and physicians have played important roles in CBW research and development. Fritz Haber, who was awarded the 1918 Nobel Prize

in chemistry for his synthesis of ammonia, is known as the father of Germany's chemical weapons program in World War I. In his speech accepting the Nobel Prize Haber declared poison gas "a higher form of killing" (Harris and Paxman, 1982). By contrast, during the Crimean War the British government consulted the noted physicist Michael Faraday on the feasibility of developing poison gases; Faraday responded that it was entirely feasible but that it was inhumane and he would have nothing to do with it (Russell).

Many scientists who explicitly acknowledge the ethical conflicts involved in work on weapons argue that a higher ethical principle—the imperative of defending one's country or helping to curb what is perceived as evil or destructive—permits or even requires participation in such work. Dr. Theodor Rosebury, who worked on BW during World War II, based his participation on his belief that crisis circumstances that were expected to last for only a limited time required that he act as he did. "We were fighting a fire, and it seemed necessary to risk getting dirty as well as burnt," he later wrote (Rosebury, 1963). Rosebury refused to participate in BW work after the end of the war (Rosebury, 1949).

Other scientists resolved their ethical dilemma by arguing that their work on weapons was designed to reduce the devastation of war. For example, while working on "nonlethal" CBW in the 1960s Dr. Knut Krieger argued that his research would lead to decreased fatalities: "If we do indeed succeed in creating incapacitating systems and are able to substitute incapacitation for death it appears to me that, next to stopping war, this would be an important step forward" (Reid).

Relevant ethical concerns about "defensive research" on BW by biomedical scientists include issues of content, safety, context, and locus (Lappé).

CONTENT. The Japanese laboratory established in 1933 to develop BW was called the Epidemic Prevention Laboratory. One of its activities was supplying vaccines for troops bound for Manchuria, but its major work was developing and testing BW (Powell). Military forces today could conduct research on the offensive use of BW under the cover of defensive research because offensive and defensive research are joined inextricably in at least some phases of the work (Huxsoll et al.). In the parts of the work in which offensive and defensive efforts are parallel new forms of organisms may be found or developed that would be more effective as biological weapons. The possibility that offensive work on BW is being done in the United States under the cover of defensive work has been denied by the leaders of the BDRP, who point out the areas in which the two types of research diverge (Huxsoll et al.). Critics nonetheless raise questions about the ambiguity of BDRP research, arguing that "these efforts are highly ambiguous, provocative and strongly suggestive of offensive goals" (Jacobson and Rosenberg; Piller and Yamamoto; Wright).

SAFETY. Many analysts believe that CW or BW research, even if it is truly defensive in intent, may be dangerous to surrounding communities if toxic materials or virulent infectious organisms are released accidentally.

CONTEXT. CW or BW research, even if it is defensive in intent, can be viewed by a potential military adversary as an attempt to develop protection for a nation's military forces or noncombatants against weapons that that nation might wish to use for offensive purposes, thus permitting that nation to protect its own personnel in a CW or BW first strike. In fact, the military justification for preparing altered organisms is that they are needed for the preparation of defenses. It is therefore impossible for adversaries to determine whether a nation's defensive efforts are part of preparations for the offensive use of weapons.

LOCUS. Fears in this area usually are based on military sponsorship of defensive BW research. Even if that research is relatively open, other nations may view with suspicion the intense interest of military forces rather than civilian medical researchers in vaccines and treatments against specific organisms. Those fears can feed a continuing BW arms race.

More generally, concern has been expressed about the militarization of genetic engineering and biology in general. Characterization of biological weapons as "public health in reverse" therefore may have an even broader and more sinister meaning: The entire field of biology, along with and aspects of it such as the use of human genome research to design weapons to target specific groups, may be in danger of military use for destructive ends (Piller and Yamamoto; Wright). The imprisonment of a chemist by the Russian government and the revocation of his university diploma for publishing an article describing the development of new, highly toxic CW illustrate the restrictions that are placed on scientists who do CBW research (Janowski).

Ethical Issues for Physicians

The first question that arises is whether it is constructive to view certain ethical responsibilities as unique to the physician's social role. Theodor Rosebury described the response to physician participation in work on BW during World War II: "There was much quiet but searching discussion among us regarding the place of doctors in such work … a certain delicacy concentrated most of the physicians into

principally or primarily defensive operations." Rosebury went on to point out that the modifiers *principally* and *primarily* are needed "because military operations can never be exclusively defensive" (Rosebury, 1963). What is seen as the special responsibility of physicians is based largely on an ethical responsibility not to use the power of the physician to do harm (*primum non nocere*). Although the Hippocratic oath seems to apply to the relationship of the physician to an individual patient, its meaning has been broadened by many to proscribe physician participation in actions harmful to nonpatients.

In regard to research on offensive weapons of war there seems to be a consensus that physicians participate in such research at their ethical peril even if their country demands it or they think it useful for deterrence or other preventive purposes. However, because of the ambiguity of defensive work on BW, the dilemma for the physician is not easily resolved even for those who believe that defensive efforts are ethically permissible.

Some proponents of defensive research on BW have argued that it is entirely ethical—that in fact it is obligatory—that physicians work on it. According to this perspective, not only will defenses be needed if such weapons are used against the United States, that work also may be useful in developing protection against naturally occurring diseases (Crozier; Huxsoll et al.; Orient). Other analysts believe that it is unethical for physicians to play a role in military-sponsored BW research because it has a strong potential for intensifying a BW arms race and helping to militarize the science of biology, thus increasing the risk of the use of BW and the destructiveness of their effects if they are used (Jacobson and Rosenberg; Nass, 1991; Sidel, 1991).

The question is: Where on the slippery slope of participation in preparing for the use of BW should physicians draw the line? If physicians engage in civilian-sponsored research on disease control that carries an obligation to report all findings in the open literature even if the research may have implications for BW, that participation, most analysts agree, cannot be faulted on ethical grounds. However, when physicians engage in military-sponsored research in which the openness of reporting is equivocal and the purposes are ambiguous, it is difficult to distinguish their work ethically from work on the development of weapons.

As was noted above, the BWC prohibits any "development, production, stockpiling, transfer or acquisition of biological agents or toxins" except for "prophylactic, protective and other peaceful purposes." The responsibility for government-sponsored medical research for prophylactic, protective, and other peaceful purposes in the United States lies largely with the National Institutes of Health (NIH) and the Centers for Disease Control (CDC). The NIH or the CDC therefore might be given the responsibility and the resources for medical research of this type. The U. S. Army still may want to conduct nonmedical research and development on defense against BW, such as work on detectors, protective clothing, and other barriers to the spread of organisms. Under this proposed division of effort that research is less likely to be seen as offensive, provoke a BW race, pervert the science of biology, and involve physicians (Sidel, 1989).

A different type of ethical issue related to CBW arose during the Persian Gulf War in 1991. The United States provided protective measures such as immunization against botulinum toxin and anthrax for its military forces. Despite the fact that some of those measures were experimental, no informed consent procedures were used and compliance often was required. Furthermore, the measures were made available to military forces but not to noncombatants in the area (Annas; Howe and Martin).

In addition to the ethical dilemmas involved in these decisions it may be unethical for physicians to ignore the issues involved in CBW. One of the greatest dangers of those weapons may be the apathy of the medical profession toward them. The fact that BW are the weapons with which physicians may become engaged and the ones about which they have specialized knowledge gives physicians a special responsibility not only to refuse to work on them but also actively to work to reduce the threat of their development or use.

Conclusion

Physicians and biomedical scientists should support methods for international epidemiological surveillance to detect the use of BW and investigate incidents in which use has been alleged after an unexplained disease outbreak (Geissler, 1986; Nass, 1992a, 1992b) and support the Vaccines for Peace Programme for the control of "dual-threat" agents (Geissler and Woodall). Support also might be given for measures to strengthen the BWC through the introduction of the verification proposals that were put forth at the 1991 BWC Review Conference (Falk; Rosenberg and Burck; Rosenberg). With regard to chemical weapons, biomedical scientists and physicians might support effective implementation of the 1993 CWC (Smithson).

More broadly, physicians may wish to explore the connection between CBW and nuclear weapons. It has been argued that by refusing to reduce their vast stockpiles of nuclear weapons substantially and refusing to agree to

verifiable cessation of nuclear weapons testing and production, the nuclear powers provoke nonnuclear powers to contemplate the development and production of CBW for deterrence against nuclear weapons. The U.S. Defense Intelligence Agency reported that "third world nations view chemical weapons as an attractive and inexpensive alternative to nuclear weapons" (U.S. General Accounting Office; Zilinskas, 1990a, 1990b). There is much that physicians can do, for example, through the International Physicians for the Prevention of Nuclear War, the organization that received the 1985 Nobel Peace Prize, and its affiliates in many countries to reduce the provocation and proliferation of weapons of mass destruction caused by the continuing nuclear arms race.

Individual physicians and scientists can add to the awareness of the dangers of CBW by signing the pledge sponsored by the Council for Responsible Genetics "not to engage knowingly in research and teaching that will further development of chemical and biological warfare agents." U.S. physicians also may wish to support legislation to transfer all medical aspects of biological defense from the military to the NIH or the CDC. Physicians may help awaken the medical profession to the dangers of CBW and nuclear weapons by adding a clause to the oath taken by medical students upon graduation from medical school, similar to the oath for medical students in the former Soviet Union, requiring them "to struggle tirelessly for peace and for the prevention of nuclear war" (Cassel et al., p. 652). The clause might be worded as follows: "Recognizing that nuclear, chemical, and biological arms are weapons of indiscriminate mass destruction and threaten the health of all humanity, I will refuse to play any role that might increase the risk of use of such weapons and will, as part of my professional responsibility, work actively for peace and for the prevention of their use."

WHISTLEBLOWING IN HEALTHCARE

• • •

The term *whistleblowing* is a metaphor, apparently derived from a referee's use of a whistle to call a foul in a sporting event. It refers to a disclosure made by a member or former member of an organization about some practice within the organization. Whistleblowing can be internal (disclosure to someone in higher authority in the organization) or external (disclosure to outside persons or organizations such as government agencies, public-interest groups, or the news media). The term is most commonly used to describe disclosure to persons outside the organization, and it is external whistleblowing that is the focus of discussion here.

The whistleblower is a person, usually willing to be identified publicly, who makes an unauthorized disclosure regarding some action or practice within the organization that the person judges to be ethically wrong or unacceptably dangerous. Whistleblowing takes place in business, in government, and in the professions. In healthcare, the most common example in the ethics literature is whistleblowing by nurses about physician behavior. With increased attention being given to ethical issues throughout the healthcare organization, it can be expected that, in the future, the examples of potentially justified whistleblowing in healthcare will be focused nearly as frequently on the business side of the organization as on the clinical side.

Whistleblowing is unauthorized disclosure. As such, it almost always involves activity that management considers disloyal to the organization. In addition, organizations and individuals can be harmed, perhaps in an irreparable manner, by public accusations. Retractions or corrections of false or unfair allegations seldom receive the same degree of public attention as the initial accusations. These considerations of disloyalty and harm have led many ethicists to stress the conditions that must be met before individuals should feel justified in blowing the whistle. It is also important to recognize, however, that the organization has a responsibility to prevent the need for whistleblowing and to treat the whistleblower fairly.

Responsible Whistleblowing

Even when potential whistleblowers are motivated by a desire to protect other individuals or society in general, they need to be careful lest they do more harm than good. Ethical or responsible whistleblowing is usually understood to mean that all of the following conditions are met:

(1) The person has clear evidence that the organization or someone in the organization is engaged in activity that is seriously wrong or that has a high potential for doing serious harm.

(2) The charge to be made by the whistleblower is accurate and accusations against any individuals are able to be substantiated.

(3) The wrongdoing or the danger to be disclosed must be serious enough to justify risking the harm that will likely result to the organization and to some individuals once the public disclosure is made.

(4) Reasonable attempts to prevent the wrong through internal consultation and reporting have been made and have failed. Potential whistleblowers should attempt to use methods of reporting within the organization before going outside, in spite of the frustrations and delays internal mechanisms can sometimes cause. (It should be recognized, however, that in some situations internal efforts to prevent the wrong are not feasible or would simply lead to an effective cover-up.)

(5) There is a reasonable possibility that the disclosure will help prevent or mitigate the harm or wrong or that the disclosure will lesson the likelihood that similar actions will occur in the future. (This condition should not be interpreted too rigidly. In many cases, it is exceedingly difficult to calculate the potential consequences that may result from acting. Furthermore, it may sometimes be legitimate just to call attention to the reality in order to have a better-informed public.)

When these conditions are all met, blowing the whistle might best be considered an ethical responsibility, not just an ethically permissible act; all employees have some responsibility to protect the public from serious harm when possible.

The Organization: Prevention and Protection

While much of the discussion of whistleblowing in the ethics literature has focused on the responsibility of the potential whistleblower, there is also a need to recognize the responsibilities of management. Many healthcare organizations now have corporate compliance programs that have mechanisms for internal reporting of suspected wrongdoing (including anonymous reporting to the compliance officer). However, unless and until employees and medical staff see that changes are made when concerns are raised internally, they will still be faced with the question of whether to go public. Management is in a weak position to claim that an employee should not blow the whistle out of loyalty to the organization if management does not adequately attend to reported problems. One of the key reasons why some nurses believe they have a responsibility to blow the whistle publicly on physician behavior is that their experience is that internal complaints have led to no changes at all.

In addition to following up quickly and with thorough investigations when staff report what they perceive to be serious wrongdoing, management can take other steps to prevent staff from concluding that they have no alternative but to blow the whistle. Those who make internal reports or complaints should be protected from any recrimination or discipline, as long as they make the report in good faith (which should be assumed until proven otherwise). Trying to protect the organization from doing harm should be rewarded, not penalized.

Organizations also have a responsibility to deal fairly with employees who do blow the whistle. In the history of whistleblowing in business, a common outcome has been the firing of whistleblowers. This has been the case, even when there was evidence that the whistleblower did, in fact, expose a serious wrongdoing that was not being addressed internally. It is difficult, if not impossible, to justify ethically the firing of an employee because the person blew the whistle on actions that seriously threaten the public good after making reasonable internal attempts to achieve a change. The ethical healthcare organization recognizes that loyalty to the public good takes priority over loyalty to the employer.

WOMEN AS HEALTH PROFESSIONALS, CONTEMPORARY ISSUES OF

• • •

After three decades of increasing numbers of women entering previously male-dominated health professions, few academic health centers have what might be considered a "critical mass" of women full professors, much less women leaders. A brief status report on women in academic medicine introduces a discussion of recent research on why gender differences in the advancement of professionals persist. For instance, no matter how complex the technical requirements of a woman's occupation, Western culture expects her to be more nurturing and emotionally accessible than a man. At the same time, it places a low value on caretaking roles, in terms of both prestige and financial remuneration. Forward-looking institutional strategies to enhance the development of women health professionals target features of the work culture that may be "simply the norm" but that disadvantages women. The concluding section of this entry attempts responses to the questions: Is the increasing number of women entering medicine and other health professions mitigating the impact of gender? And how is gender diversity changing the profession?

Status Report on Women in Academic Medical Centers

Of all the health profession schools, the most extensive data is available on medical schools (and they are largest in terms of budget and size); therefore, this statistical report centers on women in academic medicine. Most trends and findings

cited would apply as well to other health professions that were male-dominated until recently.

In 2001 women constituted 45 percent of U.S. medical students, 39 percent of dental students, and 41 percent of osteopathic students (by comparison, women are 55% of enrollees in four-year colleges/universities). The number of men applying to medical school has been declining faster than the number of women. For instance, between 1995 and 2001, the number of men applying to medical school declined by 33 percent, compared to 17 percent for women. If this rate of change continues, by 2005, half of first-year medical students nationally will be women.

The proportion of full-time medical school women faculty in 2001 was 28 percent (in dental schools, 25%, and in osteopathic schools, 39%). The proportion of medical school instructors who are women has been steadily increasing and is now 46 percent, but only 12 percent of full professors are women.

