To determine if particles can be transported to biofilms, mixed population drinking water biofilm reactors were challenged with slug dose inoculations of carbon particles in the size range of either 1.2 to 8μm or 1.2 to 50μm in diameter. The retention of the carbon fines in the biofilms over time in the presence and absence of disinfection was followed using microscopy techniques. A low percentage (20%) of the small fines initially attached to the biofilm. In contrast, nearly 70% of the larger fines were retained, resulting in a 10-fold increase in carbon mass in the biofilm over that seen with the smaller carbon fines. The larger fines were retained more effectively in the biofilm, but a reduction of nearly 80% of the particles was observed over the three-week experiment. In addition to specific information on the carbon fines, general observations on the response of biofilms to monochloramine (1 mg/L influent concentration) and free chlorine (0.5 mg/L influent concentration) were obtained. Although it took considerably longer, monochloramine ultimately decreased the number of culturable biofilm cells to essentially the same level as free chlorine. The reduction of culturability by approximately three logs was not reflected in loss of viability as assessed by staining techniques; this decrease was only one log. Neither disinfectant caused significant loss nor detachment of biofilm cells from the surface as documented by total cell counts. As determined using activity stains, the biofilm organisms in proximity of the carbon particles did not exhibit reduced susceptibility to the disinfectants, nor was there an accumulation of bacteria around the fines. These results suggest that large particles can be retained in biofilms, but that their effect on the biofilm ecology may be limited (88).

These studies were then extended to investigate the potential for previously colonized carbon particles to act as a mechanism for transporting bacteria to an established biofilm. The larger fines were incubated in the presence of *K. pneumoniae* and then added as a slug dose to biofilm reactor systems. The coliform was monitored in the biofilm using a monoclonal antibody and epifluorescence microscopy. The particles did transport the bacteria to the biofilm surface, resulting in colonization. Over the three-week period, the coliform did not appear to replicate, nor were there cells detected in areas other than the proximity of the carbon particles. If free chlorine was added, there was preferential removal of the coliforms and carbon fines over that of the general heterotrophic population, but 10% of the initially introduced organisms and 20% of the carbon fines remained in the biofilm. Because the detection method was a monoclonal antibody, there is no information available about the culturability or viability of the remaining target bacteria (89).

These findings answer some of the concerns that utilities have had over the release of colonized filter fines from GAC filters into distribution systems. Even if the fines are colonized and attach to the biofilm in numbers comparable to the numbers of culturable heterotrophs present, there is no apparent long-term impact on the biofilm. Disinfection preferentially removed the carbon particles, and there was no dramatic proliferation of an environmental coliform in the biofilm.

CONCLUSION

With growing demands on water resources and the need to respond to increasingly stringent water quality regulations, the use of GAC and BAC will become more widespread in drinking water treatment. GAC will become colonized with organisms, and this is encouraged when BAC treatment is utilized. For biological treatment, BAC appears to be the support medium of choice in most cases because of higher biomass and greater resiliency

against shocks to the system. Colonization of GAC with indigenous organisms appears to reduce the potential for long-term persistence by pathogenic bacteria, although indicator organisms and opportunistic pathogens may become a component of the ecosystem within the filter. Even though disinfectant-resistant particle-associated bacteria are released from properly operated filters and these particles may associate with distribution system biofilms, typical disinfectant regimes have controlled these potentially deleterious effects. On the basis of the results of research and practical experience, it is apparent that the overall benefits of granular activated carbon filtration and biological filtration far outweigh the concerns that may be expressed about deleterious microbiological impacts on potable water.

GREEN FLUORESCENT PROTEIN (GFP)

ROBERT S. BURLAGE
Oak Ridge National Laboratory
Oak Ridge, Tennessee

A powerful tool of molecular microbiology was created with the description of GFP. First described in its natural

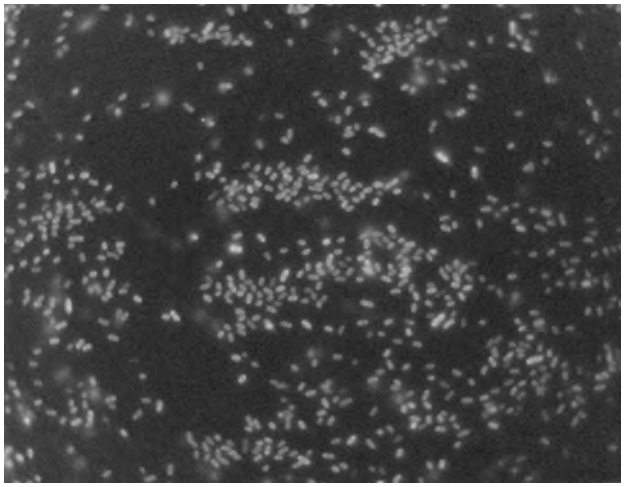

Figure 1. GFP-labeled bacteria as seen under the epifluorescent microscope. Magnification 1000X. Because the bacteria do not need to be fixed before staining, they can be viewed as a wet mount, allowing the observer to see them interact in real time. See color insert.

host, the jellyfish *Aequorea victoria*, this protein emits a bright green fluorescence when excited by ultraviolet light (UV). The utility of this protein for molecular analysis was shown after the gene for GFP was cloned and introduced into other species, both prokaryotic and eukaryotic (Fig. 1). When expressed, the gene faithfully produces GFP, which then folds into the fluorescent configuration and becomes very noticeable. Applications involving the expression of this gene became very popular, and the number of users of this technology is steadily increasing.

Information on GFP is also contained in the encyclopedia entry on BIOREPORTERS: LUCIFERASE AND GFP, and the interested reader is advised to refer to that entry for a detailed analysis of the structure of GFP. This article discusses the science and technology of GFP use, mostly in prokaryotic organisms. This is not an exhaustive analysis, but instead demonstrates the versatility of the system while acknowledging the limitations. Variations of the GFP have also been produced and these are discussed.

GFP and Its Relatives

GFP was studied extensively as a purified protein from the jellyfish before it was used as a marker by Chalfie and coworkers (1). This work opened the door for further experiments in marking cells of all description with the *GFP* gene. All the bioreporter genes discussed in this article are commercially available. Convenient cloning vectors are offered, which enable rapid construction of gene fusions. The leader in this area is acknowledged to be Clontech (*http://www.clontech.com/*), which offers a full range of plasmid vectors for both prokaryotic and eukaryotic work. In addition, some of these genes are available from investigators in transposon vectors that facilitate mutagenesis in many microbial strains (2,3).

By mutagenesis of the GFP some very useful variants have been isolated. These include alternative emission colors (e.g., cyan, yellow) and mutations that are more easily expressed in prokaryotic organisms. A particularly valuable variant of GFP has been described by Andersen and coworkers (4). They attached a short peptide to the carboxy terminus of GFP, which makes it far more labile to proteases than the wild-type version. This allows GFP to be used as a bioreporter of dynamic expression signals, and not merely as a plus or minus response.

The latest bioreporter gene to be introduced is the red fluorescent protein (RFP). The gene for RFP was isolated from *Discosoma*, a type of coral from the Indo-Pacific ocean (5). It has an excitation maximum at 558 nm and an emission maximum at 583 nm, making it a very attractive choice for tracking microorganisms. The red emission wavelength is rarely found in nature, and so the background will almost certainly be negligible. It is anticipated that many researchers will take full advantage of RFP. A description of the fluorescent characteristics (6) and the detection of RFP in a biological system (7) have recently been published.

MOLECULAR CHARACTERIZATION

The *GFP* gene has been sequenced, and descriptions of the protein are available (8,9). The protein is not especially fluorescent until it forms a fluorescent center, defined by three amino acids near the center of the protein. The reaction is shown in Figure 2. After this center is formed, the protein becomes extremely fluorescent, and the ring structure is very difficult to disrupt. The reaction comes about through an autocatalytic reaction, that is, the GFP protein catalyzes its own change. This is very convenient because only a single gene is needed for the synthesis of the bioreporter. Cofactors are not needed for the reaction (another great advantage), however,

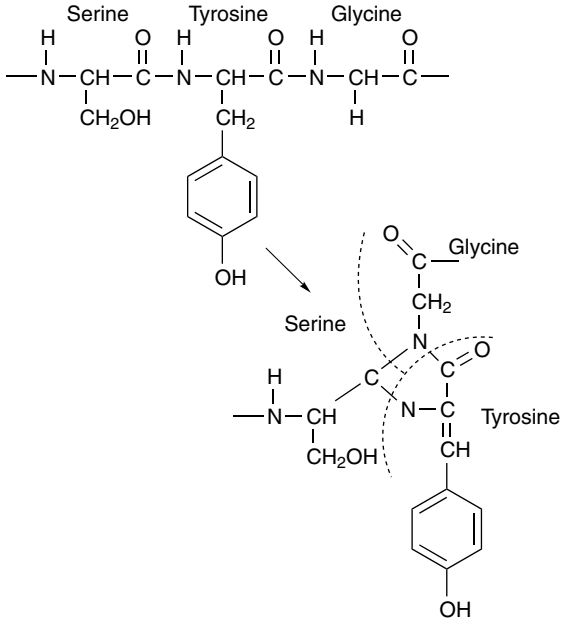

Figure 2. The folding of GFP into a fluorescent chromophore require the three internal amino acids shown.

it does require molecular oxygen, although in small concentrations. This requirement effectively restricts the use of GFP in obligate anaerobic microorganisms.

APPLICATIONS IN ENVIRONMENTAL MICROBIOLOGY

The most obvious use of GFP in bacteria is, as a readily identifiable marker (i.e., a tagant), so that the cells can be located and enumerated. This is true even in mixed culture conditions because the GFP-tagged cells will be easily identified. "Mixed cultures" include virtually every environment outside of controlled laboratory conditions, and therefore the use of GFP has lead to an explosion of research in this area. Before fluorescent biomarkers were available, the cells could be labeled with fluorescent antibodies, or the cells could be enumerated on selective agars, but these methods had substantial problems. With GFP, the cells can be examined under natural conditions and without destruction of sample material.

Fluorescent cells are easiest to see under the microscope. The UV excitation may cause other cells and particles to fluoresce, but they will appear dull in comparison to GFP-tagged cells. The variety of environments in which this technique has been attempted is quite impressive, and demonstrates the utility of fluorescent markers. An excellent review is available (10). A few examples can be cited here:

- Biofilms present unique challenges in examination because they are difficult to analyze in real time. Aspiras and coworkers (11) introduced GFP into *Streptococcus gordonii* to track the cells in a simulated oral biofilm community. This work has obvious implications for the study of the cause of dental caries, which is promoted by complex microbial communities on the surfaces of the teeth. Christensen and coworkers (12) studied gene exchange in environmental biofilms by detecting the passage of a plasmid tagged with the GFP gene. They were able to show that plasmid transfer was a rare event, which is useful information for planning other environmental release experiments.

- Soil communities may have many thousands of species in a single gram of material. Differentiating between your strain of interest and all others is a difficult task. Boon and coworkers (13) studied an activated sludge community containing a GFP-labeled *Comamonas testosteroni* strain. They were able to show survival of the strain over long periods of time. Tresse and coworkers (14) used a GFP-labeled *Moraxella* strain to follow survival in soil while it was catabolizing nitrophenol. Survival of an introduced microorganism is essential if it is to perform a bioremediation task to completion.

- Both freshwater and marine environments contain high concentrations of microorganisms. Enumeration of GFP-labeled *Escherichia coli* cells in a freshwater stream microcosm was performed by Leff and Leff (15). In an experiment analogous to the work mentioned earlier (12), Dahlberg and coworkers (16) examined plasmid transfer between species in a marine environment. They found much higher rates of plasmid transfer, suggesting that conjugation may be far more frequent in marine environments.

The preceding examples rely on constitutive expression of GFP to mark the cells, but it can also be used to detect gene expression in a time-dependent manner. In this regard it's use is closest to the work performed with eukaryotes, in which GFP is used to detect when a particular gene is expressed, for instance, in a developing embryo. This comparison is evident in the work of Kataoka and coworkers (17) in their study of *Streptomyces lividans* colony development. They found a gene that was expressed primarily during colony differentiation, and followed the activity of the gene, both temporally and spatially as the colony developed. Joyner and Lindow (18) isolated a gene that encodes a membrane receptor for a siderophore and fused it to the *GFP* gene. This creates a sensitive sensor for ferric iron in the environment, which they used to evaluate iron bioavailability on plant tissues. Hansen and Sorensen (19) produced a sensitive bioreporter of mercury by fusing the promoter of the *mer* operon to GFP. This proved to be as sensitive as comparable bioreporter constructs, utilizing the bioluminescent *lux* genes. The wild-type version of GFP was largely unsuitable for such assays because the GFP protein is so unusually stable. The protein persists for hours to days inside most bacterial cells, and therefore dynamic responses of genes over time cannot be studied. However, the new unstable versions of GFP described by Andersen and coworkers (4) have opened up this possibility.

An unusual use of GFP was described by Fischer and coworkers (20). They isolated a strain of *Pseudomonas* that responded to the explosive trinitrotoluene (TNT), and fused the TNT-responsive gene to GFP. When applied in the field, the bacteria responded to trace amounts of TNT and began to fluoresce. By finding the fluorescent bacteria one can find the source of the explosive, such as a landmine or other ordnance. To obtain clear images in the field, a laser-induced fluorescence imager (LIFI) system was employed. A computer-enhanced scan of one of these images is shown in Figure 3. During the field test, the bacteria pooled on the vegetation at the site, which was possible because of the waxy layer found on the blades of grass. TNT conducted through the plants then triggered the *GFP* gene and a concentrated signal was seen. In the figure, the strongest fluorescent image is seen in the middle of the blades of grass, which are easily discernible against the nonfluorescent background. This result demonstrated that vegetation was no impediment to the field application of the GFP-based technique, but was in fact, enhanced by it. In this figure, the actual location of the TNT was about 0.5 m from the brightest fluorescent spot, suggesting that root trails conduct the TNT efficiently.

One of the most popular uses of GFP is in the study of plant–microbe interactions, particularly with respect to the root zone of plants. It has long been recognized that microbial activity around the roots is important in the health of the plant, but the interactions are very

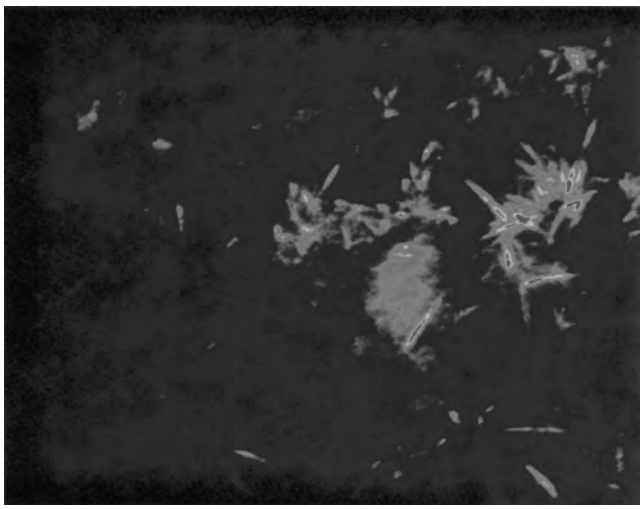

Figure 3. TNT-sensitive bacteria containing GFP were sprayed on a field containing buried landmines. Trace amounts of TNT reach the surface through plants. Shown here are plants (blades of grass) that have been sprayed with the bacteria and which are fluorescing because of GFP. A false color image shows red as being the most intense fluorescence and blue as the least intensity. Length of the figure is approximately one meter. See color insert.

difficult to examine because of the complex and dynamic nature of the microbial communities, the effects of soil particles, the presence of plant exudates, and other factors (hydrology, mineralogy, and temperature). Observing the survival and activity of cells in situ is a big improvement over the previous method of enumeration by plate counting of strains that had been given an antibiotic resistance marker.

Three recent reports have described the interaction of *Pseudomonas* species in the rhizosphere of barley (21–23). Typically, these experiments involved the use of fluorescence microscopy to visualize the bacteria on the root zone, and confocal laser scanning microscopy to visualize the three-dimensional structure of the bacteria on the developing roots. To investigate a plant–microbe symbiotic relationship, Gage and coworkers (24) used a GFP-labeled *Rhizobium* strain and watched the progress of infection threads in the rhizosphere.

FUTURE DEVELOPMENTS

The examples cited earlier show the range of projects that can be aided by employing GFP. Fluorescent proteins are both valuable and versatile, however, there are certain critical areas where improvements could be made. New colors (emission spectra) have been the trend in recent years. With the addition of useful bioreporter genes in cyan, blue, green, yellow, and red, all on convenient cloning vectors, the number of possibilities increase. However, it should also be stressed that changes in the excitation spectrum of a bioreporter are just as useful. This was the basis for the first successful alternative GFP molecule, the red-shifted GFP (RS-GFP) (25). In this molecule, the emission maximum was nearly unchanged from the wild-type molecule, but the excitation maximum was shifted to a higher wavelength ("red-shifted"). In addition, it may be possible to identify molecules that fluoresce outside of the visible spectrum, especially in the infrared region.

An area of special concern is the development of bioreporters for obligate anaerobic microorganisms. The fluorescent proteins require small amounts of oxygen to form their chromophore, and therefore completely anaerobic conditions are incompatible with bioreporter function. A fluorescent molecule that is independent of oxygen is therefore highly desirable.

This article will focus on the moderately and extremely halophilic microorganisms isolated from "extreme environments "as defined by Horikoshi and Grant: "those in which a restricted range of organisms can grow; the majority of organisms are excluded" (1). Typical niches for halophilic microorganisms are hypersaline environments such as salt lakes (e.g., the Dead Sea, the Great Salt Lake, alkaline soda lakes), salterns distributed all over the world, etc. (2). Despite what may seem like rather hostile conditions, salt lakes can be highly productive ecosystems. Archaeal and bacterial halophiles are not the only microorganisms found. Eukaryal algae are the major phototrophs in most salt lakes. Moderately halophilic microorganisms were also isolated from seawater and estuarine environments. Anaerobic halophiles, including extremely halophilic methanogenic Archaea, have been isolated from hypersaline environments, but they are not dealt with in this article.

DEFINITION OF HALOPHILIC MICROORGANISMS

Kushner (3) and Kushner and Kamekura (4) defined various categories of halophiles, halophilic (salt-loving) microorganisms. Slight halophiles grow best in media containing 0.2 to 0.5 M NaCl (1.2 to 2.9%, w/v), moderate halophiles are defined as microorganisms growing optimally in the presence of 0.5 to 2.5 M NaCl (2.9 to 14.6%), and extreme halophiles grow best in media containing 2.5 to 5.2 M (saturated) NaCl.

On the other hand, halotolerant microorganisms grow best in media without added salt as well as in the presence of relatively high concentrations of NaCl (e.g., 1 M). Extremely halotolerant microorganisms extend their growth range to more than 2.5 M NaCl. It should be pointed out that the salt requirements of halophiles depend on the growth conditions such as temperature, concentrations of other minor salts, particularly magnesium ions, presence of growth factors, and so forth. Furthermore, some halophiles are able to grow in the presence of high concentrations of salts other than NaCl, such as $MgCl_2$, KCl, RbCl, or CsCl (4).

Living organisms are classified into three domains: Bacteria (Eubacteria), Archaea (Archaebacteria), and Eukarya (Eukaryotes) (5,6). Most of the moderate halophiles belong to bacteria, whereas most of the extreme halophiles are members of the domain Archaea. Sometimes the term *extreme halophiles* is used as a synonym of the group of members of the family Halobacteriaceae of the domain Archaea, but strictly speaking, this is not correct. Some of the members of Halobacteriaceae are moderate halophiles, and there are a few extremely halophilic bacteria.

"Approved Lists of Bacterial Names" published in 1980 (7) included a few species of extreme halophiles: *Halobacterium cutirubrum*, *Halobacterium halobium*, *Halococcus morrhuae*, etc. isolated from the Dead Sea, solar salts, salted codfish, or hides. Also included were a few species of moderate halophiles, *Flavobacterium halmophilum* (now *Halomonas halmophila*), *Micrococcus halobius* (now *Nesterenkonia halobia*), *Paracoccus halodenitrificans* (now *Halomonas halodenitrificans*), *Planococcus halophilus* (now *Marinococcus halophilus*), *Pseudomonas beijerinckii*, *Vibrio costicola* (now *Salinivibrio costicola*), etc. Besides these strains, there are some isolates that have been used for physiological and biochemical studies (8).

During the last two decades, numerous halophiles have been isolated from extreme environments. Because they were assigned to many taxa mainly according to their phenotypic characteristics, their taxonomy was in a flux. The situation has been solved gradually by

chemotaxonomic methods as well as by phylogenetic analyses of their 16S rRNA gene sequences, and generic and specific names of some isolates have been altered recently. In this article, the updated situation of the halophiles will be presented.

HYPERSALINE ENVIRONMENTS

Most of the hypersaline habitats such as the Dead Sea, soda lakes, and many solar salterns are located in hot and dry areas in the world (2). Individual salt lakes vary considerably in their ionic compositions because the nature of surrounding rocks, geology, and general climatic conditions determine the predominant ions (9). In addition to these environments exposed to the surface of the earth, there are subterranean hypersaline environments, some of which are accessible as rock salt mines or alternatively as materials indirectly accessible through solution mining. These environments once presumed to be devoid of any living organisms are in fact habitats of a variety of microorganisms. Heavily salted cod or hide for preservation and food for which high concentrations of salts are used during preparation, for example, fish sauce or soy sauce, are also hypersaline environments.

In the following sections, halophilic microorganisms are dealt with in the order of halophilic Archaea, halophilic bacteria, and halophilic Eukarya.

HALOPHILIC ARCHAEA

Isolation of Halobacteria

Members of aerobic halophilic archaea are classified within the single family Halobacteriaceae in the order Halobacteriales (10). They are also known by the trivial names *halobacteria* and *haloarchaea*. Most of the halobacteria are pigmented pink to red because of the presence of carotenoid pigments. Microorganisms of the domain Archaea are known to lack murein, the peptidoglycan polymer consisting of N-acetylmuramic acid and N-acetylglucosamine, and are thus insensitive to beta-lactam antibiotics such as penicillins. Cytoplasmic membranes of noncoccoid species of halophilic Archaea are surrounded by S-layers of glycoproteins, whereas coccoid species (genus *Halococcus* and *Natronococcus*, discussed later) possess rigid cell wall made of polymers of heteropolysaccharides (11). Most of the strains grow best at concentrations of 3.5 to 4.5 M NaCl. To compensate for the high salt concentrations in the environments, the organisms accumulate mainly KCl, up to 5 M.

The cell envelopes of the coccoid halobacteria are stable in the absence of salts. Those of noncoccoid isolates maintain their integrity only in the presence of high concentrations of NaCl or KCl. Upon gradual dilution of the culture with water, the cells change their shape, through irregular forms, to spheres that finally undergo lysis. A similar phenomenon may happen in the natural hypersaline environments on heavy rainfall.

Historically, studies on the extreme halophiles were initiated to isolate microbes that caused spoilage of salted fish, meat, or hides (12). Thus, most of the media for extreme halophiles are based on hydrolyzates of proteinaceous materials, such as casamino acids, tryptone, yeast extract, etc. Maximum recovery rates of halophilic Archaea were reported to be obtained on media containing natural brines and a whole-cell extract of *Hbt. cutirubrum* (13).

Bacto-Peptone from Difco should not be used in the cultivation of extreme halophiles because it contains high concentrations of bile acids that cause lysis of cells. Analyses of various peptones showed that the Bacto-Peptone contains 2.9 mg/g glycocholic acid and 3.7 mg/g taurocholic acid, glycine and taurine conjugate of cholic acid, respectively as the major bile acids. Lysis in 25% NaCl solution containing 1% Bacto-Peptone is specific for noncoccoid halobacteria. No lysis was observed with *Halococcus* and *Natronococcus* cells, methanogenic archaea, or halophilic eubacteria. Peptone Bacteriological Technical from Difco and Oxoid Bacteriological Peptone are recommended for use in media because they contain practically no cholic acid (14). In some of the past ecological studies of saline environments, Bacto-Peptone was used as a component of media, thus, probably having caused underestimation of halobacterial community.

Salts required to be added are high concentrations of NaCl, depending on the strains to be isolated (see description of each genus), enough amounts of KCl (e.g., 0.2%), and relatively high concentrations of magnesium as $MgSO_4$ or $MgCl_2$. To isolate alkaliphilic haloarchaea, sodium bicarbonate is added or pH is adjusted from 9 to 11 by adding NaOH, and the magnesium concentration is reduced to less than 0.1%; otherwise, precipitates of magnesium hydroxide disturb the clarity of media. The pH is adjusted from 5.0 to 5.5 to isolate strains that are able to grow at acidic condition. In order to isolate strains of halophilic Archaea from environments in which the halophilic bacteria are dominant, penicillin G is added to the media to inhibit growth of contaminant bacterial halophiles.

Media, liquid or agar plates, to which samples were inoculated, are incubated at temperatures depending on the microorganisms to be isolated. All halophiles known so far are able to grow at 30 to 37 °C, but a few strains are able to grow at low and high temperatures; *Halorubrum lacusprofundi* grows well at 4 °C, while *Haloterrigena thermotolerans* is able to grow up to 60 °C. When cultivated on agar plates, Petri dishes should be sealed by vinyl tape or placed in a plastic container to prevent drying of the agar surface. Some strains show very slow growth on agar plates compared with that in liquid media.

Members of the 15 Genera of Halobacteria

The family Halobacteriaceae contains 15 valid genera. Readers are recommended to consult chapters on halobacteria, Vol. 1 of the 2nd edition of the Bergey's Manual of Systematic Bacteriology (15), for the relevant references. In this article, the generic names will be abbreviated according to the recent proposal (16).

Halobacterium. *Halobacterium* is the type genus of the family Halobacteriaceae. *Halobacterium salinarum* is the only species of this genus, with strain NRC 34002 as the

type strain. *Halobacterium cutirubrum* and *Hbt. halobium* are now included in *Hbt. salinarum* as belonging to the same species (17). *Halobacterium salinarum* contains two major membrane glycolipids, sulfated triglycosyl diether-1 and sulfated tetraglycosyl diether, structures of which are depicted in reviews (18,19). These two glycolipids are signatures of the strains of this genus because they have not been detected in any members of other genera. Strains of *Hbt. salinarum* require at least 3 M NaCl. Most strains grow best at 3.5 to 4.5 M and growth occurs even at saturated NaCl. Thus, they are extremely halophilic sensu stricto. They also require relatively high Mg^{2+} concentration (0.05 to 0.1 M) and a pH range of 5.5 to 8.0. Optimum temperature is 50 °C. Many strains are pigmented a deep red. They require several amino acids for growth. Strains of *Hbt. salinarum* were isolated from such environments as the Dead Sea, solar salts, salted codfish, or hides. However, analysis of natural communities of halophilic Archaea, such that occur in hypersaline lakes, has shown that *Halobacterium* is not dominant and is outnumbered by members of other genera. This was shown by characterization of strains isolated as colonies on agar plates (20), by analysis of glycolipids extracted directly from the communities (21,22), and by analysis of sequences of cloned 16S rDNA amplified from DNA extracted from the communities (23).

A procedure for the specific enrichment and isolation of strains of the genus *Halobacterium* was designed on the basis of their ability to grow anaerobically by fermentation of L-arginine (24). Anaerobic enrichment cultures were set up by inoculating 10-mL portions of brine in 150-mL screw-capped glass bottles completely filled with growth media with added 5 g/L L-arginine, and inoculating the bottles in dark. After 7 to 10 days incubation at 35 to 38 °C, a growth of motile long, rod-shaped cells was detected. Thin layer chromatography of glycolipids of the cultured cells showed that they all are members of the genus *Halobacterium*; they had the two characteristic glycolipids.

Haloarcula. Seven species of this genus have been isolated from various hypersaline environments. They are listed in the following text with their optimum NaCl concentrations for growth in parentheses. *Haloarcula vallismortis* (formerly *Halobacterium vallismortis*) (4.3 M) from salt pools of the Death Valley, California; *Har. argentinensis* (2.5 to 3.0 M) and *Har. mukohataei* (3.0 to 3.5 M) isolated from saltern soil in Argentina; *Har. hispanica* (3.5 to 4.2 M) from marine salterns in Spain; *Har. japonica* (3.5 M) isolated from saltern soil in Japan; *Har. marismortui* (3.4 to 3.9 M) from the Dead Sea; and *Har. quadrata* (3.4 to 4.3 M) isolated from a brine pool in the Sinai Peninsula, Egypt. The following unvalidated strains have also been known but they are not well characterized. *Haloarcula sinaiiensis* (2.5 to 3.5 M) from a Red Sea sabkha (discussed later); "*Har. californiae*" (3 to 4 M) isolated from a Californian saltern; and "*Har. aidinensis*" (3.4 M) isolated from Aidin salt lake in China. Thus, all members of this genus are extremely halophilic. Minimal Mg^{2+} requirement for growth is 0.005 to 0.05 M. They do not require amino acids for growth.

The major membrane glycolipid of these species is triglycosyl diether-2, except for *Har. mukohataei*, which has the sulfated diglycosyl diether-1. Details on the difference of this species from other members of *Haloarcula* were discussed elsewhere (25).

Strictly square-shaped, gas-vacuolated, flat halophilic Archaea were first found in the Gavish Sabkha, a coastal brine pool in the Sinai Peninsula, Egypt. Their presence has since been documented in a variety of hypersaline environments, but no pure culture is available. A recent fluorescence in situ hybridization (FISH) has suggested a probable positioning of the Sinai square halophile in the genus *Haloarcula*. A. Oren's group noticed that a saltern crystallizer pond in Eilat, Israel was dominated, more than 55%, by a similar kind of square halobacteria. They analyzed the glycolipids of cells collected from 10 L brine and found they contained the glycolipid sulfated diglycosyl diether-1.

Halobaculum. Enrichment cultures in which Dead Sea water or sediment was used as inocula have yielded three species of extreme halophiles, *Haloferax volcanii* (discussed later), *Har. marismortui*, and *Halorubrum sodomense* (discussed later). A mass bloom of halophilic Archaea developed in the Dead Sea in the summer of 1992. The glycolipid present in the biomass was the sulfated diglycosyl diether-1, suggesting that the dominant organisms were relatives of the genus *Haloferax* (discussed later). One isolate from the biomass, a pleomorphic rod-shaped organism, was further analyzed and named as *Halobaculum gomorrense*. This isolate requires a relatively low level of NaCl for growth; a combination of 1 M NaCl and 0.8 M $MgCl_2$ supported growth. Optimum growth occurs in the presence of 1.5 to 2.5 M NaCl and 0.6 to 1 M $MgCl_2$.

Halococcus. Many strains of *Hcc. morrhuae* have been isolated from sources such as offshore seawater, saline lakes, salterns, salted products etc. *Halococcus saccharolyticus* was isolated from ponds of a Spanish saltern, and *Hcc. salifodinae* was isolated from rock salt obtained from an Austrian salt mine. All strains of the three species require at least 2.5 M NaCl for growth and 3.5 to 4.5 M for the best growth.

The cells of *Halococcus* species do not lyse in distilled water, not even with N-lauroylsarcosine, a detergent that causes complete lysis of noncoccoid halobacteria (26). The *Halococcus* cells are also resistant to repeated freezing and thawing. They have a thick, rigid cell wall of sulfated heteropolysaccharides (10). They contain the sulfated diglycosyl diether-1 as the major membrane glycolipid.

Haloferax. This genus now contains four species. *Haloferax volcanii* was originally isolated from the Dead Sea by enrichment in a complex medium containing 0.2 M Mg^{2+} and 4 M NaCl, but best growth occurs in media containing 1.5 to 2.5 M NaCl; thus, *Hfx. volcanii* is a moderate halophile. *Haloferax denitrificans* isolated from salterns in San Francisco, California, grows in media containing 1.5 to 4.5 M NaCl. *Haloferax gibbonsii* was isolated from a saltern in Spain; best growth occurs in the presence of 3 to 4 M NaCl and 0.2 M Mg^{2+} at 40 °C, but 2 to 3 M NaCl at 30 °C. *Haloferax mediterranei* isolated from a

saltern in Spain grows in the presence of 1 M to saturated NaCl. Optimum temperature is 43 to 54 °C depending on the growth medium. A similar strain "*Hfx. alicantei*" was also isolated from the Spanish saltern. Strain D1227 isolated from soil contaminated with highly saline oil brine near Grand Rapids, Michigan, was also shown to belong to the genus *Haloferax*. Growth occurs over the range of 0.86 to 5.2 M NaCl, and the optimum concentration is 1.7 to 2.6 M. The strain is extraordinary in its ability to use a variety of aromatic compounds (benzoic acid, cinnamic acid, 3-phenylpropionic acid, 3-hydroxybenzoic acid, etc.) as sole carbon and energy sources. All members of this genus contain the sulfated diglycosyl diether-1 as the major membrane glycolipids.

Halogeometricum. Halophilic archaeal strains were isolated from solar salterns of Cabo Rojo, Puerto Rico. Three strains were similar in morphological and physiological properties and lipid compositions, and they were designated as *Halogeometricum borinquense*. The cells are very pleomorphic and motile. They require at least 8% NaCl for growth, with an optimum at 3.5 to 4 M NaCl and 0.04 to 0.08 M Mg^{2+} at 40 °C, pH 7. The structure of major glycolipid of this species is not known.

Halorhabdus. *Halorhabdus utahensis* was recently isolated from a sediment sample collected from the southern arm of the Great Salt Lake, Utah. Growth was possible from 10 to 30% NaCl, with an optimum at 27%, at pH 5.5 to 8.5.

Halorubrum. *Halorubrum saccharovorum* was isolated from a saltern in San Francisco. The cells grow optimally at 3.5 to 4.5 M NaCl. *Halorubrum coriense* isolated from a saltern along Corio Bay near Geelong, Australia, grows optimally at 2.2 to 2.7 M NaCl. *Halorubrum distributum* was isolated from saline soils in Russia. The cells grow best in media containing 2.5 to 4.3 M NaCl. *Halorubrum lacusprofundi* isolated from Deep Lake, Antarctica is exceptional for halobacteria in that the cells are able to grow at as low as 4 °C. The optimum condition is 2.5 to 3.5 M NaCl and 31 to 36 °C. *Halorubrum sodomense* was isolated from the surface water sample of the Dead Sea. The cells grow in media containing between 0.5 M (in the presence of 1.5 to 2 M Mg^{2+}) and 4.3 M NaCl, and optimum growth is achieved at 1.7 to 2.5 M in the presence of 0.6 to 1.2 M Mg^{2+}, a condition close to that for *H. gomorrense* isolated also from the Dead Sea. *Halorubrum trapanicum* was originally isolated from solar salt in Trapani, Sicily. The cells grow from 2.5 to 5.2 M NaCl. Some strains of this species with apparently different morphologies have been circulated for many years, and finally a neotype strain was deposited as NCIMB 13488.

Halorubrum vacuolatum isolated from the alkaline soda lake, Lake Magadi, Kenya, is the only alkaliphilic species in this genus. It grows optimally at 3.5 M NaCl, pH 9.5. No glycolipids have been detected, whereas most other species of the genus *Halorubrum* are characterized by the presence of glycolipid, sulfated diglycosyl diether-3, but an exception has been reported: sulfated diglycosyl diether-5 was found in *Hrr. trapanicum*.

Haloterrigena. *Haloterrigena turkmenica* was proposed to accommodate the following three strains. *Halococcus turkmenicus* isolated from saline soils collected in Turkmen (Turkmenistan) grows optimally in media containing 15 to 25%. NaCl. A strain designated as GSL-11 was isolated from the Great Salt Lake.

Recently, another species *Htg. thermotolerans* was isolated from a solar saltern in Puerto Rico. This is the most thermotolerant extreme halophile known so far. The optimum temperature is 50 °C, and growth is possible up to 60 °C. Optimum NaCl concentration for growth is 3.0 to 3.5 M.

Natrialba. *Natrialba asiatica* was isolated from beach sands with granular salts attached in Japan and *Nab. taiwanensis* was isolated from solar salts produced in Taiwan. *Natrialba asiatica* is able to grow at 2.0 to 5.3 M NaCl, but requirement for NaCl for growth is partially replaceable by KCl. Growth is obtained in a medium containing 1 M NaCl and 1.6 M KCl, but no growth occurs in 2.6 M KCl without added NaCl. Both *Nab. asiatica* and *Nab. taiwanensis* are exceptional in the family Halobacteriaceae in that they are not pigmented. The contents of bacterioruberins were less than 0.1% of that of *Hbt. salinarum*. Cultivation under illumination does not cause pigmentation of cells on agar slopes. They have a glycolipid disulfated diglycosyl diether-1.

Natronobacterium magadii, an alkaliphilic halobacterium isolated from Lake Magadi, Kenya, was transferred to the genus *Natrialba* as *Nab. magadii*. Growth occurs in media containing 2 to 5.2 M NaCl, with an optimum at 3.5 M at pH 9.5. No glycolipid has been detected in *Nab. magadii*, but the *Natrialba* strain SSL1 isolated from the saline and alkaline brine (7.2 g salts/l, pH 9.0) of Sambhar Salt Lake, India has a minor amount of glycolipid diglycosyl diether-4. Recently, a variety of extreme halophiles were isolated from hypersaline ponds in Northern China: "*Natronobacterium chahanensis*", "*Nbt. chahannaoensis*", "*Nbt. innermongoliae*", and "*Nbt. wudunaoensis*." These strains may belong to the genus *Natrialba* as judged from their 16S rRNA gene sequences.

Natrinema. The members of this recently established genus were isolated many years ago from salted hide and salted codfish; thus, they probably originated from solar salts used for the salting. They have long been assigned to several species of the genus *Halobacterium*, but a recent detailed study has established the new genus *Natrinema*, which includes *Natrinema pellirubrum* and *Nnm. pallidum*. These strains grow best in media containing 3.4 to 4.3 M NaCl. The third species *Nnm. versiforme* was isolated recently from Aibi salt lake in China. It also shows optimum growth at 3.4 to 4.3 M NaCl in the presence of 0.15 M $MgCl_2$. All these species have several unidentified glycolipids.

Natronobacterium. The alkaliphilic members of Halobacteriaceae form a distinct physiological group, because they require not only high NaCl concentrations, but also high pH and low Mg^{2+} concentrations for growth. They have been isolated from a variety of alkaline,

hypersaline lakes and soils. Microscopically, the isolates consist of rods and cocci and were accordingly separated into two genera, *Natronobacterium* and *Natronococcus*. The genus *Natronobacterium* used to contain four species as described earlier, but after phylogenetic analyses *Nbt. gregoryi* turned out the only species of this genus. *Natronobacterium gregoryi* was isolated from the solar salt pans at Lake Magadi, Kenya and grows best in media containing 3.5 M NaCl at pH 9.5 to 10.0. The cells lack major amounts of glycolipids in their membranes. Recently, the group of W.D. Grant has isolated a variety of alkaliphilic Archaea from several soda lakes in the Kenyan section of the East African Rift Valley (27,28).

Natronococcus. *Natronococcus occultus* isolated from the solar salt pans at Lake Magadi, Kenya grows optimally at 3.5 to 3.6 M NaCl, pH 9.5. *Natronococcus amylolyticus* isolated from the same lake grows optimally at 2.5 to 3.4 M NaCl, pH 9.0. The cells of these species retain the coccoid form even in distilled water, as do the cells of the strains of genus *Halococcus*.

Natronomonas. Alkaliphilic strains were isolated from highly saline and alkaline lakes of Wadi Natrun, Egypt, located in a desert depression west of the Nile delta. All lakes showed pH values of approximately 11 and a total salt content of generally more than 30%. Main brine components were chloride, carbonate, sulfate, sodium, and a minor amount of potassium. The concentrations of Mg^{2+} and Ca^{2+} were below detection level. An isolate *Natronomonas pharaonis* grows in media containing 2.2 to 5 M NaCl at pH 7.7 to 9.3, with 3.5 M as an optimum.

Natronorubrum. Two alkaliphilic Archaea were isolated from sediment of the Bange Soda Lake (pH 10, 18 °C) in Tibet. They required at least 12% NaCl and pH between 8 and 11 for growth. Optimum NaCl concentrations were 22.5 and 20%, respectively. They were designated as *Natronorubrum bangense* and *Natronorubrum tibetense*.

Physiological Characteristics of Halobacteria

Archaeal halophiles have a number of unique features not found in bacterial and eukaryal halophiles. Some of the features are described later (29).

Bacteriorhodopsins. Many halobacteria have retinal-based pigments capable of the light-mediated translocation of ions across the cell membrane (30). The best known of these is the bacteriorhodopsin (bR). When *Hbt. salinarum* is grown under low oxygen tension and illumination, purple membranes, hexagonal crystalline patches containing bR as the only proteins, are formed in the cell membrane. The bR with one molecule of retinal absorbs light and catalyzes an outwardly directed transfer of protons across the membrane. ATP is generated as the protons pass back into the cell through a membrane-bound ATPase. Some strains of the genera *Haloarcula* and *Halorubrum* are known to produce similar bR proteins.

Other retinal pigments are halorhodopsin (inwardly directed Cl^- pump), sensoryrhodopsin, and phoborhodopsin. The last two are responsible to phototactic responses of halobacteria. Because halobacteria grows perfectly well in the dark, the systems are not essential for their growth, but there is no doubt that the possession of bacteriorhodopsin confers survival value on cells under sunlight exposure in natural hypersaline environments.

Carbon Dioxide Fixation. Cells of halobacteria have been shown to fix carbon oxide. Thus, halobacteria might contribute significantly to the light dependent fixation of carbon dioxide in the hypersaline environments. The primary reactions involved have been suggested to be reductive carboxylation of propionate, glycine synthase reaction, or formation of pyruvate (22). The enzyme was of Calvin cycle, ribulose-1, 5-bisphosphate-carboxylase/oxygenase, was purified from *Hfx. mediterranei* grown heterotrophically, but further extensive studies are required for the elucidation of mechanism of carbon dioxide fixation in nature.

Gas Vesicles. Some halobacterial strains, *Hbt. salinarum* and *Hfx. mediterranei*, produce buoyant, intracellular gas-filled organelles called *gas vacuoles* consisting of aggregates of individual gas vesicles. It is believed that the accumulation of gas vesicles allows the halobacterial cells in natural hypersaline niches to float at the surface, thus increasing the availability of both oxygen for respiration and light for the photophosphorylation using bacteriorhodopsin in the case of *Hbt. salinarum*.

Halocins. Halocins are bacteriocidal proteins produced by halobacteria. Halocin producers make growth inhibition zones around colonies grown on lawns of other halobacterial cells. It is now believed that the production of halocin is a practically universal feature of noncoccoid halobacteria. Well-characterized halocins include Halocin H4 produced by *Hfx. mediterranei* R4, Halocin H6 from *Hfx. gibbonsii*, Halocin Hal R1 produced by a *Halobacterium* sp. GN1, and Halocin S8 produced by an unidentified halobacterium strain S8a isolated from salt crystals from the Great Salt Lake (31). A recent investigation of 12 brine samples obtained from Israel, California, and Spain, however, failed to detect any halocin activities. Thus, the contribution of halocins in the competition between different halobacteria in hypersaline environments might not be so strong (32).

HALOPHILIC BACTERIA

To isolate bacterial halophiles from hypersaline environments, Bacto-peptone may be used as a component of media to inhibit growth of archaeal halophiles, or penicillin may be added. Because it is not possible to cite all of the original references in the following descriptions, only a relevant review (33) and representative papers are cited.

Bacillus and Related Genera

There have been some reports on halophilic strains of *Bacillus*. A strictly aerobic, gram-positive, rod-shaped, spore-forming, moderate halophile was isolated from a piece of rotting wood on the seashore of Nauru Island in

the Central Pacific Ocean. A taxonomic study included the strain into the genus *Bacillus* as *Bacillus halophilus*.

A group of 91 moderately halophilic, gram-positive, rod-shaped strains were isolated by a Spanish research group from enrichments prepared from water samples of the Dead Sea collected 57 years ago by B. Volcani. All strains formed endospores and were motile, strict aerobes. They grow in media containing 5 to 25% (w/v) total salts, (a mixture of salts of the same composition of seawater) and showed optimum growth at 10% salts. Eighteen strains chosen as representatives from physiological and biochemical characterizations were designated as *Bacillus marismortui*.

Strains of another moderately halophilic species *Bacillus salexigens* were isolated from salterns and hypersaline soils located in different geographic areas of Spain.

Two moderate halophiles isolated from hypersaline sediments of the Great Salt Lake were designated as representatives of a new genus *Halobacillus* as *H. litoralis* and *H. trueperi*. This genus now comprises *Halobacillus halophilus*.

Low G + C Cocci

Marinococcus albus is a gram-positive motile moderately halophilic coccus isolated from solar salterns. Strains of the species are nonpigmented, able to grow over a wide range of NaCl concentrations with optimum growth at 1 to 2.5 M NaCl. *Marinococcus halophilus* is also able to grow optimally at 1 to 2.5 M NaCl. The cells are pigmented a yellow-orange and many strains have been isolated from salterns, saline soils, sea sands, or salted mackerel.

Salinicoccus roseus is a pink-red-pigmented moderately halophilic coccus isolated from soils and ponds of a solar saltern in Alicante, Spain. Optimum growth occurred at 10% NaCl. *Salinicoccus hispanicus* isolated from the same location is another species of this genus. They are pigmented a reddish orange and grow optimally at 10% salts.

Tetragenococcus halophilus is a moderately halophilic lactic acid bacterium easily isolated from salted fermented foods containing more than 25% NaCl, for example, salted anchovies. The cells are tetrad cocci and grow in the presence of wide range of NaCl concentrations, 1 to 25%, with optimum growth at 7 to 10% NaCl. *Tetragenococcus muriaticus* is another species isolated from fermented squid liver sauce.

High G + C Cocci

Nesterenkonia halobia is a moderate halophile isolated in Japan from an imported solar salt. G + C content is 70 to 71.5 mole%. The strain grows best in Sehgal and Gibbons complex medium or Nutrient Broth with 1 to 2 M NaCl or KCl. Recently, six coccoid moderate halophiles isolated from ponds and saltern in Huelva, Spain were shown to belong to this species. Another *Micrococcus* sp., "*Micrococcus varians* subsp. *halophilus*" strain 41 to 3 isolated in Japan from a mash containing 18% imported solar salt for soy sauce fermentation has been used for physiological characterization and studies on extracellular enzyme production (8). This strain is unique in its ability to grow abundantly in media containing high concentrations of salts other than NaCl, such as 1.5 M LiCl, 3.0 M KCl, 2.0 M RbCl, 2.5 M CsCl, etc. (4).

Actinomycetes

The extremely halophilic actinomycete *Actinopolyspora halophila* was isolated in a laboratory in Ottawa as a contaminant on unsterilized plates of complex medium containing casamino acids, yeast extract, and salts including 25% NaCl. The strain is extraordinary in that it requires a minimum salt concentration of 12% for growth in liquid media, and best growth occurred in liquid medium between 15 and 20% NaCl. Thus, this is a bacterial extreme halophile, sensu stricto. Another species of this genus, *A. mortivallis* was isolated from a soil sample obtained from Death Valley, California. It is moderately halophilic, with optimum growth around 10 to 15% NaCl. *Actinopolyspora iraquiensis* isolated from a saline soil sample obtained in Iraq grows optimally at 10 to 15% NaCl.

Nocardiopsis halophila is another moderate halophile isolated from a saline soil sample obtained in Iraq. This organism grows in media containing NaCl up to 20%.

Flavobacterium-Bacteroides

Moderately halophilic orange and yellow pigmented, rod-shaped bacteria are readily cultured from Organic Lake, a hypersaline meromictic lake in the Vestfold Hills region of the Australian Antarctic Territory. Two new halophilic species *Flavobacterium gondwanense* and *Flavobacterium salegens* were proposed. They grow up to 20 and 15% NaCl, respectively, with 5% as optimum.

Proteobacteria

Members of the genus *Rhodospirillum* grow preferably photoheterotrophically under anaerobic conditions in the light, but they also grow under microaerobic to aerobic condition in the dark. A moderately halophilic species *Rhodospirillum salinarum* grows faster under aerobic conditions in the dark at 6 to 15% NaCl. Under anaerobic conditions in the light, the cells are more halophilic requiring 15 to 21% NaCl for optimum growth. This strain was isolated from terminal crystallization ponds of solar salt production plants in Portugal. *Rhodospirillum salexigenes*, another moderately halophilic species isolated from seawater, grows between 5 and 20%, with the optimum at 6 to 8% NaCl.

Many halophilic strains belonging to the gamma subclass have been isolated from various extreme environments. Recently, many of them have been reclassified into the family Halomonadaceae, which comprises three genera, *Halomonas*, *Chromohalobacter*, and *Zymobacter* (34). *Zymobacter palmae*, the only species of the genus, has not been reported to be halophilic. The genus *Halomonas* was created to accommodate a group of moderately halophilic, gram-negative, rod-shaped strains isolated from a solar salt facility in the Netherlands by direct surface spread plating on agar plates containing

8% solar salt produced at the study site. The strains were able to grow over a wide range of salt, from 0 to 32% salt at temperatures of 23 to 37 °C, and from 3.5 to 20% salt at 15 °C and 45 °C. Optimum growth was obtained in complex media containing 3.5 to 8% solar salt at 30 to 37 °C. These typical moderate halophiles were designated as *Halomonas elongata*. Many species of the genus *Halomonas* have been isolated from salterns, The Dead Sea, Antarctic saline lakes, etc. The following are concise descriptions of some species.

Halomonas pantelleriense, with an optimum at 10% NaCl, was isolated from the hard sand of the volcanic lake of Venere in the island Pantelleria in the south of Sicily, Italy by enrichment in a medium with 10% NaCl, pH 9.0. *Halomonas salina* isolated from various saline habitats in Spain grows optimally at 5% salts at 32 °C and 7.5% salt at 42 °C. *Halomonas eurihalina*, which shows optimum growth in media containing 15% salt at 42 °C, are isolated from various hypersaline habitats, as well as seawater. *Halomonas variabilis* is one of the many moderate halophiles isolated from the hypersaline surface water of the north arm of Great Salt Lake. The cells grow well between 1.2 M and 4.9 M NaCl with optimum growth at 1.6 M. *Halomonas halophila* isolated from hypersaline soils of Alicante, Spain is a moderate halophile that grows best at 7.5% salt at 32 °C. *Halomonas halodenitrificans* isolated from meat-curing brines requires at least 3% NaCl and grows optimally at 4.4 to 8.8%. The following species are slightly halophilic or halotolerant: *Halomonas aquamarina*, *H. cupida*, *H. desiderata*, *H. halmophila*, *H. halodurans*, *H. magadii*, *H. marina*, *H. meridiana*, *H. pacifica*, *H. subglaciescola*, and *H. venusta*.

Chromohalobacter marismortui was isolated from the Dead Sea. The cells are yellow or violet blue pigments and grow optimally at about 10% salts. *Chromohalobacter canadensis* NRC 42112 was isolated as a contaminant on a 25% NaCl-agar plate in a laboratory in Ottawa. The cells grow optimally at 8% NaCl at 30 °C, but at 45 °C they require at least 8% NaCl for growth. *Chromohalobacter israelensis* Ba1 was isolated from unrefined solar salt obtained from the Dead Sea. Optimum growth occurred at 8% NaCl and 30 °C.

Pseudomonas beijerinckii was isolated from salted beans and remains a valid species of the genus *Pseudomonas*, but 16S rRNA gene sequence suggested strongly that this species is a member of the family Halomonadaceae.

Other Halophilic Bacteria

Arhodomonas aquaeolei was isolated from a petroleum reservoir production fluid derived from subterranean brine. The cells grow between 6 and 20% NaCl, and optimum growth occurs in the presence of 15% NaCl.

Several strains of moderately halophilic bacteria were isolated from the head of an oil-producing well on an offshore platform in southern Vietnam. One strain that grows at 0 to 3.5 M NaCl with an optimum of 0.85 M (5%) NaCl could degrade n-hexadecane, pristine, and some crude oil components, and was designated as *Marinobacter aquaeolei*.

Two moderately halophilic strains were isolated from kusaya gravy, a traditional Japanese fermented brine. They grow in media containing 0.5 to 9.0% NaCl (w/v) with an optimum of 3%, and were designated as *Marinospirillum megaterium*. *Marinospirillum minutulum*, was isolated from putrid infusions of marine mussels.

Salinivibrio costicola, formerly *V. costicola*, is a moderate halophile originally isolated from rib bone in a sample of Australian bacon, but similar strains have been isolated from various hypersaline environments. In a survey of microbial populations in a multipond saltern, vibriolike strains were shown to be dominant organisms in saltern ponds that had intermediate salt concentrations of 10 to 15%.

Cyanobacteria

Cyanobacteria are widely distributed and a diverse collection of unicellular to multicellular oxygenic photosynthetic bacteria. It is believed that they are common inhabitants of extremely saline habitats. Species commonly found in hypersaline habitats are *Aphanothece halophytica*, *Aphanocapca marina*, *Chroococcus minor*, *Entophysalis granulosa*, *Microcoleus chthonoplastes*, *Schizothrix arenaria*, *Spirulina subsalsa*, etc. Only *A. halophytica* and *S. arenaria* are found in salinities of 25 to 33%. Sometimes cyanobacterial cells form mats, from which halobacterial strains are also isolated (2). The presence of microbial mats on the bottom of ponds of salterns is effective to seal the bottom and prevents the leakage of brines.

HALOPHILIC EUKARYA

Dunaliella is the best known and possibly the most ubiquitous Eukarya in hypersaline environments. It is a unicellular green alga that often assumes an orange to red coloration because of the synthesis of β-carotene in strong brine. It is an obligatory phototrophic, oxygenic, aerobic organism. As primary producers, *Dunaliella* may introduce new organic matter into brine up to NaCl saturation. The cells achieve osmotic balance by intracellular accumulation of glycerol compatible with protein and enzyme functions (2,35,36). Another green algae encountered in hypersaline environments is *Asteromonas gracilis* that grows at NaCl concentrations of up to 4.5 M.

Several *Dunaliella* species are able to proliferate over nearly the entire range of salt concentrations while maintaining a low internal salinity. *Dunaliella salina*, *D. viridis*, *D. parva*, *D. tertiolecta*, and *D. minuta*. The first two species *D. salina* and *D. viridis* have been reported from numerous hypersaline thalassic (marine) and athalassic environments. *Dunaliella parva* is the only species found in the Dead Sea.

Dunaliella salina grows best in 12% salinity and tolerates up to 35%, whereas *D. viridis* grows optimally in 6 to 9% salinity and tolerates up to 23% salinity. Thus, *D. salina* was dominant in the northern arm of the Great Salt Lake (discussed later) and in the southern arm *D. viridis* is a dominant species.

ECOLOGICAL ASPECTS OF HYPERSALINE ENVIRONMENTS

Enumeration of Archaeal and Bacterial Halophiles

Enumerations of halophilic microorganisms in natural brines are difficult to conduct. In addition to the general drawbacks of direct microscopic counting (difficulty in distinguishing between living and nonliving cells), the pleomorphic nature of some halobacteria makes it difficult to distinguish them from inorganic particles of similar size. A. Oren of the Hebrew University of Jerusalem designed a method to estimate cell numbers of noncoccoid halobacteria in natural brines by using bile acids as specific lysis-reagents of noncoccoid halobacteria as described earlier (see Isolation of Halobacteria) (37,38). A 10 mL aliquot of brine was centrifuged. To another aliquot of the same brine was added 0.1 mL of 0.3% sodium deoxycholate, incubated for five minutes, then centrifuged. Supernatants were removed, the remaining brines stirred to make even cell suspension, and cell densities were counted under phase contrast microscope. Sodium deoxycholate has been shown to lyse cell of halobacteria examined so far except for members of the genera *Halococcus* and *Natronococcus*, which possess rigid cell walls as described earlier. Cells of eubacterial halophiles are also resistant to cholate. Thus, the difference in cell counts between with and without sodium cholate treatment represents the cell numbers of noncoccoid members of the Halobacteriaceae.

Another approach is the use of antibiotics specific for Archaea and bacteria. Addition of Archaea-specific inhibitors, for example, anisomycin, to the Dead Sea brines virtually abolished the incorporation of amino acids, whereas the addition of bacterial inhibitors, for example, cycloheximide, had little effect. This is an evidence to support the view that halobacteria make up the overwhelmingly dominant population in environments with salt concentrations of more than 25% (39). Although generation times of isolated halobacteria are several hours in general in organic complex media, generation times of halobacterial population in natural brines were measured as 54 to 120 hours.

16S rRNA Sequences Recovered from Hyper Saline Environments

In recent years, diversity of archaeal and bacterial halophiles in hypersaline environments has been studied by analysis of 16S ribosomal RNA genes amplified by PCR from DNA extracted directly from samples using archaeal, bacterial, or universal primers. Molecular phylogenetic studies indicate a much greater phylogenetic and probably physiological diversity of halophiles than was assumed previously. For example, several archaeal sequences obtained from sample of crystallization pond in Alicante, Spain were found to be different from all other 16S rRNA gene sequences of isolated species (40). Novel bacterial sequences were recovered from samples of crystallizer ponds with salinity from 30 to 37% (41).

The same approach was taken for sediment samples from the Colne Point Salt Marsh located in northeast Essex, United Kingdom (42). Although the salinity of the sample was only about 0.8 M NaCl, a variety of sequences were detected in gene libraries related to different halobacteria. Some sequences were closely related to those from genera *Natrialba* and *Haloferax*. This is an unexpected result because cultivated halobacteria, except for coccoid forms, are known to lyse in hypotonic solution, such as 0.8 M. It has been speculated that within the soil granules there might be microniches with sufficiently high NaCl concentration to maintain the life of halobacteria. The author of this article has succeeded in isolating rod-shaped, pigmented halobacteria from the sands of an Indonesian saltern, which had been washed repeatedly with seawater.

Solar Salterns

Solar salterns are artificial, extremely thalassohaline (seawater derived) environments consisting of multiponds of a discontinuous salinity gradient, which are commercially operated for producing NaCl. In the course of the evaporation of seawater by the solar irradiation and wind blow, a sequential precipitation of calcium carbonate, calcium sulfate (gypsum), and sodium chloride (halite) occurs, but magnesium chloride remains soluble.

Extensive microbiological studies have shown that these ponds can be divided into three categories. In the first step, seawater is concentrated to about three times its original salinity. The microflora is similar to that of seawater, with great species diversity and a low cell number of individual species. At the second step, salinity is increased from three to seven times of seawater, and brines become dark owing to the growth of *Dunaliella* spp. and many species of moderate halophiles. The third step is characterized by hypersalinity, up to saturation, and often, a dense microbial community of halobacteria and red *Dunaliella* spp. causes bright red color. After crystallization of halite, bitterns remain, which are rich in Mg^{2+} and apparently devoid of life. This has been believed to be due to extremely high Mg^{2+} concentrations, but it is also shown that halobacteria are entrapped within the fluid inclusions of salt crystals. Cells of halobacteria are commonly visible within fluid inclusions in salt crystals formed in salterns and salt lakes (43,44) (see Salt Deposits/ Evaporites/ Rock Salts). Those entrapped halophiles in solar salt (10^5 to 10^6 cfu/g salt) are able to survive at least for several years. Thus, when the solar salt was used for the curing of hides or preservation of harvested cod fish, herring, etc., the halophiles caused spoilage of those products by forming “pink eye” on salted fish or “red heat” on cured hides.

In a study of salterns in Alicante, Spain (45), scores of colonies according to the pigmentation was used as an indicator of bacterial and archaeal halophiles; red to pink colonies were scored as halobacteria. The nonpigmented organisms were shown to be more common in ponds containing up to 6 to 14% salt, whereas red-pigmented colonies began to appear at about 18% salt and was dominant at about 27 to 30% salts. Isolated nonpigmented strains grew in 2 to 10% salt, and predominant genera were *Salinivibrio*, *Flavobacterium*, *Alcaligenes*, and *Chromohalobacter*. On the other hand, the red-pigmented strains required at least 20% salt. The bile acid method as described earlier was applied

successfully to estimate the contribution of halobacteria to the bacterial mass and activity in solar salterns (38).

Many other ecological studies have been conducted on other salterns such as a major salt-producing plant in Mexico, Western Salt Company near San Diego, California, a solar salt facility located in Bonaire, Netherlands Antilles, etc. (46).

Halobacteria are the most halophilic organisms as described earlier, and they form the dominant microbial population when hypersaline waters approach saturation, frequently imparting a red or pink coloration to the brines. The carotenoid pigments of halobacteria trap solar radiation, increasing the ambient temperature and evaporation rates in salterns, thus promoting rapid precipitation of salts. Neutral salt lakes and solar salterns may contain 10^7 to 10^8 cells/mL as judged from microscopic examination (37). Salt yields may be diminished in nutrient-poor pond systems, in which fertilizers may be added to stimulate the growth of halophiles.

Solar Lake, Sabkhas, Pools, and Lagoons of Sinai

Sea-marginal environments subject to hypersalinity include a variety of tidal flats and depressions, salt marshes, lagoons etc. The Red Sea coast of the Sinai Peninsula is noted for several hypersaline environments. Solar Lake is a small (50×140 m) sea-marginal pond. Salinities at mixing periods in summer are 15 to 18% and in the stratification period, September to July, a salinity gradient occurs from 6% at the surface to 16 to 18% at the bottom. Microbiological studies have shown that the predominant microbes are cyanobacteria (*A. halophytica*, *A. littoralis*, *Oscillatoria salina*, etc.), diatoms, and heterotrophic bacteria (2).

Sabkhas are smooth, flat plains or salt flats that gradually grade upward from a tropical sea, or they are separated from the sea by a low or permeable barrier. Sometimes hypersaline brines are formed within the sediments and occasionally on top of them. Many halophilic cyanobacteria (*A. halophytica*, *S. arenaria*, etc.) and halobacteria of the genus *Haloarcula* have been isolated.

The Dead Sea

The Dead Sea is an athalassohaline (not seawater derived), terminal lake in the Syrian-African rift valley, 410 m below sea level, the lowest point on the earth's terrestrial surface. The inflow comes mainly from the Jordan River, and the only outlet of water is evaporation. The level is reported to be lowering at a rate of 0.5 m annually owing to extensive exploitation of the Jordan River and the extreme aridity of the region (annual precipitation is about 60 mm). The chemical composition of surface water is 1.8 M Mg^{2+}, 1.7 M Na^{+}, 0.4 M Ca^{2+}, with a total salinity of 33% (wt/vol). The Dead Sea has been used as an economic resource for more than 10,000 years for obtaining salts.

The Dead Sea had long been considered a hypersaline hostile environment devoid of any living organisms. The first microbiological studies of the Dead Sea were conducted by Elazari-Volcanii in the 1930s. The microorganisms observed included many halobacteria and a phytoflagellate of the genus *Chlamydomonas* or *Dunaliella*. So far many extreme and moderate halophiles have been isolated from the Dead Sea; *Har. marismortui*, *Hfx. volcanii*, *Hrr. sodomense*, *H. gomorrense*, *C. marismortui*, *C. israelensis* Ba1, etc. Brine shrimp *Artemia*, densely populated in the Great Salt Lake, is absent. Recently, many halobacterial strains were isolated from samples of the Dead Sea water collected 57 years ago. Most of them were shown to belong to the genera, *Haloferax*, *Halobacterium*, and *Haloarcula* (47).

A. Oren conducted quantitative studies on the microbiology of the Dead Sea (48). In the winter of 1979 to 1980, massive rain floods diluted the upper water layer. In the summer of 1980, mass development of the green unicellular alga *D. parva* (8,800 cells/mL) and red Archaea (2×10^7 cells/mL) was observed. The dense community of red halobacteria imparted a reddish color to the lake. Growth of halobacteria depends on organic matter produced by *D. parva*, the only primary producer in the lake. The *Dunaliella* community declined rapidly at the end of the year 1980, but a stable community of halobacteria of about 5×10^6 cells/mL subsisted in the upper water layer for more than two years. This bloom disappeared at the end of 1982 as a result of complete mixing of the water column. During the period of 1983 to 1991, the lake was holomictic and no *Dunaliella* cells were observed and viable bacterial count was very low. Unprecedented heavy rain floods during the winter of 1991 to 1992 caused a rise of water level by almost 2 m. Thus, the upper water column was diluted down to 70% of the ordinary salinity. In May 1992, *Dunaliella* appeared again (up to 3×10^4 cells/mL) and a bloom of red halobacteria (3×10^7 cells/mL) imparted a red coloration of the lake. A. Oren intensively demonstrated the role of glycerol in the nutrition of microorganisms of the Dead Sea (49).

In connection with the relatively rapid decline of the bloom, Oren and coworkers observed electronmicroscopically the presence of high numbers of viruslike particles in water samples from the Dead Sea in October 1994, when the halobacterial number was declining. The viruslike particles, 0.9 to 7.3×10^7 /mL, outnumbered the halobacteria. In November 1995 to January 1996, the number of viruslike particles declined to less than 10^4/mL (50).

The Great Salt Lake

This lake is located in the arid Great Basin deprived of rainfall by the Sierra Nevada. The Great Salt Lake is the remnant of a prehistoric freshwater lake, Lake Bonneville. Geologic evidence from the area surrounding the lake basin indicates at least ten cyclings within the last 100,000 years from freshwater Lake Bonneville to the highly saline Great Salt Lake passing through a marinelike salinity stage twice during each cycle. The present day Great Salt Lake is merely the latest low water point in the most recent cycle (51). In 1959, a semipermeable rock railroad causeway was completed across the lake. Because there is a considerable evaporation of water, as a result of the arid climate, and 95% of the water entering the lake flows into the south end, the causeway has created practically two lakes at

different elevations. The water chemistry of the Great Salt Lake is in marked contrast to that of the Dead Sea. The ion composition of water from the northern arm of the Great Salt Lake is essentially the same of concentrated seawater, approximately 10 times, whereas the Dead Sea is principally a magnesium chloride lake. The southern arm is less saline.

One more important physical difference between the Great Salt Lake and the Dead Sea is temperature. The water temperature of the Dead Sea is generally between 21 and 36 °C, whereas that of the Great Salt Lake ranges from −5to + 35 °C. The air temperature over the lake ranges from −30to + 45 °C.

Microbiological study of Great Salt Lake began as early as 1930s by Zobell and coworkers. The northern arm community consists primarily of, on the order of biomass, halobacteria, two algae *D. salina* and *D. viridis* as the primary producer, *Artemia salina*, a brine shrimp, and brine fly. Peak densities of *D. salina* reported were 3 to 10×10^3/mL.

Moderate halophilic bacteria such as *Pseudomonas halophila*, *H. variabilis*, *H. litoralis*, *H. trueperi* predominate in surface water of the south arm, whereas halophilic Archaea such as *Halobacterium* spp., *Halococcus* spp., *Haloterrigena* strain GSL11, and *Hrd. utahensis* make up a predominant population in the north arm. The number of bacterial and archaeal halophiles range from 4 to 10×10^7 cfu/mL. In spite of the high numbers present, rates of breakdown of organic compounds, for instance, hydrocarbons, are reported very low.

Ammonia is the key nutrient controlling biological process in the Great Salt Lake. Little or no ammonia is detected in winter, and *Dunaliella* survives in a dormant state; in summer bacteria and Archaea excrete ammonia, on which the algae multiply, then the brine shrimp population continues to excrete ammonia, supporting a dense algal and archaeal bloom (36).

The picture described in the preceding text may have lost some of its validity because it is reported that the salinity of the north arm has decreased recently as a result of massive rainfall.

Alkaline Saline Habitats

The stable, naturally occurring alkaline hypersaline environments are the results of geologic, geographic, and climatic conditions. Because of the high level of carbonate minerals from the surrounding rocks, the pH is quite high, 10 to 12; thus, contents of soluble magnesium and calcium ions are very low (52). Lake Magadi of Kenya, Wadi Natrun lakes in Egypt, Sambhar Salt Lake in India, and Bange Soda Lake in Tibet are sites that have been studied geochemically and microbiologically. Total salinity may vary, from 70 to 394 g/L.

These lakes are densely populated by halophilic and alkaliphilic Archaea as well as alkaliphilic halophilic bacteria. The blooms of alkaliphilic halobacteria are observed sometimes. The following strains have been isolated: *Natrononococcus* spp., *N. pharaonis*, from Wadi Natrun lake, *Nrr. bangense* and *Nrr. tibetense* from Bange Soda Lake in Tibet. A bacterial halophile, *H. pantelleriense*, was isolated from Venere Lake, Pantelleria island of Italy, *Bacillus haloalkaliphilus* from Lake Gabara in the Wadi Natrun. From Lake Magadi, Kenya, many halophiles have been isolated: *Hrr. vacuolatum*, *Ncc. occultus*, *Ncc. amylolyticus*, *H. magadii*, etc.

An extensive microbiological study was conducted on many soda lakes in the East African Rift Valley (53). The salinities of these lakes range from 5% total salts to saturation. The microflora was astonishingly diverse: many gram-negative alkaliphiles related to the family Halomonadaceae, whereas gram-positive alkaliphiles were found in both high and low G + C divisions, including the genus *Bacillus*. On the other hand, alkaliphilic archaeal isolates were closely related to *Natronobacterium* and *Natronococcus*.

Antarctic Hypersaline Lakes

There are a few cold saline lakes in the Antarctic, such as Lake Vanda, Lake Bonney, Don Juan Pond, Deep Lake, etc. (2). Don Juan Pond is an extremely hypersaline, ice free body of water in the Wright Valley, with an average depth of 11 cm. It is essentially $CaCl_2$ brine. According to a report the total ion content was 339 g/L, but it is also reported that there is a seasonal dramatic variation in the composition. There are controversies over the possible life in the presence of high Ca^{2+} content of this pond.

Deep Lake is located in the Vestfold Hills. It is 36 m deep, ice free, and hypersaline throughout (ca 28% salinity); the salinity is believed to be derived from evaporated seawater. *Halorubrum lacusprofundi* is a halobacterium isolated from this lake.

Salt Deposits/Evaporites/Rock Salts

Salt deposits are the relics of ancient hypersaline evaporitic environments now buried, crystallized from brines. Theoretically, the complete evaporation of a column of seawater 300 m deep would precipitate about 4.8 m of salts. There have been many reports on the isolation of halophilic bacteria from subsurface salt deposits and underground brines (43). Norton and coworkers performed typical explorations (54). They isolated halophilic bacteria from two rock salt mines: Winsford salt mine in Cheshire, and Boulby potash mine in Cleveland, England. Both are estimated to be formed around 225 million years ago, and the mining operations were at depth of 170 m and 1,200 m, respectively. Spreads of brines and moist salts that were diluted or dissolved in media produced diverse populations after incubation for two to three weeks. Eighty to 90% of colonies were white- to cream-colored. Efflorescences and moist salts from Winsford had approximately equal numbers of white/creamy type and red bacterioruberin type colonies. In contrast, all Boulby samples yielded only red-pigmented halobacteria.

To recover microorganisms from the inside of rock salts, small fragments (2 to 5 g) of rock salt newly exposed by blasting were selected and dropped into vials of absolute alcohol for surface decontamination. After several hours, the salt fragments were transferred to sterile enrichment media, and incubated at 37 °C. By this procedure, positive enrichment was obtained from approximately 500 g of rock salt inoculum. The efficacy of the surface

sterilization procedure was established by the following control experiments. Orange-pigmented halobacteria were incorporated into halite crystals, and the crystals were placed into a suspension of pink-pigmented halobacteria for four hours, and then transferred to vials of absolute alcohol. Following the immersion for two hours, the crystals were transferred back to media, which yielded only orange-pigmented halobacteria.

Eight rock salt isolates, seven from Winsford and one from Boulby, together with randomly selected 46 red isolates from brine and effloresence were analyzed for their polar lipid patterns. Most of them were assigned to the genera of *Halorubrum*, *Haloarcula*, *Halobacterium*, and *Halococcus*.

The group of Vreeland in the United States did another survey of halophiles in rock salts (55,56). The Waste Isolation Pilot Plant is an underground repository built by the U.S. Department of Energy approximately 650 m below ground level near Carlsbad, New Mexico. The repository is constructed on Permian age Salado salt formation for the safe, permanent, underground disposal of defense-related radioactive wastes. This site has been shown to experience little geologic disturbance since its original deposition. Vreeland' group conducted a survey of the bacterial populations existing within the facility. Bacterial populations heterogeneously distributed throughout the mine, and populations in some mine areas reached as high as 1×10^4 cfu/g NaCl. A biochemical comparison showed the presence of extreme halophiles with wide biochemical diversity. In a most recent survey, they selected a 250 million-year-old salt crystal from the Salado salt formation; delicate crystal structures and sedimentary features indicated the salt has not recrystallized since its formation. After careful sterilization of the surface with strong alkali and acid, they succeeded in isolating a spore-forming bacterial halophile, *Salibacillus marismortui*, from a brine inclusion (57). This finding indicates that spores can effectively be immortal, and has raised fascinating questions. What is the biochemistry that allows the spores to survive for so long? Where else on the earth and to what depth might ancient life be lurking?

The Salar de Atacama located in northern Chile is a large salt deposit (approximately 300 km^2) at 2,700 m above sea level. Samples were taken from water, soils, and sediments of various salt concentrations, 3 to 10% total salts, and many moderate halophiles were isolated, including strains belonging to the genera *Marinococcus*, *Acinetobacter*, etc.

Other Saline Extreme Environments

Solar salts are produced in salterns distributed all over the world, exported and imported, and used in the production of many salted foods. As described earlier, halobacteria are known to be incorporated into the NaCl crystals. The solar salts are also contaminated with halophilic bacteria. Thus, halobacteria are easily isolated from foods containing a high content of solar salts. Many strains of *Hbt. salinarum* and *Halococcus* spp. are isolated from salted foods such as bachalao (dried salted codfish), curing of anchovies, Thai fish sauce containing 25% NaCl. Bacterial halophiles are isolated from salted foods, and some of them are able to grow in complex media containing either 1 to 4 M NaCl or 1 to 4 M KCl (58).

Leaves of a desert plant *Atriplex halimus* are known to excrete salts, predominantly NaCl, to salt bladders through salt glands. The dominant organisms isolated from the salt-coated leaf surfaces were orange-pigmented *Pseudomonas* spp. growing at 0.05 to 20% NaCl.

CONCLUSION

Aerobic halophilic microorganisms in hypersaline environments have been surveyed. It has been a sort of surprise to find so many different halophiles distributed throughout the saline niches. Although strictly anaerobic, extremely halophilic eubacteria (e.g., *Haloanaerobium lacusroseus* isolated from the sediment of hypersaline Retba Lake near Dakar, Senegal) and halophilic methanogenic archaea are known, no obligately anaerobic members have been found in the family Halobacteriaceae. Also, extremely thermophilic halobacteria able to grow at 70 or 80 °Care still to be isolated.

There are many more hypersaline extreme environments not referred to in text that await further geochemical and microbiological studies, for example, Lake Assal of French Somaliland, Zuni Salt Lake in New Mexico, Hot Lake in Washington, hypersaline lakes in Saskatchewan, Canada, Lake Eyre, and other hypersaline lakes in Australia, deepsea hypersaline basins, etc. (2). Novel halophiles are waiting to be isolated from these saline habitats.

The readers are recommended to consult excellent reviews (59,60) on the biotechnological applications of the halophiles.

HALOPHILES: ANAEROBIC PROKARYOTES FROM HYPERSALINE ENVIRONMENTS

JEAN-LOUIS GARCIA
BERNARD OLLIVIER
Universités de Provence et de la Méditerranée
Marseille, France

BHARAT K. C. PATEL
Griffith University
Brisbane, Australia

Numerous aerobic and anaerobic extremophilic microorganisms have been isolated in recent years, but most attention has focused on thermophilic and hyperthermophilic microbes from domain *Bacteria* such as the members of the orders *Aquificales* (e.g., *Aquifex* species) and *Thermotogales* (e.g., *Thermotoga* species), and the family *Thermanaerobiaceae* and from domain *Archaea* such as the members of the orders *Thermoproteales* (e.g., *Thermoproteus* and *Pyrobaculum* species) and *Thermococcales* (e.g., *Thermococcus* and *Pyrococcus* species) (1–4). There are a number of reasons for the interest in such extremophilic microbes: (*1*) The analysis of central metabolism may reveal adaptations to thermal environments, (*2*) modifications in their pathways may lead researchers to identify novel/modified biomolecules, (*3*) the

potential usefulness of extremophilic enzymes in industrial processes due to improved stability of enzymes under a range of adverse conditions, and finally (*4*) the search for new and more ancient organisms after the recognition of archaeal life by Woese and coworkers (5). These studies have provided us with essential information about primary biochemical pathways operating in these organisms, which may unravel the puzzles of early cellular evolution.

Halophiles, a group of extremophilic microorganisms, have also created an interest among researchers. Halophiles have an obligate requirement of NaCl for growth and can thus be differentiated from halotolerant microbes that can grow either in presence or absence of NaCl. Three groups of halophiles are currently distinguished on the basis of NaCl growth requirements (6): (*1*) The slight halophiles, which grow most rapidly in the presence of NaCl concentrations between 2 and 5% (0.34 to 0.85 M), (*2*) the moderate halophiles, which grow most rapidly at NaCl concentrations between 5 and 20% (0.85 to 3.4 M), and (*3*) the extreme halophiles, also called hyperhalophiles, which grow most rapidly at NaCl concentrations ranging between 20 and 30% (3.4 to 5.1 M). The moderate and the extreme halophiles possess a large and diverse array of intracytoplasmic osmotic solutes that enable them to adapt and inhabit terrestrial and subterrestrial ecosystems with high salt concentrations (7). Research on these solutes has provided an insight into the various biochemical strategies employed by these microbes for maintaining and regulating osmotic balance essential for their survival and growth in such harsh environments (8).

We present a review on the characteristics of the strictly anaerobic halophiles that include carbohydrate fermenters, sulfate-reducers, methanogens, and phototrophs, and discuss their ecology and their involvement in the oxidation of organic carbon as an energy source.

THE ENVIRONMENTS AND PHYSICOCHEMICAL CHARACTERISTICS

Saline and hypersaline environments contain between 4% and saturated (34 to 35%) NaCl. The most saline environments observed on this planet include the inland terrestrial lakes (e.g., Dead Sea, and Great Salt Lake) and subterrestrial ecosystems (e.g., oil reservoirs). Solar salterns produced as a result of human activities, estuaries, and shoreline rockpools exposed to intensive evaporation also become extremely saline with NaCl concentrations reaching saturation.

Saline and hypersaline terrestrial ecosystems vary and fluctuate dramatically in ionic composition, total salt concentrations, and pH. As a result of this, a highly versatile and adaptative microflora that can cope with such environmental fluctuations develops. Most saline lakes possess close to neutral pH (e.g., the Great Salt Lake, the Dead Sea, and the Orca Basin in the Gulf of Mexico) but some are alkaline with pH ranging from 9 to 10 (e.g., the Big Soda Lake, the Mono Lake, and the Soap Lake of the Great Basin of the Western United States) (9). Sodium and/or Chlorine ions are the predominant ions in neutral pH environments (e.g., the Great Salt Lake, Lake Assal, and marine salterns), but Mg^{++} and Ca^{++} are also important components (10,11), especially in alkaline brines. Large variations in the sulfate concentrations of saline and hypersaline environments occur with up to 21.22 g/L recorded for the Soap Lake (9). The presence of sulfate is important because sulfate-reducing bacteria play a crucial role in the terminal stages of organic matter decomposition in these environments.

Both salinity and pH are compatible with bacterial activity in oil reservoirs and various halophilic anaerobes have been recovered from these ecosystems (12). The waters in oil formation vary from fresh to salt-saturated, with pH between 5 and 8. Microbes have never been cultured from oil reservoirs whose in situ temperature exceeds 130 to 150 °C, indicating that the principal determinant in limiting microbial life in oil reservoirs is temperature.

Organic Matter and Its Availability in Hypersaline Environments

Most of the organic matter found in hypersaline ecosystems is because of aerobic and/or anaerobic microbes, but some eukaryotes (e.g., the brine shrimp *Artemia salina*, brine flies, and the algae *Dunaliella salina*) also contribute to organic matter availability in these environments. Algae and plants growing nearby may also contribute organic matter into the hypersaline environments (13). Therefore, a large number of biopolymers including cellulose, hemicelluloses, pectine, chitin, and proteins and also monomers such as glycerol or betaine may contribute to the overall carbon cycle within hypersaline environments. The extremely halophilic members of domain *Archaea* contain high concentrations of salts in their cytoplasm, but the halophilic and halotolerant members of domain *Bacteria* have only low levels of salts in their cytoplasm that are regulated by synthesizing or accumulating a large number of different organic osmolytes, also known as compatible solutes (14,15). These osmolytes contribute to the overall carbon cycle in saline and hypersaline ecosystems and are available as growth substrates.

Organic osmotic solutes accumulate under increasing salt concentrations (13,16,17) and include polyols (glycerol and arabitol), sugars and sugar derivatives (sucrose, trehalose, and glucosylglycerol), and amino acids, their derivatives, and quaternary amines (glycine betaine, and ectoines). Glycine betaine has been reported to be present in members of the genus *Halorhodospira* (formerly *Ectothiorhodospira*) (18,19), *Methanohalophilus* (20–23), and *Cyanobacteria* (24). In *Cyanobacteria*, sucrose and trehalose accumulate in osmotically stressed cells (24), whereas glycerol is the major compound that enables growth of the unicellular green alga, *Dunaliella*, in saline habitats (25). A novel class of compatible solutes called ectoines (cyclic N-acetyl diamino acids) have been identified and isolated from *Halorhodospira*, an extremely halophilic archaeon (16,26). Various organic osmotic solutes including β-glutamine, β-glutamate, N-acetyl- β-Lysine, and glycine betaine (20–23,27) have been detected in halophilic methanogens. The strategy of accumulating osmotic solutes to regulate salt concentrations is energetically expensive (8) with synthesis of small

molecules (glycerol, glycine betaine, and ectoines) being less energy consuming than that of the larger molecules (e.g., disaccharides). The synthesis of glycerol, so far identified only in eukaryotic halophiles, the most inexpensive to produce in terms of energy (8). Caldas and coworkers (28) have reported that the osmoprotectant glycine betaine, which accumulates in eukaryotic and bacterial cells, also acts as thermoprotectant in *Escherichia coli*. Recently, Kuntikov and Gorlenko (29) have demonstrated that the interrelation between halotolerance and thermotolerance, which exists in some halophilic green sulfur phototrophic bacteria, cannot be explained based entirely on osmolytes and therefore other factors may also play a role.

Organic Matter Decomposition

Under normal conditions, acetate, a key intermediate in anaerobic degradation of organic matter, is oxidized by sulfate-reducing bacteria and methanogens, thereby preventing its accumulation in nature. However, an abnormal accumulation of volatile fatty acids (VFA) including acetate and hydrogen occurs in sediments with salinities above 15% (30,31) suggesting that the acetoclastic process but also hydrogen oxidation in the presence of electron acceptors such as sulfate and/or carbon dioxide is very limited (31). Skyring (32) reported that acetate oxidation occurred in moderately saline sediments via sulfate reduction. Brandt and Ingvorsen (33) isolated pure cultures of sulfate-reducers capable of acetate oxidation at salinities below 13% but enrichment cultures with greater than 20% NaCl were never obtained. In addition, methanogens isolated to date from saline sediments are specialized in utilizing methylated compounds (e.g., methylamines) (34) rather than acetate.

Hydrogen also accumulates in hypersaline sediments with up to 200 μM dissolved hydrogen being measured in sediments of the Great Salt Lake (35). This seems to indicate that the catabolism of reduced compounds such as butyrate or propionate hardly occurs via interspecies hydrogen transfer. Accordingly, hydrogen and formate but not propionate, acetate, or lactate stimulate the reduction of sulfate from Dead Sea sediments (31). Further proof of this comes from enrichment studies initiated with sediments of a hypersaline lake (340 g/L salts) in Senegal. Acetate, propionate, and butyrate were not metabolized even after two months of incubation (36). A number of hydrogenotrophic moderately halophilic sulfate-reducers such as *Desulfovibrio halophilus*, *Desulfohalobium retbaense*, and *Desulfovibrio oxyclinae* have been reported to grow at NaCl concentrations greater than 15% (8,34). The most halotolerant (12% NaCl) hydrogenotrophic methanogen reported to date was isolated from an oil reservoir (37).

It is evident from the data presented above that even if oxidation of acetate and hydrogen was possible, the process would be slower than that of carbohydrate fermentation and would result in the accumulation of acetate and other VFA in saline and hypersaline sediments. It has been suggested that the energy requirement for the cells to adapt their growth at high salinities is too expensive and this may therefore preclude the existence of some trophic groups of microorganisms usually important for establishing complete mineralization of organic matter (e.g., hydrogenotrophic and/or acetotrophic methanogens and the dissimilatory complete oxidizing sulfate-reducing bacteria) (8). Although, the absence of acetotrophic methanogens in hypersaline environment might be the result of little energy available from the substrate and also the need for these microorganisms to synthesize organic osmoprotectants considered as energetically expensive molecules (8), the thermodynamic parameters of the methanogenic reaction from hydrogen cannot completely preclude the possible existence of hydrogenotrophic methanogens (8). In addition, it is possible that such hypersaline environments may be inhabited by other hydrogenotrophic homoacetogenesis performing anaerobes such as *Acetohalobium arabaticum* (38) and *Natrionella acetigena* (39).

Microbial Ecology

Although there is a marked difference between the microbial community structures of terrestrial hypersaline sediments with NaCl concentration greater than 15% and the slightly or moderately saline ones, photosynthetic bacteria represent the major primary producers in all these environments (40). And although aerobic and anaerobic microbes have been successfully recovered from all terrestrial hypersaline environments, anaerobes have always been considered to be the dominant microorganisms of subsurface terrestrial hypersaline environments such as saline oil fields (12). However, recently, this dogma has been challenged because microbiological studies on subterranean salt deposits have demonstrated that they can also inhabited by the aerobic haloarchaea (41). Interestingly, the authors reported that no difference was observed between the 16S rDNA sequence of surface and subsurface haloarchaea populations. Because the subterranean salt deposits studied are considered to be ancient evaporites of hypersaline environments, the authors speculated that halobacteria may be able to survive for long periods in deep subterranean environments (41). The marine salterns, on the other hand, develop a variety of saline gradients because of the salt extraction process, and not surprisingly, possess the greatest diversity of halophilic and halotolerant bacteria observed in saline and hypersaline environments. Slight halophiles are recovered from the primary ponds of salterns, whereas the intermediary ponds in which the seawater is concentrated to salinities of around 10 to 20% NaCl, contain a larger number of moderate halophiles. The ponds representing the final stages of NaCl crystallization processes are inhabited mainly by the extremely halophilic organisms including aerobic members of the domain *Archaea* (35) and to a lesser extent by members of domains *Bacteria* and *Eucarya*.

The number of extremely halophilic anaerobic members of domain *Bacteria* that have been isolated from anoxic hypersaline environments is far less than the extremely halophilic aerobic archaeal counterpart. The anaerobic extremely halophilic members of domain *Bacteria* include *Halanaerobium lacusrosei*, which grows optimally in the

presence of 20% of NaCl (42) and the phototrophic sulfur-oxidizing *Halorhodospira halochloris* that grows optimally in the presence of 21% NaCl (19,43). Phototrophic sulfur-oxidizers are widespread in a narrow zone of anoxic sediments of sulfide-rich hypersaline environments that receive light. They use various substrates as carbon sources and use sulfide as an electron donor for photosynthesis. Diverse populations of phototrophic sulfur-oxidizing bacteria are encountered throughout the different salt concentrations of marine salterns. The primary ponds of marine salterns (8 to 10% NaCl) contain the most numbers of phototrophs, with moderate and/or extreme halophiles inhabiting the more saturated salt ponds (44). The extremophilic methylotrophic anaerobic archaeon *Methanohalobium evestigatum*, which is unable to oxidize hydrogen and acetate, produces the highest concentration of methane in the presence of 25% NaCl (45).

The sulfide from the anoxic sediments of hypersaline ecosystems is produced mainly by sulfate reduction. Because sulfate is one of the major inorganic components of seawater (25 mM), its concentration increases to saturation in the salterns and hence precipitates in the form of calcium sulfate (gypsum). As a consequence, sulfate is never a limiting factor for sulfate reduction in salterns and in other hypersaline environments and is used by sulfate-reducing bacteria as a final electron acceptor for oxidizing hydrogen and various low molecular weight organic compounds (e.g., lactate, ethanol, etc...). It is generally accepted that both the phototrophs and sulfate-reducers contribute significantly to the turnover of the sulfur cycle in the anoxic zones of hypersaline environments.

Halophilic mesophilic and thermophilic anaerobes have also been isolated from the saline subsurface environments (e.g., oil field environment). Rengpipat and coworkers (46,47) reported their isolation from oil-water injection filters and Gevertz and coworkers (48) reported the first isolation of a halanaerobe, which grew optimally at 2.5% NaCl but did not above 10%, from oil brines. Five moderately halophiles were also isolated from the hypersaline brines of the Southeast Vassar Vertz Sand Unit in United States. These isolates produced acids, solvents, and gases from carbohydrates (49,50). Moreover, these microorganisms were capable of forming ultramicrobacteria under particular physiological conditions, thereby making them suitable candidates for microbial enhanced oil recovery (12).

CHARACTERISTICS, TAXONOMY, AND PHYLOGENY

Halophilic anaerobes have a varied physiology and this is reflected in their phylogenetic distribution. The physiological groups include mesophilic or thermophilic carbohydrate/peptide fermenters, sulfate-reducers, and methanogens. Phylogenetically, they are distributed in domain *Bacteria* as members of the order *Thermotogales*, the green sulfur bacteria, *Deferribacter* assemblage, order *Spirochaetales*, the *Proteobacteria* (α and γ divisions) and orders *Clostridiales* and *Halanaerobiales* of the low G+C DNA containing gram-positive group, and in domain *Archaea* as members of the kingdoms *Crenarchaeota* and *Euryarchaeota*. The scheme for phylogeny described in this section has been modified from Collins and coworkers (51) and takes into account the proposed changes to be published in the new edition of the Bergey's *Manual of Determinative Bacteriology*.

Anaerobic Halophilic Members of Domain *Bacteria*

Order *Thermotogales*. Members of the order *Thermotogales* are exclusively thermophilic anaerobes and represent the second deepest branch in domain *Bacteria* (52). Within this order, the slight halophiles are represented in the genera *Geotoga*, *Petrotoga*, *Thermotoga*, *Thermosipho*, and *Marinitoga* (53) (Fig. 1; Table 1). All utilize carbohydrates with acetate being the major fermentation end-product formed. *Thermotoga maritima* is a hyperthermophile (growth temperature optimum of 80 °C) (54) that uses elemental sulfur and thiosulfate as a terminal electron acceptor.

***Deferribacter* Assemblage.** *Deferribacter thermophilus*, a gram-negative slightly halophilic (optimum growth in 2% NaCl) thermophilic (optimum growth temperature of 60 °C) anaerobe was isolated from the production water of Beatrice oil field in the North Sea (U.K) (55). It is unique among halophiles because it obtains its energy from the reduction of manganese (IV), iron (III), and nitrate in the presence of yeast extract, peptone, casamino acids, tryptone, hydrogen, malate, acetate, citrate, pyruvate, lactate, succinate, and valerate. Phylogenetic analysis of the 16S rRNA gene indicates that it forms an independent line of descent with the moderate thermophile "*Flexistipes sinusarabici*" as its closest relative (Table 1; Fig. 1).

The Green Sulfur Bacteria. The halophilic members of green sulfur bacteria are also phototrophic and seven species belonging to four genera have so far been described (Table 1; Fig. 1). They grow optimally at salinities between 2 and 5% NaCl and are therefore regarded as slight halophiles. They have been frequently isolated from marine environments although they are also present in abundance in the first ponds of marine salterns (6 to 8% NaCl concentration) connected to the sea (34). Green sulfur bacteria have also been observed in hypersaline environments but none have yet been isolated (56).

The halophilic members of the green sulfur bacteria, like their phototrophic counterparts represented in the Alpha division of *Proteobacteria* (see following text), accumulate sugars (trehalose or sucrose), and N-acetylated compounds such as N-acetyl-glutaminyl glutamic acid (34) for osmoregulation.

Order *Spirochaetales*. Four validated moderately halophilic species of the genus *Spirochaeta* have been described (Fig. 2). Of these, *Spirochaeta smaragdinae* isolated from a deep subsurface Congolese oil field habitat is the only subsurface spirochaetal strain described to date (57). Three other species, namely, *Spirochaeta africanus*, *Spirochaeta alkalica*, and *Spirochaeta asiatica* are haloalkalophiles and produce acetate, ethanol, lactate, and hydrogen from carbohydrate fermentation (58).

The *Proteobacteria.* The phylum *Proteobacteria* is currently divided into five divisions, namely, α, β, γ, δ, and ε. Slight, moderate, and extreme halophiles are represented in only two out of the five divisions, namely, the α and δ divisions. The phototrophic halophiles are housed in the α division, whereas the gram-negative sulfate-reducers and the non-sulfate-reducer, *Hippea maritima*, are housed in the δ division.

The *α Proteobacteria.* The α-division of phylum *Proteobacteria* comprises a number of phototrophic halophiles (Table 2; Fig. 2) that require H_2S and/or hydrogen, and organic compounds for anaerobic growth and active radiation for photosynthesis (59–65). Slightly photosynthetic halophiles are usually isolated from marine environments, whereas the moderate to extreme photosynthetic halophiles have been successfully isolated from hypersaline habitats. Moderately phototrophic halophiles isolated from hypersaline ponds of marine salterns grow optimally with salinities between 6 and 11% NaCl (Table 2). They belong to the genera *Rhodovibrio*, *Roseospira*, *Rhodothalassium* (formerly *Rhodospirillum*), *Halochromatium* (formerly *Chromatium*), *Thiohalocapsa* (formerly *Thiocapsa*), *Ectothiorhodospira*, and *Rhodovulum* (Table 2). The most halophilic phototrophic isolated so far are *Halochromatium salexigens* (66), *Thiohalocapsa halophila* (67), and *Rhodovibrio salinarum* (68).

Extremely phototrophic halophiles have most commonly been isolated from alkaline brines in athalassohaline (nonsaline marine water) environments such as desert lakes (43,69). They require about 20 to 25% NaCl for optimum growth and are members of the newly created genus *Halorhodospira* (formerly *Ectothiorhodospira*). The three species of this genus that have been isolated and described include *Halorhodospira abdelmalekii* (69), *Halorhodospira halophila* (70), and *Halorhodospira halochloris* (43) (Table 2).

Phototrophic halophiles use various reduced sulfur compounds to produce corresponding oxidized sulfur compounds with sulfate as the final product. They also actively participate in anaerobic degradation of cellulose and organic compounds in anaerobic halophilic communities (80). They are therefore regarded as one of the major trophic groups responsible for cycling of carbon and sulfur living in hypersaline environments.