With regard to the proportion of men and women faculty at each rank, these proportions have remained remarkably stable, especially at the full professor rank (Bickel, 2001). For instance, in 2001, 10.9 percent of all women faculty and 30.9 percent of all men faculty were full professors; in the mid-1980s, these proportions were 9.9 percent and 31.5 percent, respectively.

In 2001, 14 percent of tenured medical school faculty (all ranks) were women. Between 1995 and 2001, the percent of women with tenure actually dropped from 14 percent to 12 percent, about the same proportional decline as the percent of men tenured (32% to 28%) (Bickel, 2001). Data from the Association of American Medical College's Faculty Roster System also reveal that the average annual rate of women faculty attrition (9.1%) exceeds that of men (7.7%) (Yamagata).

With regard to academic administrative roles, in 2001 women chaired approximately 214 departments (91 basic science and 123 clinical departments [including interim and acting chairs]), which is about 8 percent of all medical school chairs. This total constitutes an average of just 1.7 per medical school, and at least 20 of 125 medical schools have no women chairs (most of these have never had one). The specialties with the largest number of women chairs are microbiology, pathology, anesthesiology, family medicine, obstetrics/gynecology, and pediatrics (Bickel, Clark, and Lawson).

By 2002 the number of women assistant, associate, and senior associate deans at American medical schools totaled approximately 422 (an average of three per school); three schools had no woman in a decanal position. As of July 2002, women held deanships at eight of the 125 U.S. medical schools (two were interim positions). In osteopathic schools, women held three of nineteen deanships and in dental schools, none.

Continuing Disadvantages Related to Professional Opportunities

Numerous studies from the late 1990s and early 2000s have elucidated continuing gender differences in professional opportunities and advancement. Although these areas are highly interrelated, the findings are presented below under five headings: specialty choice, sexism and mental models of gender, acquiring mentoring, practice-related areas of career disadvantage, and the intersection of gender and ethnicity.

SPECIALTY CHOICE. The specialty choices of women physicians have changed little despite their large increases in numbers, with comparatively few women entering surgery and most subspecialties. Why are women not distributing more evenly across specialties? The weight of tradition from earlier eras when women physicians were restricted to treating women and children (Bickel, 2000) explains in part why high proportions of women physicians continue to enter obstetrics and gynecology, pediatrics, general internal medicine, and family practice. But the paucity of women entering surgery also points to characteristics of the field, including hours that may preclude having a healthy family or personal life, and a lack of positive role models (Biermann). Women who enter training, however, do not drop out of surgical residencies at a higher rate than men. The American College of Surgeons' analysis of the 1993 entering cohort found that male and female U.S. and Canadian graduates had the same attrition rate from surgical residencies (Kwakwa and Jonasson). The largest study of women physicians (U.S. medical school graduates between 1950 and 1989) found that women surgeons are less likely (43%) to have children than nonsurgeons (71%) but reported a higher level of satisfaction with their specialty than nonsurgeons (Frank, Brownstein et al., 1998).

Thus, the more prestigious (and better paid) *curing* specialties continue to be male dominated (Bickel, 1988). One issue of equity related to women physicians' concentration in what might be termed the *caring* specialties is that listening and counseling skills are sometimes viewed as qualities inherent in women rather than acknowledged as technical proficiencies that deserve recognition and recompense.

SEXISM AND MENTAL MODELS OF GENDER. Harassment and sexism continue to detract from the education and

opportunities of women health professionals. Even medical school department chairs admit to witnessing inappropriate sexual behavior including pressuring women to participate in sexual relationships (Yedidia and Bickel). Almost half of American women physicians believe they have been harassed during their careers, and most cite medical school as the location. In this national study, harassment was associated with depression, suicide attempts, and a desire to switch specialties (Frank, Brogan, and Schiffman). Abused students are more likely to lack confidence in their clinical skills and in their ability to give compassionate care (Kassebaum and Cutler; Schuchert).

As troublesome as overt sexual harassment continues to be, subtler forms of bias pose a much larger challenge to women's development as professionals. U.S. society associates decisiveness, rationality, and ambition with men, and gentleness, empathy, and nurturance with women (Tong). Such stereotypes, however, deny individuals the opportunity to be appraised positively on the basis of their unique traits. Indeed, men or women who act "against type" tend to be dismissed or marginalized. The "feminine" man who displays more sensitivity or emotion than is culturally normative risks derision; the assertive woman is perceived as "uncaring" and "unfeminine."

These widely shared schemas about males and females also include expectations about their professional competence (Valian). Medical school department chairs confirm that lack of recognition and respect of women in routine interactions was prevalent (Yedidia and Bickel). Women report feeling "invisible" and frequently having their contributions at meetings ascribed to men (Valian). Both men and women asked to rate works of art, articles, and curricula vitae give lower ratings when they believe they are rating the work of a woman (Valian, 1998). An analysis of peer-review scores for postdoctoral fellowship applications revealed that women applicants had to be 2.5 times more productive than the average man to receive the same competence score (Wenneras and Wold). Students judge women faculty who are not nurturing much more harshly than they do men professors who are not nurturing (Sandler, Silverberg, and Hall).

Thus, without being conscious of their "mental models" of gender, both men and women still tend to devalue women's work and to allow women a narrower band of assertive behavior (Valian). Under such conditions, women cannot realize their full potential, nor can they care for their patients with maximum effectiveness. "Mental models" persist in part because individuals, especially dominant personalities, tend to ignore information that runs counter to their stereotypes (Fiske). Features common to clinical medicine, such as time pressures, stress, and cognitive complexity, also stimulate stereotyping and "application error" (i.e., inappropriate application of epidemiological data to all group members) (Geiger). Nonetheless, most scientists and physicians appear to believe that they work in a meritocracy and that they are not influenced by stereotypes (Bickel, 1997). Some even conclude that women are advantaged compared to men. Apparently, while individual men do not feel powerful, power is so deeply woven into their lives that it is most invisible to those who are most empowered (Kimmel). Equity demands, however, that health professionals accept responsibility for unlearning whatever stereotypes interfere with their evaluations of patients, students, and colleagues.

ACQUIRING MENTORING. While most studies find that women faculty are as likely as men to have a mentor, women gain less benefit from the mentor relationship. One internal medicine department found that mentors more actively encouraged men than women protégés to participate in professional activities outside the institution and that women were three times more likely than men to report a mentor taking credit for their work—an unethical practice rarely discussed (Fried, Francomano, and MacDonald). Women cardiologists report their mentors to be less helpful with career planning than men do and more commonly noted that their mentor was actually a negative role model (19% of women versus 8% of men) (Limacher, Zaher, and Wolf).

These challenges in obtaining mentoring are particularly unfortunate because, for a variety of reasons, women have a greater need for mentoring than men do (Bickel, 2000).

Not only does Western culture tend to devalue women's work, women tend to be more modest than men about their achievements; they are less apt than men to see themselves as qualified for top positions even when their credentials are equivalent or superior (Austin). Moreover, women's informal networks are less extensive and less likely to include colleagues or higher-ranking people from previous institutions (Hitchcock et al.). Without the "social capital" and essential information that grow out of developmental relationships, women remain isolated. And isolation further reduces their capacity for risk-taking, often translating into a reluctance to pursue professional goals or a protective response such as niche work or perfectionism (the obverse strategy of identifying a hot topic) (Etzkowitz, Kemelgor, and Uzzi). It is significant that women experience isolation at work whereas for male health professionals work tends to be highly social and socializing. This paradox is compounded when similarly isolated women are appointed as tokens to committees and pointed to as *role models* (i.e., expected to be *solutions* to a *problem*). If women seek affiliation through a women's group, they may be labeled as needy, lesbian, or *rabble-rousers.*

Many men have difficulty effectively mentoring women because of lack of experience with career-oriented women or because they find it easier to relate to women in social than in professional roles. A contemporary approach to mentoring builds on the recognition that styles and advice that worked for the mentor may not work for a protégé (Thomas) and that advice applicable even five years earlier may no longer be helpful. Thus, many chairs and senior faculty could use assistance in techniques of active listening, avoiding assumptions, and providing supportive feedback that also stimulates the protégé's professional growth (Bickel et al, 2002).

PRACTICE-RELATED AREAS OF CAREER DISADVANTAGE. A large national study conducted in 2000 found that compared with men, women physicians have more patients with complex psychosocial problems. Women physicians also have substantially less control of their work than men—in term of patient volume, selecting physicians for referrals, and office scheduling. Women physicians also have more patients with complex psychosocial problems, adding to their time and energy requirements, in an era when physicians are being pressured to see more patients in fewer minutes. Time spent with patients is time not spent with students, writing grants, or on their many other responsibilities. Thus, it is not surprising that women were 1.6 times more likely to report burnout than men, with the odds of burnout by women increasing by at least 12 percent for each additional five hours worked per week over forty hours. This study also found a $22,000 gap in income between men and women, after controlling for age, specialty, practice type, time in current practice, uninsured status of patients, region, hours worked, and other variables (McMurray, 2000). A 1998 survey of board-certified internists in Pennsylvania found that women earned 14 percent less per hour than their male counterparts, even after adjustment for demographic, training, practice, and family characteristics (Ness et al.).

Junior faculty have been hardest hit by imperatives in academic medicine to increase clinical loads; these imperatives disproportionately affect women (67% of women are instructors or assistant professors compared to 44% of men). Women faculty have less "protected" time for research and fewer academic resources than men (Carr et al.). In addition to pressures to simultaneously complete fellowship, start a practice and a research program, and take on heavy service and administrative responsibilities, most young faculty members are raising young children. Women physicians are actually more likely to be married (and less likely to be divorced) than women in the general population (Frank et al., 1997). And about 85 percent of women physicians have children, compared to 83 percent of the general population (Potee, Gerber, and Hall, 1999).

While family-leave policies at academic medical centers are now commonplace, they rarely allow for more than three months of leave and require women to use up annual and sick leave. Some schools have introduced less-than-full-time options; in many cases, however, users sacrifice benefits and the flexibility to return to the tenure track (Socolar et al.). Even when flexible policies exist, individuals who take advantage of the flexibility allowed may be labeled "uncommitted." Thus, the relationship between medicine and parenthood can be characterized as uneasy and not well-tolerated, especially in academic careers.

Moreover, family-related decisions can escalate into moral dilemmas. The traditional obligation of physicians to set patients' needs above their own sometimes confronts physician-parents (and especially couples who are both in practice) with difficult choices between the needs of patients and those of their own children. How are they to decide when a patient must take priority over their children? While such dilemmas are common because of the lack of easily available child care, they are rarely discussed. The profession would benefit from opportunities for practitioners who are also family caretakers to dialogue about the ethics of family responsibilities as related to the ethics of medicine. Even more helpful would be institutional approaches to improving and supporting flexibility for those with family responsibilities, such as on-site day care, emergency or sick child care, and nonpunitive leave policies. All of these features are much more readily available in Canada, Britian, and Australia than in the United States (McMurray et al., 2002).

THE INTERSECTION OF GENDER AND ETHNICITY. In 2001 the 125 U.S. medical schools had a total of 1,199 African-American women faculty (4% of all female faculty); smaller numbers of Native Americans, Mexican Americans, and Puerto Rican women added up to an additional 4 percent of women faculty. A higher proportion of women faculty than men faculty are underrepresented minorities.

Faculty from ethnic minorities are no more likely to attain senior rank than are women (Palepu et al.; Fang et al.; Bright, Duefield, and Stone). Both women and minorities face stigmatization and prejudice and difficulties in obtaining career-advancing mentoring. Thus women ethnic minorities experience "double jeopardy." A study of African-American women physicians found that the majority cited racial discrimination as a major obstacle during medical school and residency and in practice. In addition they perceived gender discrimination to be a greater obstacle than did non-African-American women physicians (More).

Psychologists have described the *just world* bias: That is, people want to believe that, in the absence of special

treatment, individuals generally get what they deserve and deserve what they get; they adjust their perceptions of performance to match the outcomes they observe (Valian). If women, particularly women of color, are underrepresented in positions of greatest prominence, the most psychologically convenient explanation is that they lack the necessary qualifications or commitment. Thus, women of color must frequently overcome assumptions that they owe their positions to affirmative action rather than professional qualifications. At the same time, minority women encounter severe *surplus visibility,* that is, their mistakes are more readily noticed and they are less likely to be given a "second chance."

Compounding all of the above extra challenges, minority female physicians are also at highest risk for institutional service obligations (Menges and Exum), including committee work, student counseling, and patient care (Menges and Exum; Levinson and Weiner). Thus, while increasing the number of ethnic minorities progressing in academic medicine presents different challenges than increasing women, the challenges overlap, for instance, in overcoming unconscious bias related to "what a leader looks like" (Bickel, 1997).

Forward-Looking Institutional Approaches

Most approaches to improve the advancement of women have attempted to "fix" or "equip" women with skills that they are perceived to lack and to add temporal flexibility to policies. While these efforts are necessary, organizational development experts concluded that such narrow approaches can have only limited success (Ely and Meyerson).

The research findings summarized above clearly raise fundamental questions about organizational culture and the ways in which work is organized. What is wrong with U.S. health systems that women have such a hard time succeeding in them? The faculty tenure system offers a striking example; it is a forced march in the early years, allowing a slower pace later on. Most women would prefer the opposite timing, allowing them more flexibility while their children are young. The most clinically productive decade for women physicians begins at age fifty.

Another example of organizational disadvantage is medicine's overvaluation of heroic individualism, with the largely invisible work of preventing crises and maintaining relationships going unrewarded. Because women tend to be doing the less visible, collaborative, relational work, their contributions remain underrecognized (Etzkowitz, Kemelgor, and Uzzi).

Thus strategies to promote women must target features of the work culture that may be "simply the norm" but that disadvantage women (Ely and Meyerson). For instance, new models of cooperation are needed to recognize and reward contributions of all members of the team. And these models must avoid expectations that women will do the "relationship" work; dialogue between the sexes is required to achieve the facilitating of *caring* and *leading* on the part of both women and men.

Much of the process by which disadvantage is created and reinforced occurs at the department level (e.g., recruitment, mentoring, access to resources). Thus, department heads are key, and one avenue to stimulate their cooperation is to emphasis diversity issues in departmental reviews (Etzkowitz, Kemelgor, and Uzzi).

The most comprehensive analysis to date of initiatives to develop women medical school faculty (Morahan et al.) found that exemplary schools focus on improvements not specific to women: heightening department chairs' focus on faculty development needs, preparing educational materials on promotion and tenure procedures, improving parental-leave policies, allowing temporary stops on the tenure probationary clock and a less than full-time interval without permanent penalty, and conducting exit interviews with departing faculty. These schools regularly evaluate their initiatives by comparing recruitment, retention, and promotion of women and men faculty and by conducting faculty satisfaction and salary equity studies. Surveying faculty about their career development experiences and their perceptions of the environment, comparing the responses of men and women, and presenting the results to faculty and administrators are particularly useful strategies.

Initiatives to develop women and to improve the work culture do not lower standards or disadvantage men. Interventions on behalf of women tend to improve the environment for men as well. When the Department of Medicine at Johns Hopkins University evaluated its interventions to increase the number of women succeeding in the department (Fried et al.), the proportion of women expecting to remain in academic medicine increased by 66 percent and the proportion of men increased by 57 percent.

With regard to ensuring that students and junior faculty obtain the mentoring they need, institutions find themselves challenged by the increasing heterogeneity of new entrants, not only in terms of gender but also with regard to ethnicity, age, values, and previous life experience. In order to competently mentor students unlike themselves, the relatively homogeneous senior faculty would benefit from opportunities to improve listening and feedback skills and to overcome engrained models of gender and race. Another strategy to increase positive emphasis on mentoring

is to evaluate faculty on how well they meet this responsibility. For instance, just as promotions committees count first authorships in major journals, some schools are also now counting *last* authorships with mentees as first authors (Grady-Weliky, Kettyle, and Hundert). Other schools now require that on each faculty member's annual evaluation, senior faculty list their protégés; trainees and junior faculty are asked to name their mentors and role models. An increasing number of schools and individual departments offer programs that facilitate mentor/protégé pairings; another positive strategy is mentor-of-the-year awards (Bickel, 2000).