The phototrophic halophiles control their osmoregulation by synthesis or uptake of organic solutes that accumulate in their cytoplasm, for example, glycine betaine (81–83). Glycine betaine biosynthesis by *Halorhodospira* species operates via methylation of glycine with S-adenosylmethionine being used as a methyl donor (82). Some members also accumulate sugars (trehalose or sucrose), whereas some accumulate N-acetylated compounds such as N-acetyl-glutaminyl glutamic acid (34). Some compatible solutes also serve as an energy reserve (8) as shown for *H. halochloris*. In this case, trehalose is produced as a minor component for osmoregulation but is degraded under mild stress (84).

The phototrophic halophiles of the α division of *Proteobacteria* can be readily distinguished from other phototrophic halophiles represented in the phylum green sulfur bacteria on the basis of their light-harvesting pigments, bacteriochlorophylls (BChls) and carotenoids used for photosynthesis (the green sulfur bacteria, discussed earlier).

The γ *Proteobacteria.* Slight to moderate gram-negative halophilic sulfate-reducing bacteria and a non-sulfate-reducing bacterium, *H. maritima*, described as slightly halophile, are included in the γ-division (Fig. 2).

Halotolerant and slightly halophilic sulfate-reducers (SRB) belonging to 11 genera and 26 species are listed in Table 3. In marine environments such SRB mainly inhabit the anoxic sediment and the bottom anoxic waters of stratified lagoons. They are also common inhabitants of subterrestrial ecosystems (e.g., the oil field environment), and their activities are responsible for serious and costly problems in the offshore oil industry (12). In the oil field ecosystem, they develop over a wide range of salinities and temperatures and can therefore be considered as ubiquitous inhabitants. Identification of SRB in oil fields by reverse sample genome probing indicated the presence of two distinct communities that could be discriminated on the basis of the salt concentration of the production waters (85). Cord-Ruwisch and coworkers (86) also reported that salt concentrations had a strong effect on the growth of oil field reservoirs SRB populations.

The subterrestrial isolates include members of the genus *Desulfovibrio* such as *D. vietnamensis* (87) and *D. gabonensis* (88). Both are mesophilic, considered to be moderate halophiles with an upper limit for growth in the presence of NaCl between 0 and 10% and between 1 and 17%, respectively, use a limited range of substrates including hydrogen and pyruvate, and incompletely oxidize lactate. *Desulfomicrobium apsheronum*, isolated from stratal waters of the Apsheron peninsula (Russia), is also a mesophile that tolerates up to 8% NaCl for growth (89), incompletely oxidizes lactate to acetate, and differs physiologically from the *Desulfovibrio* spp. described earlier by its ability to grow autotrophically. Members of the genus *Desulfobacter* have been identified by oligonucleotide probes in oil field environments (90) and *Desulfobacter vibrioformis* has been isolated only recently from a water-oil separation system (91). *Desulfobacter vibrioformis* grows optimally with 1% NaCl and uses acetate as the only carbon and energy source while dissimilating sulfate to sulfide.

The alkaliphilic slightly halophilic SRB *Desulfonatronovibrio hydrogenovorans* (92) and *Desulfonatronum palustre* (93) use a limited range of substrates that include hydrogen and formate, and ethanol, respectively.

The eight species belonging to the four genera of moderately halophilic sulfate-reducers (*Desulfovibrio*, *Desulfohalobium*, *Desulfotomaculum*, and *Desulfocella*) were isolated from various hypersaline terrestrial or subterrestrial environments and with the exception of *Desulfocella halophila* and *D. vietnamensis*, are hydrogenotrophic. Seven out of the eight moderately halophilic SRB also

use thiosulfate or sulfite as electron acceptors in addition to sulfate, and a further four species can reduce elemental sulfur to sulfide. Trüper (94) cultured a SRB from hot brines in the Red Sea that tolerated up to 17% NaCl and looked similar to *D. halophilus*, a moderate halophilic SRB isolated by Caumette and coworkers (71) from the hypersaline Solar Lake in the Sinai Peninsula. *Desulfocella halophila* oxidizes butyrate and higher fatty acids (from C_3 to C_{16}) incompletely (95). *Desulfohalobium retbaense* presents the upper limit of NaCl concentration (24%) for growth of all the moderately halophilic SRB described so far (96).

Although SRB are generally regarded as strict anaerobes, metabolic activity in the presence of oxygen has been reported for the slight halophile *Desulfovibrio salexigens* and the moderate halophile *D. oxyclinae* (97–101).

Sulfate-reducing bacteria play a crucial role at the terminal stage of organic matter oxidation in anoxic environments such as sulfide-rich soda lakes, marine, and terrestrial/subterrestrial hypersaline environments (31,72,102–106). However, only a limited range of substrates including H_2, formate, and lactate are involved in this process (35,36,96,104). In general, estimates of poor sulfate reduction in presence of acetate were noted in salinities greater than 15%. Although in situ studies of moderately hypersaline sediments has shown that a major part of acetate oxidation is performed by SRB (32), only *Desulfobacter halotolerans*, a slight halophile has shown this characteristic among pure cultures (33). This isolate from the sediments of the Great Salt Lake (Utah, U.S.), grows optimally on acetate in the presence of 1 to 2% NaCl and tolerates up to 13% NaCl. Studies on the sediments of the same lake have demonstrated that acetate oxidation occurs, albeit very slowly, at 20% NaCl, thus suggesting that acetate oxidation by moderately and/or extremely halophilic SRB, if they exist at all, may be insignificant (33). These observations indicate that acetate oxidation in hypersaline environments can occur at only low rates, thus resulting in its accumulation in sediments (31).

Low $G + C$ Dna Containing Gram-Positive Group. The members of this group include the fermentative bacteria of the order *Halanaerobiales*, Clusters XI and XII of the order *Clostridiales*, and two sulfate-reducing bacteria of the genus *Desulfotomaculum* (Table 4; Fig. 3). All members are moderate to extreme halophiles with the exception of *Desulfotomaculum geothermicum*, which is a slight halophile.

Order *Halanaerobiales*. The members of order *Halanaerobiales* are the most widely studied moderate halophiles consisting of 10 genera and 22 species. They are divided into two families, namely, *Halanaerobiaceae* and *Halobacteroidaceae*. The family *Halanaerobiaceae*, which contains 3 genera and 11 species (34,107–110), ferments carbohydrates to acetate, hydrogen, carbon dioxide, and various other metabolites such as ethanol, lactate, and VFA higher than acetate. *Halocella cellulosilytica* is the only cellulose degrader included in this family (111). However, cellulase activity has been demonstrated in a hypersaline African lake but no isolates were cultured (36), indicating that other cellulolytic halophilic bacteria may exist in nature. The family *Halobacteroidaceae* houses the remaining 12 species belonging to seven genera (112,113) all of which, with the exception *A. arabaticum*, ferment carbohydrates. The later degrades amino acids and betaine to acetate and trimethylamine (38). Five spore-forming species belonging to three different genera are also members of this family.

Extreme halophiles		
Halanaerobium lacusrosei	6–34	20
Acetohalobium arabaticum	10–25	15–18
Halanaerobacter chitinovorans	3–30	12–18
Halobacteroides lacunaris	5–30	15–18
Selenihalanaerobacter shriftii	10–24	21

Members of the order *Halanaerobiales* have their origins in saline lakes but the moderate halophile *Halanaerobium salsugo* (114), *H. congolense* (115), and *H. acetoethylicum* (formerly *Halobacteroides acetoethylicus*) (46) have all been isolated from oil field brines.

All members of the order *Halanaerobiales*, with the exception of three species of the genus *Halanaerobium*, are motile by peritrichous flagellation. Most species in the order should be considered as moderate halophiles because most rapid growth occurs with 7.5 to 18% NaCl with the exception of the extreme halophile, *H. lacusrosei*, which grows optimally with 20% NaCl, with an upper limit of growth at 34% NaCl (42). A recently described new species of a new genus, *Selenihalanaerobacter shriftii*, isolated from the Dead Sea, grows optimally with 21% NaCl, with an upper limit of growth at 24% NaCl (116). It oxidized glycerol or glucose with concomitant reduction of selenate to selenite plus elemental selenium. *Halanaerobium saccharolyticum* (117,118) exhibits a homoacetogenic pathway for the metabolism of glucose and the nonsaccharolytic *A. arabaticum* (38) performs homoacetogenesis from $H_2 + CO_2$. *Halothermothrix orenii* order *Halanaerobiales* (119) and *Thermohalobacter berrensis* order *Clostridiales* (120) represent the only true thermophilic anaerobic moderately halophiles (growing up to 68 to 70 °C, with most rapid growth at 60 to 65 °C) described to date.

Alkalitolerant heterotrophs belonging to the genera *Halanaerobium* and *Acetohalobium* have been isolated from neutrophilic salt lakes (38,121). Recent microbiological investigations of soda lakes (Lake Magadi, Kenya) revealed the presence of an alkaliphilic saccharolytic anaerobe (strain 7,986) representing a new taxon in the order *Halanaerobiales* (122). *Natrionella acetigena*, isolated from soda lakes grows optimally at pH 9.7 to 10 and ferments a limited range of substrates such as lactate and ethanol to acetate (39). Other haloalkaliphilic anaerobes have also been isolated from the sediments of the same lake (40) and are phylogenetic relatives of clostridial clusters VIII and XI and will most probably represent a new genus of anaerobic haloalkaliphiles (40).

It is noteworthy that in contrast to other members of domain *Bacteria*, halophiles of the order *Halanaerobiales* are unique in using the salt-in strategy for growing at high salinities (8). They balance the osmotic pressure of the environment with high intracellular KCl concentrations and generally do not produce organic osmotic solutes similar to the aerobic members of the order *Halobacteriales*, domain *Archaea* (8).

Members of Cluster XI and XII. *Clostridium halophilum* is a moderate halophile and grows optimally with 6% NaCl (range 1.5 to 10%) (123). Strains of the haloalkaliphile *Natronoincola histidinovorans* have been isolated from soda deposits in Lake Magadi, Kenya (124). The strains grow optimally in the presence of 8 to10% NaCl (range 4 to 16%) at pH 9.4 using substrates such as histidine and glutamate. The end-products of amino acid fermentation are acetate and ammonium. Analysis of 16S rDNA sequence of both species indicates that they belong to cluster XI of the low G+C DNA containing gram-positive bacteria. *Thermohalobacter berrensis*, a member of cluster XII, is a motile gram-negative nonsporulating rod-shaped bacterium isolated from the sediment of a French solar saltern feeding canal (120). The optimum temperature for growth is 65 °C (range 45 to 70 °C) and the optimum NaCl concentration for growth is 5%

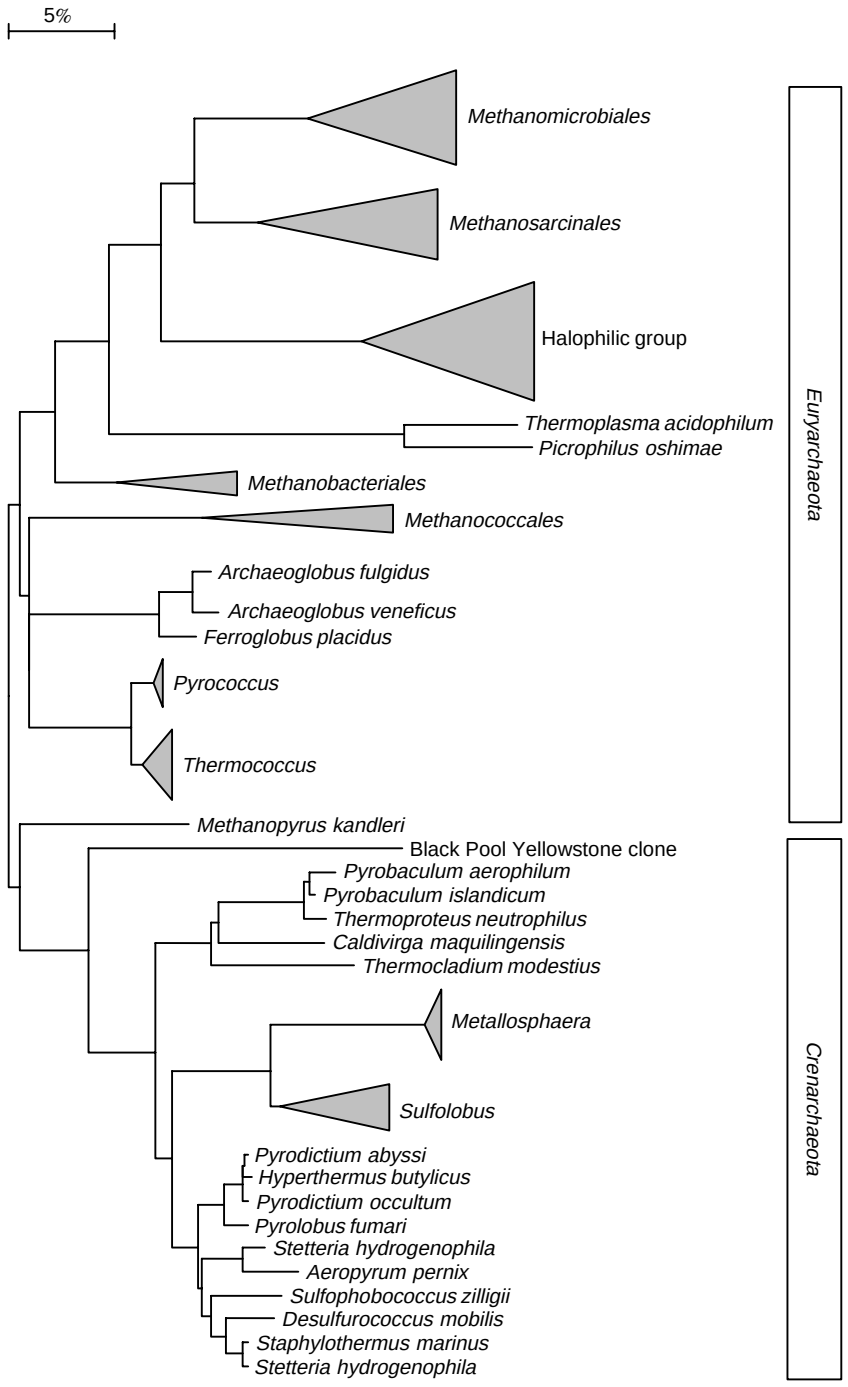

Figure 4. Dendrogram showing the position of methanogens and fermentative archaeons in domain *Archaea*. Bar indicates evolutionary distance.

(range 2 to 15%). It ferments carbohydrates, pyruvate, and biotrypticase. Acetate, ethanol, hydrogen, and carbon dioxide are produced from glucose fermentation.

Genus *Desulfotomaculum.* Only two species of the genus *Desulfotomaculum* family *Peptococcaceae*, which originate from subterrestrial environments, have been described as halophiles. *Desulfotomaculum geothermicum*, a slightly halophilic thermophilic sulfate-reducer, isolated from geothermal groundwater, completely oxidizes its substrates (125), whereas *D. halophilum*, isolated from oil field reservoir, is a moderately halophilic mesophilic sulfate-reducer that oxidizes incompletely a limited range of substrates such as lactate and ethanol to acetate (126).

Anaerobic Halophilic Members of Domain Archaea

The Methanogens. Seventeen species of slightly halophilic or halotolerant methanogens belonging to orders *Methanococcales*, *Methanomicrobiales*, *Methanosarcinales*, and *Methanopyrales* (Fig. 4) have been mainly isolated from marine sediments or subsurface environments such as hydrothermal vents. They show a salinity range from 0 to 12% NaCl and most

*only for thermophiles.

rapid growth from 1.2 to 4.8% NaCl and include hydrogenotrophic (e.g., members of the genus *Methanococcus*) and methylotrophic microorganisms (e.g., members of genera *Methanococcoides* and *Methanolobus*). Extreme to hyperthermophiles (e.g., *Methanocaldococcus jannaschii*, *Methanoignis igneus*, and *Methanopyrus kandleri*) have been reported among the slightly halophiles. Moderately to extreme halophilic methylotrophic methanogens belonging to order *Methanosarcinales* (Fig. 4) comprise three genera and six species (Table 5). Most of them are obligate moderately halophilic cocci, isolated mainly from sediments of hypersaline lakes or lagoons, with growth ranging from 1 to 21% NaCl and most rapid growth from 3.6 to 15% NaCl, with the exception of the extreme halophile *M. evestigatum* (45) with growth ranging from 15 to 30% NaCl and having most rapid growth at 25% NaCl. Marked differences in optimum pH and temperature for growth were observed. One species, *Methanosalsus zhilinae* (127,128), is alkaliphile; the others are neutrophiles. *Methanosalsum zhilinae* and *M. evestigatum* are moderately thermophilic bacteria with a temperature optimum of 45 °C and 50 °C, respectively. Methylotrophic methanogens such as *M. zhilinae* (127) and *Methanolobus oregonensis* (129), which grow optimally around pH 9.0, were isolated from alkaline lakes.

A halotolerant hydrogenotrophic methanogenic irregular coccus belonging to order *Methanomicrobiales* (Fig. 4), and growing at up to 12.5% NaCl with most rapid growth at 5% NaCl, *Methanocalculus halotolerans*, was recently isolated from an oil well (37); it uses $H_2 + CO_2$ only in the presence of acetate as carbon source (Table 5). It represents so far the hydrogen-oxidizing methanogen growing in the widest range of NaCl concentration (from 0 to 12%). It has been suggested that the ability of *M. halotolerans* to grow in a wide NaCl range and optimally at NaCl concentration close to that of the oil well from which it was isolated might be indicative of its indigenous origin (37). Identically, *Methanohalophilus euhalobius* (formerly *Methanococcoides euhalobius*) (130) isolated from stratal fluid of the Bondyuzhskoe oil field was shown to be dependent on calcium for growth. This physiological characteristic was attributed to development of this microorganism in these stratal brines having a high calcium content. Accordingly this feature might have been indicative of indigenicity of this methanogen to the oil field environment (131). Beside these two microorganisms isolated from the subterrestrial environment, isolation of other methanogens has been successful from slightly saline to saline oil well waters in the mesophilic range of temperature (12). It has been demonstrated in studying the Bondyuzhskoe oil field (131) that the methanogenic activity decreased with an increase of salinity. In addition, the role of methylamine as the methanogenic substrate increased with the mineralization of stratal waters,

suggesting that methylotrophic methanogens are also representative of subterrestrial saline ecosystems as already described for terrestrial saline to hypersaline environments (12,34). *Methanosarcina siciliae* H1350, isolated from an oil well at High Island in the Gulf of Mexico, was described as a slightly halophilic methylotrophic methanogen unable to use acetate as the energy source (132,133).

Hydrogen may be an important energy source for methanogens in oil field environments (12) and may explain the presence of microorganisms similar to *M. halotolerans* in saline oil reservoirs. In addition, the specific presence of methylotrophic methanogens in saline to hypersaline oil field waters is also probably indicative of the availability of methylated compounds such as methylamines in the oil field waters as already reported for terrestrial hypersaline environments in which these compounds may originated from the breakdown of osmoregulatory amines (34). It is noteworthy that methanogenesis but also sulfate-reducing activity from acetate have not been reported so far in moderately to hypersaline oil reservoirs, thus suggesting that the process of acetate oxidation is most hardly to occur at high salinity similarly to what has been generally observed in terrestrial hypersaline environments (8,34).

Methanogenesis has been reported from various saline and hypersaline ecosystems including a submarine brine pool in the gulf of Mexico (134), an alkaline lake (135,136), the Great Salt Lake (35,137), and the lake Retba in Senegal, West Africa (36). In most of these environments, a strictly methylotrophic activity related to methanogens has been observed and an absence of H_2 and acetate oxidation via methanogenesis has been noted. Several methanogens using methylated compounds (methylamines, trimethylamine, methanol, and dimethysulfide), but not acetate or hydrogen have been isolated from such ecosystems (31,129,138–141). Halophilic hydrogenotrophic and acetotrophic methanogens were also found to be absent in the Solar Lake sediments (Sinai) with salinity around 7% (142) though methanogenesis occurred at 8.8% salt concentration with $H_2 + CO_2$ in the terrestrial Californian Mono Lake (9) that is the highest salt concentration at which methanogenesis from $H_2 + CO_2$ has been demonstrated to occur in nature in a terrestrial ecosystem. The upper NaCl concentration so far reported for methanogens using hydrogen or formate is 8.3% (73). This indicates that methylotrophic substrates is the most important energy source for methanogenesis followed by hydrogen but not acetate in these environments.

In slightly saline ecosystems such as marine sediments in which sulfate is not limiting, sulfate-reducing bacteria are known to outcompete methanogens in particular for hydrogen and acetate (135). In moderately to hypersaline ecosystems that contain larger amounts of sulfate than marine ecosystems, the major pathway for hydrogen and acetate oxidation is via sulfate reduction. The existence of methanogens in hypersaline environments is therefore related to the presence of noncompetitive substrates such as methylamines, which mainly originate from the breakdown of osmoregulatory amines (e.g., glycine betaine). Consequently, it is generally admitted that methanogenesis does not contribute to the mineralization of carbohydrates because they do not use acetate and/or hydrogen at NaCl concentration higher than 15%. Above this concentration, sulfate reduction is probably the preferred way for oxidizing hydrogen and in a minor extent acetate and occupies a crucial function in the final steps of carbohydrate degradation. However, this function decreases when salt concentration increases in hypersaline environments.

The Fermenters. Numerous thermophilic and slightly halophilic members of domain *Archaea* that have been isolated from thermal environments and in particular from deep-sea volcanic habitats (Table 6), require between 1.5 and 4% NaCl for optimum growth. Most of these slightly halophilic archaea belong to the genera *Thermococcus* and *Pyrococcus* (Kingdom *Euryarchaeota*) and represent one of the deepest branch within the domain *Archaea* (Fig. 4). Most of them ferment proteinaceous compounds and reduce elemental sulfur to sulfide and can grow optimally at temperature above 80 °C (1,4). There are only three representatives of slightly halophiles within Kingdom *Crenarchaeota* (Table 6; Fig. 4). They belong to genera *Pyrodictium* and *Stetteria*. *Pyrodictium brockii* and *P. occultum* grow optimally at 105 °C, whereas *Stetteria hydrogenophila* grows optimally at 95 °C; they are therefore considered as hyperthermophiles.

CONCLUSION

Halanaerobes including fermenters, sulfate-reducers, phototrophs, and methanogens have been recovered from both the terrestrial and the subterrestrial ecosystems. They belong to various phylogenetic groups and comprise the low G+C DNA containing gram-positive group, the *Proteobacteria*, deep-branching members of the order *Thermotogales*, the green sulfur bacteria, and order *Spirochaetales* within domain *Bacteria*, and the Kingdoms *Euryarchaeota* and *Crenarchaeota* within domain *Archaea*. Fermentative bacteria grow on a wide range of substrates, including carbohydrate and/or proteins, and produce a variety of volatile fatty acids with acetate being the common end-product formed. The most intensively studied halanaerobes are the mesophilic thermotolerant fermenters that belong to the order *Halanaerobiales*. The members of the order *Halanaerobiales* are divided into two families, namely, *Halanaerobiaceae* and the *Halobacteroidaceae*. Although *H. cellulosilytica* is the only cellulolytic microorganism so far described in order *Halanaerobiales* (111), *A. arabaticum* grows on betaine and trimethylamine (38) and is the only halanaerobe that performs homoacetogenesis from $H_2 + CO_2$. The existence of thermophilic moderately halophilic anaerobes is limited so far to *H. orenii*, a member of the order *Halanaerobiales* (119) and *T. berrensis*, a member of the order *Clostridiales* (120). The nature of metabolites produced by fermentative bacteria leads to the development of microbial communities in which SRB appear to play an important role. For example, ethanol and hydrogen produced by the halanaerobic fermenters are known to be common growth substrates for halophilic sulfate-reducers. The accumulation

Table 6. Slightly Halophilic Fermentative Members of Domain *Archaea* (see Fig. 4 for Phylogenetic Representation)

Species	Salinity Range (% NaCl)	Optimum Salinity (% NaCl)	Optimum Temperature °C
Euryarchaeota			
Caldococcus litoralis	1–6	2.5	88
Ferroglobus placidus	0.5–4.5	1.8–2	85
Pyrococcus abyssi	0.7–5	3	96
P. furiosus	0.5–5	2	100
P. horikoshii	1–5	2.4	98
P. woesei	nd	3	100–103
Paleococcus ferrophilus	2–7.3	4.3	80

T. alcaliphilus	1–6	2–3	85
T. barophilus	1–4	2–3	85
T. celer	nd	3.8–4	88
T. chitinophagus	0.8–8	2	75
T. fumicolans	0.6–4	1.3–2.5	85–90
T. gorgonarius	1–5	2–3.5	80–88
T. guaymasensis	1–5	3	88
T. hydrothermalis	1.5–5	2–2.5	80–90
T. litoralis	1.8-6.5	nd	85
T. pacificus	1–6	2–3.5	80–88
T. peptonophilus	1–5	3	85
T. profundus	1–6	2–4	80
T. siculi	1–4	2	85
Crenarchaeota			
Stetteria hydrogenophila	0.5–6	2–3.5	95
Pyrodictium brockii	0.2–12	1.5	105
P. occultum	0.2–12	1.5	105

of acetate, produced as one of the end-product of carbohydrate fermentation by halanaerobes and/or incomplete oxidation of lactate and ethanol by SRB, at salinities higher than 15%, indicates that the rate of acetate oxidation via sulfate reduction or methanogenesis is most probably slow or nonexistent (31,34). This hypothesis is strengthened by the isolation of only moderately halophilic hydrogenotrophic sulfate-reducing bacteria that incompletely oxidize lactate to acetate in hypersaline sediments. Activity of these hydrogenotrophs is thought to be responsible for most of the biological sulfate reduction, considered as an important process in hypersaline ecosystems (104). No extremely halophilic sulfate-reducer has so far been isolated, and *D. retbaense*, a hydrogenotroph with a growth upper limit in the presence of 25% NaCl, remains the most halophilic sulfate-reducing bacterium (96). It will therefore be challenge for researchers to isolate new SRB from hypersaline ecosystems that grow at higher salinities than that reported for *D. retbaense*. A second alternative would be to add suitable compounds (e.g., osmolytes) in the growth media that would allow the currently isolated strains to cope with higher salinities. Saline and hypersaline ecosystems, in contrast to most other ecosystems, offer no competition between hydrogen- and/or acetate-utilizing SRB and methanogens because the latter use methylated compounds such as methanol, methylamines, trimethylamine, or dimethylsulfide that do not serve as energy sources for halophilic SRB (31). In addition, the most important source of methylamines for methanogens is probably glycine betaine decomposition (38), a widespread osmoprotectant found in eukaryotes and prokaryotes living in hypersaline ecosystems. The presence of methanol in hypersaline sediments is thought to be a result of a pectinolytic activity (74), which has been demonstrated in *Halanaerobium praevalens*.

As recently reported by Oren (8), life at high salt concentrations is energetically costly. Although members of the *Halanaerobiales* balance the osmotic pressure of the medium with high intracellular KCl concentrations, methanoarchaea, phototrophs, and sulfate-reducers may balance it by synthesizing organic solutes (8). Consequently, the absence of metabolic pathways such as the acetoclastic reaction pathway in halophilic methanoarchaea may have resulted from bioenergetical constraints necessary to cope with life at high salt concentrations (8). In this respect, aspects on physiological investigations in hypersaline terrestrial or subterrestrial microbes is a promising research area. Besides, experiments to be undertaken to improve our knowledge in understanding the different ways that microorganisms use to adapt their growth in hypersaline conditions, the challenge of successfully isolating new types of halophilic anaerobes is still open. In addition, studies of these halophiles may also provide biochemists with organisms from which new polymeric substances, enzymes, or osmolytes of industrial interest could be harvested.

HELICOBACTER PYLORI

E. W. RICE
U.S. Environmental Protection Agency
Cincinnati, Ohio

The bacterial pathogen *Helicobacter pylori* is an etiological agent of both acute and chronic gastritis. The organism is found in the human stomach and upper gastrointestinal tract. It has been associated with peptic and duodenal ulcer disease and the development of gastric carcinoma (1,2). *Heliobacter pylori* is a spiral-shaped bacterium equipped at one end of the cell with multiple, powerful flagella that readily enable it to move in the viscous fluids found in the gastric mucosa. The organism produces large amounts of urease enzyme which assists in neutralizing acids in the microecological niche of the gastric mucus–producing epithelial cells. It has been shown that *H. pylori* can convert from the spiral shape to a coccoid form. The significance of the coccoid form is currently unclear with regards to its role both in the disease state and in the transmission of the organism (3,4).

Heliobacter pylori is a fastidious organism and thus very difficult to culture from environmental sources. Most studies on occurrence in the aquatic environment have been limited to the use of molecular methods using polymerase chain reaction (PCR) amplification. Recovery and survival studies in water have been conducted with seeded organisms using cultural methods, autoradiography, and PCR analysis (5–7). Results from these studies suggest that the organism may be capable of surviving in aquatic environments.

The mode of transmission for *H. pylori* is not fully understood. Person to person contact has been proposed as the most likely method. The oral-oral route, the gastro-oral route, and the fecal-oral route have all been proposed as possible means of dissemination. Epidemiological studies have shown an increased prevalence among lower socioeconomic groups dwelling under crowded living conditions (8), suggesting that sanitation practices may play an important role in transmission of the organism. *Heliobacter pylori* has been reported in the feces of children from an area of endemic infection (9). Studies employing PCR amplification techniques have suggested the presence of *H. pylori* nucleic acids in sewage and drinking water. Other studies using microscopic immunological procedures have reported the occurrence of respiring cells in surface and ground water sources (10). Epidemiological findings have cited increased risk factors for infection associated with drinking water (11) and the consumption of uncooked vegetables irrigated with untreated sewage water (12). Pure culture inactivation studies have shown that the organism is sensitive to disinfection and is readily inactivated by chlorine (13). Further research regarding occurrence and mode of transmission should help elucidate the potential risk of this organism as a waterborne pathogen.

HEPATITIS VIRUSES (HAV-HEV)

KHIN SAW AYE MYINT
Armed Forces Research Institute of Medical Sciences (AFRIMS)

Jakarta, Indonesia

Hepatitis A virus (HAV) and hepatitis E virus (HEV) are the two known viral hepatitis etiologies associated with enterically transmitted hepatitis disease. Worldwide occurrence of both HAV and HEV is both sporadic and epidemic in nature and is predominantly featured in the developing world; poor sanitation through fecal–oral routing characterizes the environmental dimension predisposing transmission (1–4). Both HAV and HEV have been implicated as causative in most outbreak episodes involving hepatitis (5). The preponderance of epidemic enteric hepatitis cases can be attributed to HEV in that most children have already been exposed to HAV by the time of adolescence, particularly in developing areas (Table 1). Moreover, HEV epidemics have generally been found to impact sizeable populations, often overwhelming immunologically and environmentally susceptible populations: some examples include 10,000 cases in Kathmandu (1973–74), 20,000 in Kashmir (1978), 11,000 in Kashmir (1981–82), 15,000 in Kashmir (1981–82), 79,000 in Kanpur (1991), and 20,000 in Mandalay (1976–77) (5). Epidemic HEV occurrence on the Indian subcontinent, first recognized from the 1955 outbreak (affecting 30,000 persons) in New Delhi, has since been identified as a significant public health concern throughout South Asia and as a major epidemic and sporadic disease entity, whereas HAV is probably the leading cause of sporadic, clinically recognized viral hepatitis (6). While HEV is molecularly distinct from HAV, it is also proving to be epidemiologically distinguishable (Fig. 1). Notably, HEV is uniquely synonymous with high case fatality rates (CFRs) in pregnant women, approximating 10–24% in affected populations, whereas CFRs associated with acute HAV infections are generally less than 1/1,000 persons, although rates as high as 1.5/1,000 and 27/1,000 among groups aged less than 5 years and more than 50 years, respectively, have been reported (7). As with HEV, most HAV infections in young children do not usually translate into acute, clinical disease episodes (8–10). Finally, the sporadic or epidemic forms of HEV, unlike HAV, are not ubiquitous in occurrence relative to geography: sporadic cases of HEV predominate in places such as North and East Africa (the Horn), in contrast to more outbreak-related recognition in Southeast Asia (10–14).

HEPATITIS A

Biology

HAV is a nonenveloped RNA virus of 27–28 nm diameter (Fig. 2) with icosahedral symmetry, belonging to the *Picornaviridae* family. There are four recognized genotypes based on primary sequence variability, but only one known serotype (15). Many strains of HAV have been described on the basis of different growth characteristics, nucleotide sequence, or geographic origin (16).

STABILITY

Stability of HAV is determined under both optimized laboratory and natural field conditions. HAV is extremely heat stable and temperatures above 60 °C are necessary to destroy infectivity (17–19). HAV is highly stable at low pH; the purified HAV remains infectious for up to eight hours of exposure to pH 1 at room temperature (20). It is resistant to many detergents such as Nonidet P40 and deoxycholate as well as to organic solvents such as ether, chloroform, and trichlorotrifluoroethane (19,21). HAV can resist higher levels of chlorine than other enteroviruses (22) and its resistance to inactivation is more remarkable in its natural state in feces, water, or wastewater (23). Exposure of 30 minutes to a free residual of 2.0- to 2.5-mg chlorine per liter is required to completely inactivate HAV (22). A lower level of 0.2 mg/L is required for complete inactivation (23) when chlorine dioxide is used because it is more microbiocidal. HAV is extremely resistant to chloramines, and treatment with 10 mg of residual chloramines per liter for nearly two hours is necessary for inactivation (24). HAV can be reliably inactivated by autoclaving (121 °C for 30 minutes), treatment with a 1 : 4, 000 dilution of formaldehyde at 37 °C for 72 hours (25), or exposure to ultraviolet irradiation (25). At 20 °C, 0.25–0.38 mg/L of ozone is required for complete inactivation of HAV (26), however, under different laboratory conditions and using a different strain of HAV, an increased concentration was required, at 1 mg/L (27). Quaternary ammonium formulations containing 23% HCl (toilet bowl cleaner), 2% gluteraldehyde, or sodium hypochlorite with free chlorine in excess of 5,000 ppm are recommended for effective surface disinfection (28) as several commercially available disinfectant preparations act poorly against the virus (29).

The survival of enteric viruses in water depends on a large variety of physicochemical and biological factors, the most important being temperature (30). The survival time increases considerably as the water temperature decreases. The T99 (the time required to inactivate 99% of microorganisms) is reported to be 19–20 days at 25 °C for HAV (31). HAV can survive in experimentally contaminated freshwater, seawater, and wastewater for

Table 1. Main Epidemiologic Differences Between Hepatitis Viruses A and E

	Hepatitis A	Hepatitis E
Mode of transmission	Fecal–oral: Person-to-person (major) Food-borne (common) Waterborne (minor) Blood transfusion (rare)	Fecal–oral: Waterborne (major) Person-to-person (minor) Food-borne (minor)
Geographic distribution	Worldwide prevalence Infection is universal in developing countries	Central and Southeast Asia, Indian subcontinent, Middle East, Northern and Western Africa, Mexico
Seasonal pattern	Fall, winter in temperate zones Rainy season in tropical countries	During or after rainy season
Age preference	All age groups Children in developing countries	Young to middle-aged adults
Sex predilection	Equal	Higher in males
Mortality in pregnancy	Not increased	10–24%
High-risk groups	Institutions for the intellectually handicapped, daycare centers, homosexual men, intravenous drug users, travelers to endemic areas	Travelers to endemic areas

Note: This table was produced by Dr. Khin Saw Aye Myint.

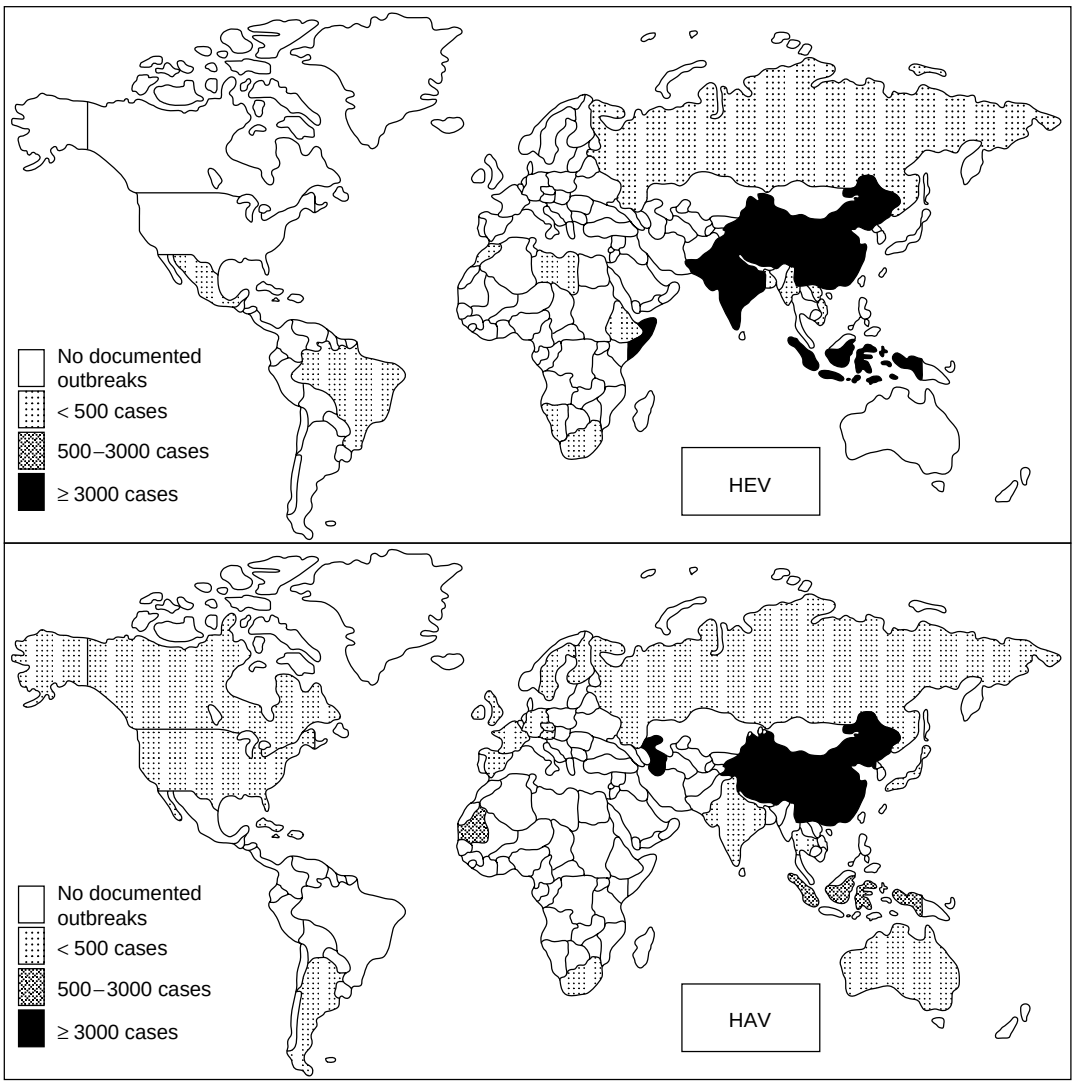

Figure 1. Worldwide outbreaks of hepatitis E virus (HEV) and hepatitis A virus (HAV), 1987–2000. Reflects largest instance of documented epidemic occurrence by country. [This graphic mapping presentation was produced by Kanti Laras, Emerging Disease Program U.S. NAMRU-2, (e-mail address: Kanti@namru2.med.navy.mil) based on an exhaustive review of the literature and compilation of 49 publications].

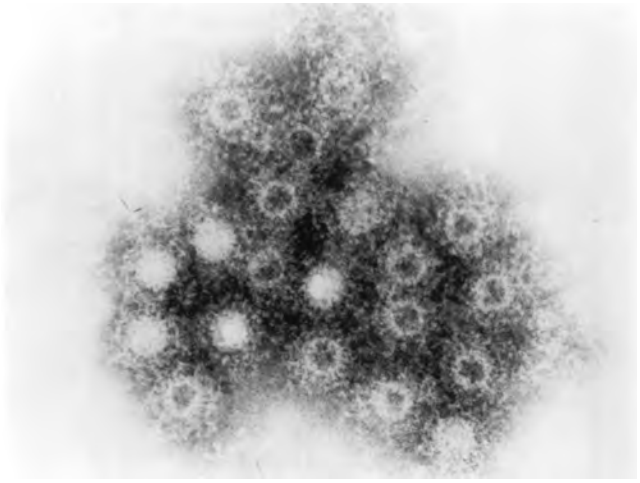

Figure 2. Immunoelectron microscopy of 27-nm HAV particles from the bile of an experimentally infected owl monkey. The virus particles are heavily coated with reagent antibody to HAV from the convalescent-phase serum of another owl monkey. (Photograph kindly supplied by Dr. John Ticehurst, U.S. Food and Drug Administration and Johns Hopkins Medical Institutions.)

as long as three months (32), and it is reported to last for nearly eight months in artificial sterile seawater (33) and at least six months in sampled groundwater after an outbreak (34). The survival of HAV in mineral water is longer at 4 °C compared to room temperature and is still infective after 300 days at room temperature (35).

It is shown that an increase in fat content contributes to the heat stability of HAV as higher exposure times are needed to achieve a 1 log reduction in virus titer in cream, when compared to skim and homogenized milk (36).

The life span of enteric viruses in immersed shellfish varies according to the microbiological quality and temperature of the water. HAV does not replicate but rapidly accumulates, and has persisted for about seven days in mussels. Conventional depuration does not provide adequate protection against the transmission of HAV (37,38). An internal temperature of 85 to 90 °C is necessary for complete inactivation of HAV in shellfish (39,40).

HAV can survive for a long time on several types of routinely used materials (41). Stability of HAV on environmental surfaces depends on relative humidity (RH), temperature, and type of surface contaminated (41,42). HAV survival is enhanced at high RH and low temperatures, especially on nonporous environmental surfaces (41).

ANIMAL RESERVOIR

The presence of antibodies in some species of nonhuman primates (great apes, Old World and New World monkeys) at the time of capture indicates that a reservoir of infection might be present in their natural habitat. There are several reports of isolation of HAV-related viruses from monkeys, several of which have significant sequence variation and minor antigenic divergence from human HAV (43,44).

VIRUS EXCRETION

Duration of virus excretion is based largely on studies in volunteers as well as epidemiologic observations and studies in experimentally infected animals. Large numbers of virions are excreted in the feces during the late incubation period and early acute phase of the disease (45–47). Fecal shedding of HAV can be studied by immunoelectron microscopy, radio- or enzyme-immunoassay, molecular hybridization and Reverse Transcriptase-Polymerase Chain Reaction assays. Recent studies using highly sensitive PCR have indicated that infected persons can excrete HAV for three months or longer (48,49).

VIRUS TRANSMISSION (TABLE 1)

Person to Person. The most predominant mode of transmission is from person to person via the fecal–oral route. Transmission is generally limited to close contacts, especially those within families. Infection rate is highest in young children, who are frequently involved in the spread of infection in households (50). Highest virus concentrations are found in feces (10^7 to 10^9 infectious doses per ml), blood (10^3 to 10^5 infectious doses per ml), and in saliva (10^0 to 10^5 infectious doses per ml) (51).

Food- and Waterborne-Transmission. About 0.4% of the documented hepatitis A in the U.S.A. is food-borne (52). In many countries, an important cause of outbreaks appears to be consumption of raw or undercooked shellfish (53). Shellfish feed by filtering large quantities of water, as a result they accumulate and retain virus in their digestive tract and tissues (54). HAV may survive in shellfish for months. Shellfish are often eaten raw or steamed, and these preparations are inadequate for virus inactivation. Food may also be contaminated during restaurant preparation or at the supplier's. Other vehicles that have been involved in outbreaks of hepatitis A include cold foods typically eaten raw or uncooked, such as milk and dairy products, fruits, meat, pastries, lettuce, and caviar. HAV is transmitted not only by raw food but also by food heated at temperatures insufficient for the virus inactivation. Although waterborne epidemics of hepatitis A have been well documented (55), waterborne transmission plays a minor role in developed countries and accounts for less than 1% of all cases seen in the United States (56). Transmission of HAV by sewage-polluted recreational water has been reported in many developing countries (57), however, there are no data indicating that a significant number of cases occur in this way (58). Nevertheless, recreational HAV exposures principally associated with swimming and bathing, for example, recreational lake water and jacuzzi, respectively, are frequently reported, temporarily and spatially focused, outbreak phenomena (57,58).

Blood Transmission. Although HAV is present in the blood for a significant period during the incubation period and early acute phase of the disease, blood-transmitted hepatitis A appears to be a rare event and only a few cases of posttransfusion hepatitis have been reported (59).

METHODS OF HAV DETECTION

Detection in Clinical Specimens

Specific diagnosis for Hepatitis A is readily made by an enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay test for specific IgM (60,61). IgM anti-HAV can be detected in 95 to 100% of patients with acute hepatitis A at their first clinical presentation and usually persists for three to six months. IgG anti-HAV may also be detected at the onset of disease. The titer increases during the first weeks after onset of illness and reaches a maximum after 6 to 12 months. Immunological methods, molecular hybridization, or PCR commonly used for environmental and research studies are not practical for general clinical use. Similarly, virus isolation is impractical for diagnosis because it is insensitive, inconsistent for clinical isolates, cumbersome and time-consuming.

Detection in Environmental Samples

Environmental detection includes recovery of virus concentration and assay. A number of concentration methods have been developed; most suffer from limitations and there is no single method that can be used to detect HAV in all types of samples. Most concentration methods have achieved adequate virus recoveries with samples that have been experimentally inoculated with known quantities of HAV (62–70). Some methods have been used successfully under field conditions to recover the virus in naturally contaminated environmental samples (64,71–75). The concentration method should be customized depending on the volume of water needed to be concentrated, the probable virus concentration, and the presence of interfering substances. To monitor virus recovery efficiency, seeded samples should be included as internal controls whenever field samples are processed (76). Different techniques that have been successfully used for HAV concentration from environmental samples are described later.

HAV Concentration by Adsorption-Elution Methods

HAV HAV can be concentrated by adsorption to microporous filters and recovered by elution (77–80). The eluent can be a high-pH 0.05 M glycine buffer, a 1–3% beef extract solution at pH 9.5 to 10, or a combination of 1 to 3% beef extract-0.05 M glycine (62,68,81). The elution process is generally a single step in which the eluent is forced under pressure through the filters. HAV is efficiently adsorbed by both negatively or positively charged microporous filters (62,82,83). Efficient virus adsorption with electronegative filters requires preacidifying (usually pH 3.5) the water and the addition of multivalent cationic salts. Electropositive filters adsorb viruses efficiently over a wide range of pH without the need for chemical modifications of water. The efficiency of these filters is influenced by the amount of humic acid and other organic compounds present in the water (84,85).

For small sample volumes (86) the adsorbed virus can be eluted with a small volume of fluid. But environmental water samples are usually collected in large volumes to increase the chance of detecting low quantities of HAV. For such large volume samples, the adsorbed viruses are eluted with approximately one liter of eluent and the eluates are further concentrated to final test-volume samples suitable for virus assay (75,81). There are several techniques used for secondary reconcentration, including organic flocculation (87), ammonium sulfate flocculation (88), modified polyethylene glycol (PEG) precipitation (64), ultrafiltration (89,90) and readsorption to, and elution from, smaller diameter microporous filters (91). HAV in nonproteinaceous eluates (glycine buffer) originating from finished tap water or other waters containing low concentrations of organic matter can be reconcentrated by adsorption–elution with smaller filters (92,93).

HAV Concentration by Organic Flocculation

Organic flocculation involves precipitating viruses by acidifying eluates (beef extract or beef extract-glycine) to pH 3.5, recovering the viruses adsorbed to the flocs by centrifugation, and resuspending the pellet in small volumes of phosphate buffer for virus assay (87). Beef extract, casein, or powdered skimmed milk are usually used for flocculation. The efficiency of HAV recovery may be increased by using powder instead of paste beef extract (62). HAV can be concentrated 100- to 10,000-fold onto microporous filters and an additional 10- to 100-fold by organic flocculation (79,94).

HAV Concentration by Ammonium Sulfate Flocculation

Ammonium sulfate flocculation is an efficient method to reconcentrate HAV from beef extract eluates at neutral pH (65). This method is based on the ability of saturated ammonium sulfate to flocculate beef extract at neutral pH (88). HAV is adsorbed to the flocs and the virus-containing flocs are recovered by centrifugation. It is suitable for small volumes of all types of water but detoxification is necessary before the virus can be assayed in cell culture. It can be used as a primary or a reconcentration procedure.

HAV Concentration by Polyethylene Glycol (PEG) Precipitation

PEG, a chemically inert, nontoxic, water-soluble synthetic polymer known to precipitate a number of proteins, can be used either as a primary or secondary method for HAV concentration. For reconcentration, the eluate is adjusted to a neutral pH, supplemented, and incubated with PEG at a final concentration of 8% (wt/vol.). The precipitated HAV is centrifuged and the pellet is resuspended in 0.15 M phosphate buffer (pH 9) and recentrifuged to collect the supernate for virus assays.

PEG precipitation can be used with a variety of water samples and is unaffected by high concentrations of humic acid (64,68). It can also efficiently reconcentrate HAV in eluates from wastewater, sediments, and shellfish samples (64,69,70). PEG precipitation is superior to the organic flocculation method for HAV recovery under both laboratory and field conditions, and can be used without extensive pH treatment (64). Double precipitation with

PEG results in small volume concentrates suitable for sensitive HAV detection (68,95).

HAV Concentration by Ultrafiltration

Ultrafiltration is a process that separates particles according to their molecular weight. The membranes for ultrafiltration are defined according to the molecular weight cutoff (MWC), which is the molecular weight above which most microorganisms are retained by the membrane. HAV can be concentrated by several commercially available ultrafiltration units, depending on the volume of sample to be treated (68,72,96–98). The ultrafiltration method has several advantages: pH adjustment or additional multivalent cationic salts are not required (89,90) and organic compounds or proteinaceous solutions do not interfere with the virus recovery. HAV is successfully concentrated by ultrafiltration from a variety of environmental samples (72,83,97,99). Ultrafiltration can either be used as primary or secondary concentration.

HAV Concentration from Sludge

HAV is recovered from sludge through two steps, virus extraction and concentration to a small volume (72,100). The extraction method varies depending on different kinds of sludge. The sample is first centrifuged and the sludge pellet is suspended in an eluent (3–10% beef extract solution or glycine) with an alkaline pH, followed by homogenization. This can be done by mechanical agitation (101), magnetic agitation (102), or sonication (103). The homogenate is then recentrifuged to recover the supernate, which is neutralized to pH 7.2. Concentration of the supernate is generally done by organic flocculation, PEG precipitation, membrane adsorption—elution, or ultrafiltration for efficient HAV recovery. Freon treatment can be added before recovering the supernate (66).

HAV Concentration from Shellfish

The processing method involves homogenizing the mollusk tissues in their intervalvular fluid and extracting the viruses from the homogenate by a modified adsorption–elution–precipitation method (104). The extract is further purified and concentrated by a procedure involving fluorocarbon (Freon) extraction and PEG precipitation (64,69,70,105,106). The PEG precipitation method can obtain a high level of recovery (>90%) of HAV from shellfish (64,105). Clam tissues are more acidic than oyster tissues and constant readjustment of pH during the concentration procedure is important for effective recovery of HAV (92). Other commonly used concentration procedures for shellfish are organic flocculation (69) and ultrafiltration (107).

HAV Concentration from Food

The procedure involves washing food samples with a guanidinium phenol–based reagent (TRIzol solution), clarifying the wash retentates by centrifugation followed by extraction of the viral RNA-containing aqueous layer with chloroform, and precipitating in isopropanol (108). The equivalent of 10^2 viral genome copies of HAV seeded onto delicatessen meat could be detected by this method (108).

Identification of HAV in Sample Concentrates

Cell Culture Assays. Cell culture is the classic method by which the infectivity of HAV can be tested. Since most HAVs lack cytopathic effects (CPE), virus growth can be demonstrated by inoculation into the human hepatoma cell line PLC/PRF/5 and detection by radioimmunofocus assay (RIFA). An alternative method is to test RNA extracts from cell cultures by hybridization. However, conventional cell culture techniques have limited sensitivity, especially for the wild-type strains from field samples (109).

Molecular Biology Techniques. The most rapidly growing area of detection is based on the specific identification of viral nucleic acids by hybridization and PCR. Although dot blot hybridization is reported to be useful for the rapid detection of naturally occurring HAV (63,105,110,111), improvement of test sensitivity will be necessary for the detection of low level of viruses in many field samples (105). PCR can be used to enzymatically amplify to detectable levels nucleic acid sequences that are present in low copy numbers in field samples. The sensitivity of the PCR technique and confirmation of PCR amplification should be evaluated by techniques such as oligonucleotide probe hybridization and nested PCR assays. Nested PCR increases both sensitivity and specificity enabling the detection of low concentrations of HAV (112). The drawback of PCR is that it cannot be used for quantification or determining the infectivity of the virus. RT-PCR-based detection of HAV uses primers focused on HAV target sequences from areas in the 5′ noncoding region and the regions coding for the VP3-VP1 capsid protein or the 3D RNA polymerase (113,114). Natural strains of HAV share a high degree of nucleotide identity and can be expected to react specifically with these target sequences.

Modified versions such as antigen-capture PCR (AC-PCR) (115) and immunomagnetic capture (RT)-PCR (IC-PCR) (70,73,116) have been employed for environmental detection. AC-PCR is based on the capture of virus particles by binding to a HAV-specific monoclonal antibody, followed by PCR, and IC-PCR uses magnetic beads coated with anti-HAV antibodies against surface epitopes of HAV. In addition to avoiding the concentration of inhibitory substances (73), these methods have the advantage of indicating the presence of intact viral particles, suggesting possible infectivity (116). This is of great public health significance as there is no reliable confirmation method to determine infectivity of natural HAV strains. IC-PCR is 100- to 1,000-fold more sensitive than RT-PCR (116). Multiplex-PCR, a rapid and cost-effective method for simultaneous detection of HAV and other enteric viruses with a single amplification procedure, has recently been developed (98).

Removal of PCR Inhibitors. PCR cannot be performed with most concentrated water samples unless reaction inhibitors are removed before RT and/or the amplification reaction (PCR). Humic acid and other organic materials

that are concentrated along with viruses in environmental samples may interfere with nucleic acid polymerase function (117). Various methods to remove PCR inhibitors from environmental samples have been described (118–120). Beef extract, which is commonly used for eluting adsorbed viruses, also contains high concentration of proteins, salts, and other solutes (121) that can interfere with molecular detection methods. Sample concentrates can be purified by removing inhibitory substances prior to PCR by chemical means such as phenol-chloroform extraction (75,110), guanidinium isothiocyanate (GIT) extraction (70,111), or by physical means such as sephadex gel chromatography (68,74,119,120). A proprietary protein-precipitating agent, Pro-Cipitate, can also be used to further purify viruses in sample concentrates for RT-PCR (68,69,106). A combination of purification measures can be used to efficiently remove PCR inhibitors (68). Removal of shellfish polysaccharides from nucleic acid is also necessary before viral RNA can be detected. In addition to the above methods, the cationic detergent cetyltrimethylammonium bromide (CTAB) is also effective for removal of shellfish polysaccharides (105). CTAB can selectively precipitate nucleic acids while leaving proteins and polysaccharides in solutions (122).

Indicators of HAV Contamination in Aquatic Environments

Monitoring for hepatitis A in aquatic environments is not in the best interest for public health protection because the virus is present in very small concentrations in the environment; methods are not yet practical for the purpose of routine monitoring.

Bacterial Indicators. At present, viral contamination of water and wastewater is based mostly on bacteriological quality indices. Monitoring the traditional bacterial indicators (*Escherichia coli* fecal streptococci and coliforms) is rapid, easy, and inexpensive, but HAV is more resistant to environmental conditions, sewage or water treatment processes than current bacterial indicators (123). Studies have showed that HAV contamination is not associated with *E. coli* (124) and fecal coliforms (110,125). Outbreaks of HAV from water and food considered to be safe based on bacteriological standards (126,127) indicate that more reliable microbial indicator systems are needed.

Bacteriophages. (see BACTERIOPHAGE AS INDICATORS) Bacteriophages are viruses that arise from host bacteria that become infected and subsequently lyzed. Three basic groups of phages have been proposed as candidate indicators for enteric viruses: somatic coliphages (128), F-specific (F^+) bacteriophages (129), and phage-infecting *Bacteroides fragilis* (130). B40-8 phage infects *B. fragilis* HSP40, which is considered of human origin (130,131). As a result of their inability to multiply in the environment (131,132) and resist water treatment better than other phages (133), B40-8 are potentially useful as indicators of the virological quality of water. However, *B. fragilis* phages are found in low concentrations in groundwater, and the techniques for detection are more complicated than those used for other phages (134). There is no association of bacteriophage with hepatitis A virus recovery (124,135).

Other Viral Indicators. It has been suggested that enterovirus could be used as an indicator of HAV presence (117,136). However, there is little correlation between enterovirus and HAV occurrence; river water samples that were negative for enterovirus have been found positive for HAV (137), and conversely, river water and tap water samples positive for enterovirus were negative for HAV (112). More recently, it has been suggested that the detection of adenoviruses by PCR could be a better indicator of enteric viruses than enteroviruses as they are more stable in various environments and are more resistant to water treatment (138). However, HAV is more resistant to disinfection than human adenovirus (134).

PREVENTION

General

Providing populations with clean water, proper waste disposal, and improved living conditions rapidly reduces the incidence of hepatitis A. General hygienic measures are also most important in limiting person-to-person transmission. Transmission by foodhandlers can be reduced by training on proper hygiene and foodhandling practices. Proper handwashing during all phases of food preparation should be emphasized. The public needs to be educated that HAV is heat sensitive and that infection can be avoided by adequate heat treatment. Shellfish should be heated for 1.5 minutes at 85 to 90 °C for consumption (39). Travelers to developing countries should be advised to eat only properly cooked food and be careful with uncooked vegetables and shellfish.

HAV Passive Immunization

Until recently, the mainstay of hepatitis A immunoprophylaxis available has been passive immunization by means of pooled immunoglobulin (IG). If administered before exposure, passive immunization can reduce the incidence of hepatitis A by up to 90% (139). Postexposure prophylaxis with IG is also effective if administered within two weeks of exposure and will usually prevent or reduce the severity of disease (140).

HAV Active Immunization

Inactivated and live-attenuated vaccines against hepatitis A have now been developed as a result of progress in hepatitis A research. A safe and highly effective formalin-inactivated whole virus vaccine of high efficacy has been licensed throughout the world (141–143). In addition, a live-attenuated vaccine has been developed (131) and a novel vaccine antigen delivery system, termed *virosomes*, has been utilized to construct hepatitis A vaccines (145,146).

HEPATITIS E

Biology

Hepatitis E (HEV) is an icosahedral, nonenveloped, positive sense single-stranded RNA virus of 27 to 34 nm

(Fig. 3). The virus remains unclassified, although its genomic organization most closely resembles that of caliciviruses and is substantially different from that of picornaviruses such as HAV (147). The first complete nucleotide sequence for HEV was published by Tam and coworkers in 1991 (148). To date, four different strains (Burma, Mexico, Pakistan, and China) have been completely sequenced (149). A recent phylogenetic analysis of 26 HEV strains, based on nucleotide sequence, revealed three principal genotypes: Asia Africa (I), United States (II), and Mexico (III) (150). The HEV genome has three overlapping open reading frames (ORFs), with the nonstructural proteins located at the 5′ end of the 7.5 kb genome and the structural protein(s) located at the 3′ end. Although most of the structural proteins are coded within ORF2, all three ORFs contribute to the morphology of HEV (151). Studies showed that physicochemical properties of HEV regarding size, morphology, sedimentation coefficient, and buoyant density closely resemble those of caliciviruses (148,152). Subsequent analysis of nonstructural genes has shown similarity to the alpha-viruses, furoviruses and rubella viruses (153). To date, HEV is known to exist as a single serotype, that is, HEV isolates from different geographic regions share the same antigenic pattern. Accurate characterization of HEV has been hampered because of a lack of a tissue culture system, and the biology of HEV is poorly understood.

STABILITY

HEV is reportedly more labile than HAV. HEV does not survive exposure to high concentrations of salt, including cesium chloride, or freeze-thawing (154), but it is unaltered by exposure to trifluorotrichloroethane (155). The viral particles tend to lose their integrity after routine laboratory procedures, whereas in the environment they are more stable and survive exposure to extreme conditions (156). Epidemiological data suggest that boiling water may inactivate HEV (157,158). However, no data are available regarding the efficacy of water and wastewater disinfectants, including chlorination, in inactivating HEV.

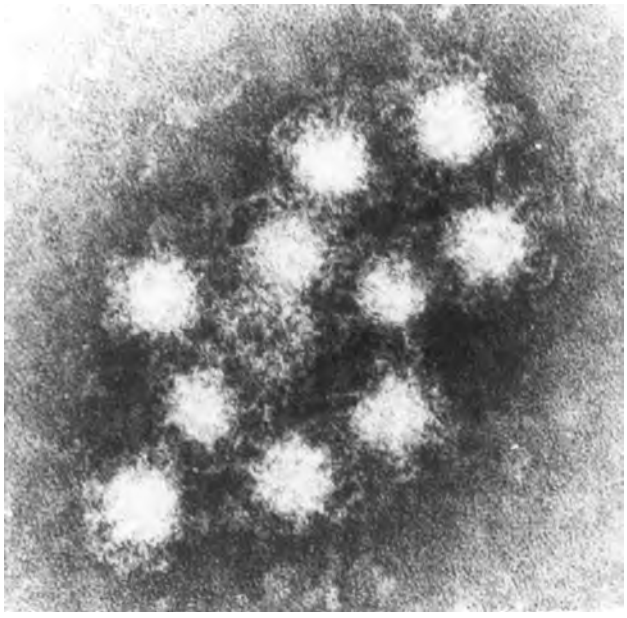

Figure 3. Immunoelectron microscopy of 29-nm HEV particles from the bile of an experimentally infected cynomolgus monkey. The virus particles are heavily coated with reagent antibody to HEV from the acute-phase serum of another cynomolgus monkey. (Photograph kindly supplied by Dr. John Ticehurst, U.S. Food and Drug Administration and Johns Hopkins Medical Institutions.)

ANIMAL RESERVOIR

Various species of nonhuman primates are known to be susceptible to HEV infection, at least under experimental conditions (155,159). It has been shown that some of these species can be infected in their natural habitat (3). In an endemic area of Nepal, naturally acquired HEV specific antibodies were detected in chickens, pigs and rats (160). Recent evidence suggests that swine may be an important reservoir of infection in the United States (161) and Taiwan (162,163). The possible ramifications of this zoonotic reservoir give caution to future xenotransplantation into humans (164). HEV was detected by immunoelectron microscopy in the blood of wild rats and mice trapped near an outbreak of hepatitis E in Kirgizia (165). Recently, it was reported that anti-HEV was prevalent in rodents throughout the United States, providing evidence that rodents might be a natural reservoir of HEV (166). These findings suggest that HEV may be a zoonotic virus, however, there is no evidence supporting the transmission of HEV from animals to humans.

VIRUS EXCRETION

Fecal excretion of HEV is in low titers compared to HAV and occurs predominantly during the first week of jaundice (167), but may persist for 14 days after the onset of clinical illness (168). The viral particles are fragile in vitro and little is known about their viability in the environment.

VIRUS TRANSMISSION

Fecal-oral transmission (Table 1) is well documented for HEV. Most hepatitis E outbreaks are caused by fecally contaminated water. Use of river water for drinking and cooking, personal washing, and human excreta disposal were all significantly associated with high prevalence of HEV infection in Southeast Asia (10). Epidemic situations often arise during the rainy season or floods when sewage waters gain access to open water reservoirs (169,170). Unlike HAV, which has a 10 to 20% secondary attack rate among household contacts, there is low incidence of person-to-person transmission, around 2% (157,171,172). The low titer of infectious virions shed in the feces during infection may account for the decreased secondary spread of hepatitis E (173). No chronic or carrier state has been reported following infection with hepatitis E (174). Only a few cases of food-borne transmission have been

reported (175,176), and food-borne hepatitis E is regarded as of small significance. In these cases, shellfish was identified as the vehicle for transmission.

METHODS OF VIRUS DETECTION

Detection in Clinical Specimens

Molecular cloning of the HEV viral genome has led to the development of sensitive and reproducible diagnostic tests, including enzyme immunoassays for antibody by immobilization on recombinant proteins or synthetic peptides (159,177–181). An excellent, comprehensive review of HEV detection, collection, and storage techniques was published recently (182). IgM anti-HEV appears early during clinical illness but disappears rapidly over a few months. IgG anti-HEV appears a few days later and persists for at least a few years (183). Commercially available ELISA helps detect antibodies of both IgM and IgG class and is useful in diagnosing acute and past HEV infection. Commercially available serological tests using recombinant proteins are more sensitive, reportedly detecting anti-HEV in 80 to 90% of patients with acute hepatitis during outbreaks of hepatitis E (178,184). Different methods to detect viral-specific nucleic acid by RT-PCR have been developed and evaluated for their efficiency in detecting viral-specific sequences (185). Recently a rapid RT-PCR procedure using universal oligonucleotide primers was developed for detection of HEV-RNA in serum (186). While HEV detection in serum or stools has high sensitivity and specificity, the process is labor-intensive, and when the method is used in less-experienced laboratories, problems of nonspecificity, primarily due to specimen contamination, might complicate the interpretation of results (187). Sensitivities for the various HEV assays have been reported to vary between 17 and 100% in nonendemic areas, suggesting caution in interpreting results from low-prevalence populations (188). Moreover, these tests may perform differently in endemic and nonendemic settings (189). Immunoelectron microscopy is not practical due to low levels of virus excretion (190).

Detection in Environmental Samples

Environmental detection of HEV has been reported (191,192), but more data are needed on applicability to various field samples. Environmental detection of these viruses requires three general steps: collecting a representative sample, concentrating the virus in the sample, and identifying the concentrated virus.

HEV Concentration by Adsorption-Elution Method

HEV from environmental samples can be adsorbed by either granular activated carbon (GAC) column (192) or membrane filters (191), and eluted with urea-arginine phosphate buffer at pH 9.0. Further reconcentration of the primary eluate is done by adding magnesium chloride, and the precipitate formed is recovered by centrifugation for virus assay.

Identification of HEV in Sample Concentrates

At present there is a lack of efficient cell culture methods for HEV, and the few reports of HEV detection in field samples is based mainly on RT-PCR with confirmation by hybridization (191,192).

PREVENTION

Although variation in pathogenicity and infectivity of HEV in one area may be due to different strains, environmental factors are a major contributor to the endemic and epidemic spread of HEV. Management of a community outbreak involves identification and correction of the environmental factors promoting fecal contamination of drinking water. Seasonal monsoons can lead to floods that can overwhelm water treatment facilities, leading to contaminated drinking water. Water treatment facilities should be upgraded, and improved hygiene standards and general sanitation could reduce transmission. Travelers to HEV-endemic regions should avoid drinking water (and beverages with ice) of unknown purity and eating uncooked shellfish, fruit, or vegetables. In an HEV epidemic, drinking water should be boiled as chlorination alone may be inadequate (158).

HEV Passive Immunization

Based on recent studies (184), immunoglobulin may be beneficial, but there have been no controlled clinical studies. Passive immunization of nonhuman primates with HEV antibodies protects them from disease after HEV challenge (193), and it is possible that prophylactic treatment, by passive immunization, may have an impact on the natural course of infection during pregnancy. This is important because pregnant woman, particularly in the third trimester, can suffer fatality rates as high as 32% (194).

HEV Active Immunization

Currently no commercial vaccine is available. The development of an inactivated or live attenuated virus vaccine has been hampered because HEV does not replicate efficiently in cell culture. Recombinant vaccines have given good results with primates against experimentally induced hepatitis E (195,196) and they may be particularly useful for travelers to disease-endemic areas and for pregnant women (183). Phase I safety and immunogenicity evaluation of a new recombinant HEV vaccine have been successfully completed in Nepalese volunteers by the U.S. Army laboratory based in Bangkok, Thailand.

In conclusion, HAV and HEV share more epidemiological attributes associated with mode of transmission, as compared with their respective, and very much distinctive, environmental morphological characteristics. Fecal–oral mechanisms contributing to the spread of both viral agents make them both highly communicable from an outbreak perspective, particularly in areas where water sanitation and hygiene are compromised. At the same time, the water-related nature of transmission allows for reasonably effective measures in preventing exposure type opportunities. Finally, surveillance attention

should be paid to changes in disease virulence against a background of increasing environmental pressures, including induced protection afforded by vaccination and even global warming.

HETEROTROPHIC BACTERIA AS INDICATORS OF WATER QUALITY

EDWIN E. GELDREICH
U.S. EPA
Cincinnati, Ohio

The heterotrophic bacteria in water comprise many diverse groups of organisms. Some of these organisms are ubiquitous to all aquatic systems, whereas others represent some contact with varying inputs of stormwater runoff, waste discharges, wildlife populations, soil, vegetation, and airborne dust particles. Their continued survival or potential for colonization in the aquatic environment are qualified by availability of nutrients, favorable water temperatures and pH, and the status of dissolved oxygen concentration. Counter influences in the aquatic environment include microbial predation by amoebae and nematodes, antagonism from competing organisms, sunlight exposure, and entrapment in sedimentation that limits the extent of

population growth. Seasonal changes in water temperature and pollution spills into the aquatic environment are other powerful influences that distort bacterial profiles and shift the dominance of these organisms at any given time (1).

It has been estimated that the community of heterotrophic bacteria may comprise up to 90% of all aquatic bacteria detected in surface waters (2) and largely are responsible for the wide fluctuations in bacterial populations noted in surface waters. Because groundwaters generally are protected from the intrusion of contaminants by a soil barrier, species diversity and density of heterotrophic bacteria are very limited and show little change.

Predominant genera of heterotrophic bacteria include *Flavobacterium, Cytophaga, Achromobacter, Acinetobacter, Alcaligenes, Moraxella, Vibrio, Aeromonas, Pseudomonas*, environmental coliforms (*Klebsiella, Aerobacter*, and *Citrobacter*), and fecal coliforms (*Escherichia* and fecal *Klebsiella*) (3). Among this wide spectrum of organisms are some species that have the ability to form brightly colored nonphotosynthetic, nondiffusible pigments (yellow, orange, pink, purple, brown, and black). This unique property is often not observed in the routine processing of water samples unless the incubation time for heterotrophic bacteria is extended beyond three days. These pigmented bacteria appear in greatest abundance in high-quality water (water supply, bottled water, and water attachment devices) and often are found to be *Flavobacterium* and some species of *Mycobacterium, Serratia, Corynebacterium*, and *Chromobacterium*. For example, the proportion of pigmented bacteria in public water supplies may represent 10–62% of the heterotrophic bacterial density. Water treatment processes, particularly granular activated carbon (GAC) filtration and disinfection may be selective factors for the occurrence of pigmented bacteria in some water supply microfloras. At the Ohio River intake, yellow-pigmented bacteria often were predominant (26% of the heterotrophic population) during the summer, all other color groups (orange, pink, purple, brown, and black) accounting for less than 6% of the total percentage of pigmented bacteria in any season (4). Why this pattern of occurrence is common is not known. Public health significance of these pigmented organisms is also not known; however, some of them are known to be plant pathogens.

Other unusual heterotrophic bacteria are known to occur in various aquatic environments such as marine waters, various waste discharges, mine drainage, heat-exchange water systems, and irrigation-return waters (5). Density magnitudes expected for these organisms may vary widely, depending on the aquatic environment and the introduced contaminants. Typical examples of heterotrophic bacterial densities in rivers and raw sewage are given in Table 1 to illustrate the impact that wastes may have on defining the state of a surface water resource.

Although heterotrophic bacterial measurements often are ignored in the characterization of safe drinking water, their general presence in water should not be ignored because this population may contain some undetected agent of pubic health concern. Any chance multiplication in drinking water systems to more than 1,000 organisms per milliliter should not be tolerated because of the concern that some chance occurrence of a pathogenic agent may reach an infective dose level. Furthermore, this situation may lead to an upgrade in density for some opportunistic pathogen presence in the water that impacts on some susceptible individuals, increases the potential for coliform colonization in a biofilm, and elevates the density for bacteria that create taste and odors. Table 2 illustrates several of these concerns with different kinds of drinking water supplies available to the public. Disinfecting water supply does suppress heterotrophic bacterial growth and dramatically reduces coliform occurrences. Although rain water generally is of excellent microbial quality on release from the atmosphere, catchment and storage provide opportunities for the greatest deterioration of its quality because there is little effort to keep the catchment area free of dust, debris, and bird fecal droppings. Many of these cisterns receive very infrequent clean-out of sediment accumulations and infrequent disinfection, and the water supply is prone to stratify rather than circulate. Such environments often lead to water-quality deterioration induced by microbial contaminants, biodegradable sediments, and poor sanitation practices. (See MICROBIAL WATER QUALITY OF RAINWATER ROOF CATCHMENT SYSTEMS).

Table 1. Heterotrophic Bacterial Densities in Various Rivers and Sewage

Water Quality	Heterotrophic Bacterial Density per mL
River Characteristic	
Remote streams	<500
Relatively clean rivers	5,000–10,000
Moderately polluted river water	25,000–50,000
Polluted river water	≤100,000
Grossly polluted rivers	≤1,000,000
Municipal Raw Sewage	
Worcester S.A.	11,100,000
Pietermaritzburg, S.A.	13,700,000

DEFINITION

The heterotrophic group of bacteria has differences in morphology, gram-staining response, and biochemical reactions but all have an essential need for energy-source compounds and trace elements that contain carbon, nitrogen, sulfur, and inorganic ions necessary for the synthesis of living cell materials. The metabolic requirements of individual species in this diverse group of bacteria vary tremendously as to the essential compounds necessary to stimulate growth (17,18). For example, some of these bacteria (autotrophic organisms) have simple nutritional requirements that include only water,

carbon dioxide (CO_2), and appropriate inorganic salts; the conversions to energy being derived from oxidation or the driving force of a photosynthetic process not unlike the metabolic activity common to plant life. *Nitrobacter* that assimilates CO_2 and obtains energy from the oxidation of nitrite to nitrate are often found in groundwaters. Sulfur and iron bacteria that synthesize basic inorganics are other examples of autotrophic bacteria that may colonize some well water supplies (19). At the other end of the spectrum there are heterotrophic bacteria that are very fastidious in their nutrient requirements, requiring a variety of very complex organic compounds such as vitamins and amino acids (growth factors) that they are not capable of synthesizing. For this reason, organisms such as *Legionella*, which have fastidious nutrient requirements, depend on the presence of by-products released by the metabolic activity of different bacteria in the aquatic flora to survive.

CULTIVATION

Maximum recovery of the heterotrophic bacterial population in water is driven by cultivation methodology. Consideration must be given to four interrelated factors: medium formulation, cultivation temperature, incubation time, and in situ placement of captured organisms on a nutrient surface for growth (20–22). Two different approaches to medium development have evolved in an attempt to stimulate optimum resuscitation of stressed organisms and bacteria with special nutritional needs for cultivation.

- Dilute Medium

  The medium must provide not only a nutrient base that mimics the dilute chemical constituent levels found in various water environments (water supply and marine water) but also be inclusive of essential salts and organics necessary for resuming the rapid cell-growth rates. Most challenging is the need to be responsive to the recovery of stressed organisms whose cell membranes are functioning poorly through dysfunctional membrane osmotic gradients and to metabolic pathways disrupted by damaged enzyme systems or starvation. Such is the status of organisms known as ultramicrobacteria. These are organisms that have become very small through gradual starvation and thereby are capable of surviving for extremely long periods of time in low nutrient waters. In this state some of these organisms develop a mucoid mutant that becomes more predominant in the population over time, whereas others may go into a resting spore stage. Detection of these organisms may be difficult if attempts are made to cultivate them immediately on nutrient-rich media. Therefore, their occurrence is often overlooked unless a very dilute medium, such as R-2A, is used with extended

cultivation time (five or seven days) at an incubation temperature of 20 to 28 °C (23).

- Enriched Medium

  For organisms that are in a vigorous state of health (e.g., fecal bacteria found in raw municipal sewage or food-processing wastes), enriched medium formulations will result in rapid bacterial growth and early visualization. Standard plate count (SPC) agar (tryptone glucose yeast extract agar) and m-HPC medium (formerly known as m-SPC medium) are examples of enriched medium formulations with cultivation established at two days in an environment of 35 °C (24).

- Incubation Temperature/Time

  Incubation temperature controls not only the spectrum of organisms that may be cultured but also the rate of growth into colonies. The traditional incubation temperature of 35 °C is not realistic for many of these organisms whose origins are water shed soils, vegetation, and nonfecal waste discharges or who are stressed by self-purification forces and have become adjusted to the environment. As a consequence, many of these bacteria respond better to a cultivation temperature that has been established between 20 and 28 °C. Incubation time is interrelated with selection of temperature for the visualization of colonies. Organisms in general grow much slower at 20 than at 35 °C so that although two or three days may be sufficient for adequate visualization of colony development at 35 °C, five to seven days are necessary to see more developing colonies on media incubated at 20–28 °C. For a few organisms, seven days of incubation is not enough time to visualize those very slow growing organisms. As a consequence, incubation for 28 to 30 days has been suggested to achieve a near "total count" of all viable heterotrophic bacteria present in a drinking water sample (25). However, this length of incubation time is impractical for routine laboratory analysis of water samples in the distribution system and provides little additional significant information about water quality. There also is the serious problem of moisture loss in the culture medium and the potential for air contamination during the extended incubation time that will impact cultivation adversely unless strict requirements for moist, sterile air in the incubator are met. As a practical consideration, the incubation time for optimizing the recovery of heterotrophic bacteria in drinking water has been set at five or seven days to fit into the normal operational schedule of the laboratory.

- Laboratory Cultivation

  The placement of organisms in contact with the medium also may influence the recovery in several ways. Selection of the appropriate laboratory procedure is critical for recovery of some organisms or the visualization of others. For example, better development of pigmentation is possible when the organisms are not imbedded in agar medium.

Pour-Plate Technique. This procedure has been a traditional method for the enumeration of bacteria in a water sample (20,21). One milliliter or less of the water sample is added to liquid agar medium that has been tempered between 43 and 46 °C to prevent heat-kill of the organisms. The appropriate medium had been previously formulated and prepared to contain selected nutrients so as to promote growth of many of the heterotrophic bacteria in water. By adding the sample portion and mixing it into the medium, viable organisms are spread throughout the culture dish that, upon cultivation, will develop into discrete colonies. Problems to consider are the choice of medium formulation, temperature of the liquid agar during sample addition, and dispersion of bacteria throughout the medium. Deep agar pour cultures may restrict growth of some strictly aerobic bacteria, whereas characteristic spreading surface growth of other bacteria on the surface may suppress development or mask visualization of neighboring colonies. Various aspects of these problems can be avoided by adequate media selection, good sample dispersion within the culture dish, and avoiding formation of water droplets from condensation of hot liquid medium during the pour plate procedure. This latter problem also can contribute to confluent surface growth that obscures accurate counting of discrete colonies.

Spread Plate Technique. The spread plate method circumvents problems associated with the pour plate technique because the inoculum is spread over the surface of a solidified agar plate (20,21). Spread plates give higher counts although precision of replicates sometimes is erratic. Much of this discrepancy occurs in the spreading technique. Although the sterile glass rod spreads the water sample over the agar surface to achieve uniform dispersion, some organisms remain attached to the spreading device and are lost in the transfer process. Because this is not a uniform loss, some variation in replicate spread plates is unavoidable.

Membrane Filter Procedure. Membrane filter techniques provide another approach to surface cultivation of organisms (20,21). The principle of membrane filtration is passage of a water sample through porous membranes (pore size typically at 0.45 microns or less) with entrapment of microorganisms on the surface of the filter. The filter is then placed over a nutrient substrate that provides passage of the nutrients to the filter surface where viable cells are nourished during cultivation in a high-humidity incubator at a prescribed temperature and time. The unique advantage of this technique is that it permits the analysis of larger sample volumes of high-quality water than either the pour plate or the spread plate agar cultivation procedures.

The only limitations to size of the sample analyzed are turbidity, bacterial density, and spreading colony formation on the filter surface. Fine sand particles are not as serious a problem as are colloidal clay or debris entrapment. These latter particulates plug the membrane filter pores and interfere with discrete colony development. Because the diameter of a standard membrane filter is 47 millimeter and the effective filtration surface somewhat less, the density limit for discrete colony development will be less than 200 colony-forming units (c.f.u.).

ORIGINS OF THE HETEROTROPHIC BACTERIAL FLORA

All natural water environments (i.e., surface waters, groundwater, springs, and marine waters) have a signature profile of bacteria that are specific to that aquatic source. In addition, there are various contributions of transient organisms from life's many controlled and uncontrolled uses of water in nature and by anthropological activities (22,26).

- Indigenous Bacteria

  These are the naturally occurring bacteria found in surface waters that are remote from wildlife and human activities or are protected from the influences of surface contamination in deep aquifiers. They largely are ubiquitous, saprophytic organisms, some of which belong to the genera *Micrococcus, Pseudomonas, Chromobacterium, Serratia, Flavobacterium, Acinetobacter*, and *Alcaligenes*. Origin of these organisms may be from particulates traveling in rain or dust storms and from interfaces with contacting soil and vegetation. Some indigenous bacteria are difficult to detect using conventional laboratory techniques because of their slow growth or fastidiousness. In recent years there has been a growing interest in these organisms because of the part they may play in the development of biofilm, particularly in groundwater, water pipe networks, cooling towers, and industrial processes (3,18).

- Transient Bacteria

  Perhaps the greatest public heath concern with natural waters is contact with organisms that are introduced in sewage discharges, food-processing wastes, urban and rural storm water runoff, animal feedlot operations, and wildlife (27,28). The microbial flora of sewage is predominantly derived from fecal wastes, bath water, food preparations in the kitchen, and urban storm water. Thus it should not be surprising to expect that a variety of pathogens shed by ill people, pets, and wildlife in the community will find their way into water resources via wastewater. Many of these pathogenic bacteria, such as *Salmonella, Shigella, Campylobacter, Yersinia*, and *Escherichia coli* 0157 : H7, are heterotrophic organisms. Fortunately, within the complex sewage flora there are many beneficial organisms that are responsible for much of the biological breakdown of degradable wastes. Some of these beneficial bacteria also have mutated to better degrade unique organic complexes released in domestic or industrial liquid wastes.

Sugar processing from beets or sugarcane, cannery food processing, and paper mill wastes also have a drastic impact on water quality. Elevated concentrations of nutrient materials released in those wastes often lead to sudden, dramatic growth of heterotrophic bacteria by depressing natural self-purification processes in receiving waters. Urban and rural storm water runoff over the water shed flush out entrapped heterotrophic bacteria from soil and vegetation as rainfall washes over ground and cement surfaces. In the rural environment, storm water runoff can be a serious vehicle of bacterial transport from animal feedlot operations (e.g., cattle, pigs, and poultry) (29,30). These agricultural activities create a massive animal waste–loading problem that may exceed that of municipal sewage in small towns nearby. If the animal wastes are not diverted to a lagoon or landfill, the storm water runoff will add extremely high levels of heterotrophic bacteria, including intestinal pathogens, to the drainage basin and receiving waters. Seepage from landfills of solid wastes in domestic garbage (Table 3) and

Table 3. Microbial Characterization of Solid Wastes from Various Cities

Waste Collection Site[a]	No. Samples	Organisms g (wet wt)[b]		
		Heterotrophic Bacteria	Spores	Total Coliforms

sludges from water processing and sewage treatment may penetrate the soil barrier and migrate into groundwater, thereby introducing microbial pollution into the nearby aquifer that otherwise would be populated sparsely with organisms.

HEALTH CONCERNS WITH AMPLIFICATION IN WATER SUPPLY

The heterotrophic bacterial population in drinking water includes many organisms that never become established in the distribution system, whereas others are more adaptive, being capable of surviving on minimal nutrients, of attachment to pipe sediments, and of actively participating in a developing biofilm. Some of these adventitious organisms may cause taste and odors; others cause in situ pipe corrosion, interfere with coliform detection, or are transferable antibiotic-resistant organisms. Microbial populations in water leaving the treatment plant generally are below 100 organisms per milliliter but rapidly increase to densities that often are 1 or 2 logs higher at static water locations in dead ends of the distribution system and in building plumbing systems. Two factors play a part in these situations: no available disinfectant residuals to suppress growth and the presence of warm water conditions in building pipe networks. Such microbial population expansions in drinking water may be of no health risk to most people in the community, however, some of the bacteria may present a opportunistic risk to some individuals under severe health stress.

- Opportunistic Pathogens

  Opportunistic pathogens generally are considered to be organisms that exist as part of the normal body microflora but under certain situations can cause disease in a compromised host. In general, these are the organisms that when found in large enough numbers and under optimum conditions, may have the potential to cause an infection in susceptible individuals (3). Such organisms particularly become invasive in some individuals [e.g., the elderly, newborns, acquired immune deficiency syndrome (AIDS) victims, cancer patients receiving chemotherapy, burn cases, dialysis patients, trauma patients, and individuals receiving organ transplants].

  Infective dose levels for a 50% attack rate among healthy children and adults may range up to 10^{10} cells per dose. Although the number of cells required to achieve an infective dose by ingestion may seem unlikely, the volume of water used to take a shower or bath easily can supply this density during a given exposure period. By contrast, the density of such opportunistic organisms needed to establish infection in newborn babies, postoperative or immunosuppressed patients, and the elderly with infirmities are much lower than that in healthy individuals. The route of exposure may be ingestion, inhalation, or body contact with water supply. A large part of the problem is due to colonization of these organisms in water attachment devices used in the home, hospitals, and clinics (3,22). Acinetobacter infections have been associated with the use of ventilator spirometers, room humidifiers, and moisturized Wright respirometers. Other organisms such as *Pseudomonas* have been the agent in a waterborne outbreak in a newborn nursery, provide a major threat to recovery from serious burns, and can be the source of infections from dental equipment; *Legionella* has been a respiratory agent in indoor air climate–control devices; and nontuberculous *Mycobacterium* has been involved in the spread of infections from aerosolized whirlpool therapy. Several studies have suggested that water supply organisms are part of the problem but not necessarily the major source of nosocomial infections in the hospital environment.

- Antibiotic R-Factor Transfers

  Heterotrophic bacteria in water supply, recreational waters, and whirlpools that are resistant to one or more antibiotics may pose a health threat if these strains are opportunistic pathogens or serve as donors of the resistant factor to other bacteria that could be pathogens (3,22). Antibiotic-resistant (R-factor) bacteria may originate in fecal wastes of ill people taking antibiotics or farm animals being fed antibiotics. On entering waste-treatment systems, these bacteria come in contact with receptive organisms and may pass on their resistance factors through plasmid transfers while in the process basin. In so doing, some of these bacteria acquire multiple antibiotic resistance. Treatment does not destroy all of these antibiotic-resistant organisms and those that survive pass into the wastewater effluent released to receiving waters. Much the same scenario of multiplication and transfer contact occurs with farm animal wastes as it is spread by stormwater runoff over the drainage basin and into streams and lakes. Downstream, these waters often are the source of raw water used in water supply treatment. Although treatment processes inactivate or remove many introduced antibiotic-resistant organisms (e.g., *Aeromonas, Hafnia*, and *Enterobacter*) from the source water, a shift of this transmissible factor to other organisms (e.g., *Pseudomonas* or *Alcaligenes* group, *Acinetobacter, Moraxella, Staphylococcus*, and *Micrococcus*) may occur (32). In the process some of the surviving organisms that acquire multiple resistance to different antibiotics also are resistant to disinfectant exposure. Many of these transformations occur in the established biofilm found in activated carbon or mixed media filtration basins. The reason for the common occurrence of streptomycin resistance among bacteria that survive chlorination is not known. In a typical population of 100 heterotrophic bacteria that may be present in a glass of drinking water, 40 to 70 of these organisms could be expected to have some antibiotic-resistance factors (32). What health risk this presents when the heterotrophic bacterial population in water supply ranges above 1,000 organisms per milliliter is not clearly understood yet.

COLONIZATION IN WATER SUPPLY

Heterotrophic bacteria are a major nuisance in water supply (e.g., biofilm creation in well casings, treatment basins, distribution systems, biologically mediated corrosion of pipe materials, and producers of unpleasant tastes and odors in static water areas) (3,18). Biofilms of iron and sulfur bacteria in well casings eventually may overwhelm efforts to extract water from the aquifer even when high concentrations of disinfectant are applied to inactivate the organisms. Treatment process management that includes routine flushing of basin walls, connecting flumes and coagulant agitators with high-pressure water jets can be very effective in suppressing the development of biofilms.

Water quality produced at the plant begins to change soon after it enters the distribution system and arrives at the home, office, or hospital tap. It has long been recognized that water must be keep moving in the distribution system to maintain the best microbial quality. Once it reaches a static zone, water quality begins to change because of microbial colonization that may or may not be of public health significance. Sites for colonization of heterotrophic bacteria will be found in slow-flow areas of the pipe network where water demand is low, in tanks with stratified water storage, in areas of changing pipe diameters, and in pipe network dead ends. These are the locations where the disinfectant residual is diminished and the sediment often accumulates and becomes the nutrient substrate for bacterial accumulation and colonization. Beyond the service meter, bacterial colonization of various water attachment devices found in homes, hospitals, and clinics are also sites for potential colonization.

Water supply systems in larger housing projects, high-rise office buildings, hotels, hospitals, and large public buildings exacerbate the problem of deteriorating water quality as a consequence of static water storage and of infrequent water demands created in variable occupancy rates and type of activity (3). Cold water storage in high-rise buildings must be covered to prevent introduction of contamination from nesting birds and atmospheric dust and to prevent the growth of airborne algae. Various heterotrophic bacteria also may enter via airborne contamination and eventually colonize the accumulating bottom sediments. Static water in building plumbing networks is often at warm water temperatures that stimulate bacterial growth year-round. Even new plumbing networks may present a problem of deteriorating water quality as a result of construction practices that introduce dust, dirt, and excessive solder flux in the lines during pipe assembly. Solder flux can be a nutrient source and an attachment site for numerous heterotrophic bacteria.

Building water supply attachment devices have a significant impact on the microbial quality of water. Long stagnation of public water supply in the warm environment of a building water system encourages various heterotrophic bacteria, including *Legionella*, to colonize pipe joint packing materials, valve stem seals, vacuum breakers (used in backflow prevention), and faucet aerators (33). Hot water tanks in homes and hospitals should not be overlooked as a cause of water-quality deterioration. If thermostats on hot water tanks are set below 55 °C as an energy-conservation measure or to prevent scalding of patients, growth of *Legionella* may occur in the hot water tank. In such situations, legionellae densities may reach infective dose concentrations either in the hot water tank or in an attached showerhead (34,35). Most residential hot water tanks are heated from the bottom, near the cold water–entrance pipe so that the water supply can be quickly heated to above 55 °C; however, after years of use, sediments may accumulate at the bottom of the tank and provide a heat-buffered environment for Legionella colonization. Water in large institutions is often heated by internal steam coils located at middepth in the tank; thus the cooler water in the bottom may not be heated sufficiently to kill *Legionella* (See *LEGIONELLAE*).

HETEROTROPHIC BACTERIA: AN OPERATIONAL INDICATOR OF MICROBIAL QUALITY

There are a variety of bacteria to be found in all natural aquatic environments and their kind and magnitude have often been used as a criterion of water quality (Table 1). Such arbitrary classifications based on consensus opinion are only a gross indication of water quality and have little scientific correlation to health risk, appearance, taste, odor, and intended use of the water. The problem with such a broad characterization is that the composition of the heterotrophic bacterial profile is so variable and sensitive to the ecology of the water as to make any interpretation of sanitary significance very difficult. Nevertheless, the use of a heterotrophic bacterial measurement continues to be applied as a broad indication of treated water supply quality. More definitive information can be found through periodic monitoring for shifts in the profile of dominant species in the population or by daily monitoring to detect a magnitude of changes in population densities. Perhaps the development of a rapid test (<4 h) for this general group of bacteria might prove useful as an alert (early warning system) to water-quality changes (waste spills and sewage bypasses) over the water shed, the buildup of assimilable organics in water treatment process basins, or the sudden emergence of cross-connections at sensitive locations on the pipe network.

PUBLIC WATER SUPPLIES: TREATMENT, DISTRIBUTION, AND STORAGE

Heterotrophic bacterial densities are not used as an enforceable criterion and standard in public water supplies; however, their occurrence is used often to evaluate treatment performance, as an alert to clean pipe networks before restoration of a protective disinfectant residual, and as an integral part of the condition-acceptance agreement with contractors before acceptance of new pipe lines (36). These applications should be dependent on use of a dilute media such as R-2A medium and incubation at 28 °C for five days or more to achieve optimum recovery data.

Water plant operators need to be alert to the possible colonization and amplification of heterotrophic bacteria

in process basins. An example of the magnitude of heterotrophic bacteria to be found in various water treatment processes and the effectiveness of treatment barriers may be seen in Table 4. Because of the fractured nature of GAC and the organic characteristics of the process water, these particles can be a more attractive substrate than sand for bacterial colonization. Colonization of sand and mixed media filtration beds is often accelerated when the plant must recycle wash water from the backwashing of these process basins. Without adequate treatment of backwash water, more heterotrophic bacteria and biodegradable nutrients will be inserted into the process water (Table 5). The concern is that spiraling elevation in densities and selective dominance of some undesirable opportunistic pathogens may break through the treatment train and enter the finished water supply.

Using aerobic spore-forming heterotrophic bacteria as a measure of disinfectant effectiveness is a more critical indication of inactivation for some pathogens in process water than the conventional practice of using chlorine-sensitive coliforms. These spore-forming organisms are more resistant to conventional disinfection practices and their physical removal appears to parallel that

of physical entrapment and removal of *Giardia* cysts and *Cryptosporidium* oocysts through different treatment configurations (39).

The United States Environmental Protection Agency does not have a specified standard for heterotrophic bacterial densities in finished water entering the distribution system. Most water treatment operations using disinfection have a finished water quality ranging from <25 to 500 heterotrophic bacteria per one milliliter. This range is subject to some variation depending on the medium and procedure used in the heterotrophic bacterial determination.