Medical schools' approaches to eliminating sex discrimination and harassment have included sporadically distributed informational resources and occasional educational programs; by and large the effectiveness of such efforts has not been evaluated. Medical educators' increasing emphasis on professionalism in general shows more promise in drawing positive attention to responsible physicians' attitudes and behaviors (Epstein and Hundert; Wear and Bickel). However, more attention to barriers created by mental models of gender and race would strengthen most professionalism initiatives. Likewise, programs designed to improve patient communication skills should include assistance in overcoming gender stereotypes.

Finally, there are encouraging trends in medical education toward problem-based learning and toward the incorporation of women's health into the curriculum. Both require interdisciplinary bridges and teamwork, actually furthering a sense of community within academic medical centers. And adding a focus on women's health also frequently incorporates a more holistic and community orientation into the curriculum (Donoghue, Hoffman, and Magrane).

Conclusion

Gender differences in professional and leadership opportunities persist, yet perceptions of these continuing inequalities are not widespread. The number of women entering the health professions, and even becoming faculty, actually obscures the work that remains—part of which is persuading many that academic medicine still greatly favors the development of men. Actually, many male physicians and medical students are concluding not only that equal opportunity has been won but also that women tend to have an "affirmative action" advantage. Many young women entering medicine, surrounded by women peers and unaware of their predecessors' struggles, are assuming that women may be freely choosing to reap fewer rewards than men for their work but that they themselves will not have to settle for less (McCorduck and Ramsey). Thus, impetus for change is lacking, as the women who are not realizing their potential tend to be invisible or to disappear.

Is the increasing number of women entering medicine and other health professions mitigating the impact of gender? Recent studies comparing the careers of men and women consistently show that increases in the number of women is *not* reducing gender disparities in advancement nor the power of mental models of gender. Reducing the power of gender stereotypes in medicine is a moral imperative because healthcare professionals have a duty to ensure that perceptual bias does not interfere either with the best possible patient care or with clinicians' responsibilities as role models for and teachers of students of both genders. Healthcare professionals' effectiveness depends in large part on their sensitivities to others, that is, their ability to "hear" and "see" individual patients.

Is gender diversity changing the medical profession? Too many diverse forces (e.g., technological, economic, political) are shaping modern medicine to link any one change to the increasing numbers of women providers, especially given the extent to which men and women share characteristics. But the primary difficulty in answering this question is that too few women have achieved leadership positions to allow comparison with the records of their male predecessors.

That the health professions are not realizing the full value of their investment in women is not only an injustice, it is also evidence of poor stewardship. These careers involve considerable personal and public resources, but the leadership potential of most women continues to be wasted. This is a collective loss—all the more unaffordable given the leadership challenges facing the health professions. It is highly likely that women leaders can make a positive difference: "Women have lived in *embedded* roles, roles intimately interwoven into the warp and woof of the social context … serving as links between other roles, between generations, between institutions, between the public and private domains.… Consequently women are no newcomers to the complications generated by interdependence and diversity" (Lipman-Blumen, p. 289).

Gender equity will always be an elusive concept and goal; for one thing, women are as different from each other as men are from each other. Nonetheless, leaders owe it to future generations of trainees and patients to create an environment of equal opportunity—where assumptions and judgments about individuals' competencies and preferences are not colored by their sex, where women's goals and traits

are as valued as men's, and where nonpunitive options facilitate the combining of professional and family responsibilities. The future of the health professions is inextricably linked to the development of its women professionals.

WOMEN AS HEALTH PROFESSIONALS, HISTORICAL ISSUES OF

• • •

Historically, women's roles in healthcare were primarily as caretakers and nurturers; as wives, mothers, and nurses; and in their responsibility for children, the sick, the aged, and the disabled. When instrumental healing roles became more technical and financially lucrative, women met resistance to their assumption of those roles. This attitude often was based on mistrust of their capacities and the departure their work in healthcare represented from their more traditional roles, especially because they might compete with men.

Early History of Women in Healthcare

Women have always been healers as well as caretakers; they have acted as pharmacists, physicians, nurses, herbalists, abortionists, counselors, midwives, and *sagae* or "wise women." They also have been called witches. In the physician role, however, society rarely permitted them to perform in the same capacities and positions as men.

THE ANCIENT WORLD. Early Egyptian steles refer to a chief woman physician, Peseshet, and in 1500 B.C.E. women studied in the Egyptian medical school in Heliopolis. In the Chinese record in 1000 B.C.E. female physicians were in positions that encompassed activities other than traditional midwifery and herb gathering. There also were medical roles for women in the Greek and Roman civilizations. In Rome physicians were often slaves or freed slaves; it is likely that many were women. Women who entered medicine were frequently members of medical families and practiced together with their family members. The physician husband of a second-century woman physician wrote for his wife's epitaph, "You guided straight the rudder of life in our home and raised high our common fame in healing—though you were a woman you were not behind me in skill" (Anderson and Zinsser, p. 61).

Throughout history women have been special attendants to other women, assisting with labor and delivery,

providing advice on the functions and disorders of their bodies, and tending newborns. Because childbirth was considered a normal rather than a pathological process, it was not thought to be part of medicine. Soranus of Ephesus, a first-century C.E. physician practicing in Rome, believed that women were divinely appointed to care for sick women and children. Among the criteria he delineated for those practicing medicine, inluding women, were literacy, an understanding of anatomy, a sense of patient responsibility, and ethical concerns, particularly in regard to confidentiality.

During the first few centuries of the spread of Christianity, women ordained as deaconesses by bishops with the consent of the congregation appear to have played a significant role in healthcare. Although little is known about their work, many of those deaconesses became the first parish workers and district nurses (Shryock, 1959). Among those women were Saint Monica, the mother of Saint Augustine, and Fabiola, who founded a hospital at Ostia in Italy in 398 C.E.

After the fall of the Roman Empire, medicine continued along two paths: monastic medicine, which lost touch with older traditions, and Arabic medicine, which developed in Persia and transmitted the heritage of Greek medicine to Europe. Arabic medicine produced notable practitioners and hospitals run by male and female "nurses." During the Crusades women staffed infirmaries and clinics in Jerusalem and along the European routes to the Holy Land.

THE MIDDLE AGES. Medical scholarship flourished in the ninth century at the University of Salerno in Italy and continued to develop through the tenth and eleventh centuries (Corner). At that time women apparently studied medicine at the university. Although little is known about most of those early women physicians, eleventh-century records reveal the existence of Trotula, a woman faculty member at Salerno who is said to have written important texts on obstetrics and gynecology and to have headed a department of women's diseases. Her most important work, *De Passionibus Mulierum,* remained the major reference on that subject for several centuries. The authorship of this and other works was attributed to her husband or to other male colleagues (Corner; Achterberg). Trotula suggested that infertility could be attributed to the male as well as the female. In cooperation with the "Ladies of Salerno," a group of women physicians, Trotula established the first center of medicine that was not under Church control.

The M.D. degree was first awarded in 1180, apparently only to men. One of the notable figures of the twelfth century was Hildegard of Bingen, a scientific scholar, abbess, writer, composer, and political adviser to kings and to the pope. She wrote two medical textbooks, *Liber Simplicis Medicinae* and *Liber Compositae Medicinae,* presumably for use by the nurses who were in charge of the infirmaries at Benedictine monasteries. Her textbooks described a number of diseases, including their courses, symptoms, and treatment, as well as scientific data on the pulsation of blood and the regulation of vital activities by the nervous system. Hildegard's writings also demonstrated an understanding of normal and abnormal psychology.

In the medieval period affluent women were active in medicine, particularly in Italy, where the universities were accessible to them. In 1390 Dorotea Bocchi earned a degree in medicine from the University of Bologna and followed her father as a lecturer in medicine at that university. In 1423 Constanza Calenda, the daughter of the dean of the medical faculty at Salerno, lectured on medicine at the university in Naples. Women also were qualified and permitted to practice medicine in France, England, and Germany. They generally were limited in practice to specifically defined roles, including bleeding, administering herbs and medicines, and reducing fractures, as well as practicing midwifery. As early as 1292, however, women in Paris worked as "barber surgeons," practicing what was known of surgery. Until 1694 widows automatically were allowed to continue practicing if their specific form of medicine had been their husbands' field.

From the thirteenth to the seventeenth centuries the number of physicians was low, and the role of women healers was particularly important in meeting the healthcare needs of the population. During that period women practiced as physicians, surgeons, bone setters, eye healers, and midwives. It generally was believed that women were better suited for the treatment of women's diseases.

During the fifteenth century women obtained higher degrees by presenting medical theses, and during the fifteenth century and the early part of the sixteenth century women began to excel in innovative techniques and made important contributions to medicine. They served kings, royal families, and even armies in Europe.

Although it is assumed that the number of women in medicine was small, their healthcare work in the Middle Ages caused enough concern that by 1220 the University of Paris succeeded in preventing them from gaining admission to medical school. In 1485 Charles VIII of France decreed that women could not work as surgeons.

By the fourteenth century the licensing of physicians was well established, although women rarely were allowed to sit for licensing examinations. In 1322 university-trained male physicians brought a suit against Jacoba Felicie de

Almania in France, claiming that in practicing without appropriate training and licensing, she endangered patients. Patients testified to her skill; Jacoba argued that she was both physician and nurse to her patients. She also emphasized that many women would not seek treatment for their illnesses if they had to see a male physician. Because she did not have the correct university degree, she not only was barred from medicine but also was excommunicated from the Church. Women who practiced outside their licensed specialities, for example, midwives who functioned as physicians, also were condemned.

THE RENAISSANCE AND AFTERWARD. By the end of the fifteenth century, as medicine became an academic discipline and a more established profession in several centers in Europe, the movement to exclude women from the formal practice of medicine gained momentum. That movement coincided with the ideology of misogyny as it was articulated by Heinrich Kraemer and James Sprenger in *The Malleus Maleficarum* (1486), a treatise on identifying and dealing with witches. Witch-hunting capitalized on the widespread belief in the spiritual and mental inferiority of women, a belief that was fueled by the Church. Even when active witch-hunts subsided, their effects remained. Women were effectively eliminated from performing medical roles other than traditional caretaking and midwifery.

Before the sixteenth century it was not possible for a man to be a midwife; it was a capital offense in some places. As medicine and surgery were differentiated from each other in the fifteenth and sixteenth centuries, some male barber surgeons began to practice midwifery. By the late fifteenth century licensing examinations were given, generally by a doctor and a midwife. Increasingly, concern was expressed by physicians and the laity about whether midwives were knowledgeable enough to recognize when it was appropriate to call for a consultation with male physicians and surgeons.

The sixteenth to eighteenth centuries produced several outstanding female midwives, including Louyse Bourgeois, who in 1609 became the first midwife to publish a work on obstetrics, a book that became the basic text for midwifery in Europe. Nonetheless, with the invention of the obstetrical forceps in the seventeenth century by the Chamberlens, a family of male midwives and barber surgeons, obstetrics was pushed closer to the realm of the male practitioner. In 1634 Peter Chamberlen III attempted to establish a corporation of midwives in England with himself as the governor, a move that was resented by female midwives. Increasingly, men began to participate and compete in that profession, particularly in serving the upper classes. By the eighteenth century men controlled all areas of medicine except midwifery and nursing, and even in those areas women increasingly were required to practice only under male supervision.

By the beginning of the seventeenth century women were denied access to medical training and then prohibited from belonging to professional associations. University training was required, and women were not admitted to universities. Despite exclusion from formal training and practice, women continued to provide for the healthcare needs of family members and others in the community, especially the poor, who had no other access to healthcare.

Women in Early American Medicine

In colonial North America the healing role of women was critical to survival, and many women assumed medical roles. Ann Hutchinson, the early seventeenth-century dissident religious leader, worked as a general practitioner and midwife. Because there were relatively few university-trained physicians and no medical schools in the colonies, medicine was practiced by those who appeared to be particularly talented, and an apprenticeship system began to evolve. Two women listed as physicians in Boston in the seventeenth century later were denounced as witches, and no other woman practiced medicine in Boston until Harriot Hunt, after apprenticeship training, opened a medical office in 1835.

Eighteenth-century American medicine had no unified concept of medical care; a variety of views of practice and training offered various programs of study and concepts of healing. In that setting the role of women was extensive and complex because the medical care of families was frequently the responsibility of women.

Most women practitioners were midwives. Many went to Europe to train, as the first school for midwives in the English colonies was not started until 1762. The early training of midwives was based on the assumption that most obstetrical practice would remain in the hands of women. This did not occur in colonial North America, although it was the case in many parts of Europe.

In 1765 John Morgan founded the first university-connected, so-called regular American medical school at the University of Pennsylvania. Its formal, scientifically based curriculum departed from the almost exclusive apprenticeship training that existed in the colonies and was more reflective of European standards of that time. By excluding women, it began a tradition of barring them from formal medical training and forcing them into "irregular" training. Many women without diplomas, however, set up flourishing practices. They were trained in the homeopathic, eclectic, or "irregular" traditions, which tended to be less prestigious.

Women in Nineteenth-Century Medicine

In 1847 Elizabeth Blackwell became the first woman to be admitted to a "regular" medical school in the United States; she graduated first in her class at Geneva (New York) Medical School in 1849. The New York State Medical Association promptly censured the school, and when her sister, Emily Blackwell, applied a few years later, she was rejected. Emily subsequently received an M.D. from Western Reserve Medical College in Cleveland after her acceptance to Rush Medical College in Chicago had been rescinded in response to pressure from the state medical society.

Ann Preston began her medical studies in 1847 as an apprentice to a Quaker physician. After two years she applied to and was rejected by four medical schools. In 1850 she established the first regular women's medical college in the world, the Women's Medical College of Pennsylvania. She and her students recalled their experiences at the Pennsylvania Hospital: "We entered in a body, amidst jeerings, groaning, whistlings, and stamping of feet by the men students. On leaving the hospital, we were actually stoned by those so-called gentlemen" (Alsop, pp. 54–55). This account was corroborated by the *Evening Bulletin* of Philadelphia.

In 1847 Harriot K. Hunt, who earlier had established an irregular practice in Boston despite her lack of an M.D. degree, applied to Harvard Medical School. Although supported by the dean, Oliver Wendell Holmes, she was rejected for admission. After hearing about Elizabeth Blackwell's acceptance, she again applied for admission and was accepted. However, she was denied a seat when the all-male class threatened to leave if women or blacks were admitted. Not until almost a hundred years later, in 1946, did Harvard Medical School begin to admit women.

By 1850 two additional all-female medical colleges were founded, one in Boston and one in Cincinnati. Both were "irregular" schools. The Boston Female Medical College was designed primarily to prevent male midwifery, which its founder, Dr. Samuel Gregory, felt trespassed on female delicacy. The school was founded in 1848 and offered a medical degree by 1853, but it was always financially troubled and did not have a good reputation. In 1856 it changed its name to the New England Female Medical College and began to recruit new faculty members, including Marie Zakrzewska, who helped develop a pioneering clinical training program. In 1873 the school merged with Boston University.

In 1855 the National Eclectic Medical Association formally approved the education of women in medicine, and in 1870 it became the first medical society to accept women as members. Traditional medical societies, however, continued to be closed to women. In his 1871 American Medical Association (AMA) presidential address Alfred Stille criticized female physicians for being women who seek to rival men, who "aim toward a higher type than their own" (Ehrenreich and English, p. 26). Negative attitudes toward the presence of women in medicine appeared to be supported by accumulating "scientific" evidence that supposedly supported the inferior status of women on biological grounds, including the idea that their brain capacity was less than men's. A book published in 1873 by Edward Hammond Clarke fueled the controversy: In *Sex in Education: or, A Fair Chance for the Girls* he stated, "Higher education for women produces monstrous brains and puny bodies" (Clarke, p. 41). It echoed Charles Meigs's 1847 statement, "She [woman] has a head almost too small for the intellect but just big enough for love."

The debate about women's intellectual capacity induced Harvard Medical School to offer the Boylston Medical Prize in 1874 for the best paper on the topic "Do women require mental and bodily rest during menstruation and to what extent?" The winning research was submitted by Mary Putnam Jacobi. When the judges discovered the sex of the author, they hesitated about awarding the prize but finally did so (Walsh). Putnam Jacobi had found, contrary to prevailing views, that the majority of women in her sample did not suffer incapacity. Her study was followed by several others, all with similar findings. Despite such work and evidence, the barriers to women did not fall.

Even women who managed to obtain medical training were refused admittance to medical societies, and hospitals denied them appointments. Female physicians in the United States began to open their own hospitals and clinics. In 1857 Elizabeth and Emily Blackwell founded the New York Infirmary for Women, where they cared largely for indigent women, and in 1865 the Women's Medical College of the New York Infirmary opened. Paternalistic attitudes coupled with the difficulty women had in obtaining hospital privileges led Marie Zakrzewska in 1862 to found the New England Hospital for Women, owned and operated entirely by women.

The role of women in medicine, including the productivity and lifestyle of female physicians, continued to be debated vigorously. In 1881 Rachel Bodley, dean of the Women's Medical College of Pennsylvania, surveyed the 244 living graduates of the school and found that despite persistent beliefs to the contrary, the overwhelming majority were in active practice. Those who had married reported that their profession had had no adverse effect on their marriages and that marriage had not interfered with their work.

By the end of the nineteenth century women physicians were being accepted into many medical societies. The Massachusetts Medical Society admitted women in 1884, and the AMA seated a woman delegate in 1876 but did not accept women formally until 1915 (Morantz-Sanchez, 1985). Women physicians began to form their own associations. There were several attempts to build a national organization of women physicians, beginning in 1867. The *Women's Medical Journal* was started in 1872. In 1915 the National Women's Medical Association was founded. It was renamed the American Medical Women's Association (AMWA) in 1919 and was condemned by many male physicians. To alleviate people's fears the AMWA required that its members also join the AMA, and it held its meetings together with that organization.

Female separatism was a double-edged sword. Although it gave women a special place in the care of women and children, it also was used to exclude women from more extensive roles in medical education and from the increasing influence and prestige of the profession.

Financial contributions from women philanthropists (such as M. Carey Thomas, Mary Elizabeth Garrett, Mary Gwinn, and Elizabeth King) forced the Johns Hopkins Medical School in 1889 to accept women on the same terms that it used for accepting men. However, this did not result in large numbers of women being admitted and did not appear to increase the number of appointments of women to faculty and leadership positions (Walsh).

Following Johns Hopkins's lead, however, 75 percent of other, already existing medical schools began to accept women as students. By 1894 over 66 percent of women medical students were enrolled in regular medical schools (Walsh). The student body at Tufts Medical School was 42 percent female. Women also received a disproportionate number of the academic honors in their graduating classes.

Women Physicians in Europe and Canada

In 1859 the American Elizabeth Blackwell was placed on the British Medical Register; in the following year the British Medical Association ruled that persons with foreign medical degrees could not practice in Great Britain. In 1865 Elizabeth Garrett Anderson became the first woman to qualify to practice medicine in that country. She did that by passing the apothecaries' examination; the regulations of that guild did not exclude women. The rules were changed shortly afterward. In France, although women were allowed to study at the Faculty of Medicine in Paris, they could not become interns and thus could not complete their training.

The Royal College of Physicians in Edinburgh attempted to exclude Sophia Jex-Blake in 1869 by stating that a single woman could not attend medical school. Jex-Blake organized a group of seven women, and together they completed the first year of training. Attacks on female students from male peers, however, prompted some public support from people who were outraged that these "indelicate and ungentlemanly" men would be seeing female patients. Four years later the university won a lawsuit allowing it to refuse to grant degrees to women. Women in other European countries also experienced hostile and even violent attacks by their male peers.

The first continental European university to accept women was the University of Zurich in 1865. By the 1870s other Swiss universities had followed its lead. In Russia women were allowed to attend medical schools in 1872, partly because a number of Russian women already had studied medicine in Zurich. Negative attitudes toward women were fueled by the assassination of Czar Alexander II by a woman. After that event, from 1881 through 1905, universities in Russia were closed to women.

Many of the women who graduated from medical schools in those countries were from middle-class or upper-class backgrounds. Often they had fathers or other family members in medicine; they entered the profession to join the family practice.

The first woman doctor to practice medicine in Canada, James Barry, a graduate of the University of Edinburgh, was a British Army medical officer who became inspector general of hospitals in Canada in 1857. She was able to practice because she was thought to be a man. After her death Dr. Barry was discovered to have been a woman (Hacker).

Nineteenth-Century Midwifery

There was considerable opposition to the practice of midwifery by women in the mid-nineteenth century, particularly in the United States. In 1820 John Ware, a Boston physician, is said to have written *Remarks on the Employment of Females as Practitioners of Midwifery,* in which he raised objections that were based on his view of women's moral qualities. He stated: "Where the responsibility in scenes of distress and danger does not fall upon them when there is someone on whom they can lean, in whose skill and judgement they have entire confidence, they retain their collection and presence of mind; but where they become the principal agents, the feelings of sympathy are too powerful for the cool exercise of judgment" (p. 7).

In addition, economic and class issues played a role in women's exclusion from medicine. Midwives came primarily from working-class, rural, and poor backgrounds. They charged less than physicians did for their services and were more likely to care for the poor. With the beginning of obstetrics as a medical discipline, physicians feared economic competition from midwives.

Some physicians objected to midwives on the basis of the allegedly lower quality of healthcare they provided. However, in the 1840s two physicians, Oliver Wendell Holmes and Ignaz Semmelweiss, reported on the spread of puerperal sepsis (childbirth infection). Semmelweiss found that there was a lower incidence of it in women who were assisted in delivery by midwives. He deduced that because medical students and physicians did not wash their hands when they moved from the autopsy room to the delivery room, they spread disease. The warnings of both doctors were ignored by most of the medical profession, and controversy continued about the adequacy of midwives.

By the turn of the twentieth century about 50 percent of all babies in the United States were delivered by midwives. Midwives were held responsible for childbirth illness and puerperal sepsis, as well as neonatal ophthalmia (inflammation of the eyes generally related to maternal gonorrhea), because it was believed by many people, especially in the medical profession, that they were not sufficiently trained to prevent those illnesses. Under mounting pressure, many states began to pass laws forbidding midwifery, many of which remain in effect.

Evolution of Nursing in the Nineteenth Century

The practice of nursing was sponsored primarily by the Church until the mid-eighteenth century, when the London Infirmary appointed a lay nurse. Nursing was seen as a low-status occupation; records show long working hours and low pay. Dickens's novel *Martin Chuzzlewit* (1844) focused attention on the quality of the nursing care given by pardoned criminals, aging prostitutes, and other women of questionable morality and interest who functioned as nurses.

At the time of the Crimean War Florence Nightingale responded to the need for nursing reform and established military and then civilian nursing. In 1860 she founded a school for nurses in London that had a rigorous curriculum and specific guidelines for nursing as a profession. She met opposition from the medical profession, many of whose members felt that "nurses are in much the same position as housemaids and need little teaching beyond poultice-making and the enforcement of cleanliness and attention to the patient's wants" (Dolan, p. 230).

The first nursing schools recruited upper-class women who were "refugees from the enforced leisure of Victorian ladyhood" (Ehrenreich and English, p. 34). Despite their aristocratic image, nursing schools began to attract more women from working-class and lower-middle-class homes. Those advocating the nursing profession saw the nurse as the embodiment of Victorian femininity and nursing as a natural vocation for women, second only to motherhood. Nightingale viewed women as instinctive nurses, not physicians: "They have only tried to be men, and they have succeeded only in being third-rate men" (Ehrenreich and English, p. 36).

Women in Twentieth-Century Medicine

By the beginning of the twentieth century women were seeking admission to medical schools in increasing numbers. Because of an oversupply of physicians, however, salaries and prestige were diminishing. Some people blamed the situation on the "feminization" of the profession, and many schools began to decrease the number of women they accepted. Women also had more difficulty obtaining internships and residencies. Because all but one of the female institutions (the Women's Medical College of Pennsylvania) had consolidated or closed, many women had nowhere to train.

The conviction that women were not able to perform effectively as physicians and the belief that women would be damaged by pursuing a difficult career intensified. Women physicians seemed to be unable to develop a consolidated and effective strategy to resist that negative attitude. In 1905 Dr. F. W. Van Dyke, the president of the Oregon State Medical Society, stated, "Hard study killed sexual desire in women, took away their beauty, brought on hysteria, neurasthenia, dyspepsia, astigmatism and dysmenorrhea. Educated women could not bear children with ease because study arrested the development of the pelvis at the same time it increased the size of the child's brain and therefore its head. This caused extensive suffering in childbirth" (Bullough and Voght, pp. 74–75).

At that time academic medical schools were developing formal medical curricula. Proprietary medical schools also were increasing in number. The education they provided was focused primarily on an apprenticeship model, and there was little monitoring of the quality of the education. Because of the oversupply of doctors produced by those two systems, with consequent competition for patients as well as a lack of mechanisms to assess quality and monitor performance, the AMA asked the Carnegie Foundation to investigate the condition of medicine and make recommendations for dealing with the situation. The foundation commissioned Abraham Flexner, a schoolteacher with no medical

expertise, to perform the study. In his 1910 report Flexner stated: "Medical education is now, in the United States and Canada, open to women upon practically the same terms as men. If all institutions do not receive women, so many do, that no woman desiring an education in medicine is under any disability in finding a school to which she may gain admittance. Now that women are freely admitted to the medical profession, it is clear that they show a decreasing inclination to enter it" (Flexner, pp. 178–179, 296).

Flexner's report concluded that medical education required higher standards for training and provided an important impetus for establishing medicine as an academic discipline. It resulted in the closing of many medical schools, especially the proprietary ones; unfortunately, because women continued to have difficulty gaining admission to many of the university-affiliated and more prestigious medical schools, the schools that were closed were the ones that traditionally had admitted substantial numbers of women and members of minority groups. This had the effect of lowering the numbers of women physicians in the United States.

Women physicians gained some status as a result of their patriotism during World War I, when the AMWA campaigned to have women physicians commissioned on the same basis as men. Although that effort was rejected by the government, the AMWA urged women physicians to contribute to the war effort. Fifty-five women physicians practiced medicine by signing specific contracts with the military. They received neither military status nor benefits (Walsh). At Johns Hopkins the percentage of women medical students dropped from 33 percent in 1896 to 10 percent in 1916. At the University of Michigan the percentage of women medical students dropped from 25 percent in 1890 to 3 percent in 1910 (Walsh).

The number of female physicians in the United States continued to be low until the 1970s. Other countries continued to report greater percentages of female physicians. In 1965, for example, women accounted for 7 percent of all U.S. physicians. The Soviet Union reported 65 percent female physicians; Poland, 30 percent; the Philippines, 25 percent; the German Federal Republic, 20 percent; Italy, 19 percent; the United Kingdom and Denmark, 16 percent; and Japan, 9 percent (Lopate).

Medicine was viewed as a male profession in the United States more than it was in most other countries. Some scholars hypothesize that this occurred because medicine had higher prestige and income than did many other professions and therefore interested men more. Others believe that the dominance of men adds prestige and that men demand better compensation. The reasons for the gender stereotyping of professions, however, is complex and has cultural as well as political determinants. Many areas of work are sex-role-stereotyped. This occurs because of the perception that men or women are better at certain functions. For example, in the United States women were considered to be more suited to caretaking roles and men were considered to be better in more instrumental and technological activities. Thus, although medicine presents a melding of these stereotypes, women were not considered capable of performing in the increasingly technological aspects of the field. Even in a revolutionary society such as Cuba, where these stereotypes are disparaged, there is a persistence of traditional roles for women in healthcare; 30 to 40 percent of Cuban physicians are women, but virtually all nurses and midwives are women.

In the United States the choice of a specialty and the specific positions held by women in their fields of expertise reveal a pattern that has held since women began to be admitted to medical schools. In the 1970s the fact that women would assume primary care roles was used as an argument for increasing their numbers in medical schools. This has proved to be correct. Women characteristically have entered primary care fields including pediatrics, internal medicine, family practice, and obstetrics and gynecology, as well as psychiatry, pathology, and some medical subspecialties. There has been more diversification in the choice of medical specialties for women in recent years, but the numbers in the higher-paid technically oriented surgical fields continue to be low. (Accreditation Council on Graduate Medical Education).

In the United States and other countries academic and administrative appointments as well as other decision-making positions are held almost exclusively by men, whereas the majority of women physicians tend to be involved in direct patient care. Women continue to constitute almost 30 percent of full-time medical school faculty, but they are concentrated in the lower academic ranks and do not advance at the same rate as do their male colleagues (Bickel).

In countries where women have made significant progress in terms of their influence in the healthcare fields changes have occurred most often in times of war, physician shortages, or major cultural reorganization. In Russia midwives proved to be effective as doctors in the Russo-Turkish War of 1870, beginning the influx of women into medical schools. However, after the 1917 revolution, as the prestige of medicine declined, women were admitted in greater numbers. By 1940, 62 percent of Soviet physicians were women, and by 1970, that number had risen to 72 percent. As in the United States and other countries, however, Russian women held a disproportionately small number of senior positions. The *feldschers* (semiprofessional health workers) in the Soviet Union were primarily women.

The rise of female health professionals in China occurred along with the reorganization of the medical-care system and of Chinese society under the People's Republic after 1949. About half of Chinese physicians were women. In the countryside "barefoot doctors" (peasants, primarily women, with basic medical training) provided medical care without leaving their regular work to meet the needs of fellow workers (Sidel and Sidel).

Women's Evolving Role in Healthcare

The blurring of roles and the overlapping of areas of function in a healthcare have raised important questions about roles and responsibilities, for example, among primary care physicians, physician's assistants, and nurse practitioners as well as among psychologists, psychiatrists, psychiatric social workers, and psychiatric nurses. In the United States economic factors rather than specific expertise, experience, or skills have become important determinants of decisions about which practitioners will provide care. Less well trained practitioners may be favored by payers because their services are less costly. Many of these healthcare providers are women. There are few objective guidelines for determining the scope of practice. For example, in providing routine physical examinations, obstetrical care, anesthesia, psychotherapy, and minor medical and surgical procedures, professionals of varied backgrounds and training may provide similar services. There are insufficient data assessing the outcomes of this practice.

Since 1945 there has been more regulation of medical practice in the United States, and healthcare increasingly has been paid for or subsidized by governments and/or private insurance companies. Health maintenance organizations and other managed-care models have evolved. With this has come a diminution in physicians' authority and, more recently, income. At the same time there have been fewer white men applying to medical school and more women and minority group members; as a result, almost 50 percent of medical students are women and increasing numbers are from minority groups (Lorber).

The demands of work and family life as well as the nature of the process of attaining medical leadership positions continue to result in the presence of few women in major healthcare policy decision-making positions. As a result, less has changed and women have had less of an impact on practice, research, and education in medicine than was predicted in the 1970s, when the demographic shift began. There has been evidence of some changes in practice with the increase in the number of women physicians; for example, some preventive tests are more likely to be performed depending on the sex of the patient and the physician, and there are differences in practice styles related to gender. Most of the changes in the practice patterns of physicians appear to be related more to economics and political factors than to gender. However, the development of a focus on women's health and an emphasis on gender biology, including an expansion of research in this area, have been fueled largely by women physicians and scientists and by the women's movement, beginning in the 1960s. This has been important for women's health and represents a substantial contribution by women to medicine.