Heterotrophic bacteria are being used in a variety of ways to characterize changes in the microbial quality of water supply in distribution systems (3,36). The most common use of heterotrophic bacterial data from the distribution system is to determine when lines need to be flushed to remove sediments and restore disinfectant residual. Although the heterotrophic bacterial count of water entering the distribution system generally will be below 100 organisms per milliliter, this density will often rise to several thousand organisms per milliliter at the ends of the lines and in areas of slow flow. Flushing the pipe network not only removes much of the sediment accumulation but also the organisms colonizing these sites. The net result is cleaner water and restored disinfectant residual at the ends of the distribution system. Water authorities using chloramination carefully monitor the heterotrophic bacterial density for significant increases as an indication to flush lines and possibly return to free chlorine residuals for a few weeks. The purpose is to disrupt the buildup of organisms that cause taste and odors in their utilization of free ammonia available from the conversion of free chlorine to chloramines.

For many years, many state and local water authorities have required contractors of new water lines to demonstrate that before acceptance, pipe sections not only were coliform-free but also had less than 500 heterotrophic bacteria per milliliter. The intent is to demonstrate that the line is clear of soil contamination that might have been introduced during construction. When the test is done on successive days, the data may provide some evidence of regrowth potential from deposited sediments. Another approach is to hold a sample from a new line at room temperature for several days, then examine it for elevated densities of the heterotrophic bacterial population. If the heterotrophic bacterial density increases to 1,000 or more organisms per milliliter, some protective sediments still are present in the pipe and the new pipe work needs another line-flushing and a test for bacterial regrowth. This repeat protocol is important because the practice of line-flushing followed by heavy doses of free chlorine for 24 hours often result in a negative coliform result but not necessarily an indication that the lines are free of soil and other debris.

Long-term storage of water supply (4 weeks or more) in enclosed reservoirs is not desirable. During these quiescent water periods, persisting heterotrophic bacteria begin to grow in the sediments, biofilm expands over the interior wall surfaces, and the water stratifies. These actions cause a further degradation in the microbial quality of the drinking water supply. For these reasons, the utility often selects a site downstream of the storage tank to monitor general bacterial quality of the static stored water supply. The evaluation may demonstrate that stored water has deteriorated when heterotrophic bacterial counts rise from below 100 organisms per milliliter to several thousand organisms per milliliter. Any evidence of coliform occurrences or substantial growth of the heterotrophic bacterial population should signal the need to drain the tank, to inspect tank interior and air vents for corrosion, to remove sediments, and to refill with fresh chlorinated water supply. The net result is cleaner water and restored disinfectant residuals.

RURAL WATER SUPPLIES

Rural water supplies may originate from surface water (farm ponds and creeks), naturally occurring outcroppings of the water table (springs), cisterns to store water from roof or hillside catchments, dug wells of less than 75 meters depth to catch surface water runoff, and drilled wells with casing installed that may reach more than 1,000 meters into an aquifer. The heterotrophic bacterial flora of these supplies reflect the status of barrier protection from surface drainage, septic system leaching fields and wildlife activity over the catchment area. Many of these bacteria have a strong aggressiveness that can initiate vigorous biofilm growth in the static water situations such as in well casing, water pipe, water-storage tanks or cisterns, and attachment devices. Mixed populations of indigenous organisms and transient contaminants provide opportunities for cooperative adjustments within the microbial community for survival and possible growth in an otherwise austere water environment. Some of the aquatic bacterial genera (e.g., *Pseudomonas, Aeromonas, Acinetobacter*, and *Alcaligenes*) become so adjusted to their ecological environments that soon they dominate the heterotrophic bacterial flora in specific situations. Selective dominance of iron and sulfur bacterial biofilms may clog the well casing so tightly that extraction is impaired or taste and odors become so offensive that the well must be abandoned (19). In waters containing significant concentrations of nitrates, numerous nitrate or nitrite bacteria become dominant and create unpalatable tastes and odors. Many of these situations are acerbated by nitrate-nitrogen concentrations around barnyards and corrals (40).

The most important, unanswered question concerning heterotrophic microbial populations in rural drinking water supplies is their health effect. There is growing evidence that substantial densities of some heterotrophic bacteria in these supplies may provide a significant health risk to some people. Some of these organisms may be multiple antibiotic–resistant (41). Also of growing concern are the reports of large densities of some opportunistic pathogens (*Flavobacterium, Legionella, Mycobacterium* avium complex, *Pseudomonas, Serratia, Staphlycoccus*, and several fungi) that may be present in these untreated water supplies (9). Sensitive subpopulations at risk to many untreated rural water supplies are the elderly, infants, pregnant women, AIDS victims, and individuals with diabetes.

HETEROTROPHIC BACTERIA IN ALTERNATIVE WATER SUPPLIES

Further treatment of the public water supply by the consumer to remove taste of chlorine, enhance the chemical quality, or provide a barrier to protozoan pathogens are available to the public. These alternative drinking waters include bottled water, stored public water supplies, and point-of-use devices. Such choices place responsibility for acceptance of water quality on the consumer who foregoes the protection afforded by public water authority oversight except during emergency situations caused by disasters, outbreaks, and noncompliance with safe water regulations. In both alternatives there may be microbial degradation of the product in terms of heterotrophic bacterial buildup that goes unseen and not understood by the consumer.

- Bottled Water (see BOTTLED WATER, MICROBIOLOGY OF)

  Storage of a safe drinking water supply in containers does circumvent potential exposure to contamination problems associated with distribution systems; however, storage in a container in itself introduces a different environment that may lead to microbial deterioration. Water packaged in a plastic bottle or in larger containers for use as a portable or emergency supply of drinking water is in a static environment. The rate of change in bacterial density is related to a variety of factors including assimilable organic nutrients in the water, organisms competing for dominance in the microbial flora, water pH characteristics, and shelf life under ambient temperatures (42). High-quality bottled waters undergo slow rates of change because generation of the indigenous organisms may take hours, not minutes and the available nutrients are in trace amounts. Waters bottled from sources that have fluctuating water quality and perhaps an occasional coliform quickly deteriorate. Emergency bulk supplies of drinking water are generally derived from some municipal water source and over time in storage will follow similar patterns of microbial quality change.

  The source of bottled water is often groundwater or protected springs but may be reprocessed public water supply. It can be argued that these special water sources will contain few organisms and those present are indigenous to the source and not of any public health concern. Yet, there have been several waterborne outbreaks that have been caused by the use of bottled water. Between April and November 1994, Portugal had a cholera epidemic that caused 2,467 confirmed cases and 48 deaths (43). Most of the country was affected and the source of the outbreak was found to be in the consumption of a particular brand of commercially bottled water and poorly cooked shellfish. The source water may have been contaminated from cholera-infected individuals living on the water shed or involved in the bottling operation. This case clearly illustrates the importance of water shed protection for groundwaters and springs that may have a poor soil barrier to safeguard quality from surface-runoff contamination.

  Source protection remains of highest priority as do sanitation practices in the bottling plant to avoid fecal contamination. What remains as a concern is the storage history of the product before and after the consumer purchases the product. During this time interval, the heterotrophic bacterial population will undergo a significance increase in density and a possible shift in dominant species. Bottled-water refrigeration in the supermarket will slow the progressive deterioration in microbial quality. As might be anticipated, the microbial quality of freshly bottled water (within 48 h of bottling) is excellent in most cases. In a study of 129 freshly bottled water collected directly from 25 different bottlers, only 10% had an initial heterotrophic plate-count density greater than 500 bacteria per milliliter (11). Total coliforms were detected in six samples; one sample reported also to contain fecal coliform bacteria. Another coliform-positive sample also contained 42 *Pseudomonas aeruginosa* per 100 milliliters.

  Bottled water with high densities of heterotrophic bacteria always are of concern because these increased densities may make it more difficult for the laboratory to detect fecal pollution and pathogens that also might be present. Excessive densities of heterotrophic organisms (more than 1,000 organisms per milliliter) in a water sample can desensitize both the multiple-tube test (including the P-A test) and the membrane filter total coliform procedure. Organisms such as *Pseudomonas* species and *Flavobacterium* strains can suppress the growth of total coliforms, preventing detection of gas production in lactose fermentation broth and spreading growth over the surface of the membrane filter that interferes with coliform sheen development on M-Endo media. These interference problems may be avoided with the use of chemically defined coliform media although high densities of *Aeromonas* and *Flavobacterium* may give occasional false readings in the total coliform and E. coli tests, respectively.

  The other concern with high-density populations in bottled water is the possible emergence of significant densities of some opportunistic pathogen that may be of health risk to some consumer with health problems. How much a concern this really is continues to be debated because the research evidence still is inconclusive for a variety of situations. There is no doubt that for individuals debilitated by some illness or treatment that undermine the natural body–immune system exposure to bottled water with *Pseudomonas*, *Flavobacterium*, or *Acinetobacter* may acquire a secondary infection from such opportunistic pathogens (42).

  Studies on the various genera and species of heterotrophic bacteria in bottled water have revealed that *Pseudomonas* species (many being multiresistant to antibiotics) often are a dominant part of this bacterial population as storage time increases. *P. stutzeri, P. diminuta, P. maltophilia, P. putida,*

P. fluorescens, and *P. acidovorus* have been reported in densities of 10^3 to 10^5 organisms per milliliter (44), largely because these organisms can slow down their metabolic activity to survive on minimal nutrient concentrations available in protected aquifers. *P. aeruginosa*, most prevalent *Pseudomonas* in human disease, is rarely found in high-quality bottled waters. When introduced through contamination of the source or in bottling operations, this organism will maintain a stable density and then decline to nondetectable densities after six to seven months (42,45).

- Stored Emergency Water Supplies

  The requirements for stored emergency water supplies set aside for use in cases of shipwreck, at times of natural disasters, or during wartime devastations are unusual. These stored supplies may be used for drinking water among the stressed population that also could include those injured in the disaster (1,9). Examination of the bacterial populations in emergency supplies of water stored after approximately five years revealed that 22.8% of 167 samples contained species of *Flavobacterium* and 16.2% contained species of *Pseudomonas*. Flavobacteria were frequently dominant and the counts ranged from 10 to 26,000 per milliliter. This information suggests that after years of long-term storage, nutrients are reduced and organism subsistence is in balance until the containers are contaminated during opening for inspection and sampling.

  For this reason, stored water must be of good bacteriological quality that goes beyond monitoring for fecal contamination and recognizes the concerns with opportunistic pathogens. Ensuring the continued availability of a high-quality emergency water supply over extended storage periods is difficult. Initially a high-quality source water must be selected and care taken when filling and sealing storage containers so as to prevent contamination with bacteria and dust particulates. Because the quality must be maintained indefinitely, all emergency water supplies should be given supplemental disinfection during annual inspections and before use.

- Point-of-Use Treatment Devices (see Home Treatment Devices — Microbiology of Point of Use and Point of Entry Devices)

  Home water supply treatment devices have a significant impact on the microbial quality of public water supplies. Although treatment devices may be very effective initially in providing microbial or chemical improvement in the public water supply, their effectiveness may diminish because of unpredictable service life of the filter, ambient water temperatures, frequency of static water conditions, poor maintenance, and unit design that create sumps where bacteria can grow in the moist ambient environment. The inclusion of a carbon filter in some of these devices to remove organics, taste, and odor will also provide an ideal habitat for microbial colonizations with subsequent releases of additional heterotrophic bacteria into product water.

Adventitious organisms passing through the distribution system may become transient colonizers in a carbon filter for varying periods of time (46). A study on occurrence and persistence of various heterotrophic bacteria passing through several different point-of-use devices from a dechlorinated tap water revealed that coliform bacteria were released from one or more carbon filters during periods ranging from 1 to 10 months, although the treatment devices being evaluated in a pilot study were not challenged with any coliforms during a 12-month test run. Three coliforms species were detected in single samples at various times rather than for prolonged periods: *Enterobacter aerogenes* (4 times), *E. cloacae* (4 times), and *Klebsiella pneumoniae* (once). These observations suggest that occasional coliform occurrences in public water supply may be more readily detected by monitoring the passage of tap water over time through a carbon filter device than from scheduled grab samples taken periodically from distribution-sampling sites. Because the point-of-use devices had been disinfected before the beginning of this study period, the organisms must have been present in the dechlorinated distribution water passing through the test system and were able to survive and multiply to some extent in the individual treatment device filter cartridge. Other organisms detected in the dechlorinated tap water and the number of times isolated during the 12-month study were *Alcaligenes* spp. (twice), *Serratia marcescens* (4 times), S. *rubidaea* (twice), and on different one-day occasions, *Pseudomonas cepacia*, *P. fluorescens*, and *P. maltophila*. Although the densities initially increased 10–100 times more than those of dechlorinated tap water, these densities tended to stabilize after several months.

In a pilot study to challenge carbon filter treatment devices with heterotrophic bacteria that would be anticipated in cross-connections, line breaks, or back siphonage, it was revealed that carbon filter units provide an ideal environment for colonization and opportunities for bacterial release into the product water (47). This could be of particular concern if there is infrequent filter replacement by the user. Among the organisms released in product water were *Klebsiella pneumoniae*, *Aeromonas hydrophila*, and *Legionella pneumophila*. Other heterotrophic bacteria (*E. coli and Salmonella*) did not pass through the carbon filters under test. This was thought to be due to the aggressive competition of other organisms in the high-density heterotrophic population colonizing the water treatment filters.

Static water conditions overnight or for longer intervals provide opportunity for continued growth of organisms colonizing carbon filters (13). In fact the first draw of water in morning samples had higher bacterial densities than at any other time during the day or evening (Table 6). In winter the carbon filter on the nonchlorinated source water produced water with lowest bacterial densities. These results suggest that warm water and ambient air temperatures are important factors that stimulate the higher densities on all filters during summer months. This phenomenon was even more pronounced with third faucet units that had a 1 log higher bacterial density

Table 6. Microbial Quality Deterioration Related to Static Periods Without Use

Average HPC per ml	Nonchlorinated Source				Chlorinated Tap Water Carbon # 3 (Control)

Data revised from E. E. Geldreich and D. J. Reasoner, in G. A. McFeters, ed., Drinking Water Microbiology: Progress and Recent Developments, Springer-Verlag, New York, 1990 (13).

in the morning than from a full service unit located under the sink, probably because water demand was limited to drinking use only, thereby providing more static water contact time in the carbon bed. Whether individuals who consume water from a biologically active filter suffer adverse health effects is dependent on the bacteria involved, the number of organisms ingested, and the individual's general health and resistance to the particular organism(s).

Although the heterotrophic bacterial flora that colonize carbon filters often may reach 10^2 to 10^5 organisms per milliliter, there appears to be no apparent health risk to most people based on conclusions from recent epidemiological studies of carbon filters in home use. Perhaps these established microbial populations are a significant factor in preventing many overt pathogenic strains of bacteria from successfully colonizing and persisting in carbon filter treatment devices. The trade-off may be the chance colonization and release of some opportunistic pathogen that successfully competes within the bacterial flora and becomes predominant, thereby representing a health risk to some susceptible individuals using these devices.

CONCLUSION

Heterotrophic bacteria comprise a diverse population of bacteria in the aquatic environment. Many of these bacteria are ubiquitous and of no sanitary significance. Their origins are a reflection of water contact with soil, vegetation, airborne dust particles, and the fecal wastes of all animals. Their survival is a reflection of the status of natural self-purification forces including water chemistry, water pH, aeration of receiving waters, sunlight exposure, microbial antagonisms, and predation by bacterial predators. Counteracting forces that depress the natural die-off of heterotrophic bacterial populations in water include discharges of poorly treated waste and stormwater runoff over the water shed.

Among the heterotrophic bacteria of concern are those that are pathogenic, opportunistic, or carriers of R-factor transfers. Contact with these bacteria may come from exposure to water supply, recreational waters, whirlpools, and aerosols in climate-cooling devices. Unfortunately, differentiation of these organisms of concern is not practical in routine monitoring, so the approach has been to limit the "total" density of all heterotrophic bacteria in a water contact situation, thereby limiting the number of such organisms of concern to below a risk level.

No single examination of a water sample will detect all of the heterotrophic bacteria to be found in a water sample because of varying nutrient requirements, unique incubation temperatures, and extended incubation-time requirements. Regardless of these limitations to their complete detection in a single test, the concept of relating density of heterotrophic bacterial populations to water quality continues to be used for a measure of water treatment effectiveness and indication of microbial colonization in water supply distribution pipe networks.

Areas to be explored are the use of a rapid test (<4 h) for detecting heterotrophic bacteria in an early warning monitoring system that might be used to detect a change in water quality over a water shed designated for drinking water source use and the development of a heterotrophic bacterial profile technique (fingerprinting) in water samples to identify origin of pollution.

HIGH HYDROSTATIC PRESSURE: MICROBIAL INACTIVATION AND FOOD PRESERVATION

BIBEK RAY
University of Wyoming
Laramie, Wyoming

The metabolic and physiological activities associated with the growth and multiplication of most microbial cells are well regulated and occur within a narrow range of hydrostatic pressure (as well as with other physical

parameters). There are some barophilic microorganisms, which are grouped together with the extremophiles, that need higher pressure for growth and survival. Generally, the barophiles need a hydrostatic pressure for these functions well below 100 MPa (1). As the hydrostatic pressure is increased to 100 MPa and above, microbial cells start to lose viability, which under a given set of conditions is directly proportional to the pressure level. Destruction of bacterial spores requires pressure of 700 MPa or more, although they can be induced to germinate and outgrow at a pressure of about 300 MPa (2).

Because high hydrostatic pressure (HHP) in the range of 100 to 800 MPa can destroy microbial cells and inactivate some bacterial spores, there is an interest in using this as a potential nonthermal technique to destroy food-borne spoilage and pathogenic microorganisms to enhance the shelf-life and safety of food. The concept of preserving food by destroying microorganisms by HHP was originally applied by Hite in 1899 (3). He showed that the shelf-life of raw milk, following pressurization at 600 MPa for 1 hour at 25 °C, could be extended for 4 days. He and his coworkers also pressurized several fruits at about 800 MPa to achieve commercial sterility, and the products remained unspoiled even after five years (4). For the next 70 years there was no report available on the application of HHP in food, although sporadic reports were published on the viability loss of microbial cells, bacterial spores, and viruses in broth or buffer suspensions by HHP as well as by the combination of pressure, pressurization time, and pressurization temperature. Since the 1980s and more particularly in the 1990s, a large number of studies have been conducted in many countries to determine the viability loss of food-borne microbial cells and spores at different pressures in combination with different pressurization times and temperatures and in the presence of several antimicrobial compounds during pressurization (2,5,6). The success of these studies is evidenced by the commercial marketing of several pressure processed foods in Japan by 1991 and afterward in a few European countries and the United States (2,5–9). This is probably the shortest time in the history of commercial food processing that it has taken between studying a novel food processing technique and successfully marketing of a food that has a high rate of consumer acceptance. Initial success was with low pH foods pressurized to kill aciduric bacterial cells, molds and yeasts, but not bacterial spores (since low pH prevents spore germination). At present, high pH foods are also being studied and these will require destruction of the bacterial spores to reach commercial sterility (as in canning).

The HHP (also called high pressure processing, HPP and ultra high pressure processing, UHP) technique, as opposed to most prevalent thermal treatments, is a uniquely three-dimensional process comprising pressure, pressurization time, and pressurization temperature. If one or more effective antimicrobial compounds is incorporated during pressurization, the process can become four-dimensional with a very high microbial destruction capability. The process involves placing a packaged-food inside a closed steel chamber containing water (or a mixture of water and a little oil to prevent water from freezing at a high pressure) followed by closing the chamber hermetically and pumping more liquid inside the chamber (Fig. 1). The pressure increase is instantaneous and transmitted uniformly throughout the liquid as well as in the food mass, relatively independent of shape, size, viscosity, and composition of the food and packaging material. Once the desired pressure is reached, pumping of more liquid is stopped and the valve in the opening is closed holding the pressure in the liquid constant. At the end of the pressurization period, the valve opens automatically and the excess liquid flows out of the chamber by gravity during decompression. Depending on the pressure unit, the come-up time could be one to two minutes and the come-down time could be less than 30 seconds. During pressurization, the temperature of the food rises about 3 °C per 100 MPa due to adiabatic heating, but then reverts to the original food temperature following decompression. Also, during pressurization, the volume of a food mass is reduced by about 10 to 15% between the range of 300 to 700 MPa, but then reverts to original volume following decompression. The liquid in the chamber, if necessary, can be heated to a desired temperature by installing a heating coil around the wall of the unit. For a food to reach a temperature of the liquid during pressurization, it is necessary to heat it prior to

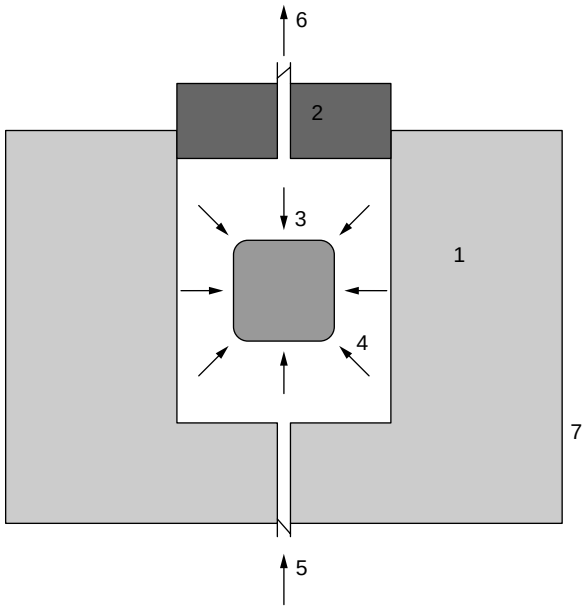

Figure 1. Schematic diagram of a high hydrostatic pressure vessel (7). The food package (4) is put in liquid (3) inside the chamber (1), which is closed at the top with a movable cylinder (2) with an opening and a valve (6) to remove air and excess liquid prior to pressurization. Once the chamber is closed, excess liquid is pumped through the inlet tube (5) that has a valve which closes when the desired pressure level is reached. The pressure is maintained constant during pressurization time, at the end of which the inlet valve (5) opens and the excess liquid is removed from the chamber by gravity. The liquid in the chamber can be heated by installing a heating coil around the vessel (7). The process is clean, energy efficient, and requires relatively less space compared with other food-processing methods. See color insert.

putting the food inside the chamber. Pressurization does not have any detrimental effect on the covalent bonds of food components. Thus there is no loss of vitamins and minerals as well as no change in color and flavor. However, pressurization breaks noncovalent bonds such as ionic, hydrophobic interaction, and H-bonds. As a result, macromolecules (of food and microorganisms) undergo unfolding during pressurization and may not correctly refold during decompression, leading to an alteration in the original structure. This, in addition to killing microorganisms, has opened the possibility of developing novel products especially when the food has a high protein content (2,5,6,10).

In addition to preserving foods by destroying microorganisms, HPP has been found to have many other novel applications in food processing. Some of these are listed in Table 1. Because of its versatile applications in food, HPP has currently generated worldwide interest and is being considered to be a major technology to be used to produce food in the twenty-first century. Among the different applications, this article covers only the destruction of microorganisms by HHP (6,10).

INACTIVATION OF BACTERIAL CELLS

Sublethal Injury and Viability Loss

Studies with pure cultures of several food-borne gram-positive and gram-negative bacterial suspensions, either in buffers or in bacteriological media, have revealed that following pressurization, a population generally has three distinct groups of cells, namely, the uninjured or normal, the sublethally injured, and the dead (11). The three groups are differentiated arbitrarily on the basis of physiological and metabolic characteristics (12–14). While the normal subpopulation of cells retains the characteristics of the original strain and the dead cells permanently lose the ability to multiply, the sublethally injured cells develop several distinct but transient characteristics. These cells become sensitive to many chemical compounds to which the normal cells are resistant, and temporarily lose the ability to multiply and some metabolic activities. These altered characteristics are associated with the structural and functional changes or "injury" to the cell wall, cell membrane, some enzymes, ribosomes and DNA. In this subpopulation, the injured cells differ greatly in the degree or extent of injury; some being highly injured while some others have very little injury as observed from their rate of repair (Fig. 2). Once they are exposed to a favorable environment, these injuries are repaired by the cells themselves through metabolic activities. Following repair, the cells regain the normal characteristics of the strain including the ability to multiply. Before repair, if they are exposed to some adverse chemical or physical environment to which the normal cells are resistant, the injured cells lose viability. This fact has been exploited to increase the viability loss of a bacterial strain by pressurizing it in the presence of some other physical or chemical parameter(s) and is discussed later.

The usual procedure to differentiate the injured population from the normal population, among the survivors, following exposure to hydrostatic pressure is to enumerate the colony forming units. The cell suspensions before and after pressurization are enumerated simultaneously in two agar media, one of which is selective and the other nonselective (Fig. 2). The two media are formulated in such a way that the bacterial strain forms equal numbers

Table 1. Some Potential Applications of HHP in Food

Antimicrobial applications
To destroy microbial cells at lower pressure range
To destroy bacterial spores at higher pressure range
To germinate bacterial spores at lower pressure range
To prevent microbial growth in unfrozen food
Novel product development
To produce fruit and vegetable products with natural taste
To improve color of fruit products and egg yolk
To facilitate gelation of proteins without heat
Improved food processing
To tenderize meat
To enhance cheese ripening
To open valves of shellfish
To inactivate undesirable food enzymes
To thaw frozen food rapidly
To store food unfrozen at −20 °C
To inactivate allergens and toxins

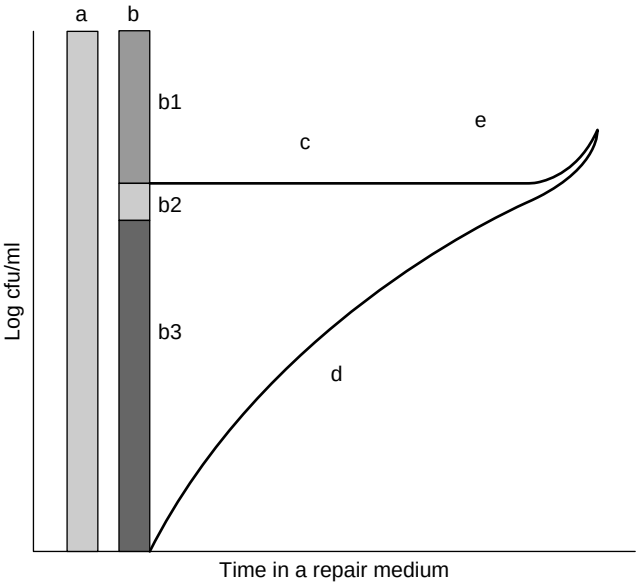

Figure 2. Schematic presentation of the effect of pressurization of a normal bacterial cell suspension (**a**) leading to production of three subpopulations (**b**), namely, dead cells (**b1**), normal cells (**b2**) and sublethally injured cells (**b3**). During subsequent incubation of the cells in a favorable environment for a period, the total survivor counts (b1+ = b2 = c) in a nonselective agar medium remain unchanged, suggesting no cell multiplication. However, the counts on selective agar medium increases rapidly (**d**) due to repair of injury and regain in resistance to selective environment; the rate of repair differs due to differences in the extent of injury among different cells. Cell multiplication starts following repair of injury as indicated by simultaneous increase in counts in both media (**e**). See color insert.

of colony forming units (cfu)/ml in both media before pressurization. Generally, one or more antimicrobial agents (for e.g., bile salts, NaCl, etc.) are included in the nonselective medium to convert it to a selective medium. The compound is used at a concentration that will inhibit growth of the injured cells, but not of the normal cells. Following pressurization and plating, only the normal survivors will form cfu on the selective medium, whereas all the survivors will form colonies in the nonselective medium (since the injured cells can repair and multiply in it). The fraction of injured cells is then calculated from the differences in cfu in the two media (11–13).

In general, at a lower pressure range (about 100 to 200 MPa) the fractions of both dead and sublethally injured cells in a bacterial suspension is low. As the pressure increased to between 300 and 400 MPa proportionately, there will be more cells with sublethal injury and also more dead cells. Above 500 MPa, the number of dead cells becomes much higher than the number of sublethally injured or normal cells. Other characteristic effects of pressure treatment on bacterial cells include a higher sensitivity of gram-negative than gram-positive bacteria, and a greater sensitivity of exponential-phase cells than stationary phase cells to a particular pressure; the latter difference is more pronounced between 300 and 600 MPa. In addition, bacterial species and strains within a species differ greatly with respect to the damaging effects of hydrostatic pressure, which again is more evidenced at a low pressure than at a high pressure range (2,5,6).

Sublethal Injury. Metrick and coworkers (15) reported that following pressurization of two serovars of *Salmonella* at 230 MPa for 30 minutes at 25 °C, there was a 3-log difference in cfu between the nonselective tryptic soy agar (TSA) medium and selective eosin methylene blue agar medium supplemented with 2% NaCl (EMBSA medium). The injured cells could not form colonies due to their developed sensitivity to 2% NaCl, to which normal cells were not sensitive. They also reported that a subsequent incubation of the pressurized cells for 2.5 hours at 37 °C in a chicken broth, but not in a phosphate buffer, enabled the injured cells to repair their transient sensitivity to NaCl and regain the ability to multiply and form colonies in EMBSA. The sensitivity of the injured cells to NaCl suggests that pressure most likely produced reversible injury to the inner membrane of the cells. Kalchayanand and coworkers (12,16–18; unpublished data) observed sublethal injury among the survivors of pressure-treated *Listeria monocytogenes, Escherichia coli* O157:H7, *Salmonella* Typhimurium, *Staphylococcus aureus, Leuconostoc mesenteroides, Lactobacillus sake, Pseudomonas fluorescens*, and *Serratia liquefaciens* strains. Depending on the species, the cells showed sensitivity to bile salts [suggesting cell wall or outer membrane (OM) injury; (12,14)], and NaCl (suggesting cytoplasmic membrane or inner membrane injury) both of which could be repaired in appropriate environments. The number of cells in the injured population greatly varied with bacterial species and strains and pressurization conditions (Table 2). Similar observations were also made by Alps and coworkers (18). Ludwig and coworkers (19) found that pressure-injured cells of *E. coli* have reduced the ability to form colonies on violet red bile agar medium due to their sensitivity to bile salts and crystal violet. They also became susceptible to the lethal effects of lysozyme, nisin, and EDTA at concentrations that were ineffective against normal cells. Susceptibility of cells to these three compounds was observed only during pressurization but not after pressurization. Since the lipopolysaccharide (LPS) molecules in the OM of *E. coli* provide protection against the antimicrobial effects of the above three compounds, it could be that during pressurization, the physical state and permeability barrier imposed by LPS molecules changes but after decompression is restored to the original state. A similar situation has been reported in freeze-injured *E. coli* cells (14).

Viability Loss. The inability to multiply permanently and form cfu by the bacterial cells in a nonselective agar medium, following a stress such as pressurization, has usually been used to determine viability loss or death. Major studies have been conducted with several food-borne pathogens to determine the rate and level of viability loss, that is, the D-values (time in minutes to reduce viability by 1-log cycle of a bacterial strain under a given condition) as well as pressurization parameters that could reduce viability of a strain by 6-log cycles to ensure safety to the consumer. Many of these studies have been discussed in several recent reports (2,5,6,19,20). The predominant pathogens studied include strains of *Salmonella* serovars (16–18,21), *Listeria monocytogenes* (16–18,20–28), *Escherichia coli* O157:H7 (16–21,29,30) *Vibrio parahaemolyticus* (22,24), *Yersinia enterocolitica* (21,31), *Staphylococcus aureus* (10–16,21,29), and *Campylobacter jejuni* (32). Some of the indicator, spoilage, and lactic acid bacteria studied were *Escherichia coli* (14,32), *Serratia liquefaciens* (16),

Table 2. Pressure-Induced Sublethal Injury Among Foodborne Pathogens

Pathogens	Unpressurized (log_{10} cfu/ml)	Pressurized (log_{10} cfu/ml)		
		Dead	Injured	Normal
Listeria monocytogenes Scott A	11.8	6.8	2.1	2.9
Staphylococcus aureus 581	9.8	5.7	4.1	<0.1
Salmonella typhimurium M1	10.2	5.0	5.2	<0.1
Escherichia coli O157:H7 #932	10.1	8.7	0.9	0.5

The cell suspensions in 0.1% peptone solution were pressurized at 345 MPa for 5 minutes at 25 °C. The nonselective medium was tryptic soy agar supplemented with 0.6% yeast extract (TSY-agar). The selective media used were: TSY-agar with 7.5% NaCl for *Staphylococcus*, modified Oxford (MOX) agar for *Listeria*, xylose lysine deoxycholate (XLD) agar for *Salmonella* and violet red bile (VRB) agar for *Escherichia* strains.

Pseudomonas species (16), *Citrobacter* species (33), *Streptococcus* species (32), *Leuconostoc* species (16), and *Lactobacillus* species (16,34). Most studies were conducted in phosphate buffer, saline or peptone broth. However, some studies were conducted in food systems, namely, milk, sea food, chicken, pork, beef, liquid egg, cheese, salsa, and others. The results of these studies can be summarized as follows (2,6):

- Gram-negative cells are relatively more sensitive to HHP than gram-positive cells. A higher sensitivity is also observed among rods than cocci and among exponential growth phase cells than stationary phase cells.
- There is a considerable variation in pressure-resistance among different bacterial species and among strains of the same species.
- Bacterial cells are more resistant to pressure in food systems than in a bacteriological broth or in a buffer. Resistance increases with the increase in food density and lipid content.
- A low pH, high A_w or the presence of an antimicrobial compound during pressurization enhances viability loss.
- Viability loss also increases with the increase in pressure, pressurization time and pressurization temperature (especially above 35 °C; see next section).
- Pressure-induced sublethally injured cells, when exposed to low pH, mild heat, antimicrobial agents, or repressurization, lose their ability to repair and grow.

Interaction of Several Parameters

The bactericidal efficiency of hydrostatic pressure processing is dependent on three parameters, namely, the pressure level, pressurization temperature, and pressurization time. Other parameters can be adjusted, namely, the environment of the material (food) being pressurized, in the form of low pH (below 6.5) and/or antimicrobial compounds (such as preservatives), to enhance bactericidal efficiency. Depending on the food system, all four parameters can be combined to achieve a desired level of destruction of pathogenic and spoilage bacteria, even under a moderate level of pressurization.

In one study, cells of four pathogenic and four food spoilage bacterial strains from the early stationary growth phase, were suspended in 0.1% peptone solution and exposed to a combined effect of hydrostatic pressure between 107 MPa and 483 MPa, pressurization temperature between 25° and 60 °C, and pressurization time between 5 and 30 minutes (16,17). The viability losses of the strains were determined from the differences in cfu/ml before and after a given treatment. In general, the results showed that the viability losses of the eight strains ranged between <0.1 and 1.5 log cycles at 138 MPa in 5 minutes at 25 °C. By raising the pressure to 345 MPa under the same conditions of pressurization, the viability losses (or death) increased to between 0.9 and ≥8 log cycles. By raising the pressurization temperature to 50 °C even an exposure of 107 MPa for 5 minutes raised the viability losses of the strains from 0.2- and 2.9 log cycles at 25 °C to 1.8- and ≥7.8 log cycles at 50 °C. However, increasing the pressurization time from 5 minutes to 30 minutes did not increase the viability loss, which remained around 1 log cycle. These results indicated that pressure per se', even at mild temperatures above 35 °C, has a much more detrimental effect on bacterial cells than pressurization time above 5 minutes. Similarly, viability loss increased proportionately with the increase in pressure at any pressurization time and temperature combination. Some of these results are presented in Table 3 (16,17). In this study, cell suspensions (about 10^8 cfu/ml) in 2-ml cryovials in duplicate were subjected to combinations of hydrostatic pressure, temperature, and time, and the viability losses were determined from the differences in cfu/ml on tryptic soy agar plates before and after pressurization. These results also revealed that a much greater viability loss was achieved in all four strains both at a higher pressure and a higher pressurization temperature as compared with a longer pressurization time. Studies by Kalchayanand and coworkers (16,17) also have shown that an 8-log cycle viability loss of most food-borne bacteria could be achieved by a combination of pressurization at 345 MPa for 5 minutes at 50 °C, a combination that gave a D-value of ≤0.6 minutes. This combination of medium pressure and temperature could be of advantage over using a very high pressure (≥700 MPa) at 25 °C. Other studies have reported that a higher pressurization temperature is more detrimental to bacterial cells (18,22,29,35) than a longer pressurization time (18,22).

Several other parameters, incorporated either in a cell suspension or in a food product, during pressurization were found to enhance viability loss of bacterial cells. As mentioned earlier, pressurization not only kills bacterial cells but also causes sublethal injury to many survivors. The injury is manifested by an increase in permeability and an increase in sensitivity to many antimicrobial compounds, especially those that are cell wall and cell membrane active. In the presence of one or more of these compounds during pressurization, the injured cells also lose viability. Depending on the effectiveness of a compound, and the bacterial strain, the viability loss could be increased by an additional 2- to 3-log cycles. As the injury is reversible, the compound is most effective when it is present during pressurization.

Pressure Resistance

Bacterial strains from different genera and species differ considerably in sensitivity to high hydrostatic pressure, as they do toward many other physical and chemical parameters. As shown in Table 3 among the four species used in the study, *Leuconostoc mesenteroides* and *Listeria monocytogenes* were more resistant to pressurization at 345 MPa for 5 minutes at 25 °C than *Serratia liquefaciens* and *Salmonella* Typhimurium. Limited recent studies have shown that strains of species of food-borne bacteria also differ in sensitivity to hydrostatic pressure, especially when pressurization is done at an ambient temperature. This is of special importance in developing pressurization parameters for the destruction of food-borne pathogens. For this purpose, it is important that the strains of a

Table 3. Viability Loss of Food-Borne Bacteria by the Combined Effect of Hydrostatic Pressure and Pressurization Temperature and Time

	Log_{10} Viability Loss as a Function of

pathogen that are highly pressure resistant should be used in modeling studies.

Earlier studies reported that cells of two serovars of *Salmonella* and two strains of *L. monocytogenes*, when pressurized in phosphate buffer at 22 °C between 138 and 340 MPa differed greatly in viability loss (15,22). Variations in pressure sensitivity among three *L. monocytogenes* strains at 375 MPa and three *E. coli* O157:H7 strains at 600 MPa were also reported by Pattersen and coworkers (21). In this case, stationary phase cell suspensions in phosphate buffered saline (pH 7.0) and pressurization temperature of 20 °C for 5 to 30 minutes were studied. Benito and coworkers (35) observed that viability loss of stationary phase cells in phosphate buffer of six *E. coli* O157:H7 strains following pressurization at 500 MPa and 30 °C for 5 minutes ranged between 0.2- and 6.1-log cycles.

The pressure-resistant stationary phase cells were also relatively resistant to mild heat treatment (57 °C for 10 min), exposure to pH 2.5 (adjusted with either HCl or acetic acid) and high osmotic environment (20% NaCl in broth). However, the differences in pressure resistance disappeared when exponentially grown cells were pressurized even at 200 MPa. Exponentially grown cells, as compared to stationary phase cells, also became sensitive to acetic acid but not to HCl, possibly due to a bactericidal effect of undissociated acetic acid molecules. The researchers suggested that the difference in pressure sensitivity of cells in the two growth phases was due to a relatively greater degree of membrane damage of the pressure-sensitive strains as opposed to the pressure-resistant strains.

Alpas and coworkers (36) compared the pressure resistance of cells (suspended in 1% peptone) from late exponential growth phase of nine *L. monocytogenes* strains, seven *S. aureus* strains, six *E. coli* O157:H7 strains, and six *Salmonella* serovars following pressurization at 345 MPa for 5 minutes at 25 °C. Viability loss ranged between 0.9- and 3.5-log cycles among *L. monocytogenes* strains, 0.7- and 7.8-log cycles among *S. aureus* strains, 2.8- and 5.6-log cycles among *E. coli* O157:H7 strains, and 5.5- and 9.3-log cycles among *Salmonella* serovars. However, when one of the pressure-resistant and one of the pressure-sensitive strains of each species, taken from the late exponential growth phase were pressurized at 345 MPa for 5 minutes at 50 °C instead of 25 °C the viability losses were very high and the differences in pressure sensitivity between strains in a species disappeared (Table 4). D-values following pressurization at 50 °C were ≤0.6 in all strains except for the pressure-resistant *S. aureus* strain. The pressure-resistant strains were also relatively resistant to mild thermal treatment. In a recent study, Alpas and coworkers (18) observed that the differences in pressure resistance among these strains was most pronounced at 25 °C; as pressurization temperature was raised to 35 °C or above variation in resistance among strains started to diminish. It was suggested that the differences in pressure resistance at lower temperature could be dependent on the relative ability of the strains to resist phase transition of membrane lipids (see next section); the ability to resist a phase transition is gradually eliminated with the rise of pressurization temperature perhaps due to the increase in lipid fluidity. These results emphasize the advantage of using a moderately high temperature to eliminate the effects of pressure resistance among bacterial strains especially when pressurization is conducted ≤500 MPa.

Mechanisms of Cell Death

A bacterial cell exposed to high hydrostatic pressure (>100 MPa) is subjected instantaneously and uniformly to two major effects, the adiabatic heating (approximately 3 °C per 100 MPa) and a volume reduction (about 10 to 15% between 300 to 700 MPa at 22 °C). These effects are produced during pressurization, and on decompression, both the temperature and volume return to the original levels. Among these two parameters, the effect of volume reduction is more detrimental to cells as it can alter the structure of macromolecules and their associations through breaking of ionic bonds, H-bonds, and hydrophobic bonds. Following decompression, macromolecules may not go back to original conformations. Since many vital biochemical and physiological processes are dependent on the specific macromolecular structure, any alteration in conformation can adversely affect the ability of the cell to carry on normal metabolic activity and growth. In addition to changes in molecular configuration, a decrease in cell

Table 4. Viability Loss and D-Values After Five Minutes Pressurization at 345 MPa and Thermal Treatment at 50 °C up to Five Minutes for One Pressure-Resistant and One Pressure-Sensitive Strain from Four Species

	Viability Loss (log_{10} cfu/ml) After		Estimated D-value After

[b]Viability loss due to thermal treatment for 5 minutes at 50 °C without pressurization was ≤1.0-log cycle.

volume by pressure can also cause phase transitions for some biomolecules such as lipids and enhance reactions among cellular enzymes and other chemicals. These also can adversely affect the normal functions of a cell following decompression (2,5,6).

Both the sublethal injury and lethal injury (or viability loss) caused by pressurization, as discussed before, are the manifestations of these changes; they are enhanced as pressurization temperature is increased above the ambient temperature. The conformational alteration of the lipopolysaccharide (LPS) molecules on the surface of the outer membrane has been implicated in developed sensitivity of pressure-induced sublethally injured gram-negative bacteria to surface active agents (like SDS), lysozyme, and bacteriocins (11–14). In the normal cells, these macromolecules are stabilized by divalent cations through ionic bonds, and act as a barrier to many antimicrobial compounds and provide resistance against them. Pressurization breaks the ionic bonds and impairs the barrier function of LPS molecules, making the cells sensitive to many chemicals. Since pressurization does not disturb covalent bonds, the molecules remain intact and following decompression reform ionic bonds with divalent cations, but likely in a different way than occurred originally. This may allow the cells to regain partial resistance against some antibacterial compounds, such as lysozyme and nisin (37). For this reason, to achieve a maximum viability loss, the antibacterial compounds should be present during pressurization of the cells (or foods). Pressurization of gram-positive bacterial cells also can bring about changes in the cell wall, probably through alteration of the normal functions of surface layer proteins (16,17).

The cell membrane of gram-positive cells and the inner membrane of gram-negative cells are considered to be greatly affected by pressurization. These structures are composed of lipid bilayers in which many types of large protein molecules (with specific conformations) are embedded by hydrophobic bonds. Many of these proteins have vital functions in the transport of nutrients, synthesis of ATP and enzymatic functions for cell growth and survival. Pressurization by destroying the hydrophobic, H-, and ionic bonds can alter the conformations of these proteins and affect their functions. Although following decompression proteins try to restore their native conformations, they may end up being different from the original structures. In addition, the lipid bilayer at high pressure undergoes a phase transition from the natural liquid crystalline phase to an initially reversible gel phase, then finally to an irreversible integrated phase with reduced thickness (38). These changes, both in the protein molecules and in the lipid bilayer, impair many functions of the membrane, namely the permeability barrier, transport of nutrients, the transmembrane proton gradient and proton motive force, and the ability to synthesize ATP. The pressurized cells become sensitive to NaCl, undissociated organic acids and bacteriocins (12,16,17). Pressurization also can cause dissociation of proteins from intracellular macromolecular assemblies such as ribosomes, and alter functions of cytoplasmic enzymes. Both viability loss and sublethal injury of pressurized cells result from the combination of the changes in the cell wall (or outer membrane), cell membrane (or inner membrane) and cytoplasmic macromolecules; however, the injured cells differ in the extent or level of these changes.

An exposure to high hydrostatic pressure probably does not grossly alter the morphology, disrupt or lyse bacterial cells. However, very little information is available in this area. Recently we pressurized at 345 MPa for 5 minutes at 25 °C a suspension of the food spoilage bacterium *Leuconostoc mesenteroides* Ly and then incubated the cell suspension at 25 °C. Immediately after pressurization, the OD of the suspension (original OD: 100%, and cfu:

2×10^8/ml) increased to 142% and viability decreased to 4×10^1 cfu/ml (a loss of more than 6-log cycles). After 60-minute incubation at 25 °C, the OD reduced to 34% (a loss of 66% of original value) and viability dropped to 2×10^1 cfu/ml. Scanning electron micrographs of the cells at different times showed that immediately after pressurization, the cells remained intact, but showed slight swelling; however, after 30-minute incubation many of the cells were lysed (Fig. 3). The results showed that lysis occurred after pressurization. Further studies showed that cell lysis was due to the action of cell wall–lytic enzyme(s), since pressurization of heated (70 °C for 10 min) cells did not show such lysis. It was suggested that pressurization initially caused alterations in the cell wall and cell membrane and permealization of the membrane. The membrane damage resulted in a loss in proton and electrochemical gradients across the membrane and a loss of the ability of cells to synthesize ATP. Finally, specific lytic enzymes in the cells were activated resulting in the degradation of the cell wall. Similar observations have been made with cells stressed by other treatments that cause cell wall and cell membrane damage (39).

INACTIVATION OF BACTERIAL ENDOSPORES

Hydrostatic pressure processing was initially used for the preservation of low pH (≤4.5) food products such as fruit juices, jams, and jellies. These products were generally pressurized around 600 to 700 MPa, at 22 to 25 °C for 5 to 30 minutes. The main objectives were to destroy the aciduric microorganisms, namely, yeasts, molds, and some bacteria (such as lactic acid bacteria) that can grow in these products, as well as the vegetative cells of food-borne pathogens. The objectives here are quite similar to those for pasteurization of thermally processed foods and are not aimed at destroying thermoduric bacteria and bacterial endospores. To destroy bacterial spores, foods are given commercial heat sterilization treatment to ensure destruction of the most heat-resistant spores of the pathogen *Clostridium botulinum*. Before high pH (>4.5) foods can be produced by pressurization, it will be important to develop methods either for destroying spores of *C. botulinum* to achieve commercial sterility or preventing bacterial spores from germination, and subsequent growth now is achieved in low heat–processed meat products by incorporating nitrite and refrigerated storage. Currently, there is an interest in determining the pressurization parameters necessary to destroy spores because nitrite is considered detrimental to health due to the possibility of it changing into carcinogenic nitrosamine.

Many reports are available in the literature that describe the effectiveness of high hydrostatic pressure in combination with other parameters for the destruction of spores of several *Bacillus* and *Clostridium* species and strains (40–51). These findings can be summarized as follows (2,5,6):

- A pressure of 1000 MPa or more is required for a substantial inactivation of spores of food-borne bacteria.