WOMEN, HISTORICAL AND CROSS-CULTURAL PERSPECTIVES

• • •

A central problem of women's history is that women have been defined by men using concepts and terms based on men's experiences. Such androcentric thought pervades all domains of knowledge. Scholarship in women's studies, developed largely since the late 1960s across a broad range of disciplines, shows that attitudes, customs, laws, and institutions affecting women are grounded in religious and functionalist perspectives according to which "woman" is said to have been created from and after man; has been identified with her sexuality and defined by her sexual function; and has been confined to roles and relationships that are extensions of her reproductive capacity. Alongside this history stands a centuries-old feminist critique that challenges as self-serving and often misogynist the assumptions and intentions of the religions, philosophies, sciences, and familial and political institutions that have shaped the experiences of women in most eras and cultures. Moreover, both the definition of women and its critique reflect a Eurocentric bias that today is the subject of much criticism. This entry summarizes the scholarship produced since the mid-1970s by historians of women, reflecting their collective efforts to compensate for ahistorical assumptions and to constitute a written record both more inclusive of the experiences of women and more open to differences of perspective. It assumes that the history of women requires consideration of moral and ethical as well as social, economic, and political issues.

Women Defined

From ancient times it has been customary to define "woman," in relationship to man, as a limited and contingent part of a dimorphic species. Western cultures have placed heavy constraints on female lives, sometimes justifying these constraints by attributing to women, such as Pandora and Eve, responsibility for human misfortunes resulting from their allegedly weaker self-control or greater lasciviousness. Despite the existence of exceptional women in myth and history, most women in most historical societies have been confined to positions of dependency. Ultimately, whether on the basis of their capacity for pregnancy and resulting physical vulnerability or the use of women's fertility in forging relationships of social and economic value, women, like children, have been denied an independent voice. Seen as "lesser men" by the fathers of Western philosophy, women have been viewed as "Other," as not-man, through a discourse in which human being was embodied in the male sex (Beauvoir).

Deprived of political power and identified with sexual temptation, women have been subject to myriad laws and customs that have at once prescribed and enforced their secondary status. Men have termed women "the sex"; defined them primarily in terms of their sexuality; and, as masters of family and public power, created and staffed the institutions that control female sexuality. In the early fifteenth century, the Italian-born French author Christine de Pizan (1364–ca. 1430) challenged the prevailing androcentric definition of her sex, declaring that the evil attributed to women by learned men existed in men's minds and that, if permitted education, women would become as virtuous and capable as men.

Resistance and rebellion by individual women have a long history; and organized protest, termed *feminism* only since the 1890s, is traceable through a history that is continuous for at least two centuries. However, the condition of women has only occasionally been viewed as a general problem of social justice. The *woman question,* as it was phrased in the nineteenth century, was debated as a political, social, and economic, but rarely as a moral issue; women's rights and responsibilities were discussed as matters of expediency. In the great democratic revolutions of the late eighteenth century, the "inalienable rights of man" were not extended to women. Men, as heads of traditional patriarchal families, continued to speak for their dependents, women as well as children. While some Enlightenment philosophers, most notably Theodore von Hippel (1741–1796), had admitted the abstract equality of all human beings, and others, such as the Marquis de Condorcet (1743–1794), advocated women's accession to equal education and to full civic rights, social arrangements nevertheless made it expedient to ignore their claims. Ultimately, most efforts to improve women's status and condition have been justified on grounds of expediency: if women vote, said the suffragists of 1915, war would be less likely; if mothers earned fathers' wages, said the feminists of 1985, fewer children would live in poverty.

Most matters related to women, then, whether intellectual constructs or social institutions, whether constraining or enlarging women's options, whether produced by misogynists or feminists, have rested on utilitarian grounds. Woman, first of all as an individual human being, was rarely the subject of thought or decision; woman as wife and

mother or potential mother has been the ideal type. Even for suffragist leaders of the nineteenth and twentieth centuries, the resort to arguments of expediency over considerations of justice or ethics has itself been an expedient (Kraditor). By the 1990s, however, following two decades of reexamination of all domains of knowledge by scholars in women's studies, feminist theorists began to challenge arguments based on expediency (while sometimes using them as well) and to demand a voice in the discourse through which both knowledge and social institutions are established. Noting injustice in the treatment of women, and the absence of concern about women at the center of most modern and contemporary philosophical systems, they criticize ethical theory itself as a hegemonic expression of the values of a dominant class or gender (Walker).

It is simpler, and historically has been more effective, to argue the needs of women in terms of their differences from men—their needs as wives and mothers, their concerns with nurturant values, their familial and social responsibilities. Women often do speak "in a different voice," reflecting different moral concerns and material circumstances (Gilligan). Women have been and remain deeply divided over their own definition of self: as individuals entitled to, and now demanding, equality of treatment with men; or as persons with gender-specific differences and resulting relationships with families, friends, and communities to whom they bear responsibilities that limit individual autonomy and rights. "Equal rights feminists" have been challenged for basing their claims on an abstract concept of personhood that denies female specificity. Rather than buttressing the claims of individualism based in nineteenth-century liberal philosophy (Fox-Genovese; Pateman), they should, according to this view, emphasize the need for men as well as women to acknowledge their dependence on and debts to the communities that are essential to their existence.

Furthermore, through failure to emphasize female differences, women may continue to be measured through a single, male-constructed lens that ignores or denigrates female-specific experiences. Yet woman along with man should be the measure of all things—and the universalizing of human experience based only on consideration of dominant cultures should be avoided. Awareness of the dimensions of this "equality vs. difference" question is critical to understanding a wide range of historical and contemporary issues regarding the status of women. Can gender-specific needs of individuals such as pregnant women be acknowledged in law that also supports equality of treatment for all individuals? Can employment preferences be granted to men if, historically, most women have not pursued a given occupation? How should a history grounded in gender distinctions be interpreted (Scott)?

Scholars today recognize that neither "man" nor "woman" has a single, fixed meaning; cross-cultural and international differences defy simple definition. The concept of separate spheres of human activity labeled public and private, political and personal, society and family, however, has a long history; the reality of women's lives was obscured by these universalizing categories of analysis often used by philosophers, politicians, and professors. In the early twenty-first century, historians of women have firmly established the historicity of women, a critical first task. Women's lives, as well as their consciousness, vary, not only by era but also by class, race, age, marital status, region, religion, education, and a host of factors peculiar to individual circumstances. Implicit in this work is a political message: that changes over time past make future change conceivable. Also implicit is an accusation of injustice against a system of societal arrangements that has suppressed women, for the questions raised in this scholarship deal often with omissions, silences, and double standards. This form of scholarship elicits new knowledge and conjectures about human possibilities.

Women in Traditional Western Societies

As the story has been reconstructed, women in history have become increasingly visible (Bridenthal et al.). New anthropological studies suggest that women may have enjoyed greater equity with men in prehistorical times (Sanday). Agrarian economies with relatively little differentiation of tasks allowed for more egalitarian relationships within families; families themselves constituted societies, and participation was not dichotomized by gender, or sex roles. The classical world, with its more advanced economies, and greater wealth and militarism, vested both property rights and citizenship only in men, as heads of households. Separated into family and polity, society became a male world of civic virtue. Relegated to the household, women became men's property, and a double standard of sexuality was constructed to assure female subjection to patriarchal family interests. A woman's honor, and that of her family, was identified with her chastity. The virtue of a woman, said Aristotle, was to obey. Differentiation by class allowed some variation of roles for women; but Plato's philosopher queens aside, no women could claim equal treatment in regard to property, citizenship, marriage, criminal law, or access to social institutions. Women existed to reproduce and to serve men's needs; rights in their progeny were assigned to men.

INFLUENCE OF CHRISTIANITY. The spread of Christianity brought new possibilities for women: for some, a role in spreading the new religion; for all, a promise of spiritual equality. Christianity created new opportunities for women's voices to be heard, especially by instituting marriage laws

requiring consent and establishing, in some instances, inheritance and property rights for women. Monasteries and convents, while providing shelter for the destitute, also offered education and alternative careers for a small, often highborn, minority. The high Middle Ages saw the foundation of the first universities in the Western world, beginning in 1088 with Bologna, whose famous twelfth-century legal scholar, Gratian, incorporated into his influential study Aristotle's dualistic view of women as passive and men as active, in law as well as reproductive physiology.

This Aristotelian dualism was also advanced by the work of Thomas Aquinas in the thirteenth century; he combined his reading of Aristotle with the Christian view of creation to assert that woman was a "defective and misbegotten" man, assigned by nature to the work of procreation. The rebirth of learning thus gave new life to the hoary tradition of defining women as not-men and for men, in terms of qualities they lacked and services they provided. Renaissance thinkers transmitted across the ages classical Greece's sharp distinction between polity and household. The literature of courtly love notwithstanding, as dynastic power was reconstituted in bureaucratic and political structures, the separation of public and private arenas of human activity increased; and relative to aristocratic men, upper-class women faced new restrictions. Growth of the market economy, however, probably had a more liberating effect on rural and urban women of other classes.

Neither the Renaissance nor the Reformation, both considered watersheds in European history, brought reformed ideas about women to the fore. The advent of Protestantism meant the closing of nunneries that had allowed some women, notably those who could offer a dowry to the church, agency outside marriage. It also deprived all classes of women of the succor of the Virgin Mary and female saints. However, Protestantism did provide some literate women as well as men direct access to the word of God in the Bible. By ending clerical celibacy, it opened opportunities to ministers' wives, and ultimately, especially in the dissenting sects, it allowed women wider participation in church affairs. In the Counterreformation, some Catholic laywomen formed communities through which they provided social services for the poor, ill, and orphaned. Nuns continued to serve as teachers, nurses, and social workers. But Catholics and Protestants alike, following the biblical injunction of Paul, taught women silence in public and subjection to men in private.

URBAN VS. RURAL EXPERIENCE. Controversy over the effects of the Renaissance and Reformation on women's lives continues to fuel debate among historians of women. In an increasingly complex society, generalizations fail to satisfy: some women prospered, enjoyed education by leading humanist scholars such as Erasmus, and wielded power on behalf of dynastic lines. Urban craftsmen's wives shared in domestic production and local marketing of goods, and helped to manage artisanal workshops. City women developed professions of their own, largely in the healing arts, midwifery, and retail establishments, especially those purveying food. But most wage-earning women worked as domestic servants, frequently for a decade before marriage and sometimes for their entire lives; "maid" had become synonymous with "female servant."

However, most women, like most men, lived in rural settings, where all members of the household pooled their labor in a family economy organized to produce the goods and services essential to supporting and reproducing themselves. They lived within households and made essential contributions to the economic survival of their families. Labor needs over the family's life cycle determined the status, residence, and welfare of most people (Tilly and Scott). Only after centuries-long structural changes in agriculture and industry, in company with a demographic shift that reduced both mortality and fertility, did the employment of female productive capacity generate public debate over a "woman question." Ultimately it was a shift in the location of women's traditional work—especially making cloth and garments—from the household into the factory, and the ensuring restructuring of (especially married) women's economic contribution to the family, that created the conditions for feminist debate. Only then did the question "Should a woman work?" or "Should she have a 'right to work'?" make sense.

EFFECTS OF POLITICAL AND SCIENTIFIC DEVELOPMENTS. In addition to religious reformation and the expansion of commerce and trade, other major trends in the early modern period led to new institutions and novel ideas that affected women's lives and challenged traditional views of women's "nature." Political centralization and the rise of science also meant change in women's lives. According to one recent interpretation, the great witchcraft persecution of the sixteenth and seventeenth centuries reflected not only religious and gender conflict but also efforts to legitimize political authority by exercising new forms of social control over individual behavior (Larner). Because women's relative physical and economic weaknesses made their recourse to magic power seem plausible, and because their alleged sexual insatiability predisposed them to temptation by the devil, 80 percent of the victims of witch-hunts were female—often older, single, eccentric women lacking male protection.

Ultimately science disproved many misogynist notions about the female body. However, despite studies in embryology challenging the Aristotelian view of women's passivity in reproduction that also buttressed attitudes and customs denying them agency in society, only in the late nineteenth and early twentieth centuries were such classical and false assumptions finally displaced by scientific knowledge.

Although by the eighteenth century the economic, political, and intellectual structures that maintained traditional attitudes and institutionalized age-old practices toward women were subject to a multitude of challenges, time-honored patterns persisted. Just as in the thirteenth century Thomas Aquinas had recapitulated Aristotle, so the influential eighteenth-century philosopher Jean-Jacques Rousseau reinforced belief in woman's role as the helpmate of man. Like Adam's Eve, Rousseau's Sophie, the ideal wife of his ideal citizen, Émile, was created to serve, support, and console the chief actor on the human stage, the man to whom she was legally subject. The Napoleonic Code of 1804, and similar codes of law subsequently promulgated across Europe, required married women to obey their husbands. Voices that demanded inclusion of civil rights for women along with the "Rights of Man"—Condorcet in France, von Hippel in Germany, Mary Wollstonecraft in England—were silenced as the Age of Reason gave way to an Age of Steel. Men alone wrote and signed the new "social contract"; as "natural" dependents, women could not aspire to citizenship.

And yet women increasingly did claim civil rights. Despite the negative examples of Wollstonecraft (dead after childbirth and infamous more for her unconventional lifestyle than for her contributions to radical philosophy), Marie Antoinette, Olympe de Gouges (author of *The Declaration of the Rights of Woman and the Female Citizen,* 1791), and Jeanne Manon Roland (dead on the Jacobins' guillotine, ostensibly for having violated the boundaries of conventional femininity), and despite increasingly restrictive legal codes and an ideology of domesticity that won widespread support across class lines, new philosophic currents, based in the Enlightenment concept of human perfectibility, generated the first organized movements for women's rights.

Women in Transforming Societies

Inspired by the French Revolution, women in the nineteenth century began to form groups through which collectively to advocate improved treatment of their sex. By the mid-nineteenth century, organized groups we now call *feminist* were formed in France, England, the United States, Prussia, and even Russia, to challenge women's subject status. The new protest took place in the context of economic as well as political transformation in western and central Europe and the United States. Revolutionary changes in methods of agriculture and transportation, and the rise of an enlarged market economy, industrialization, and urbanization brought profound alteration to family structures and relationships. More young people, including women, could claim and find opportunities for social and geographic mobility and economic independence.

Especially for women, however, escape from the confines of the patriarchal family brought new vulnerabilities (Tilly and Scott, 1978). With female wages far below subsistence levels, a woman alone required assistance, and might trade sex for survival, risking dismissal from employment for her "loose morals" or extreme deprivation if deserted by her male partner.

Social reformers responded, purportedly in women's defense. Not all protesters and reformers called for *equality* for women; few, if any, entertained ideas of identical rights and responsibilities for both sexes. Utopian schemes for the total reconstruction of society aside, debate over the status of women most often focused on ways to "protect" them: to shelter traditional women's work from the intrusion of men; to safeguard women (along with children) from unsafe conditions and/or excessive hours of labor; to secure for women rights to inherited property, their own earnings, and custody of their persons as well as some share in legal authority over their children in cases of divorce. Divorce itself, largely illegal or difficult to obtain before the twentieth century, was one of many reform issues about which women themselves differed, often on the basis of class, religion, or ethnicity.

DEFINING FEMINISM. Emphasis by historians on the woman-suffrage movement, which began as a minority concern within women's groups in the mid-nineteenth century and peaked near the beginning of the twentieth, has obscured not only the larger concerns of women activists but also deep differences within feminist movements. Campaigns for "equal rights," grounded in the assumptions of liberal individualism, became dominant to a greater extent in England and the United States than elsewhere. Contemporary English-language dictionaries tend to define feminism as a movement toward political, social, educational, economic, and legal rights for women equal to those of men. This has been termed *individualistic* feminism (Offen).

The feminisms of continental Europe in that earlier era, as well as later women's movements in Third World countries, reflected a closer association with the social question—that is, with issues of class and nation—and with family

relationships and community ties. This constitutes a *relational* form of feminism. Socialist feminists, while cognizant of women's needs for education and encouragement to participate fully in political struggles in support of class goals, declined to envision as their purpose access to equal—and equally exploitative—conditions with working-class men. Others, including Catholic feminists in large numbers, insisted on improvement of women's status in order to enhance their performance in traditional women's roles and relationships. In some countries, notably the United States, a "century of struggle" for women's rights grew out of religious ferment and the recognition that no subjected person, woman or slave, could be fully responsible to God as a moral being. Nineteenth-century equal-rights feminism and the concurrent movement for "protective legislation" offered contrasting answers to the "woman question."

EQUAL BUT DIFFERENT. Differentiation between "individualistic" and "relational" forms of feminism heightens current debate over the definition of feminism. It also parallels a major controversy among feminist theorists that cuts to the heart of moral issues regarding women. Must arguments undergirding a political movement on behalf of women—the various forms of feminism—be grounded in the assumption that human beings are identical? If so, equal-rights law can be used to deny pregnant women special insurance and employment benefits. Equality so defined may demand identity of treatment.

Alternatively, to emphasize women's particularity, to focus on sexual differences, may invite legislation (and buttress attitudes) restricting women's options in the guise of acknowledging their special needs. Precisely this argument was long used to justify labor laws that denied many excellent employment opportunities to all women because they required occasional work during evening hours or involved physically demanding tasks. More recently, women workers in potentially hazardous industries have faced coerced sterilization or loss of employment on grounds of their capacity for reproduction. But to deny that women on the basis of their sex constitute a special class can also deprive them of support they may need—for example, in pregnancy. It can even, some argue, destroy the very basis for a political movement in their name and interest.

This "difference versus equality" debate, often in inchoate form, has led to extended conflict over definitions of feminism and feminist demands. It also raises fundamental issues regarding individual rights, family responsibilities, and the prerogatives of government. In the nineteenth century, reformers called for legislative action to ameliorate the worst abuses of industrialization and urbanization. Reformers ranged from British industrialists who wanted to improve the quality of the labor force to French Social Catholics who sought to base solutions to societal problems on Christian principles to Prussia's "Iron Chancellor" Otto von Bismarck, who schemed to reduce the threat of socialist revolution. Whether impelled by religious, philanthropic, political, or economic motives, they shared the recognition that such innovations increased governmental powers over persons' lives. They also found that they could succeed, against strongly held liberal tenets favoring laissez-faire practice, by exposing the physical, and allegedly moral, dangers to female (and young) persons posed by the new working and living conditions. Working women rarely spoke for themselves in these debates, and even feminist voices, largely from the middle class, were little heeded.

Beginning in the 1840s with the first laws limiting women's night work, every policy of the interventionist states, acting in lieu of a patriarchal family to regulate female behavior, extended the premise that women needed special consideration and that men must provide them with protection, even against themselves. The nineteenth-century debate over short hours and the twentieth-century controversy over state regulation of reproduction share the assumption that adult women, as individual citizens, cannot or should not be empowered to make decisions affecting their own persons. Whether arguing against a woman's working outside the home at night, on behalf of keeping her husband home from the cabaret, or championing limits on abortion, advocates of restrictive legislation link women's rights with those of others: husband, child, family, state.

Similar arguments may be employed on occasion in support of male-specific measures such as military conscription, which subordinates individual freedom to national security. Such denial of personal autonomy, however, remains the exception for men and, moreover, often brings with it rights of citizenship. Women, on the other hand, are assumed to serve the interests of others at all times, and rarely gain comparable advantage. Historically, legislation concerning women has not distinguished among them by race, ethnicity, or class, by marital status, age, preference, or capacity, assuming marriage and motherhood to be the overriding obligation and destiny of all women, and conflating childbearing with child rearing. As historians have highlighted in recent books, the interests of women and their calls for "freedom" may even be seen as at odds with those of the family. This, of course, is true especially of the type of family associated primarily with the white, Western world (Bell and Offen; Degler); studies of the African-American family in the United States, and of extended families in other cultures, stress their function as sources of strength as well (Jones).

The history of women in the twentieth century reveals the centrality of the "woman question" to the social, economic, and political concerns of many nations. During wars and revolutions, traditional notions of *women's place* and struggles over woman suffrage have been eclipsed by calls for female labor and patriotic support. Apparent feminist advances, however, have frequently led to the reinstitution of traditional norms. Following both world wars, women were summarily discharged from good-paying jobs or offered less skilled and less rewarding employment. However, structural changes in commerce and industry have escalated demand for female workers, especially in clerical, teaching, and other service occupations dominated by women; expansion of educational opportunities has augmented female literacy and professional expertise; advances in public health, nutrition, and medicine have continued to increase female life expectancy and decrease infant mortality; and new technologies have reduced the need for labor-intensive household chores. All of these changes tend to free many women for long periods of productive activity outside the family. As more and more countries have been swept into the global economy and information network, women's movements, often linked (and sometimes subordinated) to nationalism, have appeared around the world. Along with efforts to improve women's health and education, Third World feminists are challenging double standards in law and culture as well as such practices as clitoridectomy, marriage by capture, and sati (Johnson-Odim and Strobel).

Unlike earlier waves of feminist protest, the mid-twentieth-century rebirth of feminism called into action sufficient numbers of educated and strategically placed women and their male supporters to successfully challenge many social priorities and institutional structures. Though feminists are sometimes wrongly perceived as a *special interest* group reflecting only the needs and desires of middle-class white women in developed nations, their pressure, especially since the 1970s, has achieved significant change in legal status, medical treatment, and workplace conditions of benefit to all women. It has opened to women professions long monopolized by men, including medicine, law, the ministry, and the professoriate, whose collective powers of definition long buttressed gender biases. In some cases, most notably medicine, this represents a restoration to women of roles they held prior to the institution of professional schools and licensure, from which they were excluded. As healthcare providers, women today often challenge the gender distinction between male doctors who *cure* and female nurses who *care.* Women's health centers tend to stress women's need to question conventional medical procedures and to encourage women to assume an active role in determining their own treatment (Jaggar).

Women Challenging Epistemology

Modeled on the *self-help* agencies for women's health that first developed in the late 1960s and influenced medical practice, this new women's liberation movement has flourished in the academy, especially in the United States but increasingly in Europe and in some instances in Africa, Asia, and Latin America. The field of women's studies, which began as a search for feminist foremothers and a female past lost to history, has expanded across the disciplines to question old methodologies, ask new questions, identify new sources, reinterpret received wisdom, develop new female perspectives, and challenge the very construction of knowledge—not only about the *nature* of women but also about all the constructs in the natural and social sciences based on androcentric experience. Grounded in advocacy for the rights of women to equality in education, culture, and society, it is a form of moral as well as scientific inquiry.

Among the earliest paradigms developed from the new scholarship in women's studies was the *social construction of feminity.* Whether psychologists rereading Sigmund Freud, sociologists reinterpreting Erik Erikson, or historians rediscovering Heinrich Kramer and James Sprenger's notorious late-fifteenth-century handbook on witchcraft, these scholars found in the sciences as well as the humanities a pervasive confusion of description with prescription. Proceeding from male-imposed definitions of female nature and proscriptions limiting female behavior as old as written records of humankind, men as philosophers, preachers, physicians, politicians, patriarchs, and professors had labeled unconventional women abnormal, criminal, ill, even pathological—or, alternatively, not "real women." The *eternal feminine* of Western mythology falsely universalized descriptions of an idealized (implicitly) white woman (Spelman; Chaudhuri and Strobel).

Historical and cross-cultural studies that belie many such interpretations have now been done. The new women's history, increasingly inclusive of women of color and international perspectives (Offen et al.; Johnson-Odim and Strobel), lays bare the many consequences of the absence of female voices and agency, and the fundamental ways in which justice has been denied to half the human species. Women's history tells a tale of misconceptions, biases, and injustices that have oppressed women and limited their freedom of choice—and, hence, their moral responsibility. It also reveals the many and differing contributions, perceptions, and struggles that constitute the female past. Although this historical perspective faces challenges, sometimes by groups of women who remain dependent on traditional sex roles for economic support and social recognition, it nevertheless offers the potential for transformation of benefit to all (Jaggar). It rests, moreover, on the principles of justice.

To the extent that ethical considerations require attribution of personhood and personal agency to every human being, ethical behavior toward women calls for disclosure and discussion of the full record of women in history. It demands that women be defined by their particular positions within specific and changing contexts and allowed choices reflecting the full range of their human attributes. It calls for major societal change. Inspired by new knowledge and the new feminisms, women have begun as never before to speak in their own voices and to claim equality despite their differences—envisioning difference without hierarchy. The "woman question," as posed by women today, can no longer be answered in terms of expediency. The ground has shifted: in the new world, women stand along with men as individuals endowed equally, if perhaps differently, with moral rights and moral responsibilities.

X

XENOTRANSPLANTATION

• • •

Xenotransplantation is the transplantation of living cells, tissues, or organs between members of different species. In the human clinical context, xenotransplantation refers to the use of living biological material from any nonhuman species in human recipients for therapeutic purposes. The practice began with attempts to develop whole animal organs as "spare parts" to replace failing human organs. Current efforts also involve cellular applications.

Xenotransplantation is currently experimental. However, some applications have progressed to clinical trials in humans and could become available therapeutic options in the early twenty-first century. Decisions about such trials must draw on areas in which science currently offers inexact guidance, raising interrelated issues of ethics and social policy. Forging consensus on appropriate public policy is multinational in scope, often pits different stakeholders against each other, and has triggered heated debate among scientists, ethicists, and the public. In this respect, the issues raised by the exercise of social policymaking for xenotransplantation provide a good case study for more general discussions of how biomedical technology should be developed and implemented.

Organ transplantation has been hailed as one of the most remarkable achievements in medical history. The original kidney transplant successes of the mid-1950s were between genetically identical human twins, whose immune systems would not recognize each other's organs as genetically foreign (and therefore would not reject them). Soon thereafter, kidneys for transplantation were obtained from non-twin siblings, from unrelated living donors, and, finally, from cadavers. These transplants between members of the same species are known as *allotransplants,* and apart from the rare identical twin transplants, all require some form of manipulation of the recipients' immune systems to prevent rejection of the donated organ.

Medical advances, particularly the discovery of powerful new immunosuppressive drugs, have greatly increased the number of transplants performed worldwide. Today, where facilities and expertise are available, it is fairly routine to transplant kidneys, hearts, livers, lungs, and other organs and tissues between human beings. However, this very success has created a disparity between the demand and supply of organs. As a result, thousands of patients die every year while waiting to receive a suitable organ for transplant. The situation is particularly severe in developing countries. Were xenotransplantation to become an effective and inexpensive method of addressing end-stage organ failure, however, the same social and economic issues that limit the ability to maintain transplant programs in developing countries today will hinder efforts to develop and maintain xenotransplantation programs. Basic healthcare needs (such as vaccination, basic diagnostics, and drugs) and accessible clean water will compete with any advanced technology for limited healthcare dollars.

Allotransplantation raised important ethical issues, many of which continue to be debated (Dossetor and Daar). While xenotransplantation raises similar issues, especially in terms of equity of access and diversion of resources, it also raises issues pertaining to human rights, animal welfare, and public health risks.

Xenotransplantation Defined

While consensus is not universal, xenotransplantation is defined as "any procedure that involves the transplantation, implantation, or infusion into a human recipient of either

TABLE 1

Summary of Clinical Organ Xenotransplantation during the 1960s, 1970s and 1980s

Organ	Year	Source Animal	Number	Investigator
Kidney	1964	Chimpanzee	12	Reemtsma
	1964	Monkey	1	Reemtsma
	1964	Baboon	1	Hitchcock
	1964	Baboon	6	Starzl
	1964	Chimpanzee	1	Hume
	1964	Chimpanzee	3	Traeger
	1965	Chimpanzee	2	Goldsmith

(a) live cells, tissues, or organs from a nonhuman animal source; or (b) human body fluids, cells, tissues, or organs that have had *ex vivo* contact with live nonhuman animal cells, tissues, or organs." This is the definition adopted by the U.S. Public Health Services, and the Council of Europe has a similar one. This definition would include transplantation of an animal heart into a patient with heart failure, implantation of pancreatic islets for people with diabetes, circulation of blood from a patient with acute liver failure through a nonhuman liver or a device containing nonhuman liver cells, or the treatment of burn patients using human skin cells that have been grown *ex vivo* (outside the body) over a layer of mouse feeder cells. The transplantation of inert animal tissue (such as pig heart valves) does not fall under this definition.

Scientific and Clinical State of the Art: Continuing Challenges

Tables 1 and 2 summarize the attempts at clinical xenotransplantation since the 1960s. With the exception of the inexplicable survival for nine months of a kidney transplanted from a chimpanzee into a human recipient in the 1960s, all whole-organ xenotransplants have failed rapidly, despite massive immunosuppression of the human recipients. In contrast, a number of preclinical trials of cellular therapies have shown enough promise to justify progressing to clinical trials. These include neural-cell transplants to treat disorders such as Parkinson's disease, intractable epilepsy, and other degenerative neurologic diseases (Fink et al.). There have also been attempts at perfusing the blood of patients in acute liver failure *ex vivo* through nonhuman animal livers until a human liver becomes available or the patient recovers (Chari et al). However, as of April 2003, no xenotransplantation application has demonstrated a high enough level of efficacy in clinical trials to allow progression to general clinical adoption.

HYPERACUTE REJECTION. The initial technical obstacle to xenotransplantation is the phenomenon of *hyperacute rejection,* which occurs when tissue is transplanted between two distant (discordant) species, for example between pigs and humans. Hyperacute rejection is swifter and more severe than the acute rejection response usually seen in transplants between individuals of the same species. Xenotransplant rejection responses are, however, also less severe in transplants between members of closely related (concordant) species, such as between rats and mice. A carbohydrate

TABLE 2

Summary of Clinical Trials on Organ and Cell Xenotransplantation during the 1990s

	Graft	Indication	Number	Country	Presently including patients
Organ transplantation	Pig heart	Heart failure, bridging procedure	1	Poland	No
	Baboon liver	Hepatitis B with liver failure	2	USA	No
	Pig liver	Liver failure, bridging procedure	1	USA	No
Cellular grafts	Neonatal bovine cromaffine cells	Pain	more than 100	Poland, Czech Republic, Switzerland & USA	No?
	Encapsulated transgenic hamster cells	ALS	6	Switzerland	No?
	Fetal porcine neurons	Parkinson	21	USA	Yes
		Huntington	12	USA	Yes
		Epilepsy	3	USA	Yes
		Stroke	3	USA	Yes
	Fetal porcine islets	Diabetes	10	Sweden	No
	Neonatal porcine islets	Diabetes	6	New Zealand	No
	Fetal rabbit islets	Diabetes	Several 100	Russia	Yes
	Baboon bone marrow	HIV	1	USA	No

molecule known as Gal alpha-1, 3 Gal (alpha-gal) is present on all cells of most mammalian species, including pigs, which at present are considered the most likely source-animal species. Humans and closely related old-world primates such as chimpanzees lack alpha-gal, but have naturally occurring antibodies that recognize it as foreign. In hyperacute rejection these antibodies would react against the alpha-gal on pig cells, causing the blood to clot (thrombosis) and the transplanted organ to die within minutes.

Activation of complement, a substance found in blood, is part of normal defense mechanism against foreign tissue or microbes. The presence of chemical substances that inactivate complement when its work is done normally prevents thrombosis. These complement factor regulatory proteins (CRPs) are species-specific. Thus one of the scientific responses to the challenge of hyperacute rejection has been to create transgenic pigs in which the genes for various human CRPs have been incorporated into the pig's genome, and thus prevent thrombosis. Experiments in which tissue from these transgenic pigs was transplanted into nonhuman primates have shown better graft survival rates than using tissue from unmodified pigs, raising hopes that similar improved results would be reproduced in human recipients.

Another genetic approach to dealing with hyperacute rejection has aimed to alter the expression of the alpha-gal molecule on pig tissue either by inserting genes that result in carbohydrate remodeling (Sandrin et al.,1995); by a reduction in expression of alpha-gal (Sharma et al.); or by "knocking out" (removing) the gene for the enzyme that is involved in making alpha-gal (Tearle et al). A double knock-out pig, (a pig in which both copies of the gene have been deleted from its genome) was announced in 2002 (Phelps et al.). Others have focused on reducing the massive inflammatory responses.