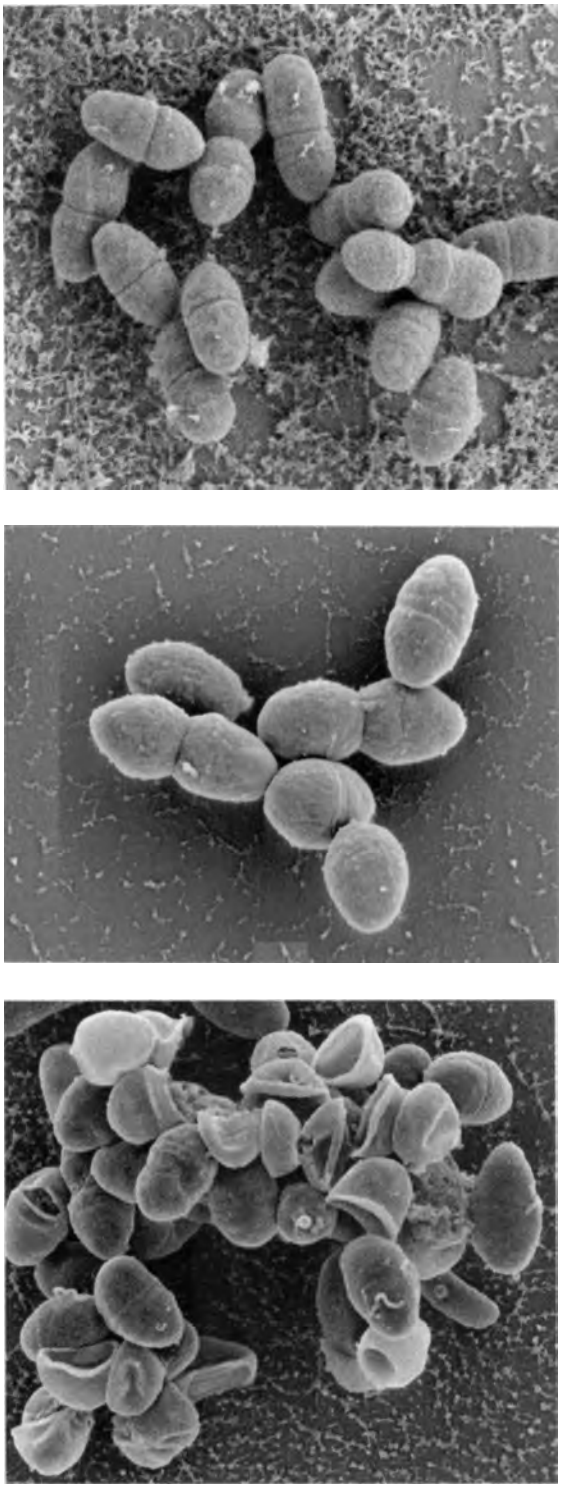

Figure 3. Scanning electron micrographs of *Leuconostoc mesenteroides* Ly cells (25,000 X). (**a**) Unpressurized control. The cells are lenticular, about 1×1.5 mμ in size diplococcal stage with distinct constriction between the two cells. (**b**) Immediately after pressurization at 345 MPa for 5 minutes at 25 °C. Pressurization caused more than 99% cell death, but the cells did not show a major visible change on the surface or on gross morphology. (**c**) Pressurized cells after 30 minute incubation at 25 °C after pressurization. Many cells were lysed (with the separation of cell wall between the two cells). See color insert.

- In general, *Bacillus* spores are relatively more sensitive than *Clostridium* spores.
- The level of destruction is dependent on the species and strain and is directly proportional to the pressure.
- An environment with high solute concentrations, low A_w, and relatively high pH provides protection against pressure inactivation of spores.
- High temperature, low pH (<5.0), and chemicals such as EDTA during pressurization enhance spore destruction.
- Many spores, depending on the species and strain and pressurization parameters, can be induced to germinate and outgrow at a pressure range around 100 to 300 MPa followed by incubation for 1 hour or more.
- Pressure-induced spores become sensitive to repressurization and other physical and chemical antibacterial treatments.

Several recent studies have been conducted to determine pressure inactivation of spores of several *Bacillus* and *Clostridium* species associated with food spoilage and food-borne diseases. A 5-log cycle reduction was achieved by pressurizing spores of a strain of *B. stearothermophilus* at 400 MPa and 90 °C (40,41). It was necessary to pressurize at greater than and equal to 700 MPa and 60 °C to obtain similar levels of inactivation of spores of strains of *B. subtilis, B. coagulans, B. cereus*, and *B. licheniformis* (42–44,51). An initial pressurization at 150 to 200 MPa followed by repressurization at 400 MPa increased spore inactivation of several *Bacillus* spp. This can be attributed to induction of germination by the initial pressure treatment followed by destruction of germinated spores by repressurization (45,46). Pressure-induced germination could be achieved by pressurizing spores in suspensions containing some salts, amino acids, and glucose (47) and incubating subsequently at 37 °C for at least 1 hour (2,5). The physicochemical events induced by hydrostatic pressure appeared to be similar to those induced by heat treatment as the spores lose dipicolinic acid and other spore components (2,5,6,44).

Several pressurization studies have been conducted with spores of *C. sporogenes* PA 3679, which is a nonpathogenic strain used as a surrogate for *C. botulinum* spores in thermal inactivation studies. The results of one study showed that a 5-log cycle destruction of PA 3679 spores required 1400 MPa at 54 °C for 5 minutes; when the temperature was increased to 75 °C, similar inactivation was achieved at 500 MPa. Also, a D-value of 0.7 was achieved by pressurizing the spores at 800 MPa and 108 °C (48,49). One study reported that very little inactivation of *C. botulinum* spores was achieved by pressurizing at 827 MPa and 75 °C (50).

Pressurization in the presence of antimicrobial compounds such as bacteriocins, lysozyme, EDTA, and other compounds has been reported to increase inactivation of both *Bacillus* and *Clostridium* spores (2,5). Since these compounds do not have antibacterial activity against the spores per sé, it is believed that they act on pressure-induced germinated and outgrowing spores. The use of these and other antibacterial compounds, such as sucrose laurate and monolaurin, in the agar media used for enumeration of spores after pressurization seemed to have a bactericidal effect against pressure-induced spores of several *Bacillus* and *Clostridium* species and strains (2,51).

We have studied pressure-induced germination of several species of *Bacillus* and *Clostridium* strains by exposing spore suspensions to pressures between 138 and 483 MPa at 60 °C for 5 minutes (Table 5). The results showed that the amount of germination induced varied widely with the species and strains. The induction

[a]Spore suspensions in 0.1% peptone solution were pressurized at 60 °C for 5 minutes at the indicated pressures. Immediately after pressurization, the samples (duplicate tubes) were kept at 4 °C for 1 hour and for 24 hour. The pressurized and control spore suspensions were then heated at 80 °C for up to 30 min and enumerated for cfu/ml by recommended methods. The difference between control and pressurized samples were used to calculate pressure-induced population. Heating at 80 °C did not cause any spore inactivation.

was much less within 1 hour but increased after 24-hour incubation at 4 °C (incubation at 25 °C in place of 4 °C, did not increase the germination amount; data not presented). At a higher pressure range of 276 to 345 MPa, the amount of germination generally did not increase; in fact, in some strains it decreased. In another study, when pressurized spores were suspended in a mixture of two bacteriocins, pediocin AcH and nisin, at 5,000 activity units/ml with or without lysozyme, all of the induced spores were killed (data not presented). This suggests that although spores are insensitive to these antibacterial compounds, they are killed following pressure induction. Thus, these biopreservatives could be incorporated into food prior to pressurization at a medium range of hydrostatic pressure (300 to 400 MPa) and at a moderate pressurization temperature (60 °C) for 5 minutes to achieve better spore destruction. During storage of the foods (at 4 °C or 25 °C), the germinated spores will be killed by the biopreservatives, preventing their subsequent growth and associated spoilage or food-borne diseases.

INACTIVATION OF OTHER MICROORGANISMS

Viruses

Many food-borne and waterborne pathogenic viruses have been implicated in causing diseases in humans. No studies have yet been reported on the effectiveness of HHP on their destruction. One reason could be, that except for Hepatitis A virus, techniques for quantitative and qualitative detection of food-borne viruses are not currently available. Since there is an interest now in using HPP for destruction of pathogenic *Vibrio vulnificus* in raw oysters and other shellfish, it could be important to see if the same treatment can also destroy Hepatitis A virus in raw oysters. In addition, in countries such as France where raw milk is used to make cheese, it would be interesting to see if bacteriophages of starter culture lactic acid bacteria, which often are present in raw milk and associated with the destruction of starter cultures and fermentation failure, could be destroyed (along with other pathogenic bacteria) by HPP. This would provide an effective means to treat raw milk prior to cheese manufacture.

Several studies have been conducted to determine the effectiveness of high hydrostatic pressure on the destruction of viruses associated with human immunodeficiency diseases. These results showed that pressurization at 400 MPa for 10 minutes destroyed over 5-log cycles of these viruses (52,53). A recent report indicated that at 300 MPa for 1 hour, HIV particles were inactivated, and the pressure-treated viral particles showed an enhanced immunogenicity (54). It could be assumed that at 400 MPa and higher, at which the foods are processed, most viruses (and bacteriophages) probably will also be destroyed.

Yeasts and Molds

The destruction of food-borne yeasts, molds, and their spores is of major interest in the commercialization of pressure-processed fruit juices, jams, and jellies. Because of their large size, most studies showed that vegetative cells of yeasts and molds are destroyed within a few minutes following exposure at 300 MPa at 25 °C. However, spores of some molds required much higher pressure and some even needed 800 MPa at 70 °C for 10 minutes for a 6-log cycle reduction. A lower pH, mild heat, presence of nisin, and repressurization for several cycles also enhanced the level and rate of their destruction (7,55–60). Electron microscopic observations have revealed that pressurization of yeast cells above 200 MPa for 10 minutes produced damage to the cell wall and altered subcellular structures, especially in the nucleus and mitochondria. For example, the nuclear membrane had pores and the mitochondrial cristae were damaged. In addition, electron dense materials occurred in the cytoplasm (61) as a result of protein degradation.

Protozoa and Parasites

Several pathogenic protozoa, such as species of *Cryptosporidium, Cyclospora, Entamoeba*, and *Giardia*, are important because of their ability to cause food-borne (and waterborne) diseases in humans. Increased consumption of raw fruits, juices, and vegetables has been associated with many outbreaks, and pressurization could be a means to reduce the incidence. A recent study has reported that pressurization of oocysts of *Cryptosporidium purvum* at 500 MPa for 1 minute in fruit juices resulted in a 5-log or more reduction in viability and infectivity. Microscopic observations revealed a crumpled appearance of the oocysts (62). Another study has also reported that the round worm *Trichinella spiralis* in meat could be killed at 200 MPa in 1 minute (63). Although there are few studies on pressure inactivation of food-borne protozoa and parasites, the general assumption is that these organisms could be effectively destroyed by hydrostatic pressure in the range of 400 to 500 MPa and low pH. With mild heating, a lower pressure range could still cause their destruction.

CONCLUSION

The results referred to in this review describe studies mostly conducted with pure microbial cultures in buffer and bacteriological media and with several food systems. In recent years, more studies are being conducted in many different food systems that include both low pH and high pH food products from dairy, meat, and fruit and vegetable (64–74) groups. In a current study, we observed that several food-borne pathogens, namely, *L. monocytogenes* and *E. coli* O157:H7 strains and *Salmonella* serovars could be destroyed completely in contaminated frankfurters by a combination of moderate hydrostatic pressure and medium heat along with a bacteriocin-based biopreservative (Table 6). These and other studies have generated enough interest worldwide among consumers and food processors to start the marketing of some products in several countries. The indications are quite favorable and there is every reason to believe that hydrostatic pressure processing will be a major method not only for the microbiological destruction and preservation of foods but also for many other

[a] Pathogens were inoculated in the meat products with or without biopreservatives (BP; a 1 : 1 mixture of pediocin AcH and nisin A at 5000 AU/g), vacuum-packaged and pressurized (HP) at 345 MPa for 5 min at 50 °C. The samples (5 per test period) were stored either at 25 °C or 37 °C and examined for the pathogens at different storage intervals.

[b] NT: Not tested due to positive results in the previous study.

[c] <10: Testing by both enumeration and isolation procedures failed to detect any colonies. Enumeration for each sample involved testing of 0.4 g product. Isolation involved adding 10 to 25 ml of enrichment broth in each sample bag followed by 24 h incubation at 37 °C, streaking of broth culture on a selective agar medium plate, incubation of plates at 37 °C up to 2 d and examination for the absence of colonies.

novel applications in food processing. HHP should also be beneficial for production of foods that otherwise are not possible to develop by existing processing methods.

HOME TREATMENT DEVICES — MICROBIOLOGY OF POINT OF USE AND POINT OF ENTRY DEVICES

DONALD J. REASONER
United States Environmental Protection Agency
Cincinnati, Ohio

Consumer concerns over the quality of drinking water have increased steadily over the past 15 to 20 years. This is primarily because of the perception of consumers, significantly influenced by news media reports that contaminants (chemical and microbiological) in municipal drinking water make it unsafe for consumption. The occurrence of low levels of disinfection by-products resulting from the reaction of chlorine or other water disinfectants with organic compounds in the water to form compounds that may be carcinogenic, mutagenic, or toxic, has been demonstrated. Waterborne disease outbreaks caused by pathogenic bacteria, viruses, and protozoa have occurred due to inadequate treatment, treatment process failures, and posttreatment contamination of potable water. In addition, the aesthetic quality of tap water varies due to source water characteristics (hardness, odor, taste, or appearance) and residual disinfectant level. Many consumers turn to bottled water or to commercially available water treatment devices that can be installed in their homes because they do not like the taste, odor, or appearance of the tap water delivered to their homes. Thus, as a result of the lack of confidence of consumers in the quality of municipally supplied tap water and aesthetic concerns related to tastes, odors, and appearance, there is a rapid growth in point of use (POU) and point of entry (POE) treatment unit sales.

According to the Water Quality Association (1), in 1999, consumer use of home water treatment systems has increased by 19% since 1997 and by 28% since 1995. Thirty-eight percent of 1,007 adults over the age of 18 surveyed in 1999 used some type of home water treatment device (1).

Home treatment POU units generally fit one of four categories: (*1*) Pour-through devices that stand alone on the counter top, (*2*) counter top units that attach to the kitchen faucet by means of a diverter valve that allows the flow from the faucet to be directed through the unit, (*3*) under the counter units that are tapped into the cold-water line and supply a separate faucet, or units that treat all the cold water going to the faucet, and (*4*) small faucet attached devices through which the tap water can be diverted (Figs. 1,2). Pour-through granular activated carbon (GAC) filter units (Fig. 2) have

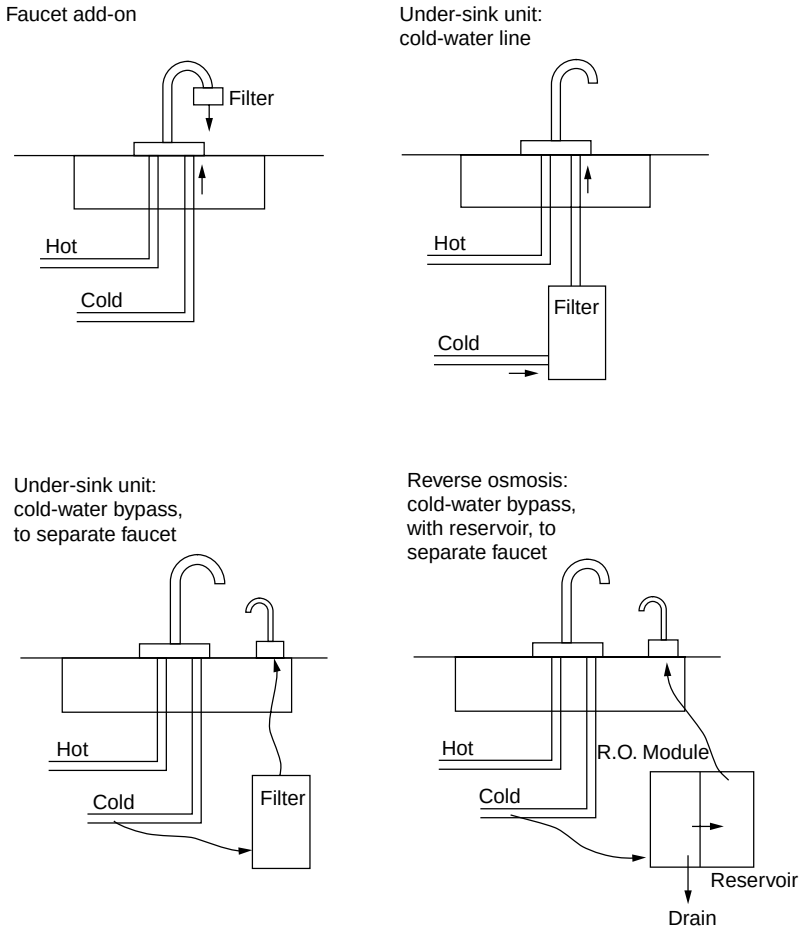

Figure 1. Basic applications of point of use units. (Modified from Fig. 2, *J. AWWA*, 75(1): 42–50 (1983), by permission. Copyright, 1983, American Water Works Association).

become extremely popular in the United States (e.g., Brita®). However, there have been very few studies of the microbiological characteristics of pour-through filter devices (see Bacteriological quality of water from POU and POE treatment devices).

Microbiological quality concerns related to POU/POE treatment generally involve the control of heterotrophic bacteria levels, measured by the heterotrophic plate count (HPC) method in treated water. The bulk of these concerns have been directed at POU/POE treatment devices that contain GAC or powdered activated carbon (PAC) that are sold as filters to improve the aesthetic quality of water, including removal of any residual disinfectant (usually chlorine) from influent water. Additional claims may include removal of particulate contaminants, including parasitic protozoan cysts and oocysts, asbestos fibers, ordinary sediment, rust and turbidity, chlorine disinfection by-products (trihalomethanes), insecticides and pesticides, and other organic compounds. Some treatment devices contain special adsorbents or ion exchange resin(s) for removal of inorganics such as lead and arsenic. These treatment devices should only be used to treat water that is "microbiologically safe" to begin with, and such a statement is generally included in the manufacturers' product literature.

In addition to the use of POU-GAC filters in home applications, such filters are also used as in-line filters to treat water going to refrigerator cold-water dispensers and icemakers, commercial icemakers, and soft drink dispensing machines. Studies of microbiological problems of these types of filters in commercial equipment applications were not found. However, based on the information from studies of similar types of GAC filters used in home treatment POU devices, unless such in-line filters incorporate a final filtration step using an absolute filter of less than or equal to 1.0 μm to remove bacteria, it is probable that high heterotrophic plate count (HPC) levels would also be found in the effluent from these filters.

GAC filters, including those that contain silver as a bacteriostatic agent, have been shown to promote heterotrophic bacterial growth. Additionally, high bacterial levels have been found in product water storage reservoirs of treatment devices such as reverse osmosis (R.O.) units. The key concern has been the possibility that ingestion of high levels of heterotrophic bacteria in drinking water may cause illness, particularly for the very young, the elderly, and for immunocompromised individuals.

POU VERSUS POE

Home water treatment devices that are installed to treat only the water at a faucet location (usually the kitchen tap), or at multiple faucets, are called point of use (POU)

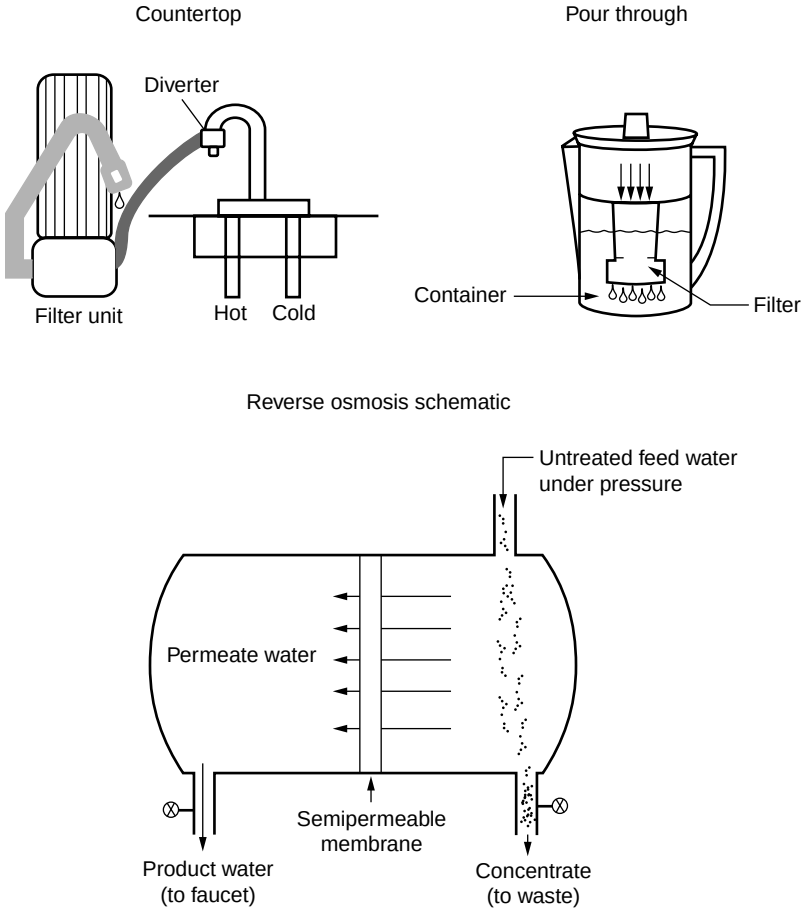

Figure 2. Countertop and pour-through point of use devices (upper) and a schematic of how reverse osmosis works.

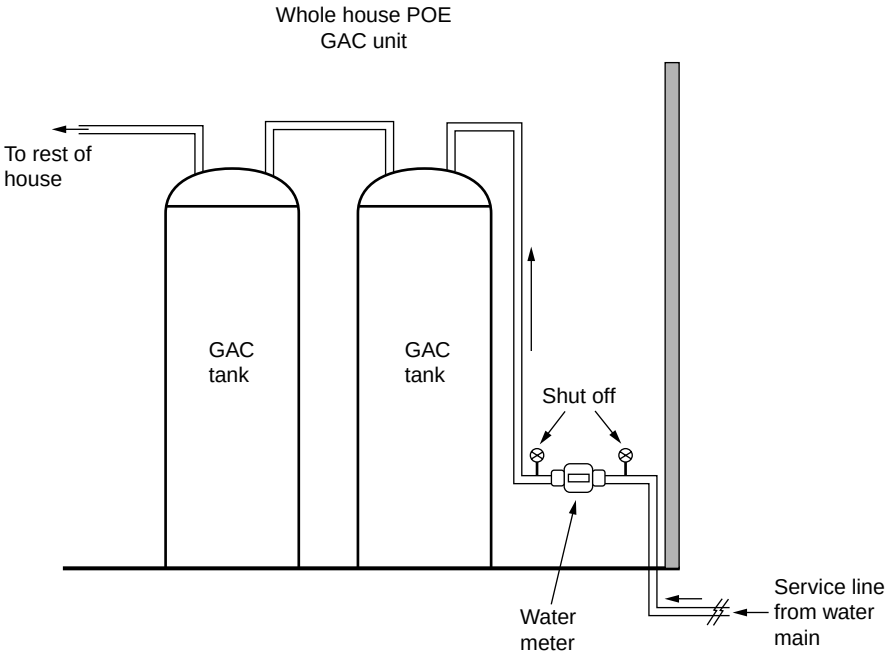

Figure 3. Example diagram of a whole-house point of entry GAC water treatment unit. Other configurations that use a combination of treatment technologies such as GAC + UV treatment, ion exchange + UV treatment, or particulate filter + GAC + UV treatment, etc., are available.

devices. Most POU drinking water systems are installed to treat water used only for drinking and cooking. Home water treatment devices that are installed to treat all the water entering the home are called point of entry (POE) devices (Fig. 3). A variety of both types of water treatment units are commercially available to consumers worldwide. This article addresses (*1*) general microbiological concerns associated with the use of some types of these treatment devices and does not address specific brands or models and (*2*) microbiological studies of POU water purifiers. It does

not address removal of chemical compounds, inorganic or organic, by POU and POE treatment devices.

TYPES OF HOME TREATMENT UNITS

Home treatment devices or appliances may use a variety of basic processes to treat water, including filtration, adsorption, ion exchange, reverse osmosis, distillation, and disinfection (2). Table 1 summarizes the basic processes that may be used by POU/POE devices and the contaminants they can remove. In some cases, combinations of two or more of these processes may be used in a single treatment device to achieve multiple treatment goals (e.g., filtration for removal of particulates and adsorption to remove chlorine, organic substances, and odors). A brief description of each of these treatment processes, their effectiveness, and some of their limitations for home POU/POE treatment is provided.

Adsorption

GAC or PAC is used to remove tastes and odors associated with chlorine or other disinfectant residual, chemical compounds produced by microorganisms such as actinomycetes, fungi, algae, iron and sulfur bacteria, and other organic chemicals. Activated carbon is obtained by destructive distillation of wood, nut or coconut shells, bones or other carbonaceous material, and activation by heating to 800–900 °C with steam or carbon dioxide. This creates a microporous structure with a very high surface area that can adsorb organic compounds. The activated charcoal is ground, sized, sieved for uniform grain size, and used to pack filtration cartridges sized according to the type of treatment unit desired. GAC filtration cartridges vary in GAC content from as little as 30 grams in a faucet mounted filter to several kilograms in large undersink devices or even more in POE filters. Some GAC POU devices use a bed of GAC, others use a pressed cake or block of activated carbon, and still others use a GAC bed followed by PAC or a diatomaceous earth precoat on the influent side of a fabric filter barrier.

GAC filters have a limited effective life because the carbon can become saturated with adsorbed organic chemical compounds, and some of these may begin to be released back into the water as sorptive sites on the GAC become filled. In addition, GAC provides an ideal environment for bacterial growth because of the tremendous surface area and the availability of adsorbed nutrients. Some manufacturers use GAC treated with silver as a bacteriostatic agent to attempt to control growth of bacteria in the filter cartridge or treatment unit.

Regular filter cartridge replacement (if so equipped) and maintenance of the filtration device in accordance with the manufacturer's specifications must be done to assure acceptable performance of the treatment device. In general, GAC treatment devices should only be used to treat drinking water that is microbiologically safe to begin with because the devices are not designed for removing and/or inactivating pathogenic bacteria, viruses, and protozoan cysts/oocysts, that is, they are not water purifiers.

Table 1. Point of Use and Point of Entry Water Treatment Processes

Treatment Process	Contaminant(s) Removed
Adsorption (activated carbon)	Chlorine, organic chemicals, tastes, and odors
Mechanical filtration	Particulates, turbidity, color, asbestos, cysts/oocysts
Reverse osmosis	Total dissolved solids, metals, nitrates, bacteria, cysts/oocysts
Water softeners, cationic	Calcium, magnesium, iron, manganese, barium, radium
Anionic	Sulfates, nitrates, bicarbonates, chlorides, arsenic
Distillation	Inorganics, dissolved solids, nonvolatile organics, volatile organics (?)
Disinfection, chemical	Bacteria, viruses
Disinfection (UV)	Bacteria, viruses, *Cryptosporidium* oocysts
Water purifiers	Bacteria, viruses, protozoan cysts/oocysts

Mechanical Filtration

Mechanical filters physically remove particles such as sediment and rust by straining. These filters may be made of porous ceramic or plastic, diatomaceous earth, or synthetic fibrous polymer materials. Fibrous filters include spirally wound acrylic or other polymeric filaments, pleated paper filters, and woven or nonwoven fabric filters. Except for R.O. membranes, POU/POE manufacturers do not use biodegradable materials in filters. The effective pore size of the filter will determine the size of particulate materials that it can remove from water. Fine filters with an effective pore size of 0.2–0.4 μm diameter can be used to remove most bacteria and protozoan cysts/oocysts from water. However, the smaller the pore size, the slower the passage of water through the filter and the more quickly the filter may become plugged if the water contains a high level of small particulates. Also, the smaller the pore size, the greater the pressure that will be needed to push the water through the filter material.

Reverse Osmosis (R.O.)

Reverse osmosis is a process by which almost all foreign materials in water, including microorganisms, minerals, and most organic materials, are separated from water using pressure to force the water through a semipermeable membrane (0.0005 μm pore diameter) into a storage tank (Fig. 2c). Production of treated water by R.O. is slow (about 1 L/h.) and about 75% of the influent water is wasted. Therefore, a storage tank is needed to collect the permeate and to provide a ready supply of treated water.

Reverse osmosis membranes may be made of cellulose acetate, cellulose triacetate, or a thin film composite membrane made of polyamid resin or other synthetic material. The thin film composite membranes are stronger than the cellulose acetate and triacetate membranes, but they cannot tolerate chlorine and a dechlorinating prefilter

is needed to protect them from chlorine in the influent water. The cellulose acetate and triacetate membranes are subject to degradation by bacteria over time and are less desirable for this reason. They can, however, tolerate chlorine and have been used in situations in which a chlorine residual was needed in the product water. As long as the R.O. membrane is intact, high quality water is produced by the R.O. device. However, once the membrane integrity has been compromised, treatment effectiveness is lost, the quality of the product water is degraded, and the storage reservoir and any other downstream components then become colonized by bacteria.

Ion Exchangers. Cation and anion exchange units are the two kinds of ion exchangers. Cation exchangers, often called softeners, exchange positively charged sodium or potassium ions for positively charged calcium and magnesium (hard water), lead, radium, and iron and manganese ions. Anion exchangers exchange negatively charged hydroxyl or chloride ions for ions such as sulfates, nitrates, and bicarbonate.

Distillation. Distillers heat water to boiling in one vessel, condense the vapor, and collect the condensate in another vessel. Dissolved solids, metals, minerals, nonvolatile organic compounds, and particles remain in the boiler vessel, and the heat kills any microorganisms. Some volatile organic chemicals (VOCs) may be carried over into the condensate vessel if heating is not carefully controlled. There are distillers that vent volatile organics, but their performance in reducing organics in the distilled product water is in question. There appear to be no microbial problems with distillers other than potential bacterial contamination of the condensate-receiving vessel.

Disinfection. Disinfection treatment units include chlorinators, iodinators, ozonators, and ultraviolet (UV) irradiation devices. Chlorinators dose a chlorine-releasing chemical such as calcium hypochlorite or sodium hypochlorite (bleach) into the water. Devices that contain iodine as the disinfectant generally use an iodinated resin that releases iodine into the water as it flows through the device. Ozonation involves the injection of ozone into the water to destroy some organic compounds and to inactivate bacteria, viruses, and unencysted protozoa. Ozone must be generated on site by the treatment unit and although it is a powerful oxidant, it does not leave a lasting residual in the water. Ultraviolet disinfection devices house a UV lamp that emits UV light at a germicidal wavelength (254 nm) that inactivates viruses and bacteria and possibly oocysts of Cryptosporidium. None of the devices in this category is able, by itself, to eliminate or inactivate all pathogenic microbes from the processed water. Protozoan cysts or oocysts generally must be removed physically, which means coupling a fine filter ($<4.0\ \mu m$) with the disinfection process, although recent studies indicate that UV exposure renders oocysts of Cryptosporidium noninfectious to a mammalian host (3,4).

Water Purifiers

Water purifiers are a special category of POU/POE treatment units that are designed to treat raw source water. POU or POE devices that are claimed to be water purifiers and are used to treat raw water must provide treatment that would assure complete removal or inactivation of all pathogenic microorganisms (viruses, bacteria, and protozoa). Such devices generally will incorporate two or more treatment processes to achieve the goal of eliminating pathogens, for example, filtration and chemical disinfection or filtration and UV disinfection. Water purifiers must be carefully evaluated for their capability to remove or inactivate bacteria, viruses, and cysts/oocysts of protozoa in test waters that are representative of worst case conditions under which the device might be used. The U.S. EPA developed a Guide Standard and Protocol for Testing Microbiological Water Purifiers (5) that specifies the testing levels and organisms to be used in testing water purifiers. The protocol is meant to be flexible to accommodate efficacy testing of all types of POU water purifiers. Manufacturers can obtain certification of drinking water treatment devices (DWTDs) through an independent testing organization such as National Sanitation Foundation (NSF) International (formerly NSF Ann Arbor, Michigan), Underwriters Laboratories (UL, Northbrook, Illinois), or Canadian Standards Association (CSA) International (formerly CSA Toronto and Ontario, Canada). Certification testing involves laboratory testing of a DWTD to verify the manufacturer's claims of contaminant reduction, a toxicological review, health effects evaluation, and performance and pressure tests to be sure that the treatment devices themselves do not contaminate the drinking water. Depending on the specific claims and the product type, certification testing of the POU treatment device for compliance with existing standards [American National Standards Institute/NSF standards (ANSI/NSF)] can be accomplished for a fee.

BACTERIOLOGICAL QUALITY OF WATER FROM POU AND POE TREATMENT DEVICES

The bacteriological quality of water delivered by the municipal water system may be significantly modified by POU/POE filters that utilize only GAC for treatment. The bacteriological quality is generally assessed by the HPC procedure and expressed as colony forming units (CFU)/mL (6). Depending on various factors, the bacterial count in public drinking water (tap water) may range from less than one colony forming unit (CFU)/mL to more than 10^3 CFU/mL, whereas the water from some POU-GAC treatment devices may range from 10^1 CFU/mL to more than 10^6 CFU/mL (Table 2). In general, in typical GAC filters, the bacterial level increases in treated product water is relative to the bacterial level in influent tap water. The magnitude of the increase may vary considerably but generally is in the range of 10- to 1,000-fold and is due to the growth of bacteria on the GAC in the filter cartridge. For a GAC-precoat combination filter, however, the density of bacteria in the product water may be lower than that of

Table 2. Heterotrophic Plate Counts (CFU/mL) in Influent Tap Water vs. POU/POE Product Water

Filter Type	Influent Mean (Range)	Product Water Mean (Range)	Reference
GAC#4–Run 1	23 (2–120)	180 (16–600)	7
GAC#4–Run 2	25 (3–100)	610 (35–8,000)	
GAC A–0 sec.[a]	9,500 (ng)[b]	84,000 (84,000–85,000)	8
30 sec.	780 (ng)	11,000 (7,900–14,000)	
4 h	160 (ng)	3,500 (3,500–3,600)	
GAC B–0 sec.	9,500 (ng)	2,800 (1,600–40,000)	8
30 sec.	780 (ng)	3,500 (2,600–4,400)	
4 h	160 (ng)	920 (830–1,000)	
GAC C–0 sec.	9,500 (ng)	109,000 (57,000–162,000)	8
30 sec.	780 (ng)	17,000 (13,000–21,000)	
4 h	160 (ng)	6,100 (4,100–8,000)	
GAC#1 (N = 95)	2,800 (100–11,000)	2,300 (130–10,000)	9
GAC#2 (N = 95)	2,800 (100–11,000)	71,000 (3,400–340,000)	8
GAC#3 (N = 95)	2,800 (100–11,000)	2,700 (290–15,000)	8
GAC#4 (N = 95)	2,800 (100–11,000)	19,000 (570–89,000)	8

Note: [a]Bacterial count after running the tap water for the time indicated.
[b]ng = not given

the influent water because of the pore size of the membrane filter in the device (10).

Bacterial growth in GAC filters depends on a number of factors including the length of time, the unit that has been in service, seasonal changes in water temperature, type of GAC, influent water quality, length of time since previous use, species of bacteria present, ambient temperature at which the filter unit is installed or kept, design of the unit, and presence or absence of a disinfectant residual.

A tremendous surface area (nominally, 1,000 nm^2/g GAC) is the factor that makes GAC so effective at adsorbing organic chemical compounds from water, it is also the factor that provides an ideal growth habitat for many of the heterotrophic bacteria found in water (12,13). The GAC surface becomes colonized by the bacteria, which along with adsorbed and extracellular material released by the bacteria, form a biofilm. The bacteria found in biofilms derive at least two benefits from attachment to the surface: (*1*) a ready source of nutrients that have concentrated at the surface added to a constant or intermittent replenishment of nutrients by water flow through the carbon and (*2*) physical protection from toxic or inhibitory chemicals. During periods when the POU device is not used, such as nighttime or vacation periods, water contained in the device stagnates and the bacteria on the GAC proliferate. The data in Table 3 show that the bacterial density in the water increases during a period of nonuse (stagnation). For the extreme case of a six-week nonuse period, the data showed that bacterial count changes were significant and the increase in CFU/ml ranged from 1-$\log_{10}$ to 4-$\log_{10}$ during the six-week stagnation period, and following resumption of use, dropped from 1- to 3-$\log_{10}$, depending on the unit (9). For nonuse periods of 20–92 hours, a granular or precoat filter showed significantly increased bacterial levels in the product water relative to samples collected before the shutdown. Interestingly, the bacterial levels in the influent water were much higher after the shutdown than they were before the shutdown, but the product water bacterial levels were much less than the influent bacterial levels, indicating that bacterial removal by the precoat filter was about 2- to 3-$\log_{10}$ (10).

Smaller time of day changes in bacterial levels in the product water were observed for four different GAC units when bacterial levels were determined in the morning following an overnight no-flow period versus bacterial levels determined in the afternoon. This was attributed to flushing during several flow periods that occurred during the day. The bacterial counts in the afternoon samples were generally, but not always, less than the morning bacterial counts.

In a study of bacterial contamination of POU filters, Daschner and coworkers (11) found that for 64% of 48 households that used water treatment devices, the bacterial counts of the product water were higher than for tap water of the same households. They also found differences in the bacterial levels as a result of storage of the product water and/or the treatment unit at 4 °C or 22 °C. For the type of pour-through filters that they evaluated (Aquafine, Brita®), bacterial levels ranged as follows: fresh filtrate (filter system stored at 22°C), HPC = 1 to >10, 000 CFU/mL versus fresh filtrate (filter system stored at 4 °C), HPC = 3 to 9,000 CFU/mL; 24 to 72-hour-old filtrate (filter system stored at 22 °C), HPC = 0 to >10, 000 CFU/mL versus 24 to 72-hour-old filtrate (filter stored at 4 °C), and HPC = 0 to 183 CFU/mL. Clearly, storage of both the filter unit and the filtered water at 4 °C was beneficial in holding down the bacterial density of the product water. After only one week of use, however, the bacterial density of freshly filtered product water was greater than that of tap water, indicating significant colonization of the GAC filter.

Daschner and coworkers (11) examined 13 newly purchased, unused filters for microbial contamination and found that the contamination at the bottom of the filter in 10 of the 13 filters ranged from 2 to 300 CFU/16 cm^2

Table 3. Effect of Non-Use Periods on Bacterial Counts in Product Water from POU Treatment Devices

Filter Type	Mean CFU/mL Before Non Use	During Non Use	After Non Use	Reference
GAC				
#1	25[a]	690,000	130	9
#2	25,000	1,100,000	11,000	9
#3	260	100,000	500	9
#4	2,600	30,000	5,100	9
Dechlor. Tap Water	11	29,000	190	9
Granular Precoat[b]				
Influent	280[c]	130,000	NG[d]	10
Effluent-1	490	22,000	NG	10
Effluent-2	540	19,000	NG	10

Note: [a]Non use period of 6 weeks; HPC numbers in all columns for this reference are mean values for a six-week period before, during and after shut-down, respectively.

(Rodac plates). When the GAC filter material was checked for bacterial contamination, 5 of the 13 filters (38%) yielded bacterial counts that ranged from 4 to 99 CFU/g. Thus the fact that filters may come from the manufacturer already contaminated with bacteria must be recognized. Identification of bacteria isolated during the study yielded *Aeromonas hydrophila*, *Pseudomonas cepacia*, *P. fluorescens*, *P. putida*, *Sphingomonas paucimobilis*, *Acinetobacter lwoffi*, and coagulase-negative staphylococci.

Bacteria Isolated from Pou-GAC Filters

Bacteria isolated and identified from POU water treatment devices are listed in Table 4. This list includes both coliform bacteria and noncoliform bacteria found in specific studies. It is unlikely that these organisms represent all the bacteria that may be found in such treatment units, but these are representative of bacterial isolates from treated drinking water in general (9). The list includes some bacteria that are known opportunistic human pathogens (e.g., *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Aeromonas hydrophila*, etc.). The occurrence of coliform bacteria on this list is not surprising because no water treatment plant is 100% efficient in removing or inactivating all microorganisms, and low levels of bacteria do survive and colonize the pipe walls of water distribution systems. Some coliform bacteria that escape disinfection are able to survive and grow in distribution system biofilms and are shed back into the water under some conditions (15).

New carbon filters become colonized by bacteria very rapidly, and the HPC/mL levels tend to spike and then drop marginally. The HPC/mL of the product water becomes relatively stable, often at a fairly high level, for filter cartridges that have been in service for more than two weeks. This is illustrated in Figure 4 to show the bacterial levels in dechlorinated tap water influent versus bacterial levels in product water for three third-faucet type GAC treatment units used in the study (16). Within two weeks of being in service, all three units showed high levels of heterotrophic bacteria in the product water, and for two of the three test units the bacterial load in the product water was the most during the first six weeks of use. The curve marked TAP in Figure 4 represents water

Table 4. Bacteria Isolated from Product Water from POU Treatment Devices

Genus and Species	Filter Type	Reference
Coliform Group		
Citrobacter freundii	GAC	9
Enterobacter aerogenes	GAC	9
Ent. cloacae	GAC	9
Klebsiella pneumoniae	GAC	9
Non coliform		
Acinetobacter calcoaceticus	R.O.	14
Acinetobacter lwoffii	GAC	11
Aeromonas hydrophila	GAC	11
Alcaligenes sp.	GAC	9
Alcaligenes sp.	R.O.	14
Chromobacterium sp.	R.O.	14
Flavobacterium sp.	GAC	8
Flavobacterium sp.	R.O.	14
Moraxella sp.	R.O.	14
Pseudomonas aeruginosa	GAC	8
Ps. cepacia	GAC	9,11
Ps. fluorescens	GAC	9,11
Ps. maltophilia	GAC	9
Ps. paucimobilis	R.O.	14
Ps. putida	GAC	11,14
Serratia liquifaciens	GAC	9
Ser. rubidaea	GAC	9
Sphingomonas paucimobilis	GAC	11
Coagulase negative staphylococci	GAC	11

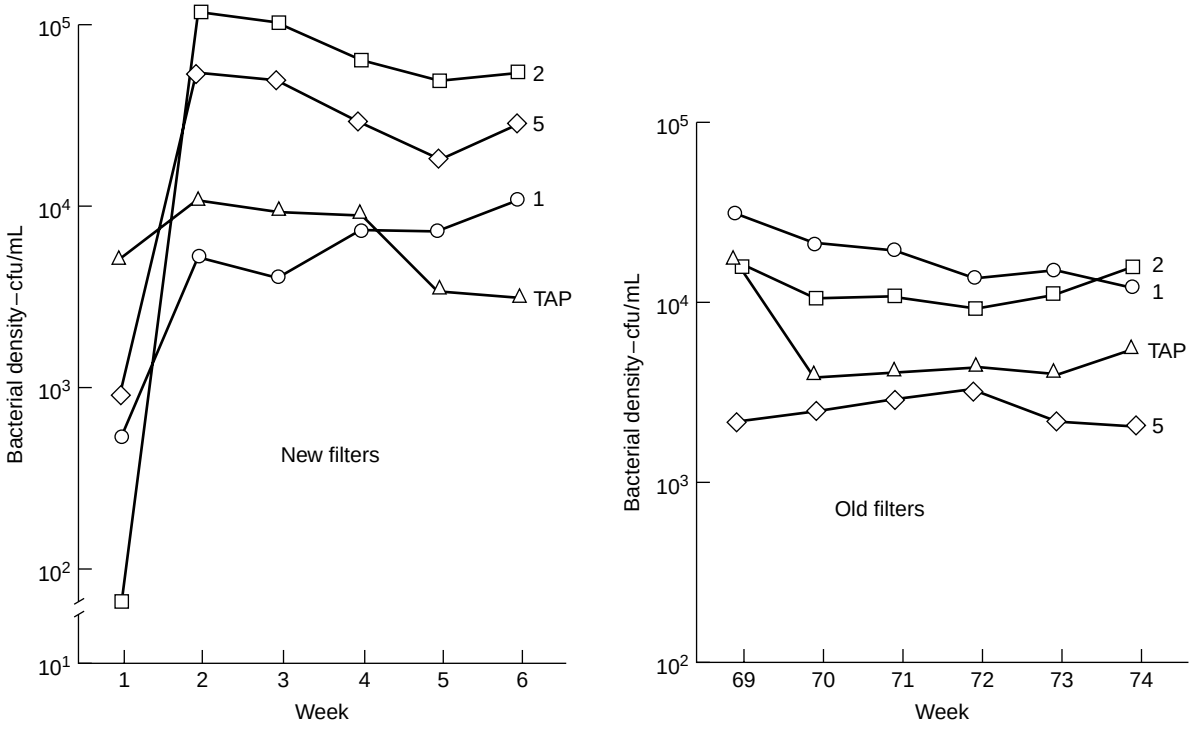

Figure 4. Comparison of bacterial densities in product water from new and old filter cartridges. The number at the end of each curve (1, 2 and 5) represents different filter units tested; TAP indicates dechlorinated tap water (modified from Fig. 12, *J. AWWA* **79** (10): 60–66 (1987), by permission. Copyright, 1987, American Water Works Association).

used as the influent to the treatment units. This feed water was municipal tap water that was dechlorinated by passage through a GAC filter. The graph of the bacterial levels for the TAP samples for both the new and the old filters (Fig. 4) showed relatively stable bacterial levels that were generally lower than the bacterial levels associated with the product water from the treatment units. This pattern was similar to that reported by Tobin and coworkers (8).

High levels of heterotrophic bacteria can develop in GAC cartridge filters and are shed into the product water, and it is not possible for the consumer to determine when a cartridge has ceased to function well in the removal of organic chemical compounds from the water. Consequently, it is important for the filter unit or cartridge to be maintained and changed according to the manufacturer's recommendations. The only clues a consumer may have that the GAC filter cartridge may need to be replaced are changes in the flow rate or taste and/or odor of the product water. However, such a change could occur before the manufacturer's recommended filter cartridge use limit is reached. If this were to happen, the GAC cartridge or the complete unit (depending on the type of unit), should be replaced. If it is economically feasible, the consumer may wish to replace the filter more frequently than the manufacturer recommends because the consumer cannot easily determine when exactly the carbon filter is no longer functional, and the bacterial concentration in the product water may achieve a very high, relatively stable level.

Bacteriostatic Filters

Some GAC treatment devices contain silver as a bacteriostatic agent to control growth of HPC bacteria. However, silver is only effective as a growth-inhibiting agent for some bacteria, not all. In addition, the effectiveness of silver may become attenuated as particulate loading and organic compound adsorption increase, and bacterial biofilm builds up on the GAC during use. Reduced effectiveness of silver may also result from loss of silver caused by leaching.

Reasoner and coworkers (16) found that two of the three GAC filters that contained silver as a bacteriostatic agent shed bacteria in the product water that were at levels as high as for GAC filter units that did not contain silver. Qualitatively, there appeared to be fewer bacterial colony types in the HPC population from silver-containing GAC filters than there were from plain GAC filters.