OTHER IMMUNOLOGICAL CHALLENGES. Hyperacute rejection is only one challenge facing xenotransplantation. Even if hyperacute rejection can be avoided, progressive phases of rejection would follow, including acute vascular rejection, cellular rejection, and chronic rejection.

Related research focuses on attempts to manipulate the immune system of higher animals in ways that would make it "tolerate" one, or a few, foreign antigens without paralyzing the whole immune system. Should immunological tolerance be achieved in humans, it would become possible to transplant organs without administering the large doses of powerful immunosuppressive drugs that leave the recipients vulnerable to dangerous infections.

PHYSIOLOGICAL BARRIERS. Physiological barriers may also stand in the way of successful xenotransplantation. For example, there is serious doubt that a pig liver will be able to sustain a human being for long. The liver is not only a detoxifying and storage organ, it is the main factory in the body for the manufacture of a large number of crucial molecules, including proteins such as albumin and clotting factors. Many of these are species-specific and will function inadequately in humans (Hammer and Thein), and some may also evoke immune reactions. In contrast, porcine insulin has successfully treated human diabetics; thus porcine pancreatic islet transplantation may offer human diabetics hope for a cure.

Xenogeneic Infections

Another reason for caution is that infections not normally encountered in humans might be transmitted from source animals to human recipients. In addition to the risk to the recipient, there is a theoretical risk that an infected recipient could transmit the infection to others. Of particular concern in this regard are infectious agents such as retroviruses that result in persistent infections and remain clinically quiescent for long periods before causing identifiable disease. During that "silent" period they can be transmitted from person to person, infecting many people before the danger is recognized.

In the past, animal viruses, such as Nipah virus and avian influenza, have been known to infect humans, resulting in outbreaks of disease of limited scope and duration (CDC, 1998, 1999). Of even greater concern is evidence that viruses once restricted to a nonhuman host species may infect and adapt to humans as a host species, as is theorized to have occurred with the HIV/AIDS pandemic (Hahn et al.). There is some controversy about whether nonhuman primates are more likely than other species to transmit dangerous infections to humans (Chapman et al). In response to widespread concern, the U.S. Food and Drug Administration produced an advisory in April 1999 against the use of primates as source animals pending adequate demonstration of safety.

Exogenous infection (infections from agents passed among animals by contagion) can theoretically be controlled by eliminating them from the source animals. More uncertainty exists about the significance of endogenous retroviruses, which exist as part of the genetic material of humans, nonhuman primates, pigs, mice, and perhaps all animals. Endogenous retroviruses are passed from one animal to another through inheritance. Unable to cause active infection in the host animal, many can produce a virus capable of causing infection in cells from other species in the laboratory. Thus, living biological material devoid of recognized microbes has an innate infectious potential of uncertain significance for xenotransplantation. Specifically, both pigs and nonhuman primates have been shown to have endogenous retroviruses that can infect human cells in the laboratory.

Since the pig is the most likely source animal for human clinical xenotransplants, endogenous retroviruses of pigs have become a major focus of research. Porcine endogenous retroviruses (PERV) exist in the genomes of all pigs. Several variants of PERV have been characterized that vary in their infectivity. It would be difficult, but perhaps possible, to eliminate PERV through breeding or genetic manipulations (Patience et al.; Stoye).

In animal experiments, short-lived (but nonclinically obvious) replicative infections have been documented (van der Laan et al.), and PERV can be transmitted from pig cells to human cells when they are cultured together in the laboratory (Patience et al.; Wilson et al.), but there is currently no convincing evidence that PERV can cause infections leading to disease in humans.This does not, of course, exclude the possibility that it may be capable of doing so given the right circumstances.

HUMAN PATIENTS PREVIOUSLY EXPOSED TO PIG TISSUE. In the past decade or so a small but significant number of patients have been exposed to various experimental forms of xenotransplantation. Several studies of these patients have found no evidence of PERV infection, despite evidence that many of those exposed exhibited "microchimerism" (they had small numbers of pig cells in their bodies which provided ongoing exposure to PERV). While many scientists do not consider that these studies conclusively establish the absence of infectious disease risk associated with xenotransplantation, they are reassuring to some extent.

Ethical, Social and Economic Issues

Research and development costs for any major new technology, including xenotransplantation, can be high. If xenotransplantation progresses from experimentation into clinical practice, the final cost is uncertain. Even beyond the development costs, many factors will contribute to the expense of a clinical xenotransplantation program, including rearing specific infection-free source animals, laboratory tests for early diagnosis of infection, specialized staff, and maintaining monitoring and surveillance regimes. Costs will also be determined by companies owning intellectual property rights to the technologies employed, the size of the market, and so on. Whether this cost will exceed the current costs of medication and extended hospital care for patients awaiting allotransplants is uncertain. It seems likely, however, that xenotransplantation, like allotransplantation, would initially benefit only a privileged few.

It has been argued that xenotransplantation efforts could be justified only if large numbers of patients could benefit at reasonable cost and with no significant diversion of resources from the healthcare system. In this light, efforts to develop applications of porcine pancreatic islets for functional cure of type I diabetes mellitus are the most easily justified. While many applications of xenotransplantation research would benefit relatively few patients, diabetes mellitus affects a large number of people and poses substantial costs to society, both in terms of economics and in years of productive life lost.

PRECAUTIONARY PRINCIPLE VERSUS RISK-BENEFIT ANALYSIS. It is possible that the public may eventually benefit indirectly from successful widespread xenotransplantation due to a decrease in the societal burdens of healthcare costs and years of productive lives lost due to chronic diseases. The public may, however, also be put at risk of infections. As a result, although the extent of the risk is not clear, many nations have regulations that would allow xenotransplant clinical trials only when using husbandry methods that eliminate exogenous infectious agents from source animals prior to transplantation, and ensuring ongoing monitoring of receipients.

As long as uncertainty about the risk to society exists, different constituencies will perceive the same scientific data on public risk in different ways. Those basing their public-policy decisions on traditional risk-benefit analysis would tend to favor patients, perhaps at the expense of the public. Many clinicians and scientists in the transplant community do this instinctively, emphasizing the benefits in terms of a moral imperative to ameliorate suffering and save lives. This attitude is reflected by the Institute of Medicine's statement that "our own humanity is diminished if, in order to protect ourselves, we turn away from others whose suffering is both clearly visible … and … devastating in … impact … we are morally obliged, not only as individuals but as a community, to accept some risk to ourselves to save our fellow human beings from more certain harm" (Institute of Medicine, p. 71). On the other hand, those who would base decisions on the "precautionary principle" (of which there are several versions) would tend to pay more attention to the public interest, perhaps at the expense of needy patients (Daar; 2001).

The precautionary principle originated in environmental risk discourse, but has been adopted into health-policy discussions partly because of the history of infections with agents that cause AIDS, mad cow disease, and so on. It is easy to misunderstand, misquote, and misuse this concept, as there is no single definition. There are two well-known formulations. The first, from Article 15 of the United Nation's 1992 Rio Declaration on Environment and Development, states: "In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation." The second, the so-called Wingspread Declaration, states: "When an activity raises threats of harm to human health or the environment, precautionary measures should be taken, even if some cause-and-effect relationships are not established scientifically."

As can be expected, the precautionary principle has become a subject of intense scholarly debate and ethical analysis (Saner). Some have argued that to be true to itself the precautionary approach requires risk-risk analysis, which would suggest an alternative formulation for the principle along the lines that "Public health and environmental policies should attempt to minimize net risks to public health and the environment based on the best available scientific information and their net anticipated cost to society" (Goklany, p. 1075).

ANIMAL ISSUES. The great British reformer Jeremy Bentham, a key figure in the development of utilitarian ethics, was also one of the earliest advocates for the humane treatment of animals. In 1780 he asked two fundamental questions: (1) "The question is not can they reason? nor can they talk? but can they suffer?" and (2) "What insuperable line prevents us from extending moral regard to animals?"

Since Bentham's time, it has become widely recognized that all vertebrates essentially perceive pain in the same way. Some argue that animals can also suffer. Animals reared in stressful conditions in captivity experience fear, boredom, isolation, and separation anxiety. Recent evidence indicates

that the great apes are capable of using language, including human words (BBC), and also exhibit forms of culture. The emotional repertoire of nonhuman primates, according to ethologists Jane Goodall and Dian Fossey, includes love, sorrow and jealousy. These attributes have led some to argue that such animals are more than just sentient beings, and that they possess intrinsic value. If so, then they must have rights. To some, ignoring these rights is a form of speciesism, a term analogous to racism, and a growing minority are embracing this view.

The awareness of such qualities of animal life raises serious questions: What is it in humans that bestows on us the right of killing an animal for our own self interest? Is it our complex use of language and tools? Is it our rationality, intentionality, consciousness, conscience, or empathy? Immanuel Kant argued that all nonhuman animals can be regarded as means to ends, and that only humans, who are "rational beings," have the intrinsic right to be considered as ends in themselves. If capacity for rational thought is the basis of intrinsic rights, some have questioned whether we are justified in using organs taken from a nonhuman primate but not those taken from an anencephalic, or severely retarded, human. Philosophic justifications for the prohibition against killing incapacitated humans for such purposes have referenced their memories, if any, their potential to grow and form lasting relationships, their capacity to be mourned for long periods, and the effect that using their organs would have on relationships between humans. Others justify this distinction based on religious or metaphysical notions of the inherent elevation of humans above other creatures. These views are not convincing to many animal rights advocates, however.

NONHUMAN PRIMATES AND PIGS. Nonhuman primates are biologically close to humans, and many humans feel an emotional attachment to them. They are a concordant species, and would therefore be easier to use as sources for xenotransplantation (from an immunological and physiological perspective) than pigs, which are a discordant species. However, there are several arguments against using them for such purposes. First, the microorganisms they harbor may more easily infect and be pathogenic in humans than would be the case with pigs. Humans have a long history of contact with the pig, and the resultant physical proximity has only rarely led to the acquisition of serious infections. Second, it is not possible to raise primates under the husbandry conditions that currently allow for the production of pig herds from which exogenous infectious agents of concern have been excluded (specific-pathogen-free pigs). Third, some primate species (e.g. the chimpanzee) are endangered. While the baboon exists in large numbers and is considered a pest in some parts of the world, it breeds slowly (and it is currently impossible to rear specific-pathogen-free baboons). Thus, a consensus to exclude nonhuman primates as source animals for xenotransplantation has emerged.

There are laws to protect research animals in many countries. Sensible guidelines include the 3 Rs of Russell and Burch (1959); namely to "reduce, replace, and refine"—to which we might now add "respect and reconsider." There are increased efforts underway to look for alternatives to animal use.

GENETIC MANIPULATION OF ANIMALS FOR HUMAN PURPOSES. The recently acquired power to manipulate the genomes of animals, including the ability to produce "double knockouts" and to clone these over several generations raises an important ethical question: Where do we draw the line? The Kennedy Report (1997) and other similar reports have concluded that the current extent of manipulating the pig's genome to incorporate human genes or other manipulations of the same magnitude raise little ethical concern provided the pig "recognizably remains a pig." Today, on balance, a case has been made that it is ethically acceptable to use pig organs, but not organs from nonhuman primates, for human xenotransplantation. At this stage of development a larger consensus exists on the importance of attending to "animal welfare" than to "animal rights."

RELIGIOUS PERSPECTIVES ON XENOTRANSPLANTATION. The views of different religions concerning xenotransplantation largely depend on the manner in which these religions consider animals and how they should be treated. From the religious perspective, it would be important that a xenotransplant not tamper with the human personality or the individual's freedom, and ability, and eligibility to bear responsibility. Minimally, all religions consider that humans have stewardship responsibilities to minimize the pain and suffering of animals being used for the benefit of humans.

Within the three major monotheistic religions (Judaism, Christianity and Islam), human beings have canonically been considered unique, with the rest of creation existing to serve humankind. The Old Testament, the first five chapters of which are canonical to both Jews and Christians, declares: "Man was made in God's image and has dominion over all other creatures and all the earth" (Genesis 1:26). In both Judaism and Islam the imperative to preserve human life overcomes many religious prohibitions.

The pig is considered to be ritually unclean in both Islam and Judaism, and it is not surprising that authorities in these two religions have been asked if the pig can be used as a source animal for organs. In Islam, the conclusion of the

majority seems to be that this would not be a barrier to xenotransplantation, based on the Shariah principle that need and necessity can allow that which is forbidden—and that, in any case, the prohibition is only to eating pig tissue. F. Rosner, a physician and scholar of Jewish medical ethics, has come to the same conclusion with regard to Judaism. There is, however, a minority opinion in Islam that pigs, because they are ritually unclean, cannot be used as source animals.

A number of thoughtful Christian commentators have written about xenotransplantation. On the whole, these are generally accepting, while emphasizing that animal suffering should be minimized. The Catholic Church addressed xenotransplantation as far back as 1956, and in 2000 Pope John Paul II restated its permissive position:

> It is not my intention to explore in detail the problems connected with this form of intervention. I would merely recall that already in 1956 Pope Pius XII raised the question of their legitimacy. He did so when commenting on the scientific possibility, then being presaged, of transplanting animal corneas to humans. His response in still enlightening for us today: in principle, he stated, for a xenotransplant to be licit, the transplanted organ must not impair the integrity of the psychological or genetic identity of the person receiving it; and there must also be a proven biological possibility that the transplant will be successful and will not expose the recipient to inordinate risk. (Transplantation Society)

Some Christian arguments against xenotransplantation have focused on the themes of "playing God" and "interfering with creation." These arguments have less emphasis in Judaism and Islam.

Hinduism, Buddhism, and some Animist traditions have not drawn such a sharp theological distinction between humans and other animals, seeing all as part of a hierarchy of creatures, with indistinct borders between them. Other religions supportive of xenotransplantation include Baha'i and Sikhism. Those that have religious concerns about xenotransplantation include Buddhism, Hinduism and Native American faiths (Council of Europe).

REGULATORY CHALLENGES. The uncertain potential for introducing xenogeneic pathogens has influenced many countries to develop specific policies that incorporate very stringent safety standards for clinical xenotransplantation. Some countries have initiated moratoria, while others have allowed limited and tightly monitored clinical trials. Several countries have developed policies that advocate caution with xenotransplantation clinical trials, requiring that they occur only with regulatory oversight and involve stringent standards for animal husbandry, particularly for screening and surveillance for infectious diseases. (Bloom; Tibbel; OECD).

The Council of Europe, the European Agency for Evaluation of Medicinal Products, and the United Kingdom Xenotransplantation Interim Regulatory Authority (UKXIRA, 2003) are developing specific policies on at least certain kinds of xenotransplants that incorporate the concepts of safety built around pre-xenotransplantation screening to prevent transmission of infection and post-transplantation surveillance to maximize the probability of early recognition and containment of any infections introduced through xenotransplantation. Further, the European Union has advocated multinational efforts toward consensus development and collaborative work to minimize threats from emerging infections in general.

Multinational organizations have recognized infectious disease issues associated with xenotransplantation as policy issues that transcend national boundaries. The World Health Organization (WHO) has produced recommendations for addressing and harmonizing issues related to infection control, monitoring, sharing of scientific information, consent, and human rights. Both the WHO and the Organization for Economic Co-operation and Development (OECD) have recommended that member states develop regulatory frameworks for xenotransplantation clinical trials, and they have taken leadership roles that encourage international collaborative efforts to minimize infectious risks and actively discourage expatriate xenotransplantation experiments in countries with poor regulatory environments.

Some professional societies were early critics of efforts to bring xenotransplantation clinical trials under special regulatory oversight. In recent years, however, most professional societies have been active advocates for clinical trials under regulatory oversight with stringent husbandry and infection surveillance standards. Many professionals working in xenotransplantation are concerned about "xenotourism" (the migration of patients across geopolitical boundaries to obtain unregulated xenotransplantation "therapies"). These patients may undergo risky procedures without adequate understanding, and they may bring unrecognized infections back to their home communities. Further, professionals who conduct expatriate xenotransplantation clinical trials potentially endanger the ability of the field to move forward in a systematic way. In an effort to discourage such practices, the International Xenotransplantation Society has adopted a rule that reports of such experiments will not be accepted for presentation at its meetings or for publication in its journals.

MANAGING POTENTIAL CONFLICTS OF INTEREST. The increasing participation of private interests in biomedical

research is an important trend. One of the key catalysts of this change in the United States was the passage in 1980 of the Bayh-Dole act, which transferred intellectual property rights to researchers funded by federal research monies. In addition, universities in many countries must now attract more private funding to function in a very competitive environment. As a result, companies and investigators with potential conflicts of interest (COI) are testing increasingly powerful experimental therapeutic interventions.

Identifying ways to deal with potential COI while introducing innovative therapies is a complex issue and a constant source of ethical tension. Many would argue that full disclosure of financial and other COI by both institutions and investigators is adequate to manage such COI. Others have argued that disclosure alone may not suffice, and that even a pilot trial should not be conducted if an institution has a major financial interest in the outcome (Emanuel and Steiner). The Institute of Medicine has observed that "Clinical trials with cellular xenotransplants are already under way, and a real danger exists that the commercial applications of xenotransplant technology will outstrip both the research base and the national capacity to address special issues raised by xenotransplantation, including the risk of disease transmission" (Executive Summary, p. 4).

TIMING OF CLINICAL INTRODUCTION OF XENOTRANSPLANTATION OF WHOLE ORGANS. Although small-scale experimental clinical xenotransplantation of cells and xenotransplantation involving *ex vivo* contact of human living cells with living nonhuman animal cells is underway in some countries, the question of when it would be prudent to translate laboratory successes into clinical trials remains open. The accepted standard is that before clinical trials are attempted in humans, preclinical research should provide proof of the principle hypothesis adequate to anticipate that humans may benefit from the experiment. lec. However, no consensus has been reached on what would constitute adequate graft survival in animal experiments to justify clinical trials. Attempts to define this crucial criterion have ranged from a median survival time of a minimum of three months to the suggestion that, although it is likely that hyperacute rejection can be prevented, xenotransplants should be delayed until there is a better understanding of acute vascular and cellular responses (Cooper et al.).

EPIDEMIOLOGICAL SURVEILLANCE AND POST-TRANSPLANT PATIENT MONITORING. In the past, infections transferred across species boundaries (e.g. HIV-AIDS, parvoviruses, SARS coronavirus) have spread globally. The development of international surveillance for xenotransplantation-associated infections has been proposed as a way to assist countries to manage risks associated with infections introduced through xenotransplantation performed within and beyond their borders (Rhonchi). Such recommendations raise concerns for many people. The concept of lifelong international surveillance of xenotransplant recipients is fraught with ethical complexities. International consensus has not been achieved on the definition of xenotransplantation, on what constitutes a xenogeneic infection or disease, on what events should be reported and by what methods, or on which individuals should constitute the population under surveillance. Whether a surveillance system should only report transmission of xenogeneic infections from recipients to their contacts, or should go further to collect information on the contacts themselves, is a source of controversy. All proposed national policies for monitoring xenotransplantation recipients are intrusive. Most advise against unprotected sex, donation of blood or other biological materials, and for education of intimate contacts. Some go further to require the consent of intimate partners for xenotransplantation, active surveillance of intimate contacts as well as xenotransplant recipients, and pre-transplantation agreements to avoid procreation post-xenotransplantation.

PATIENT-PHYSICIAN RELATIONSHIPS AND CONSENT. The perceived potential for xenotransplantation to benefit an individual while putting the larger community at risk complicates both the patient-physician relationship and the issue of informed consent. The Helsinki Declaration on Ethical Principles for Medical Research Involving Human Subjects states that, in medical research on human subjects, considerations related to the well-being of the human subject should take precedence over the interests of science and society. Xenotransplantation clinical trials present situations that may place the interests of recipients and the greater good of society at odds. If a doctor is required to think of the public interest rather than merely the interests of the immediate patient, the traditional role of the physician as patient advocate is altered. At best, this will create confusion, since the physicians must weigh the responsibility to individual patients against the public good. At worst, the doctor-patient relationship itself could become one of antagonism rather than of trust (Daar, 1997).

The current informed-consent requirements for patients who might receive xenotransplants exceed those required in most other research settings. A major question on which there is no consensus at present is the problem of what to do if a patient changes her or his mind about intrusive follow-up monitoring and the waiver or curtailment of confidentiality rights previously agreed to. Informed consent is not usually legally binding on the patient, who retains

a right to withdraw participation at any point in the investigational process.

Given the expectations of lifelong follow-up for initial xenotransplant recipients, a different kind of consent has been discussed (Daar 1999). A specific legal contract might provide enforceability of pre-transplant agreements for lifelong monitoring. Unlike the traditional consent form, such a contract would allow specific curtailment of the patient's rights (the traditional consent procedure does not, in all cases, require that a document be signed; more often than not, the signed form protects the doctor more than the patient). Such a legal contract would be a radical departure from current accepted norms, since it would directly conflict with the present emphasis on the primacy of respect for the autonomy of the research subject. Thus, these issues are fraught with controversy.

MODELS TO BUILD ON. Are there any precedents in which a patient can decide in advance what medical treatment she or he would want to receive in the future? Both "advance directives" and the so-called "Ulysses contract" fall into this category.

Advance directives are used in medicine as a means by which patients declare their wishes in anticipation of a future day when they may not be competent to make decisions. Such an instrument has been used, for example, to establish the point at which a patient desires a "do not resuscitate" status. It could be adapted to allow a mentally competent xenotransplantation recipient to make provision for intrusive post-transplant medical monitoring (with its attendant curtailment of certain rights), to continue if the recipient changes her or his mind-a situation that might occur, if, for example, the graft fails but monitoring must continue in order to protect public health.

This would be more akin to a "Ulysses contract." In Greek, mythology Ulysses was a strong, good man. He knew he would sail near the Sirens, whose enchanting songs would overcome him and cause his ship to be destroyed. He ordered his sailors to plug their ears, and, wanting to hear the songs, had himself tied to the mast of the ship, ordering his companions not to release him regardless of his subsequent demands. A Ulysses contract, then, is used for patients who are likely to experience periods of incompetence in the future, such as patients with psychiatric disorders characterized by alternating periods of therapy-induced competence and incompetence. While they are in a competent state, they can specify treatment decisions for future occasions. In the xenotransplant setting, such a binding advance directive signed by the recipient prior to the xenotransplantation could, theoretically, be used to forcibly investigate, treat, or even confine a recipient who fails to meet responsibilities to the public agreed to prior to the procedure (Daar 1999). A Ulysses contract usually assumes that the subject is so affected as to have their *true* judgment subordinated by some other pressure, while in this instance the xenotransplantation recipient may merely have changed her or his mind about cooperating with intrusive surveillance. Discussion of these options has raised concerns about the possibility of unacceptably eroding the human rights of research participants on the basis of hypothesis and fear rather than established or proximate risk.

PUBLIC ENGAGEMENT AND PUBLIC CONSENT. Some people have argued that since the public is going to be exposed to some level of risk of xenogeneic infections, the public must be consulted, and must consent, before xenotransplantation clinical trials proceed. Many national reports recommend that the public must in some way be consulted before proceeding with xenotransplantation. It is, however, difficult to define what would constitute *public consent.* Further, efforts at public education can easily merge over into propaganda, since the opinions formed by non-experts are completely dependent on the nature and presentation of the information they receive.

While some have advocated a moratorium pending public consent (Bach et al.) there are significant problems with adopting a moratorium. The majority of researchers and clinicians appear to be opposed to this position, mainly because moratoria remove from public discourse the very issues that ought to be addressed. Most researchers and clinicians would encourage increased capacity to evaluate the potential social consequences as the technology develops. Significantly, there have been no serious calls for reduction in xenotransplantation research.

Canada has undertaken a major public engagement exercise consisting of a series of forums involving education, discussion, and *citizen juries.* A subsequent report of the Canadian Public Health Association has recommended that Canada not proceed with xenotransplantation involving humans until several critical issues are addressed. It recommends, among other steps, that further efforts be made to inform and educate the public; that additional preclinical research be carried out; and that the risks and probability of benefit from clinical trials be more fully defined. It also calls for the development of legislation and regulations to cover all aspects of xenotransplantation clinical trials, concluding that there is a continuing need to involve the public in discussions about the future of xenotransplantation. This approach, however, has been criticized as being vulnerable to biases introduced by the information presented to the public (Wright). Nevertheless, this particular exercise reflects the current uncertainties surrounding xenotransplantation.

Conclusion

Xenotransplantation currently describes a multifaceted array of experimental biotechnological approaches to disease amelioration, some of which have progressed to small-scale clinical trials. The theoretical risk of infections spreading from source animal to recipient and then to contacts and the public has triggered debates on issues of science and on how biomedical technology should be developed, regulated and implemented. The specific ethical dilemmas discussed in the context of xenotransplantation reflect areas of ethical conflict and uncertainty relevant to other aspects of community life. These include the rights of the minority in the face of concern by the majority; conflicting values around decision making in the face of uncertain collective risk; the relative rights of humans and nonhuman animals; the relative value of safety versus of hope for progress; and the rights of, and appropriate protections afforded to, human subjects of research.

NATURE AND ROLE OF CODES AND OTHER ETHICS DIRECTIVES

• • •

The earliest extant documents regulating the practice of medicine are records of Egyptian laws from the sixteenth century B.C.E. and the Babylonian Code of Hammurabi, dated about 2000 B.C.E. These legal documents included guidance on what fees could be charged, what constituted competent medical care, the conditions under which a physician could be held accountable for malpractice, and what sanctions would apply. The first significant statement on medical *morality,* however, is the Hippocratic Oath (fourth century B.C.E.). Although the Oath's historical role has been critiqued by scholars such as Robert Baker, the Oath continues to play an important symbolic role in Western medical ethics.

With the notable exception of religious precepts being brought to bear on the conduct of physicians, most medical ethics documents written prior to World War II were professionally generated, that is, they were developed by physicians for physicians. Since the mid-1900s, however, a complex set of factors has challenged the professional authority of the medical profession.

The atrocities committed by Nazi physician–researchers, which led to the Nuremberg Code (Germany, 1949), and infamous cases of abuse of research subjects in the United States, such as the Tuskegee syphilis study, began to undermine trust in the profession. The various rights movements of the 1960s and 1970s and the anti-Vietnam War movement emphasized individual liberty and contributed to a general willingness to challenge authoritative traditions. At the same time, the dramatic increase in scientific knowledge and the development and use of medical technology powerfully increased the ability of health-care professionals to affect the course of people's lives and deaths. These factors, among others, contributed to an increased emphasis on respect for the autonomy and self-determination of individuals seeking health care.

With these changes came a proliferation of bioethics documents pertaining to research on human subjects, to health professionals other than physicians, and to health-care institutions. Furthermore, growing concerns over the alleged mistreatment of research animals and claims that the use of animals for any research purpose is immoral, coupled with concerns for the protection of the environment, resulted in bioethics directives that extend well beyond human medical practice. Concurrent with the increased diversity in the focus of bioethics documents, the authorship of such documents has diversified as well. Professional organizations no longer monopolize the formulation of directives governing professional behavior; religious organizations, institutions, and government agencies, for example, also set moral or legal standards for clinicians and researchers.

The resulting array of bioethics documents may be divided into three fundamental types: (1) professionally generated documents that govern behavior within the profession; (2) documents that set standards of behavior for professionals but are generated outside the profession; and (3) documents that specify values and standards of behavior for persons who are not members of a profession.

Documents Generated by and for a Profession

Although controversy exists over precisely what constitutes a profession, professions may be distinguished from occupations on several grounds (see, e.g., Barber, 1963; Greenwood, 1982; Kultgen, 1988). Professions involve a specialized body of knowledge and skill that requires lengthy education and training to acquire and provides a service to clients and to society. Once a field has achieved professional status, a trained practitioner is considered a professional regardless of employment status. Another characteristic of professions is their claim to be autonomous and self-regulating; however, with the freedom and power of self-regulation comes a concurrent obligation to establish and enforce standards of ethical behavior. Indeed, some have argued that the existence of a professional ethic is the hallmark of a profession (see, e.g., Barber, 1963; Newton, 1988; Campbell, 1982).

Professionally generated ethics documents may take the form of prayers, oaths, or codes. Prayers, such as that once attributed to the Jewish physician-philosopher Moses Maimonides, express gratitude to a deity and ask for divine assistance in developing one's skills and meeting one's responsibilities. Oaths are vows taken by individuals entering a profession to uphold specified obligations. They were frequently employed in ancient times; more recent examples

include the Declaration of Geneva (World Medical Association, 1983, 1994) and the Solemn Oath of a Physician of Russia (1993), among others. In contrast to the personal, interactive nature of prayers and oaths, codes, which are often accompanied by more detailed "interpretive statements," are collective summaries of the moral ideals and conduct that are expected of the professional.

ROLES OF PROFESSIONAL ETHICS DIRECTIVES. The importance to an emerging profession of producing its own ethics directives indicates a primary role of such documents. They help to define and legitimate a profession as well as to maintain, promote, and protect its prestige. Simultaneously, the documents function as a promise to society that the profession will maintain specified standards of practice in return for the power and autonomy that society is being asked to grant the profession.

Protection of the unity, integrity, and power of the profession, which appears to be a primary goal of the rules of etiquette governing the relationship between professionals, is a "quasi-moral" role of professional ethics documents. Although maintenance of a profession has a limited moral component in that its existence promotes the well-being of society, it especially serves the interests of those within the profession who stand to lose the monopoly on their practice should society lose faith in them. In contrast, the explicitly moral role of professional ethics documents lies in the articulation of both ideal and minimal standards of character and conduct for the professional. Both the moral and some of the "quasi-moral" guidelines form the content of the profession's promise to society and serve as a guide for determining when sanctions should be brought to bear against a member of the profession.

THE NATURE OF PROFESSIONAL CODES. In professionally generated codes, the same guideline may simultaneously help to fulfill both categories of function.

"Quasi-moral" guidelines. In addition to having an ethic, professions are characterized by the possession and practice of a specialized body of knowledge. Consequently, frequently articulated requirements include: competency to practice; restriction of professional status to those who have undergone specific educational and training programs; keeping one's knowledge current; and working to advance the existing knowledge in one's field through research (see, e.g., American Nurses' Association, 1985; Canadian Nurses Association, 1991; American Dental Association, 1994; American Psychological Association, 1992; and American Chiropractic Association, 1992).

Such requirements serve a dual purpose—to maintain the profession and to serve society's well-being. By maintaining a specialized body of knowledge, the profession ensures a monopoly in providing its services. At the same time, restricting the practice of a profession to those who are qualified and requiring that they keep their skills and knowledge current are essential elements in fulfilling society's mandate to the profession: to provide a specialized service competently and safely.

Rules of professional etiquette, such as prohibitions on criticizing colleagues in the presence of clients, the proper procedures for consultation, and the process for the adjudication of disputes, constitute another characteristic of professional ethics documents. Thomas Percival's *Medical Ethics* (1803), originally commissioned to address conflicts among physicians, surgeons, and apothecaries at Manchester Infirmary, epitomizes this characteristic. Like the competency requirements, rules governing intraprofessional behavior serve the dual purpose of maintaining the profession and serving the well-being of society. Regarding the former, public criticism of colleagues could, as Percival noted, undermine the credibility of the professional and might ultimately damage the reputation of the profession. Professionally generated documents require that questions one practitioner has about another's competence or conduct be brought to the attention of the appropriate authorities, but none to my knowledge explicitly states that the client be advised of the concern. The presumption seems to be that this arrangement, at least in most cases, will protect the client from incompetent practice at the same time as it safeguards the reputation of the professional.

In addition, rules that foster harmony between members of a profession presumably promote not only the self-interest of the profession(als) but also the well-being of society. Rules of etiquette help to maintain the unity of the profession and promote teamwork, two factors that are widely perceived to optimize the quality of patient care (see, e.g., American Chiropractic Association, 1992).