Silver is moderately effective as a bacteriostatic agent for coliform bacteria. Tobin and coworkers (8) spiked tap water with coliforms in settled sewage and compared counts of coliform bacteria in water filtered through a GAC-silver POU filter with coliform counts in water filtered through a plain GAC filter of the same manufacturer. Water samples were collected from the GAC-silver unit immediately after adding the coliform spike to the influent. The samples were quickly neutralized and analyzed, and the results showed that some coliforms could still be enumerated. After a contact time of 30 minutes before sample neutralization, no coliform could be detected. In the same samples, there was very little

effect on the total heterotrophic bacterial population. However, water samples collected from the plain GAC filter and handled in a similar fashion showed coliform counts nearly as high as the initial coliform spike level (8). In another study, an *Enterobacter aerogenes* challenge was reduced from 8,200/100 mL to 830/100 mL (1-$\log_{10}$ reduction) in 30 seconds and to less than 1/100 mL (>3-$\log_{10}$ reduction) in 17 hours; the reduction of *E. aerogenes* from 52,000/100 mL to less than 1/100 mL (>4-$\log_{10}$ reduction) occurred in 68 hours (18). In the same study, GAC-Copper yielded a similar reduction in 68 hours. However, the authors concluded in that study that the effect of silver or copper on the general heterotrophic bacterial population was negligible. The use of a precoat filter in conjunction with GAC was also effective in reducing coliform bacteria challenge levels, yielding log reductions ranging from 99% to 99.999% (2- to 5-$\log_{10}$) (18).

Although silver in GAC filters has been shown to be bacteriostatic or even bactericidal for some bacteria, including some coliforms, other bacteria have been shown to be resistant to silver. A pour-through GAC-silver treatment unit was tested to see whether the three species of nontuberculous mycobacteria (*M. avium*, *M. fortuitum*, and *M. mucogenicum*) would colonize and grow or survive (19). The results showed that nontuberculous *M. avium* colonized and grew in the device, but the other two species were never detected in the filtered water during an eight-week experiment. The three *Mycobacterium* species were further tested for susceptibility to silver by disk diffusion assay; *M. avium* grew in the presence of 1,000 μg/mL silver, whereas *M. fortuitum* and *M. mucogenicum* were inhibited by 50 μg/mL silver. When Rodgers and coworkers (19) surveyed 45 strains of nontuberculous mycobacteria (11 species) isolated from drinking water for sensitivity to silver using the disk diffusion assay, 26 isolates (57%) were resistant to 1,000 μg/mL silver, including 20 *M. avium* isolates. These researchers concluded that the presence of nontuberculous mycobacteria in drinking water treated by a filtration device that incorporates silver as a bacteriocidal or bacteriostatic agent could pose a health risk for immunocompromised consumers.

Included in the general concern over bacterial growth in POU-GAC filters is the possibility that frank or opportunistic pathogens that reach the filters may become established, multiply, and pose a health threat to the consumers. Because of this concern, various studies have challenged POU-GAC treatment units by dosing pure culture suspensions of various bacteria to determine if the bacteria would simply pass through, be retained by the filter units and survive at low levels, or colonize the filter units and multiply to higher levels than the challenge dose. Table 5 lists bacteria that were used to challenge POU treatment units in various studies and the length of time the organisms survived and were detected in the product water. In the studies reported by Geldreich and coworkers (9), Reasoner and coworkers (16), and Geldreich and Reasoner (20), there was considerable variation in the size of the challenge doses used. The doses reflect the total number of challenge cells delivered to each unit, not CFU/mL; doses varied from a low of 200 to 300 CFU to a maximum of 3.72×10^9 CFU. The higher doses were usually associated with bacteria that were more difficult to recover in attempts to establish that they could or could not survive or colonize. Some bacteria (*E. coli*, *Salmonella typhimurium*, and *Enterobacter cloacae*) appeared to pass through some of the filter units and were not recovered even a few hours (shown as <0.5 d in Table 5) after the small challenge dose. Others apparently colonized the treatment units and were detected in the product water for periods that varied from 0.5 days to as high as 150 days. Most challenge bacteria, when detected in the product water, were present at low levels ranging in mean values from 0.2 CFU/100mL to 110 CFU/100mL (9). Several bacteria that were dosed at low levels (200–300 CFU/unit) were retained by the filters, apparently colonized, and were released over periods ranging from six days (*Citrobacter freundii*) to as long as 150 days (*Pseudomonas aeruginosa* and *Serratia marcescens*). Other bacteria used to challenge the test units, although dosed at very high levels, were unable to survive or colonize the GAC treatment units for more than a few hours at best (*Campylobacter jejuni*, *Salmonella typhimurium*, and *Yersinia enterocolitica*). Finally, of three species of Mycobacterium seeded into water and filtered through a pour-through GAC-silver water treatment device, only *M. avium* was found to colonize the GAC and remain recoverable in the product water throughout the eight-week testing period (19). The authors concluded that because such an opportunistic pathogen could survive or colonize in such a unit, water treated by a POU device that relies on the bactericidal effect of silver could pose a health risk to immunocompromised consumers. This concern could be extended to some other opportunistic pathogens listed in Table 5.

A general concern raised here is whether the benefit of using POU devices to remove cysts and oocysts, heavy metals, trihalomethanes (THMs), and other contaminants outweighs the risk of infection for AIDS patients or other immunocompromised persons, posed by nontuberculous mycobacteria such as *M. avium* or other opportunistic pathogens such as *Pseudomonas aeruginosa* (cystic fibrosis) that may be found in the general heterotrophic bacterial population in nonpurified water. By and large, this concern narrows down to an issue of individual choice, but that choice needs to be based on education and an awareness of the potential risks involved in the use of nonpurified drinking water. Studies that specifically expanded on this particular issue were not found.

Based on the information presented in Tables 2 to 4, it is apparent that GAC and GAC-silver POU treatment units that do not incorporate some form of additional treatment to reduce or inactivate bacteria have generally been found to yield product water containing high numbers of bacteria. In many cases, the numbers of bacteria in the product water were several orders of magnitude greater than the bacterial levels in the water influent to the treatment units. Thus, from a bacteriological quality viewpoint, some types of GAC and GAC-silver POU water treatment units degrade the quality of the water treated although there may be aesthetic improvement based on taste and odor of the water or removal and reduction of other contaminants

Table 5. Persistence (Survival/Colonization) of Bacteria Used to Challenge POU GAC Treatment Devices

Organism	Challenge Dose CFU/Unit	Persistence Time	Reference
Aeromonas hydrophila	100–46,000	0–15 d	16
Campylobacter jejuni	1.17×10^6–3.72×10^9	0.5 d	16
Citrobacter fruendii	200–300	6–10 d	9,20
Enterobacter aerogenes	200–300	30–50 d	9,20
Ent. cloacae	200–300	<0.5 d[a]	9,20
Escherichia coli	200–300	<0.5 d	9,20
Escherichia coli	4,000,000	>17 d	21
Klebsiella pneumoniae	1,000	0–63 d	16
Legionella pneumophila	14,000,000	0.1–5.5 d	16
Mycobacterium avium	290,000	56 d	19
M. mucogenicum	48,000	<1 d	19
M. fortuitum	18,000	<1 d	19
Pseudomonas aeruginosa	200–300	150 d	9,16
Pseudomonas aeruginosa	4,000,000	>17 d	20
Salmonella typhimurium	200–300	<0.5 d	16
Serratia marcescens	200–300	30–150 d	20
Yersinia enterocolitica	Variable	0–0.5 d	16

Note: [a] <0.5 d indicates the organism was undetected in the first sample following the spike dose.

such as cysts or oocysts, inorganics (lead, arsenic, radium), or chlorinated organic disinfection by-products (THMs).

However, an observation in contrast to the negative perception of high bacterial levels in POU-GAC filters is the suggestion that high bacterial levels may be beneficial in preventing colonization of GAC filters by frank or opportunistic pathogens. This may be due to what has been termed *competitive inhibition* or *biocompetitive exclusion* caused either by inhibitory materials produced by the biofilm bacteria that act against pathogens, or simply the inability of the pathogens to compete for nutrients in the presence of a heterotrophic bacterial biofilm population, or both. The exclusion or inhibition of pathogens by resident biofilm bacteria has been shown or suggested by the results from several studies in which some pathogen challenges did not result in pathogen colonization of the filters or GAC that already had a biofilm population (Table 5) (9,16,21,22). The results from these studies and the lack of documented evidence of human illness caused by high HPC levels in drinking water form the basis for an argument that has been posed that high HPC levels in POU and POE treatment devices are beneficial in preventing colonization by pathogenic bacteria (23,24).

POU Water Purifiers

POU water purifiers pose a different concern and challenge than POU-GAC filter units because by definition, water purifiers are designed to be used to treat nonpotable water and must remove or inactivate all pathogens that might be present in the source water. Therefore, the microbiological concern focuses specifically on the performance of these treatment units for removing and inactivating microbial pathogens. Performance evaluation of water purifiers involves using a testing protocol such as that developed by the U.S. EPA (5) to test production models of a given water purifier over the manufacturer's claimed lifetime for the unit. The intention is to verify or establish that the purifier is capable of performing as claimed by the manufacturer for removal or inactivation of bacteria, viruses, and protozoan pathogens. The EPA protocol requires microbial removal or inactivation of: bacteria, *Klebsiella terrigena*, 99.9999% (6-$\log_{10}$); viruses, Poliovirus 1 (LSc) (ATCC-VR-59) and Rotavirus (Wa or SA-11) (ATCC-VR-899 or VR-2018), 99.99% (4-$\log_{10}$); and protozoa cysts, *Giardia muris* or *G. lamblia*, 99.9% (3-$\log_{10}$), or optionally for treatment units that use occlusion filtration, particles, or microspheres of 4–6 μm diameter. Because the protozoan parasite *Cryptosporidium parvum* has been shown to be a major agent of waterborne disease in the past few years, the testing protocol must be modified to test for removal of oocysts of this organism and a filtration device must have an effective pore size of 2 μm or less to remove the oocysts.

The effectiveness of several POU water purifiers for removing or inactivating bacteria, viruses, and protozoa is summarized in Table 6. All of the purifiers evaluated incorporated two or more treatment processes such as GAC pressed carbon block filtration and UV irradiation, GAC filtration and heating, candle filtration and GAC filtration and UV irradiation, or membrane filtration and iodine disinfection. Purifier testing for the studies cited in Table 6 was largely based on the U.S. EPA protocol (5).

Overall, removal or inactivation of microorganisms by the water purifiers was generally excellent when seeded water of qualities specified by the U.S. EPA protocol was used in the testing and met the protocol goals. Removal and inactivation results ranged as follows: viruses — from >99.99% to >99.99998%; bacteria — from 99.4% (heterotrophic bacteria) to >99.99999%; bacteriophages or coliphages — from >99.997% to >99.9999999%; cysts or oocysts — from 99.95% to >99.998%; yeast — from >99.9997%; fungal spores — >99.9994%; and algae — 99.99993%. Some of

the studies tested removal or inactivation of a variety of microorganisms other than those required by the U.S. EPA protocol, hence the values for heterotrophic bacteria, yeast, fungal spores, algae, and bacteriphage other than coliphage. Conversely, not all the studies tested for bacterial removal or inactivation using *Klebsiella terrigena*, the bacterial challenge organism specified in the U.S. EPA protocol. In the study by Grabow and coworkers (25) the purifier was also challenged with untreated river water and treated wastewater after the unit had been operated with seeded tap water (Table 6). With raw river water, although good removal or inactivation of heterotrophic bacteria (99.9998%) occurred, it would not have met the U.S. EPA protocol requirement for bacteria. Removal of seeded Poliovirus 1 (>99.9998%) would have met the U.S. EPA protocol requirement for virus removal or inactivation, but removal or inactivation of coliforms and somatic coliphages were only 99.97% and 99.92%, respectively. For treated wastewater, removal or inactivation of heterotrophic bacteria (99.99998%) and seeded Poliovirus 1 (99.9998%) would have met the U.S. EPA protocol requirements for bacteria and viruses, respectively, whereas total coliform removal or inactivation (>99.9998%) would not have met the U.S. EPA protocol requirement for bacteria. All the studies cited in Table 6, except those by Grabow and coworkers (25,28), tested the purifier units for 100% or greater, of the manufacturer's stated lifetime for the treatment unit. As a result, it would appear that the water purifiers functioned as claimed and produced water of potable quality throughout and beyond their ascribed lifetimes.

HEALTH EFFECTS RELATED TO HOME TREATMENT UNITS

As indicated earlier, concerns about high bacterial levels in the treated water from many POU home treatment devices are related to the potential for adverse health effects caused by ingestion of the bacteria, especially for those consumers whose immunological health status may be compromised. This includes the very young, the elderly, persons who are immunosuppressed by medical treatment because of organ transplant or cancer chemotherapy, and others who are immunocompromised because of diseases such as AIDS. Perhaps the more specific concern is whether high numbers of one or more specific opportunistic bacterial pathogens could colonize and dominate the bacterial population of a POU-GAC treatment unit so that the consumer would be exposed to a potentially infectious dose and subsequent illness. This concern prompted the experiments reported by Geldreich and coworkers (9), Reasoner and coworkers (16), and Rodgers and coworkers (19) in which POU-GAC or GAC-silver filters were challenged with specific bacterial strains to observe if they could colonize the treatment units. In fact, very few of the organisms were able to colonize and persist for any extended period (Table 5), and for those that did persist, the numbers recovered were generally low. However, the experiments did demonstrate that some of the challenge strains were able to colonize and persist in low numbers for substantial periods.

Very few studies have been conducted with the specific goal of attempting to demonstrate adverse health effects caused by ingestion of high numbers of heterotrophic bacteria in water from POU/POE home water treatment units. Two epidemiological studies conducted by Yale University researchers attempted to establish a relationship between consumption of high numbers of heterotrophic bacteria in water from POU GAC and POE filters and waterborne illness in consumers (32,33). Neither study was able to establish a direct link between ingestion of high numbers of HPC bacteria in drinking water and human illness. However, the Yale studies did not have large enough study populations to be definitive. Also, the study populations were composed primarily of "healthy" individuals or families and lacked proportional representation of consumers who may be at the greatest risk — the very young, the elderly, and other immunocompromised persons.

Results of epidemiological studies of waterborne illness conducted in Canada indicated that there was a significant level of endemic waterborne illness in consumers of municipal water that met current Safe Drinking Water Standards (34,35) of the United States and Canada. In the Payment and coworkers (34) study in a community that received tap water treated by a conventional water treatment plant, 300 RO water filtration units were installed in randomly chosen households. The rate of gastrointestinal illness (G.I.I.) in the households that had R.O. units was compared to the G.I.I. rate in a similar group that did not have R.O. water treatment. The results indicated that the households that had consumed R.O. treated tap water had a G.I.I. rate that was lower by about 35% than that of those who drank municipal tap water. Thus, the R.O. treatment units appeared to prevent a significant level of waterborne illnesses in all population subgroups within the study population.

Analysis of the microbiological data collected on the R.O. units showed that HPC levels in water from most of the units ranged from 1,000 to 100,000 CFU/ml, and weekly monitoring showed that the numbers were relatively stable (36). Further analysis showed significant univariate correlations between the HPC levels at both 20 °C and 35 °C and the G.I.I. rate, suggesting that bacteria growing in the R.O. units were responsible for an increase in the G.I.I. symptoms. However, there was no correlation between the G.I.I. rate and the amount of water consumed, which suggested that the statistical correlation with bacterial density could be spurious. A correlation was also found between the length of an illness episode and HPC counts at 35 °C, but not with HPC counts at 20 °C, suggesting that illness symptoms were more severe as the 35 °C HPC counts increased. Because there was no correlation between the amount of water consumed without further treatment (heated or used for cooking) and the HPC counts at 20 or 35 °C, the implication is that there were no negative aesthetic effects that caused a possible decrease in consumption by the study participants. The authors concluded that their data suggested that heterotrophic bacteria (35 °C plate count) that grew in R.O. treated drinking water were associated with a low incidence of gastrointestinal disease. It must be

Table 6. Effectiveness of POU Water Purifiers for Removal or Inactivation of Microorganisms

Note: [a]Type of treatment unit tested: GAC Block/UV = pressed activated carbon block filter followed by ultraviolet treatment; GAC/Heat Cycle = carbon filter plus heating to 88–94 °C; FC/GAC/UV = polypropylene candle prefilter followed by a GAC-silver filter followed by ultraviolet treatment; RO/Iodine = reverse osmosis membrane filtration followed by disinfection passage through an iodine (I_5) resin filter cartridge; MC/Iodine Resin = microfiltration followed by disinfection passage through an iodine resin bed filter.

[b]Seeded tap is used to indicate that the “Guide Standard and Protocol for Testing Microbiological Water Purifiers (U.S. EPA, 1987), or a modification of it, was used as the test procedure.

[c]Manufacturer’s stated lifetime of the treatment unit, or subunit, in gallons/liters, hours of use, or cycles, and () indicate the percentage of the lifetime the units were actually tested; (?) indicates lifetime not given in citation.

pointed out that there were no instances of illness in which G.I.I. was shown to be directly attributable to ingestion of high concentrations of HPC bacteria in the filtered water from an R.O. treatment unit. Additionally, when a redesigned epidemiological study was conducted (36) the correlation between HPC levels in R.O. treated water was not confirmed.

Concerns over ingestion of high bacterial levels in drinking water, either from municipal tap water or from home POU treatment devices, will probably continue although there have been no studies that could directly prove that the HPC bacteria do or do not cause illness in the consumer. Much of the concern is related to the perception of bacterial quality. Specifically, despite adverse news media reports concerning drinking water quality, people generally take it for granted that their drinking water is free of harmful impurities (including bacteria), whether it comes from the municipal supply or from a home treatment device that treats municipal tap water. They do not expect that there will be any bacteria in the water at all, and if they find out that there are bacteria in the water, albeit apparently harmless bacteria, they are likely to be perturbed. Their perception is that all bacteria are bad and should not be consumed. The likelihood is that for healthy, immunologically competent people, ingestion or other exposure to high numbers of heterotrophic bacteria may not pose a significant health risk. However, for immunologically compromised persons, exposure to high bacterial levels in drinking water may carry a significant risk of infection and disease. The size of the sensitive population (i.e., immunologically compromised population) in the United States is growing rapidly, and exposure to opportunistic pathogens in drinking water is becoming a matter of increasing concern. For this reason, POU home treatment units should be designed to minimize the potential for high bacterial levels in the product water.

HOT DESERT SOIL MICROBIAL COMMUNITIES

THOMAS L. KIEFT
New Mexico Institute of Mining and Technology
Socorro, New Mexico

Microorganisms of hot desert soils carry out essential nutrient cycling and soil-building functions of soil communities despite significant environmental challenges, foremost among them being extreme desiccation. Deserts are variously described as extremely arid and arid environments that receive less than 60 to 100 mm and from 60 to 100 to 150 to 250 mm annual precipitation, respectively (1,2). Semiarid lands receive from 150 to 250 mm to 250 to 500 mm precipitation and may be subject to desertification, that is, loss of vegetative cover and productivity usually as a result of human activities (1,3). Moisture availability is generally considered to be the controlling factor for biological activities in desert systems, with the moisture input occurring as infrequent, discreet, unpredictable events (2). The majority of arid and semiarid environments occur between the latitudes of 25 and 35° (1) where high temperatures occur during at least part of the year, and thus the majority of deserts can be termed hot deserts (as contrasted with cold deserts such as the Antarctic dry valleys). Maximum surface soil temperatures of hot deserts may be as high as 80°C (4). Low available moisture as well as extreme heat limit primary production and restrict the plant communities to scattered "islands of fertility." This in turn limits the availability of plant-derived organic carbon for microbial metabolism. Unique features of desert soil communities that contrast with those of more mesic systems include generally low biomass, low diversity, spatially and temporally heterogeneous patterns of biomass and activity, and adaptations for survival of adverse environmental conditions that can include low-moisture availability, extreme heat, low nutrient availability, high pH, and high salinity. Though not necessarily extremophiles, desert soil microbes do exhibit extreme tolerance of adverse environmental conditions. Microorganisms are essential to ecosystem processes in deserts. They may also be important in reclamation of disturbed, desertified systems. This article deals with hot desert conditions that influence soil microorganisms, microbial abundance and diversity in desert soils, microbial adaptations to the extremes of desert soils, and practical applications of desert soil microbiology. Previous reviews of the topic include those of Skujins (5,6) and Kieft (7).

SOIL WATER POTENTIAL

Water is usually considered to be the single overriding controlling factor for biological activities in desert ecosystems (2,4–6,8) However, nitrogen is often the limiting nutrient for plant productivity during the brief periods when water is readily available (9,10). Water potential is a measure of free energy of water in a system, for example, soil, relative to a pure water reference (11). Water potential (ψ) is measured in pressure units and is related to water activity (a_w) of a system and to the relative humidity (rh) of an atmosphere in equilibrium with the water in a system according to the following:

$$\psi = \mathrm{RT}(V_w)^{-1} \ln a_w = RT(V_w)^{-1} \ln\left(\frac{\mathrm{rh}}{100}\right)$$

where

ψ = water potential (MPa)
R = gas constant (8.31×10^{-4} m^3 MPa mol^{-1} K^{-1})
T = temperature (K)
V_w = partial molal volume of water (1.8×10^{-5} m^3 mol^{-1})
a_w = water activity, and rh = relative humidity (%).

Matric water potential (ψ_m) and solute water potential (ψ_s) are the most significant components of total water potential in soil: $\psi_{total} = \psi_m + \psi_s$. Pure water has a water activity of 1 and a water potential of 0. As a porous medium such as soil loses water, ψ_m becomes increasingly negative; as solutes such as NaCl increase in concentration, ψ_s also becomes more negative. Matric and solute water potentials impose related but different stresses on microbial cells. Cytoplasmic water potentials must approximate extracellular water potentials to avoid excessive turgor pressure, plasmolysis, or plasmoptysis (cell explosion); however, some positive turgor pressure is required for cellular expansion during growth. Microbes respond to solute water potentials by accumulating intracellular compatible solutes, a response that has been well characterized in many different microorganisms (12–15). Responses to matric water stress are less well understood: cells may accumulate intracellular compatible solutes and/or passively lose water to the surrounding medium. Matric water potentials in desert soils can be as low as −150 MPa (16). In extremely saline soils, the solute water potential can approach −41 MPa as the NaCl concentration approaches saturation. Arid and semiarid soils with poor drainage are often salt affected.

Low water potential in a porous medium has the added effect of decreasing nutrient availability. As a soil loses water, the water films on the surfaces of soil particles become thinner and also discontinuous. This limits solute diffusion and also impedes microbial motility. Solute diffusion is reduced by a factor of approximately 2 in a typical soil as the matric water potential drops to −0.1 MPa (11). Bacterial motility is essentially nil at matric water potentials below approximately −0.1 MPa (17). Filamentous organisms (fungi, algae, cyanobacteria, and actinomycetes) may be able to overcome this limitation by extending filaments through air voids in a partially desiccated soil. Matric water potential affects nutrient limitation in nearly any unsaturated soil; however, the effects are especially severe in desert soils, where the duration of desiccation stress can be months or even years. In addition to the stresses imposed by extremely low absolute water potentials, rapid changes in water potential can induce extreme imbalances in water potential between the cytoplasm and the surrounding environment. Rapid increases in water potentials as desiccated soils are wetted can cause

loss of intracellular solutes and/or plasmoptysis (18). These rapid osmotic challenges may be attenuated by extracellular polysaccharide matrices that retard water loss (19). See the section on "Low water potential: salinity and desiccation" for a more complete discussion of microbial adaptations to water potential stress.

DESERT SOIL MICROBIAL ABUNDANCE

The numbers and activities of microorganisms in desert soils are generally lower than in soils of more mesic environments. Plate counts of aerobic, heterotrophic bacteria in various hot desert soils have been measured in a range of approximately 10^4 to 10^7 cfu g^{-1} (6,7). This is at least two orders of magnitude lower than what one would expect to culture from agricultural or forest soils. Bamforth (20) counted 1 to 7×10^8 bacterial cells per gram by direct microscopy in a Sonoran Desert soil in Arizona. This total count of bacteria is also considerably lower than what one would typically find in more mesic soils. As with any soil, the total number of bacteria exceeds the number of culturable heterotrophs by a factor of at least 100. This difference likely reflects the number of dead and dying cells and the presence of viable cells with metabolisms that are not suited to the plate-count medium. As with bacteria, the biomass of fungi in desert soils is generally less than in more mesic soils (6). Typical numbers of fungi range from 10^3 to 10^4 fungal propagules per gram of soil (7). Hyphal lengths, which may be a better estimate of fungal abundance, range from approximately 10 to 200 m g^{-1} soil (7). The ratios of fungal to bacterial biomass are typically greater in deserts than in nondesert soils. Soil fungi may be favored in low-moisture environments because of their desiccation-resistant spores and the ability of filamentous fungi to grow through air-filled soil pores. Actinomycetes are similarly favored by dry conditions. Numbers of protozoa can range from less than 100 cells g^{-1} in extremely dry deserts to approximately 10^4 cells g^{-1} in semiarid soils (21–23). Parker and coworkers (23) counted 2.5×10^4 amoebae, 4.9×10^3 flagellates, and 7×10^2 g^{-1} ciliates in a Chihuahuan Desert (New Mexico) soil. The most extreme, arid terrestrial environments may have even lower numbers of microorganisms. The Atacama Desert, which may be the driest area on Earth, has been estimated to have fewer than 10 culturable bacteria g^{-1} and may be devoid of eukaryotic microbes (24).

SPATIAL AND TEMPORAL DISTRIBUTIONS

The spatial distribution of microbes within desert soils tends not to be uniform, instead, microorganisms are concentrated within islands of fertility that immediately surround desert shrubs (5,16,25–31) and also areas of concentrated animal activity (32). The transition from grassland to desert shrubland is accompanied by an increase in spatial heterogeneity of soil resources as mineral nutrients are concentrated into patches that favor the establishment of desert shrubs (33,34). The soil beneath the canopies of these shrubs is then enriched in organic carbon from root exudates, material sloughed off from roots, and accumulated plant litter, resulting in higher microbial biomass and activities. Total organic carbon (TOC), microbial biomass carbon, basal respiration rates, and soil dehydrogenase activities were all greater in soil beneath creosotebush canopies than in surrounding bare soil at a Chihuahuan desert site (29). The ratios of biomass carbon to TOC and of respiration to biomass carbon (metabolic quotient) were also higher beneath shrub canopies than in bare soil, indicating a higher proportion of readily metabolizable carbon in the canopy soils. Similar patterns were observed in an *Atriplex* shrubland and a semiarid grassland site (16). The effects of desert plants on microbial abundance are especially pronounced in the rhizosphere. The ratio of the number of rhizosphere microbes to those in the surrounding bulk soil (R/S ratio) can be 700 or more in a desert, 100 times greater than in a nondesert soil (6,7). The localization of nutrients in the immediate vicinity of mammal mounds (35,36) can also stimulate microbial activities. Ayarbe and Kieft (32) measured greater TOC, microbial biomass carbon, basal respiration, biomass carbon/TOC ratios, and metabolic quotients in the soil of banner-tailed kangaroo rat mounds than in the surrounding soil. Dhillion and Zak (37) reported higher numbers of bacteria and greater fungal hyphal lengths in the soil of western cottontail burrows than in the surrounding soil at a site in western Texas.

Temporal variations in biomass and activity in deserts are driven primarily by moisture patterns. Temporal variations in plant primary productivity in deserts have been described as following a "pulse and reserve" model in which plant metabolism and growth are stimulated by precipitation. Later, as the soil dries, a portion of the plant biomass dies, but a reserve of viable biomass retains sufficient energy and nutrient reserves to become active when moisture again becomes available. The majority of desert soil microbial activity is heterotrophy based on plant-produced organic carbon, and so microbial patterns of activity are similar to those of the primary producers. Blooms of activity follow immediately after precipitation events; these are followed by periods of slow decline in activity and biomass as the soil dries (38,39). Microbial reserve biomass includes intracellular storage compounds (e.g., poly-β-hydroxybutyrate and glycogen in bacteria), compatible solutes (e.g., trehalose and sucrose; 15), and extracellular polysaccharides (EPS). As with spatial patterns, temporal variability in biomass and activity has also been found to be greater in a desert shrubland than in an adjacent grassland (29). Temporal variances in TOC, biomass carbon, basal respiration, nitrogen mineralization potential, and dehydrogenase activity were higher in a Chihuahuan desert creosotebush shrubland than in an adjacent grassland (29).

DIVERSITY OF DESERT SOIL MICROBES

Environments in which physical and chemical parameters exert a greater influence than biological interactions on biological processes are often considered to have lower species diversity (40–42). This generalization is

likely valid for deserts, especially if soil microbial diversity reflects plant diversity, as has been suggested for broad-scale comparisons among ecosystems (43). Nonetheless, desert soil microbial communities include a very large number of microbial types, as evidenced by traditional culture-based studies (44,45), culture-independent molecular approaches (44–46,62), metabolic activity studies (47–49), and membrane phospholipid fatty acid (PLFA) profiling (50,51). Microorganisms that are typically cultured from arid and semiarid soils are not especially different from those in more mesic environments; however, the frequency distributions may be more skewed toward desiccation-tolerant forms, such as spore-formers and other gram-positive bacteria along with fungi.

Bacteria

The most commonly cultured bacteria from desert soils are members of the genus *Arthrobacter* (52). Other commonly cultivated bacterial genera include *Corynebacterium*, *Pseudomonas*, *Acinetobacter*, *Bacillus*, *Proteus*, and *Micrococcus* (6,53). Endospore-forming bacteria, especially *Bacillus* spp., but also *Clostridium* spp., can comprise a significant proportion of culturable bacteria, approaching 50% in extremely arid soils (6). Actinomycetes are important constituents of the soil community, with actinomycete propagules (mainly spores) comprising as much as 50% of bacterial communities in desert soils (6). Common actinomycete genera include *Streptomyces*, *Micromonospora*, and *Thermoactinomyces* (6). Isolates belonging to the genus *Geodermatophilus* have most often been cultivated from the surfaces of desert rocks and soils (54). *Geodermatophilus obscuras* are dark-pigmented filaments and/or coccoid cells in aggregates; their phylogenetic association is in the Frankiaceae (54). *Geodermatophilus* has been found in abundance in decaying plant litter (55) and in rhizospheres (56) in deserts. Myxobacteria, which form desiccation-tolerant myxospores and microcysts, have also been cultured from arid soils. Examples include *Archianium*, *Cystobacter*, *Stigmatella*, *Polyangium*, and *Chondromyces* (57,58).

As in most natural environments, the majority of bacteria in desert soils are not culturable by current methods. When 16S rDNA-based molecular methods for characterizing communities are applied to desert soils, the microbial diversity is revealed to be far greater than indicated by methods that rely on culturing alone (44). In comparing bacteria diversity in arid soils using culture-based and culture-independent 16S rDNA sequencing, Dunbar and coworkers (44) cultured 34 phylotypes representing three bacterial divisions, whereas the culture-independent approach yielded 498 different phylotypes representing at least seven bacterial divisions. Some of the previously overlooked, uncultivated bacteria represent novel lineages and may carry out metabolic functions not previously known in desert soils (Table 1). Kuske and coworkers (45) found a variety of bacterial 16S rDNA sequences belonging to a monophyletic but diverse group of bacteria related to the genus *Acidobacterium* in two arid Arizona soils. In a further investigation, members of the *Acidobacterium* group were found to be widespread in a variety of terrestrial environments (59). Holmes and coworkers (2000) used 16S rDNA methods to identify another taxonomically distinct group of common arid soil bacteria that are rarely, if ever, cultivated. These are high G + C gram-positive bacteria related to the genus *Rubrobacter*, and they were found to make up 2.6 to 10.2% of bacterial clone libraries derived from arid Australian soil samples. Many more novel bacterial taxa will likely be unearthed as molecular, culture-independent approaches are applied more widely to hot desert soils.

Table 1. Novel Groups of Uncultured Desert Soil Microbes Evidenced by 16S rDNA Sequence Analysis

Microbial Group	Environment	Reference
	Archaea	
Soil Crenarchaeota, closely related to sequences reported by Bintrim and coworkers (60) and Jurgens and coworkers (61)	Chihuahuan Desert, New Mexico	Kieft, unpublished data
	Bacteria	
Acidobacterium group	Sunset Crater National Monument, Arizona; Dugway, Utah	45,59
High G + C gram-positive bacteria related to *Rubrobacter*	Sturt National Park, New South Wales, Australia	Holmes and coworkers (62)

Archaea

Archaea are also present in hot desert environments; however, desert Archaea have received relatively little study. Methanogens are present, but restricted as in other soils to strictly anoxic sites, such as the centers of organic-rich soil aggregates. Extraction, amplification, cloning, and sequencing of 16S rDNA using universal archaea primers has demonstrated the presence of as yet uncultured Crenarchaeota in soils (60,61). These soil Crenarchaeota form a phylogenetically distinct group, but their metabolic function is currently unknown. We have recently found 16S rDNA sequences with close homology to other soil Crenarchaeota in a Chihuahuan Desert soil in New Mexico (Kieft, unpublished data). We also have evidence that these desert soil Crenarchaeota can form cells small enough to pass through a 0.4-μm filter (Kieft, unpublished data). Efforts are under way to cultivate soil Chrenarchaeota. Increased knowledge of the biodiversity of Archaea in desert soils is needed.

Fungi

Fungi in desert soils are generally of the same genera as those of soils in moister climates. Commonly isolated fungi

from desert soils include *Aspergillus* spp., *Penicillium* spp., *Cladosporium* spp., *Alternaria* spp., *Chaetomium* spp., *Fusarium* spp., *Mucor* spp., *Helminthosporium* spp., *Curvularia* spp., and *Stemphylium* spp. (63). Fungal activity has been characterized as being limited to temporal and spatial "windows of opportunity" that allow favorable moisture conditions (10). At the soil surface and in litter layers, these windows of opportunity occur following precipitation events. Spatially, these windows of opportunity occur in the vicinity of plants and in burrows of desert animals. The spatial and temporal heterogeneity has been credited with generating an unusually high fungal diversity in desert systems (10). Much of the characterization of fungal biodiversity in desert soils has focused on habitats associated with plants and with animal activities.

The litter layers beneath the canopies of desert shrubs provide a more favorable habitat for fungi than the open soil between plants. Zak and coworkers (10) identified species of fungi in decaying creosote wood placed beneath the canopies of shrubs at Chihuahuan and Sonoran Desert sites. Dominant fungi were *Alternaria alternata*, *Coleophoma* sp., and *Fusarium acuminatum* at the Chihuahuan Desert site; the Sonoran site was dominated by the same three species plus *Phoma* sp. and two unidentified species. Arbuscular mycorrhizal (AM) fungi are important symbionts of many desert plants, and plants infected with mycorrhizae exhibit greater drought tolerance (37). These are mostly members of the Glomaceae, with the most common species being *Glomus fasciculatum*, *G. intraradices*, and *G. mosseae* (64). Dhillion and coworkers (65) surveyed plants in a coastal desert in Chile and found that 98% of the 38 plant species present formed AM associations. In a survey of North American and Namibian desert AM fungal communities, Stutz and coworkers (64) found 21 different species of AM fungi, with similarity in species composition between the North American and Namibian sites ranging from 54 to 79%. Mycorrhizal fungi can be critically important in restoration of disturbed desert systems (66,67) (see section on Plant-Microbe Symbioses in Reclamation of Disturbed Arid Ecosystems).

The caches of seeds in the mounds of kangaroo rats have been shown to provide a favorable habitat for growth of diverse microfungi (68–70). Seed caches may be liters in volume and conditions are generally moist (68,69). Herrera (70) identified 273 fungal species belonging to 37 genera in kangaroo rat food stores at a Chihuahuan Desert site. The most common genera included *Aspergillus*, *Fusarium*, *Mucor*, and *Penicillium*. It has been suggested that the kangaroo rats have a mutualistic relationship with the fungi, in which the mammals' behavior serves to inoculate stored seeds and to maintain favorable conditions in return for unknown benefit, for example, nutritional improvement of the seeds or protection from bacterial degradation (Hawkins, 1999). The burrows of small mammals also serve as stores of mycorrhizal spores (37).

Heterotrophic Protists (protozoa)

The majority of protozoa in desert soils are types that can form desiccation-resistant cysts, and they remain encysted except for brief periods of moisture availability (23). Flagellates and amoebae are favored in arid and semiarid soils; however, ciliates can also be found (20,22). Species richness of ciliates is generally less than 10 in desert soils, whereas species richness of ciliates in mesic soils is typically in the 10 to 50 range (22). Rodriguez-Zaragoza (71) found 40 species of naked amoebae belonging to 19 genera at a desert site in Mexico; *Acanthamoeba* and *Vahlkampfia* accounted for 12.5 and 15% of the species, respectively. Arid soil protozoa have been shown to increase following the increase in bacterial prey populations that generally occurs after rainfall (22,23,71).

Algae and Cyanobacteria

Desert phototrophs can contribute significantly to primary production, and in the case of the cyanobacteria, to nitrogen fixation. They can occur as desert crusts, as lichen symbionts, and within protective endolithic, chasmolithic, or sublithic habitats (72). As with other components of desert biota, the abundance and diversity of phototrophic microorganisms is dependent on moisture availability. Lichens generally occur in higher numbers in semiarid environments than in arid deserts; the hottest, driest deserts may be entirely devoid of lichens. Cyanobacterial crusts flourish during brief periods of moisture availability and survive intervening dry periods in a severely desiccated state. *Microcoleus vaginatus* is the most common of cyanobacterial crust species in the arid western United States; other common cyanobacteria include *Lyngbya*, *Phormidium*, *Nostoc*, *Oscillatoria*, and *Scytonema* (72). Desert *Chroococcidiopsis*, which inhabits rock environments, can be the sole photosynthetic organisms in extremely arid environments (73) and may be the most desiccation-tolerant of all the cyanobacteria (73–75). Cyanobacterial crusts are important in soil aggregation and stabilization; they are also extremely susceptible to physical disturbance. (See Desert Environments: Biological Soil Crusts, this Encyclopedia.)

PLFA Profiles for Microbial Diversity

Membrane PLFA profiles serve as microbial signatures for quantifying broad groups of organisms in a community (76,77). Steinberger and coworkers (50) quantified diversity over time at arid and semiarid sites in the Judean Desert (Israel) by monitoring changes in membrane phospholipid fatty acid profiles. Both biomass (measured by the total PLFAs) and diversity (measured by the number of different PLFAs and their concentrations) were greatest in the site with the highest average precipitation. Biomass was greatest at this site following precipitation; during the dry season, biomass declined, with gram-negative bacteria (evidenced by monounsaturated and hydroxy-substituted PLFAs) declining sharply relative to other microbial groups. At the more arid sites, there was either no significant change in biomass and PLFA profiles, or a slight increase in eukaryotes (shown by polyunsaturated PLFAs) during the dry period. The PLFA approach of monitoring and comparing microbial diversity could be put to more widespread use in desert soils.

Functional Diversity

Functional diversity of microbial communities has been quantified and compared in arid soils using the community-level physiological profile (CLPP) approach (47–49), which was pioneered by Garland and Mills (78,79). Functional diversity in this case is defined by the numbers of substrates that can be utilized by a microbial community and the rates at which each of these substrates is utilized (10). This has most often been quantified using BIOLOG gram-negative and gram-positive microtiter plates, each of which contains 95 different substrates plus iodonitrotetrazolium (INT) as a redox-sensitive dye indicator. The INT dye is initially colorless but is reduced to a purple-colored formazan when a substrate is oxidized. The number of different substrates used by the community is scored and the absorbance of the dye in each well is compared to the absorbance of a control well containing dye, but no substrate. Liu and coworkers (49) assessed functional diversity along an elevational gradient in the Chihuahuan Desert (New Mexico) as part of an experiment to test the effects of grazing, seasonal drought, and fire. Functional diversity was generally lowest in the summer drought and fire treatments.

Dobranic and Zak (48) adapted the CLPP approach for use with fungal communities by using a tetrazolium dye that can be reduced by fungal electron transport systems. They named the method FungiLog and applied it to fungal communities in decaying lechugilla leaves in Big Bend National Park (Texas). The method detected significant differences in fungal functional diversity along an elevational gradient. Fungal communities in the lower elevation sites utilized the fewest substrates, that is, they had the lowest substrate richness. Sites with the highest fungal functional diversity also had the highest rates of litter decomposition.

ADAPTATIONS TO DESERT SOIL CONDITIONS

Low Water Potential: Salinity and Desiccation

As discussed earlier, water is the major factor controlling biological activities in desert soils, and the best measure of water in soils is water potential, which includes both solute and matric water potential. Solute and matric water potentials can be measured on the same scales, but the effects of these two forms of water loss on microbial cells are fundamentally different (74,80). This is evidenced by the tolerance limits for growth and activities of microorganisms. Extremely halophilic microbes can grow in saturated salt solutions at solute water potentials of −41 MPa. Some fungi can grow in concentrated sugar solutions with solute water potentials as low as −70 MPa. In contrast, the lower matric water potential limits for growth and activity of even the most desiccation-tolerant microorganisms are much higher. *Arthrobacter*, which is extremely desiccation tolerant (81), has been reported to grow at matric water potentials as low as −17 MPa; the spore former *Bacillus subtilis* has a reported lower limit of −10 Mpa; the minimum for *Pseudomonas* is reported as −5.6 MPa, and other bacteria are reported to cease respiration at −5 MPa matric water potential (74 and references cited therein). Although growth is inhibited at −5 to −17 MPa, many desert soil microbes can survive much lower matric water potentials. Surface soils in deserts can dry to −100 to −150 MPa matric water potential (16) and still contain viable microorganisms. The duration of this severe matric water potential stress can be months or even years in the most arid deserts. The amount of water that can be lost from a microbial cell under matric stress is greater than the loss from a cell in the presence of a concentrated solute (74). Enzymatic activity within the cell is thought to cease when all of the free water is lost, leaving only water bound to cell constituents (74). Further air-drying can cause the remaining cell water to be insufficient to cover cytoplasmic macromolecules with even a monolayer of water molecules (74). Air-drying has the further effect of destabilizing macromolecules, exposing them to increased oxidative stress (74). Survival of low water potential and related stress requires multiple adaptations (Table 2).

Microbial adaptations to low solute water potentials have been well documented, whereas microbial adaptations to low matric water potentials, that is, desiccation, have received much less study and are not nearly as well understood (Table 2). The best-characterized microbial response to low water potential stress is the accumulation of intracellular compatible solutes, also known as osmolytes, to match cytoplasmic water potential to that of the surrounding medium (12–15,74,94). These compatible solutes are accumulated intracellularly through transport from the external environment or they can be synthesized de novo by the cells. Sodium ions are toxic to many intracellular processes, even those of the most extreme halophiles, and so all halophilic and halotolerant organisms exclude sodium from their cells and instead accumulate solutes that are compatible with cellular function. In bacteria, these compatible solutes include relatively soluble amino acids such as proline and glutamate, sugars such as trehalose, and also KCl. Cyanobacteria and other photosynthetic prokaryotes accumulate betaines, particularly glycine betaine (15,95). Many other microbes that are unable to synthesize glycine betaine are able to take it up from the environment and use it as a compatible solute (15). Extremely halophilic Archaea exclude Na^+ and accumulate K^+ (with Cl^- as the counterion) as the sole osmolyte, even in saturated salt solutions. Many eukaryotes tend to accumulate polyols such as glycerol. The organic compatible solutes are low molecular weight solutes that stabilize proteins by enabling them to be preferentially hydrated as the cell undergoes dehydration (74). The details of microbial production and accumulation of intracellular compatible solutes in response to solute stress have been elucidated for a large number of microorganisms, and these adaptations are of major importance to microorganisms in salt-affected soils (88). However, it is not clear to what extent intracellular compatible solutes play an essential role in microbial response to low matric water potentials in natural environments. Some desiccation-tolerant bacteria can accumulate large amounts of compatible solutes such as trehalose or sucrose (20% or more by weight, 15,74,96). It has also been demonstrated that if microorganisms have been induced

Table 2. Selected Microbial Adaptations to Desert Soils

Adaptation	Reference
Adaptations to low solute water potential (saline soils)	
Accumulation of intracellular compatible solutes, for example, proline, glutamate, glycine betaine, trehalose, KCl	12,13
Adaptations to low matric water potential (desiccation)	
Accumulation of intracellular compatible solutes, e.g., trehalose, sucrose	12,13,14,74
Protein and lipid stabilization by trehalose or sucrose	74
Membrane lipid modifications: for example, conversion of monoenoic fatty acids to cyclopropyl fatty acids and *cis*-to-*trans* conversion of monoenoic fatty acids	74,82,83
EPS capsules	84
Efficient DNA repair, evidenced by gamma radiation resistance	85,86
Scavenging enzymes, for example, catalase and superoxide dismutase, to detoxify reactive oxygen species	74
Specialized dormant structures, for example, endospores, akinetes, cysts, actinomycete spores, fungal spores, and so on	87
Filamentous growth forms for bridging air gaps in unsaturated soil	88
Adaptations to low nutrient availability	
Oligotrophy (high-affinity transport enzymes, metabolic versatility, carbon and energy storage products)	89,52
Slow rates of endogenous metabolism	90
Small size	91
Starvation proteins	92
Autochthony: metabolism of ubiquitous but recalcitrant substrates	93
Specialized dormant structures, for example, endospores, akinetes, cysts, actinomycete spores, fungal spores, and so on	87

to synthesize compatible solutes, especially trehalose, or when such solutes are made available extracellularly, then a higher proportion of these cells will survive desiccation (97–100). However, rapid dehydration may preclude compatible solute accumulation. As a porous medium, such as soil, becomes desiccated, the ability of microorganisms to acquire exogenous carbon and energy sources diminishes rapidly. In desert soils, the concentrations of organic substrates in the soil solution are generally quite low, anyway. Without access to new carbon and energy, cells in a drying soil may be unable to take up or to synthesize significant quantities of compatible solutes. The alternative is passive water loss, that is, plasmolysis, and this may be the normal state of vegetative microbial cells in a dry desert soil. Bacterial cells dried to 40 and 30% rh have been found to contain about 10 and 3% water by weight, respectively (74). Specialized, thick-walled, desiccation-tolerant cells, such as endospores, cysts, and cyanobacterial akinetes, have higher amounts of cytoplasmic water per gram dry weight (74). However, it should be noted that differentiation into these specialized cell types occurs during times of high water availability and in response to other environmental cues, such as nutrient depletion.

The stage of growth may also be a factor in desiccation tolerance of microorganisms. Stationary-phase bacteria and yeast have been shown to be more desiccation tolerant than exponential-phase cells (74,97,100). Several morphological and physiological changes that occur as a cell enters stationary phase may be responsible for enhanced desiccation survival. Smaller, coccoid cells may be more structurally stable. Changes in membrane phospholipid fatty acids, for example, conversion of unsaturated fatty acids to cyclopropyl forms, may be important in maintaining membrane integrity in the face of extended desiccation and also during the stress imposed by rapid rehydration (74,82). Desiccation of membrane lipids lowers the melting temperature, causing a transition from the liquid-crystalline phase to the gel phase (74,101). Synthesis of trehalose during onset of stationary phase in some cells may also be instrumental in survival of desiccation (15). A strong case has been made for trehalose as a nearly universal protectant against desiccation damage as well as other environmental stresses (15). Trehalose, and to a lesser extent sucrose, have been shown to stabilize proteins and membrane phospholipids during dehydration (15,74,102,103). One mechanism for this stabilization may be the tendency for trehalose to form an inert glass (74,101). (See also FREEZE DRYING: PRESERVATIONS OF MICROORGANISMS BY FREEZE-DRYING, this Encyclopedia.) Trehalose is produced by a variety of organisms, including heterotrophic bacteria, fungi, and cyanobacteria; it is synthesized in response to starvation, low oxygen conditions, heat shock, and various chemical stresses; and it is known to be produced during sporulation of fungi, actinomycetes, and slime molds (15,74,104). It has even been proposed that desiccation tolerance may be engineered into desiccation-sensitive microbes by genetic manipulation to introduce or to enhance production of trehalose or other compatible solutes (74). Billi and coworkers (86) significantly increased the desiccation tolerance of *Escherichia coli* by introducing the sucrose-6-phosphate synthase gene, thereby conferring the ability to synthesize sucrose. This approach or a similar one may be useful in enhancing the desiccation tolerance of environmentally useful microorganisms, for example, pollutant-degrading bacteria; however, accumulation of trehalose or sucrose alone may not be sufficient to confer the extreme desiccation tolerance required for survival in the driest deserts (100). The reverse approach, enhancing the pollutant-degradation potential of naturally desiccation-tolerant bacteria, is also under way (105) (see section on Pollutant Degradation in Deserts)

Microbes in unsaturated porous media, that is, soils and underlying vadose zones, have been shown to accumulate large amounts of EPS (80,84). The role of this EPS in desiccation tolerance is still not well understood. The capsule may act as a sponge to retain water, thereby slowing down or attenuating water loss from

the cell (19,106–108). As an encapsulated cell begins to dry, the EPS may even contain more water than the cytoplasm (74). By maintaining a higher matric water potential in the environment immediately surrounding the cell, the EPS may also prolong nutrient availability during soil desiccation by allowing greater solute diffusion (84). The EPS may act to retain compatible solutes that are lost from a cell during rapid rehydration; these can then be taken up and used again as the soil dries. The polysaccharides of the capsule may also serve as carbon and energy storage products and may protect cell walls from damage induced by shrinking and swelling (80).

It has been suggested that the well-characterized gamma irradiation resistance of the bacterium *Deinococcus radiodurans* is actually an adaptive response to desiccation in soils rather than to high radiation doses (85). The radiation resistance of *D. radiodurans* is attributable to its unique DNA repair mechanism. Each cell contains multiple copies of its genome and can recombine fragments of these copies into an intact, repaired version of the genome following damage induced by gamma irradiation (109,110). These extraordinary bacteria are able to survive much higher gamma radiation fluxes than occur naturally anywhere in the biosphere, and so presumably the unusual repair mechanism of this organism is an adaptation to a different environmental stress. *Deinococcus* has been isolated from soil, as well as other environments that are frequently dry (110,111). Desiccation has been used a means of selecting for radiation-resistant *Deinococcus* (112). Moreover, dehydration induces the same double-stranded breaks in DNA that are caused by gamma irradiation. In support of the hypothesis that radiation resistance in *Deinococcus* is an adaptation to desiccation, Mattimore and Battista (85) demonstrated that radiation-sensitive strains of *D. radiodurans* showed significantly lower survival of severe dehydration than a wild-type, radiation-resistant strain. Presumably, DNA repair of desiccation-induced damage occurs upon rehydration of the cell. Strains of extremely desiccation-tolerant cyanobacteria of the genus *Chroococcidiopsis* have also been shown to be relatively resistant to ionizing radiation (35 to 80% survival of 2.5 kGy gamma irradiation); the DNA repair mechanism that enables this radiation resistance is also likely an adaptation to extreme desiccation (86). Desiccation tolerance in other desert soil bacteria may prove to be mediated in part by efficient DNA repair mechanisms as well.

Energy Availability

Nearly all soils are considered to be low-nutrient environments in which energy availability, especially organic carbon for heterotrophs, is severely limiting to soil microorganisms (113,114). Even though organic carbon can be a significant component of the soil mass, much of it is in a stable, recalcitrant form. Soil organic carbon is often patchily distributed and, as discussed earlier, it becomes increasingly difficult for microorganisms to gain access to it as the soil dries. For these reasons, the soil environment selects for highly efficient organisms that are able to glean organic carbon from low nutrient sources (i.e., oligotrophic microbes), microbes that can survive for extended periods without exogenous energy sources, and autochthonous microbes that are specialized for utilization of ubiquitous but recalcitrant compounds. (See Oligotrophic Bacteria, this Encyclopedia.) Essentially, this describes three different (but overlapping) styles of *K*-selected microbes, that is, ones that have evolved to allocate a significant proportion of their resources to survival rather than to reproduction (115). In hot deserts where primary production is low and soil organic carbon is concomitantly low, the selective pressures favoring these types of organisms should be especially robust; and in fact, all three of these styles of *K*-selected microbes are well represented in desert soils.

Arthrobacter spp. have been described as the archetypical soil oligotrophs in that they have relatively low maximum specific growth rates, they are able to use a wide spectrum of organic substrates, they accumulate large amounts of reserve organic carbon during times of plenty, they form small coccoid cells as nutrients are depleted, and they decrease their rates of endogenous metabolism for long-term survival of nutrient deprivation (52,89). These traits undoubtedly contribute to the dominant role that Arthrobacters play in many arid soils and are likely shared by many other microbes in hot deserts.

The diminutive size of most soil bacteria, including those in desert environments, is consistent with the generally low availability of soil organic carbon (91). Using microscopic studies Bae and coworkers (115a) found as much as 72% of soil bacteria to be dwarfs, that is, coccoid cells with diameters less than 0.3 μm. The lower limit for cell size has not been firmly established, but it has been estimated at approximately 0.2 μm diameter (91). Bamforth (20) reported that the majority of bacteria in Sonoran Desert soils are cocci, and studies at a Chihuahuan Desert site have shown that a significant proportion of soil bacteria can pass through a 0.4-μm pore-size filter (Kieft and coworkers, unpublished data). Many of these small cells are undoubtedly dwarf forms of larger bacteria that have changed morphologically in response to nutrient deprivation. Dwarfing and also fragmentation (division without growth) have been well documented in laboratory-grown cultures that have been starved (91,116–118). Others appear to be intrinsically small cells, that is, ones that do not develop into larger forms in response to nutrient amendment (119–122). Dwarf bacteria have a high surface-to-volume ratio, which favors efficient uptake of nutrients when they become available along with minimal energetic cost for maintenance of cellular functions during starvation. Initial responses to starvation usually involve a brief increase in metabolic rate to provide energy for synthesis of starvation-specific proteins (123,124). After this initial burst, microbes that successfully survive nutrient starvation for extended periods are able to diminish their metabolism to glacially slow rates, thus using endogenous substrates in frugal manner. *Arthrobacter crystallopoietes* has been shown to decrease its rate of endogenous metabolism 80-fold during the first two days of starvation (90). In an experiment in which *A. crystallopoietes* was subjected to

the combined stresses of starvation and desiccation, 50% of cells remained viable after six months and the rate of endogenous metabolism was so slow that it could be predicted that 50% of cellular carbon would remain after 12 years (81).

Autochthony is another approach to low availability of organic carbon in desert soils, and it is exemplified in the actinomycetes and fungi, which are known for their abilities to degrade ubiquitous but relatively recalcitrant soil compounds such as cellulose, hemicellulose, and lignin. The lignin-degrading white-rot fungi are a good example. Other desert microbes are also adapted for metabolizing less palatable substrates. For example, in addition to degrading a range of sugars, organic acids, and amino acids, some strains of *Arthrobacter* have been found to degrade relatively recalcitrant substrates such as lignin, petroleum hydrocarbons, and 2,4-dichlorophenoxyacetic acid (52).

Temperature Stress

Temperatures at or near the surface of desert soils or on the surface of desert rocks may be severely challenging to the survival of microorganisms. Temperatures as high as 81°C have been measured at the surface of the Saharan Desert and surface temperatures in the Sonoran Desert in Arizona can exceed 70°C (4). Fortunately for the microbes, this extreme heat normally occurs only when cells are desiccated, a condition that generally increases heat tolerance. Desiccation stress may increase the heat stability of microorganisms and their macromolecules by inducing production of stress compounds such as trehalose (15). Many different types of organisms are known to respond to a rapid upshift in temperature by producing heat shock proteins (101). The heat shock response is also known to overlap with responses to other environmental challenges. For example, cellular adaptations for starvation survival may also confer heat tolerance (124a–124c). The heat-shock protein and molecular chaperone DnaK is involved in the regulation of expression of starvation genes in *E. coli* (124c). Similar mechanisms may function in heat tolerance of desert soil microbes. High soil temperatures inhibit legume–*Rhizobium* nitrogen-fixing associations (125). Thermophiles are rare in hot desert soils and are probably present only as incidentally transported from environments that feature hot water, for example, thermal springs.

PRACTICAL APPLICATIONS

Plant-Microbe Symbioses in Reclamation of Disturbed Arid Ecosystems

Arid ecosystems are especially susceptible to disturbances such as overgrazing, mining, and intensive agriculture. Disturbance effects are often augmented by drought conditions. Efforts to restore heavily disturbed, desertified sites to native vegetation can benefit from a consideration of plant–microbe interactions (3,37). As stated earlier, the majority of desert plants are mycorrhizal. Intense grazing and soil cultivation have both been shown to reduce the abundance and diversity of mycorrhizae (126). Strip-mining activities completely remove the plant community; physical and chemical disturbances of the soil can greatly diminish AM. The weedy annual plants that typically colonize these disturbed areas as the first stage of secondary succession are less likely to have mycorrhizal associations (37,66,126a,127,128). Progression of secondary succession beyond the weedy annual plant stage can be facilitated by inoculation with propagules of mycorrhizae that can associate with plants of the native, climax community. Inoculation with nitrogen-fixing *Rhizobium* along with mycorrhizae has potential benefit in establishment of desirable legumes (67,129–131). Mycorrhizal infection has been shown to improve nitrogen fixation by legume–*Rhizobium* associations under drought stress (125,131). Further understanding of plant–microbe interactions in desert environments may facilitate more rapid and successful reclamation of disturbed arid lands.

Pollutant Biodegradation in Deserts

As with other terrestrial environments, deserts have been subjected to contamination by hydrocarbons and other pollutants. Hydrocarbons have been introduced into desert soils through spills from petroleum production, refining, and storage sites. In the aftermath of the 1991 Persian Gulf War, nearly 50 km^2 of the Kuwaiti desert was contaminated with crude oil to depths of 50 cm to 2.5 m (132,133). Bioremediation offers the most feasible technology for cleaning up the soil. Hydrocarbons are also applied to soils in landfarming operations for biodegradation of waste oil and for bioremediation of soil that is heavily contaminated with hydrocarbons; these are often sited in arid and semiarid sites. Water, inorganic nutrient availability, and oxygen are the usual limiting factors in soil hydrocarbon degradation. Biostimulation (nutrient amendment) is the most widely applied bioremediation technique. Radwan and coworkers (132) reported that addition of water and nitrate was effective in increasing rates of biodegradation of *n*-alkanes in oil-contaminated Kuwaiti soil. The numbers of hydrocarbon-degrading bacteria in their experiment reached 10^{10} to 10^{11} hydrocarbon-degrading bacteria per gram of soil. Dominant genera were *Bacillus*, *Pseudomonas*, *Rhodococcus*, and *Streptomyces*. Bioaugmentation (inoculating with pollutant-transforming microbes) has rarely been shown to be effective in accelerating bioremediation of a natural environment. In a simulated oil spill experiment using Kuwaiti desert soil, Radwan and coworkers (133) found that a single strain of *Arthrobacter* dominated the hydrocarbon-degrading community. Inoculation with other strains of hydrocarbon-degrading *Arthrobacter* isolates had no effect on hydrocarbon degradation and, in some cases, caused a decrease in the native *Arthrobacter* population. Longer-term remediation of the polluted Kuwaiti desert has led to the reappearance of native plants, and the rhizospheres of these plants have been shown to contain abundant hydrocarbon-degrading bacteria, including *Cellulomonas flavigena*, *Rhodococcus erythropolis*, and an *Arthrobacter* sp. (134).

In landfarming operations, water and nutrients are added and the soil is tilled at intervals for aeration and

mixing. In a landfarming experiment using Kuwaiti soil contaminated with 2 to 3% and 6 to 8% hydrocarbons, 80 and 60% of hydrocarbons were eliminated, respectively, during a 15-month experiment (135). Treatment with nitrogen, phosphorus, and potassium fertilizers significantly increased the amounts of hydrocarbon degraded; bioaugmentation with hydrocarbon-degrading microbes increased the initial rates of hydrocarbon disappearance, but did not change the final percentage of hydrocarbon removal. Despite frequent irrigation, rates of degradation slowed during the hottest, months and increased during the winter rainy season. Residual hydrocarbons were high molecular weight aliphatic and aromatic compounds that are relatively resistant to biodegradation. This study illustrates the potential and also the limitations of landfarming in the desert. Indigenous soil microbes have the potential to degrade enormous amounts of petroleum hydrocarbons if sufficient water, oxygen, and nutrients are applied. However, the rates of degradation decline as readily degraded hydrocarbons are eliminated, leaving residual recalcitrant hydrocarbons that will likely remain for decades or longer. Landfarming can also contribute to air and groundwater pollution.

Bioaugmentation may be useful for remediation of soils contaminated with organic pollutants that are especially refractory to biodegradation. Weekers and coworkers (105) introduced genes encoding biodegradation of recalcitrant compounds (isopropylenebenzene, trichloroethene, 3-chlorobenzoate, 4-chlorobiphenyl, and biphenyl) into naturally desiccation-tolerant, hydrocarbon-degrading strains of *Rhodococcus erythropolis*. The resulting transconjugants retained the desiccation tolerance of the recipient strains and were also shown to express the new catabolic genes and grow on the recalcitrant carbon sources. This approach may be useful for generating biodegradative strains that combine native abilities to survive under the stressful conditions of a natural environment such as a hot, desert soil with catabolic capabilities that are tailored to a particular contaminant or suite of contaminants.

CONCLUSION

The microbial communities of hot desert soils remain poorly characterized relative to more mesic environments that are more economically important, such as agricultural and forest soils. This is unfortunate when one considers that 43% of the Earth's land surface is arid or semiarid and that more than 15% of the human population lives in desert environments (3). Much has been learned in the last decade about the diversity of microorganisms in desert soils, especially because of the availability of molecular-based, culture-independent tools such as 16S rDNA amplification and sequencing. Further application of these techniques to hot desert soils can greatly expand our understanding of biodiversity of extreme environments, especially if the metabolic functions of these previously unknown organisms are determined. Plant- and animal-associated habitats are likely sources of novel microbes. Improved understanding of the functional diversity should promote understanding of desert ecosystem function and may have practical applications for restoration of disturbed, desertified arid lands. Extreme environments continue to fascinate biologists. The means by which desert microorganisms survive the multiple abuses of dehydration, rehydration, heat, and starvation are beginning to be understood, especially for a few extraordinarily tolerant organisms such as *Arthrobacter*, *Deinococcus*, and *Chroococcidiopsis*. Lessons learned from these hardy organisms may be applicable to other desert microbes and may also engender genetic manipulations to generate environmentally useful, desiccation-tolerant microorganisms.

HUMAN CALICIVIRUSES: BASIC VIROLOGY AND EPIDEMIOLOGY

JOHN S. MESCHKE
MARK D. SOBSEY
University of North Carolina
Chapel Hill, North Carolina

Diarrheal illness has undoubtedly afflicted the human species for centuries, and viruses are responsible for an appreciable percentage of diarrheal illness (1,2). Norwalk-like viruses (NLVs) are probably the most common etiologic agents of acute viral gastroenteritis in humans, and these viruses comprise a distinct genus within the family Caliciviridae. NLVs have a worldwide distribution and have been implicated in numerous common source (food or waterborne) outbreaks of gastroenteritis.

HISTORICAL BACKGROUND

Epidemic gastroenteritis with short-term, self-limited vomiting and diarrhea, and a high secondary attack rate was first described in the southern United States as a clinical syndrome in the late 1920s. The syndrome was referred to as winter vomiting disease or "hyperemesis hiemis" (3). Soon after, this syndrome was also described in the United Kingdom and elsewhere (4–6). Studies conducted from the 1940s to the 1970s repeatedly demonstrated the transmissibility of an infectious agent obtained from several outbreaks of epidemic nonbacterial gastroenteritis by serially feeding bacterial-free filtrates of outbreak stools to volunteers (7–15). However, a definitive agent was never identified for these outbreaks of nonbacterial gastroenteritis.

In October 1968, an outbreak of acute nonbacterial gastroenteritis struck an elementary school in Norwalk, Ohio. Over the course of two days, 50% of the students and teachers in the school developed classic symptoms

of epidemic vomiting disease. As in similar outbreaks, laboratory studies on outbreak specimens failed to identify a known etiologic agent. The unknown agent was shown to be transmissible to volunteers by feeding a bacterial-free filtrate from a rectal swab of a secondary case of gastroenteritis (14). Several years later, researchers discovered viruslike particles in stool material from the Norwalk outbreak using immune electron microscopy (IEM). The spherical particles appeared fuzzy with a diameter of 27 to 32 nm (16). The IEM technique was used to show a serologic response on the basis of immune aggregation of the 27 nm particles by paired sera from both volunteers, from a human volunteer feeding study and individuals who became ill during the original outbreak. This serological evidence and the virion shedding pattern suggested that the viral particles were the etiologic agents responsible for the Norwalk outbreak (16). The particles were initially considered to be parvovirus-like, on the basis of size, indistinct morphology, buoyant density, and stability in acid, heat, and ether (17,18). However, subsequent detection of a 59-kDa viral protein prompted reclassification of the Norwalk agent as a calicivirus (19). Recent genetic (nucleotide sequence and genomic organization) information supports this reclassification (20).

Subsequently, several other related or antigenically distinct 20 to 30 nm viruslike particles were identified as etiologic agents in various outbreaks of nonbacterial gastroenteritis and were named after the location of the outbreaks, including the Hawaii agent, Montgomery County agent, Ditchling agent, Marin County agent, and Snow Mountain agent, among others (21). Collectively, these agents were referred to as small round viruses, or 27-nm viruses, which led to the development of an interim classification scheme based on comparative morphology and physicochemical properties (22). This scheme recognized that small round viruses (SRVs) could be divided into two groups: the "featureless" SRVs without resolvable surface structure, including the parvo- and picorna-viruses, and a second group with distinct surface morphology, including astroviruses, classic caliciviruses, and particles with a "ragged" or "fuzzy" edge (referred to as SRSVs or small round structured viruses) exemplified by Norwalk virus. Figure 1 is a negatively stained direct electron micrograph of a NLVs. This scheme of classification was considered a temporary measure until more definitive criteria were developed. After several years of surveillance using IEM and later immunoassays, the SRSVs were found to be the most important cause of epidemic nonbacterial gastroenteritis (23–25).

GENERAL CHARACTERIZATION OF NLVs AND SAPPORO-LIKE VIRUSES (SLVs)

NLVs are nonenveloped, 27 nm by 32 nm spherical particles, which appear to have a ragged edge when viewed by electron microscopy. These particles comprise a single-stranded, positive-sense RNA genome surrounded by a protein capsid. NLVs have a buoyant density between 1.33 and 1.41 g/cm^3 (17,18). To date, no human NLVs have been effectively propagated in cell culture. Lack of a cell culture system has limited the study of the basic production and processing of viral proteins. However, the cloning of the NV genome has allowed the gene coding for the virion capsid to be cloned into various expression vectors that produced the capsid protein in culture (26–29). Capsid proteins produced using a baculovirus expression system self-assemble into viruslike particles (VLPs) that resemble empty virions and are slightly larger than actual viral particles (30–32).

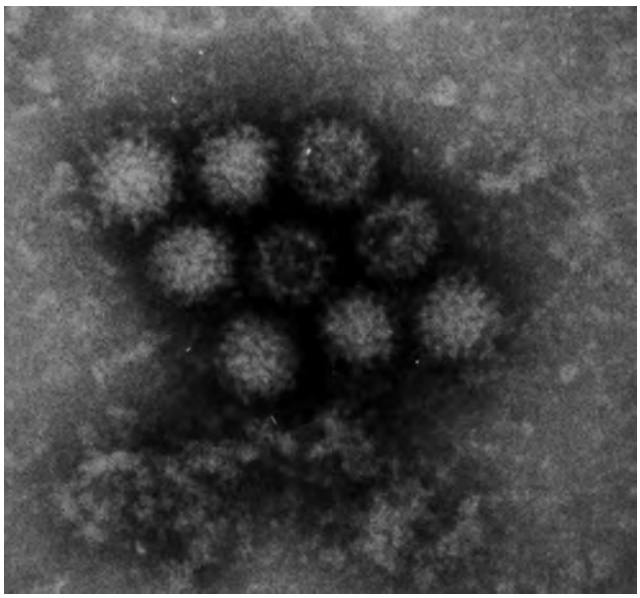

Figure 1. Negatively-stained, direct electron micrograph of a NLVs. (From Molecular Detection and Epidemiology of Human Caliciviruses by Jan Vinje, 1999.)

Other SRSVs with somewhat different surface morphology and later shown to be both serologically and genetically distinct from the NLVs were discovered. These viruses, referred to as Sapporo-like viruses or SLVs have a classical calicivirus morphology. When viewed under EM along their threefold axis, a "Star of David" pattern can be observed. The viral particles comprise a single-stranded, positive-sense RNA genome within a protein capsid. This type of virus was first observed in the feces using negative-staining EM techniques (33). SLVs have a diameter of 31 to 38 nm and their buoyant density is 1.37 to 1.38 g/cm^3 (34).

GENOMIC ORGANIZATION

The first cloned sequence of the NV genome was published in 1990, leading to rapid progress in genomic analysis of NLVs. The genome was shown to be positive-sense, single-stranded RNA approximately 7.5 kb in length, excluding 3′ terminal polyadenylation. Figure 2 illustrates the genomic organization of NLVs and SLVs. The genetic clones contained a consensus amino acid motif characteristic of RNA-dependent RNA polymerases (35). Since the original cloning of the NV genome, several other NLV sequences have been determined, including at least three full-length sequences (Norwalk, Southampton,

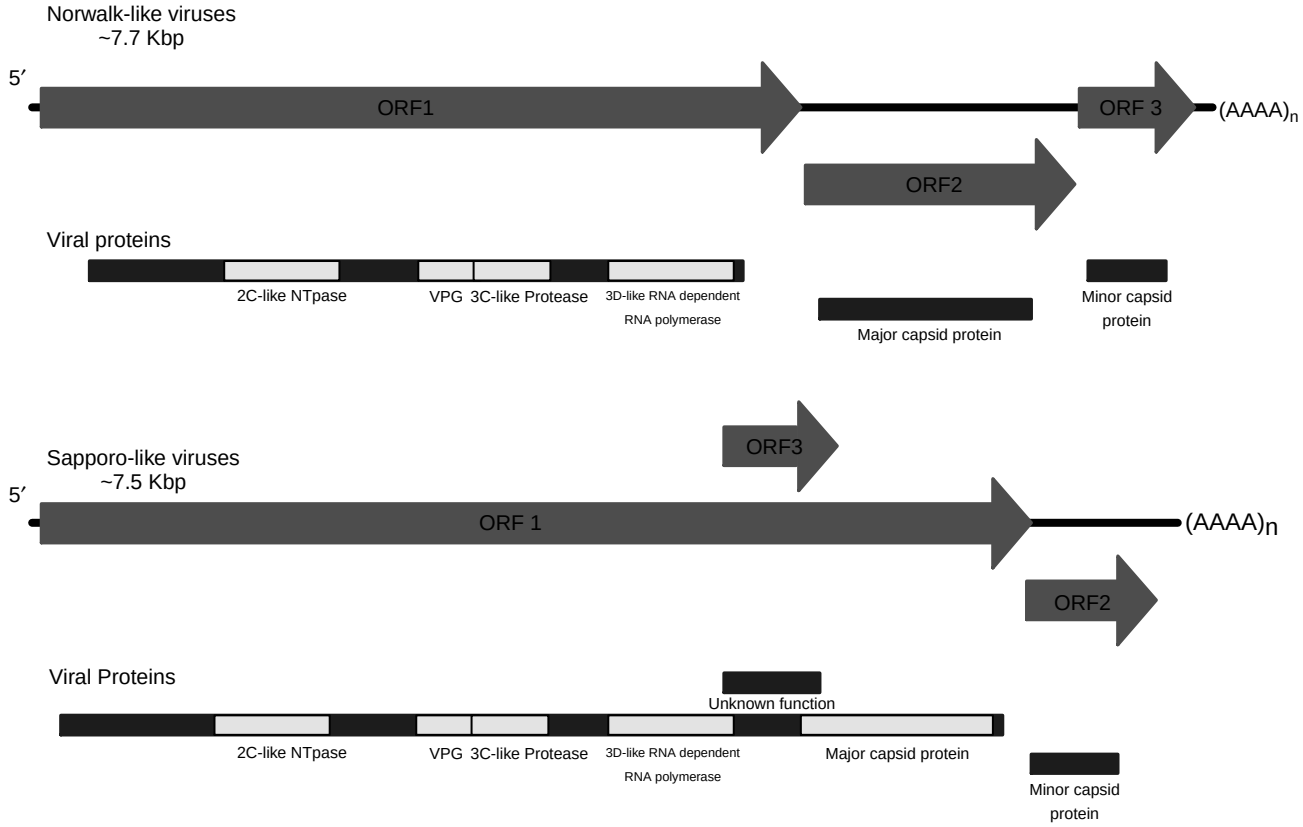

Figure 2. Comparison of the genomic organization of NLVs and SLVs. Open reading frames are indicated by red arrows, corresponding viral proteins are indicated in blue. Yellow highlighted regions represent individual proteins, presumably posttranslationally cleaved from the ORF1 polyprotein. See color insert.

and Lordsdale viruses) and numerous partial sequences, usually of the RNA polymerase region. At least two distinct genogroups have been described for NLVs (36). Genogroup I genomes (7.7 kb) appear to be slightly larger than those of genogroup II (7.5 kb). NLVs characteristically have three open reading frames (ORFs), and predicted ORFs are similar for both genogroups. ORF1 is the largest and codes for a large nonstructural polyprotein of approximately 1,700 amino acids that contains motifs characteristic of a picornaviral 2C putative helicase, 3C protease, and 3D RNA-dependent RNA polymerase. ORF2 codes for the major capsid structural protein (20). The small 3′ ORF3 codes for a basic protein recently shown to be a minor capsid protein (37). Differences in size between the viruses in the different genogroups is due to a smaller ORF1 in genogroup II. The 5′ region of ORF1 is highly variable and thought to reflect differences in secondary structure or regulatory signals between the two genogroups (20,30).

There is a frameshift between ORF1 and ORF2 in the NLV genome, so that the N-terminal amino acids of the capsid coding region overlaps the C-terminus of the RNA-dependent RNA polymerase region. Differences in the reading frame overlap between genogroups have been reported (38). Group I is reported to have a 17-nt overlap, whereas group II is reported to have a 20-nt overlap. ORF3 is also frameshifted in relation to ORF2, the first residues of the initiator codon for ORF3 overlap the terminator codon for ORF2 (38).

Production of a 3′ co-terminal polyadenylated subgenomic RNA containing ORF2 and ORF3 has been documented in animal caliciviruses (rabbit hemorrhagic disease virus, RHDV) and is thought to provide additional message for production of the capsid protein (39). Characteristically, the 5′ end of the animal calicivirus genomic RNA and subgenomic RNA are highly conserved (i.e., the 5′ terminal sequence of ORF1 is repeated at the 5′ end of ORF2) (40). Similar conserved sequences in the genomic termini of both genogroups of NLVs and the detection of RNA over 2 kb in the stool of an NV-infected volunteer by Northern hybridization suggest that the NLVs also produce a subgenomic RNA (20,41,42). However, the evidence for this remains tentative because of the lack of a cell culture system for viral replication or an in vitro translation system in which to study NLV replication events.

The genomic organization of SLVs differs from the NLVs and is more similar to animal caliciviruses. The single-stranded RNA genome is approximately 7.5 kb with 3 predicted ORFs and a polyadenylated 3′ tail. ORF1 occupies more than 90% of the genome and encodes the nonstructural proteins (2C putative helicase, 3C protease, and RNA-dependent RNA polymerase), and the major 62-kDa capsid protein (43). ORF2 is a small 3′ terminal ORF,

which is predicted to encode a 165 amino acid protein of unknown function. ORF2 in the SLVs has an analog in all other sequenced caliciviruses and corresponds to ORF3 in NLVs that has been recently shown to code for a minor capsid protein (37). Another small ORF in the SLVs is predicted to overlap the capsid coding region and encode a protein of 161 amino acids. ORF3 in the SLVs has no corresponding ORF in the NLVs (43,44). In other caliciviruses conserved sequences on the 5′ genomic terminus and the 5′ end of the capsid coding region are observed, whereas in the SLVs the level of similarity is not as great as in the NLVs or animal caliciviruses. In the animal caliciviruses these conserved regions are thought to be important in the regulation of subgenomic RNAs (43). As with the NLVs, no cell culture system is currently available for the SLVs. Consequently, production of subgenomic RNAs in SLVs cannot be confirmed. Comparison of the genomic organization of the NLVs and SLVs is illustrated in Figure 1.

Viral Proteins

Capsid Protein. The 59-kDa structural protein of NV was identified using radioimmunoprecipitation of CsCl gradient purified virions with paired (acute and convalescent) sera from infected individuals (19). The Snow Mountain (genotype II) capsid protein was found to be slightly larger, 62 kDa (45). The major capsid protein of Sapporo virus was also found to be 62 kDa (34). Computer analysis of ORF2 of several other strains is consistent with production of a single protein of approximately 60 kDa. In addition to the single capsid protein, a smaller 30-kDa protein is detectable in the feces of infected individuals (19). In baculovirus systems expressing NV capsid proteins, both 58-kDa and 34-kDa proteins were observed in the cell supernatants (27). Trypsin digest studies of baculovirus-expressed NV capsid proteins resulted in a trypsin-specific cleavage at the amino acid residue 227. The resulting cleaved protein was demonstrated to have the same size and amino acid sequence as the smaller soluble protein isolated from cell supernatants. It was also demonstrated that only the soluble 58-kDa protein and not the self-assembled recombinant Norwalk virus particles were subject to trypsin cleavage. Further, it was demonstrated that the 30-kDa protein had an identical N-terminal amino acid sequence as the 32 kDa trypsin cleavage product, thus suggesting that the soluble NV capsid proteins are subject to proteolytic cleavage in vivo (46). In another study, Japanese scientists detected NLVs in 14 related fecal isolates. In 11 of the isolates a structural protein of 63 kDa was isolated and in the other 3, a 33-kDa protein was isolated. Proteolytic and denaturing experiments failed to establish that the smaller protein was a subunit or cleavage product of the 63-kDa protein. However, the two proteins did appear to be antigenically related (47).

Studies have shown that baculovirus recombinant expression of either ORF2 alone, or ORF2 and ORF3 together, may form recombinant virus like particles (rVLPs), thus ORF3 is not necessary for formation of empty virus particles (27,48–50). However, recent studies have indicated that multiple forms of the protein expressed by ORF3, in particular, 23-kDa and 35-kDa forms, are detectable in both native NV virions and in baculovirus expression systems (37). These studies have also established through association with the formation of recombinant virus like particles (rVLPs) that the 23-kDa form of the ORF3 protein is a minor structural protein. Further, the 35-kDa form of the protein has been shown to be phosphorylated, unlike the 23-kDa form. These findings are consistent with studies on RHDV, which indicate that the equivalent protein in animal caliciviruses is a minor structural protein (51). The ORF3 protein is hypothesized to be located in the interior of the virion and to function in the encapsidation of the viral RNA (37).

Using the baculovirus-expressed capsid proteins that self-assemble into virus like particles (VLPs) resembling empty virions, the empty virion structure has been determined to a resolution of 2.2 nm by cryoelectron microscopy and computer image analysis (52). The capsids exhibit $T = 3$ icosahedral symmetry with a average diameter of 38 nm. The capsid is composed of 90 arch like capsomeres that are dimers of a single capsid protein. Deep depressions at the three- and fivefold axes result in 32 hollows surrounded by protruding arches on the surface of the capsid. Twelve of the surface hollows exhibit a small hump in the center and are located on the fivefold axis. The remaining 20 surface hollows are located on the threefold axis and appear flat. A similar architecture has also been described for a primate calicivirus (53). Further, the amino acid sequence of the capsid protein may be organized into distinct domains: (*1*) an N-terminal of 250 residues forming an 8-strand barrel in the lower shell and (*2*) C-terminal forming protruding domains. The C-terminal domains exhibit significant variation in sequence between NLVs (53).

Classic calicivirus particles, as determined by electron cryomicroscopy and computer imaging techniques on a primate calicivirus, have $T = 3$ icosahedral symmetry with 32 surface depressions at the fivefold and threefold axes. Like the NLVs, the surface depressions are surrounded by 90 archlike dimers of capsid proteins at the twofold axis (53).

Nonstructural Proteins. ORF1 of the NLVs encodes a large nonstructural polyprotein. Computer analysis of ORF1 sequence data has identified conserved amino acid motifs typical of a picornaviral 2C putative helicase, 3C protease, and 3D RNA-dependent RNA polymerase, as previously noted. Presumably the NLV polyprotein is cleaved by proteolytic enzymes analogous to cleavages of the nonstructural polyproteins of the *Picornaviridae*. Several recent studies have identified proteolytic cleavage sites in NLVs (54–56). Activity of the 3C-like protease has been demonstrated in bacterial expression studies (54,56). RNA-dependent RNA polymerase activity has been demonstrated in caliciviruses using bacterially expressed 3D-like polymerase from RHDV (57). A recent study expressing polypeptide p41, containing the motifs similar to the picornaviral 2C helicase, found no detectable helicase activity. Polypeptide p41 was demonstrated to have nucleoside triphosphate binding and hydrolysis

activities similar to the 2C protein in Poliovirus (58). There is evidence that a protein similar to the picornaviral Vpg protein is also encoded in ORF1 (55). Some animal caliciviruses have also been shown to have a Vpg-like protein associated with their genomic and subgenomic RNAs, which may or may not be required for RNA infectivity (51,59–62).

Original NV sequence data indicated that translation of ORF1 began at one of seven internal, in-frame initiator codons, three of which were favorable (20). The observed size of the ORF1 polyprotein translated from synthetic, full-length RNAs was consistent with an internal initiation site for translation at the fifth AUG. However, sequence analysis did not indicate a oligopyrimidine tract analogous to the internal ribosomal entry site of the enteroviruses, and comparison of group I and II sequences revealed extreme diversity on the 5′ proximal end of the genomes. Subsequently, an additional 12 nucleotides were found to be missing from the 5′ end of the NV and Southampton virus genomes (41,63). Within these 12 nucleotides are three in-frame initiation codons, the third of which is favored under Kozak's rules (63,64). Further, alignment of 26 bases at the 5′ end of the genome shares 88% homology with sequences at the start of the capsid coding sequence of ORF2 (63). The conserved sequences at the beginning of ORF1 and ORF2, including the presence of a favored initiation codon, suggests that NLVs begin translation nearer the 5′ terminus rather than internally.

TAXONOMY OF HUMAN AND OTHER CALICIVIRIDAE

Although originally described as parvovirus-like, on the basis of biophysical and biochemical properties, NLVs are now more appropriately classified as members of the family *Caliciviridae*. On the basis of phylogenetic analysis of nucleotide sequence data, the family *Caliciviridae* is currently composed of four genera: Lagoviruses, Vesiviruses, SLVs, and NLVs. The genus names Sapporovirus and Norwalkvirus were rejected by the International Committee on the Taxonomy of Viruses (ICTV) as it was inconsistent with ICTV nomenclature rules. Thus SLVs and NLVs were selected as provisional names until more appropriate names can be agreed upon (65). Phylogenetic analysis of the RNA-dependent RNA polymerase of the Caliciviridae indicates that SLVs are most closely related to Vesiviruses and that SLVs and NLVs are more distantly related to Lagoviruses.

Currently only two species of human calicivirus are recognized by ICTV, Norwalk virus in the NLVs genus and Sapporo Virus in the SLVs genus, although a recently isolated Vesivirus (SMSV-5) has been demonstrated to cause pathogenic lesions in humans (65,66). Both NLVs and SLVs cause gastrointestinal illness in humans. NLVs are typically associated with illness in older children and adults, whereas SLVs generally cause pediatric illness.

Historically, the term *SRSV* was routinely used interchangeably with NLVs, and the convention for naming NLVs was based on the geographic location of the outbreak. The sheer number of NLV strains, along with antigenic and genetic diversity among strains, made communication between researchers confusing. Recently, a nomenclature framework has been suggested, on the basis of the most recent decisions of the international committee on taxonomy of viruses (ICTV) (65). Under an earlier version of this framework, it was suggested that candidate human caliciviruses identified by EM should be classified as SRSVs until the virus was genetically shown to be a calicivirus, at which time it would be reclassified as a Human Calicivirus (HuCV) (67). The current cryptogram designation for a particular virus would appear as follows: Host/Genus/Species/Virus Name/Year Isolated/Country Isolated (65). For example, the framework nomenclature for Norwalk virus (NV) is Hu/NLV/NV/68/US. It has also been suggested that the cryptogram should evolve to reflect future decisions by ICTV and consensus decisions by calicivirus researchers, for example, subspecies designations and genogroupings (65).

Genogrouping and Antigenic Typing

Phylogenetic analysis of the genetic sequences of NLV strains supports their division into distinct genogroups (36,68,69). Within a genogroup, viruses share 92 to 98% amino acid homology in the polymerase region, and 77 to 98% homology in the capsid region. Nucleotide homology in the polymerase region is 72 to 88% (67). Originally two genogroups were described for the NLVs, and the SLVs were considered to comprise a third genogroup (36,70). Between genogroups I and II, nucleotide homology of the polymerase region is approximately 60%, and amino acid homology is 76 to78% (67). More recent phylogenetic analysis of NLVs and SLVs defines specific genetic clusters within the genogroups. According to a recent study analyzing the three ORFs of 31 strains of NLVs, at least 12 clusters of NLV were identifiable within two distinct genogroups, including 7 clusters in genogroup I and 5 clusters in genogroup II. A thirteenth cluster was suggested by the analysis of the ORF2 sequences (71). Another recent study analyzing the genetic sequence of ORF2 of over 100 strains found five clusters within genogroup I and 10 within genogroup II (72). Prototype strains of the genetic clusters within genogroup I include Norwalk, Southampton, Desert Storm, and Cruise Ship viruses. Genogroup II prototype strains include Snow Mountain, Bristol, Hawaii, Toronto, White River, and Gwynedd viruses. With the formal designation of NLVs and SLVs as distinct genera, it is no longer appropriate to refer to the SLVs as genogroup III. Further, it has been suggested that the SLVs should be divided into three genogroups. Genogroup I of the SLVs includes the prototype Sapporo virus and the Manchester virus. Genogroup II includes London 92 strain, and genogroup III includes the Parkville virus (73).

Until recently, the only viruses described for the NLV and SLV genera were human pathogens. However, animal viruses have recently been isolated that are closely genetically related to each genera (74–78). Recent sequence data from porcine enteric viruses have identified strains closely related to the genogroup II NLVs and the SLVs (74,77,78). Similarly, bovine enteric caliciviruses

have been isolated that are related to the genogroup I of the NLVs (Newbury agents and Jena virus) (75,76). However, phylogenetic analysis suggests that the Jena and Newbury viruses may comprise a distinct genogroup within the NLVs (72).

Early cross-challenge infectivity experiments in human volunteers and comparative serological response studies to different NLVs demonstrated that these viruses are antigenically diverse (18,79,80). As many as 14 distinct antigenic types have been suggested. Although several attempts have been made to separate the NLVs into antigenic types, there is currently no universally accepted scheme for antigenic typing of human caliciviruses. In the United Kingdom, at least four distinct antigenic types are recognized by IEM or solid-phase IEM (SPIEM) (81–83). At least six serotypes, including the four previously recognized in the United Kingdom, have been recognized in the United States (84). Nine antigenic types have been described in Japan by IEM (85). In contrast, a recent study using a panel of monoclonal antibodies identified a possible common epitope among genogroup I NLVs, but not genogroup II NLVs (86). The epitope was found to be present in the soluble 32-kDa cleavage product and was mapped to the C-terminal of the capsid protein (86,87).

METHODS OF DETECTION

Cell Culture and Animal Models

Although several animal caliciviruses have been propagated in cell cultures, human caliciviruses (NLVs and SLVs) to this point have not been propagated in this way (31,88–91). Aside from a single 1984 report of abortive replication of a candidate human calicivirus (SLV) in human embryonic kidney (HEK) cells using a trypsin containing medium, all attempts at growth in cell culture have failed (67,92). Similar unsuccessful results have been reported for studies attempting to identify a suitable animal model for NLVs. Studies attempting to induce illness in several animal types have largely been unsuccessful (21). Animals found to be inadequate models include: mice, guinea pigs, pigs, rabbits, kittens, calves, and various primates. However, studies using chimpanzees have demonstrated a serologic response and virus antigen excretion, although no apparent illness was observed (93).

Electron Microscopy

Immune electron microscopy (IEM) uses convalescent sera from an infected individual to aggregate viral particles, thus demonstrating a specific antigen-antibody reaction and also improving the detection of low concentration of virus particles. Additionally, this technique may employ paired (acute phase and convalescent) sera to identify which antigenic particles have generated an immune response (16). Despite the development of ultrasensitive molecular detection methods, EM is still the gold standard of most clinical diagnostic virology laboratories for detection of NLVs in stool specimens. Shortcomings of EM include availability of immune reagents, high detection limit, and the variable morphology of the viruses depending on preparation methods, orientation, and structural integrity.

Immunological Methods

Several immunological methods have been developed for the detection of NLVs and SLVs and diagnosis of their infections, including radio-immunoassays (RIA), enzyme immunoassays (EIA), enzyme-linked immune serum assays (also called enzyme-linked immunosorbent assay or ELISA), and immune adherence assays (IAHA) (32,94,95). IAHA is impractical for the detection of NLVs because it requires a greater quantity of purified antigen than other immunologically based methods.

First-generation immunologic detection methods were reliant on the convalescent sera of infected individuals, and therefore not practical for widespread study of NLV epidemiology. However, recent expression of rVLPs using a baculovirus expression system has allowed the production of a ready supply of hyperimmune sera to antigenically diverse NLVs. This, in turn, has led to the development of sensitive enzyme immunoassays and ELISAs (50,96–99). The sensitivity of the assays may be as little as 25 pg of capsid protein. These sensitive detection techniques have been invaluable in determining the distribution and prevalence of NLVs (96).

Molecular Methods

In the early 1990s, sensitive molecular methods based on reverse-transcription (RT) and the polymerase chain reaction (PCR) were first developed for the prototype strain, Norwalk virus (100,101). Since then, many advances have been made in RNA extraction techniques and optimization of RT-PCR protocols. These methods will be reviewed in detail elsewhere in this Encyclopedia. Briefly, improved primers have been developed to detect a wider range of NLVs, and RNA extraction techniques have been found to increase sensitivity and eliminate RT-PCR inhibition (102,103). However, a study also reported that heat release of viral nucleic acid before RT-PCR was as effective as chemical extraction procedures for sensitive RT-PCR detection (104). An internal RNA standard for RT-PCR coamplification has been proven to be effective in detecting inhibitors present in samples (104).

CLINICAL SYMPTOMS AND DIAGNOSIS

Clinical Presentation

The clinical characteristics of NLV infection have been established from volunteer studies and epidemiologic data (105). Symptoms of illness for different NLVs (Norwalk, Hawaii, Montgomery, and Snow Mountain) used in volunteer feeding studies were clinically indistinguishable (80,105,106). The incubation period of the disease is dose dependent and ranges from 18 to 48 hours, with an average time of 24 hours (38,105). Onset of symptoms is acute. The most common symptoms include nausea, vomiting, and diarrhea. Other symptoms may include headache, malaise, chills, cramping, and abdominal pain. Stools typically do not contain blood or mucous. Vomiting may be

projectile and may be a result of delayed gastric emptying (107). As many as one-third of the infections may be asymptomatic (98).

NLV infection is self-limited and rarely requires hospitalization. The common duration of illness is from one to three days. However, severe cases of dehydration resulting from NLV infection and requiring intravenous fluid replacement have been documented. Mortality from NLV is extremely rare. Deaths, although rare, are usually attributable to a predisposed condition or concurrent illness.

SLV infection is characterized by an incubation period of one to three days, followed by expression of symptoms for an average of four days (108). Symptoms of diarrhea and vomiting are common, with fever and respiratory symptoms being possible, but less likely. Subclinical infection appears to be common. In contrast to NLVs, SLVs primarily affect young children, but outbreaks in adults have been described (109). Transmission is primarily through person to person spread by the fecal-oral route, although contaminated food and water have been implicated in outbreaks (70).

Diagnosis

Presumptive diagnosis of NLV infection may be made if four criteria are met: a bacterial or parasitic agent is not identifiable, vomiting occurs in approximately half the cases, the average duration of illness is 12 to 60 hours, and the incubation period is one to two days (110). Definitive diagnosis requires isolation of NLV particles from stool samples and identifiable serologic response. However, more recent epidemiological studies of common source outbreaks, such as water- or food-borne, have relied on virus detection by RT-PCR in ill persons and in the incriminated vehicle of exposure.

Shedding

NLVs are shed typically at an approximately 10^6 virus particles per gram of feces, although shedding of up to 10^9 particles per gram of feces has been reported. Virus shedding may begin as soon as 15 hours after inoculation, although peak shedding occurs between 25 and 72 hours, corresponding with the period of clinical illness (98). Further viral shedding may persist once symptoms have ceased, up to seven days after inoculation (98,111). One account documents NV shedding two weeks post challenge (112). Shedding will also occur during asymptomatic infection (98).

PATHOGENESIS

Volunteer feeding studies have determined that the NLV dose necessary to initiate infection in an individual may be as low as 10 to 100 particles, perhaps lower (21,113). One study examining Norwalk virus dose-response in humans found 70% of individuals developed infection, when exposed to a dose of 6×10^3 RT-PCR detectable units. A dose of 6 RT-PCR detectable units was demonstrated to cause infection in 20% of individuals exposed (113). Although not detected in the cells, viral replication is presumed to occur in the mucosal epithelial cells. Biopsies of the proximal small intestine (jejunum) from infected volunteers show intact mucosa with blunting and shortening of the villi (106,114,115). Other characteristic pathology seen in individuals infected with Norwalk virus include disorganization of the epithelial cells, vacuolization of the cytoplasm, and mononuclear infiltration of the lamina propria. Hyperplasia of crypt cells was also common. Dilation of both the smooth and rough endoplasmic reticulum and swollen mitochondria have also been documented at the ultrastructural level (106,114,115). Additionally, alkaline phosphatase and trehalase activity was found to be decreased. Transient maladsorption of D-xylose, fat, and lactose was also observed during acute infection (114). The characteristic histological lesions and biochemical alterations associated with NLV infection are reversible. Normal histology and biochemical activity returns to baseline levels within two weeks postillness (106,114).

IMMUNITY

Despite numerous volunteer studies and epidemiologic investigations, immunity to NLVs is not well understood. Currently available assays do not directly detect neutralizing antibody, thus the protective effect of serum antibodies remains unclear (67,116). Early multiple challenge studies did describe a serotype-specific short-term protective effect (6 to 14 weeks) by serum antibodies against reinfection. However, the protective effect was not long term (80,117). Long-term immunity to NLV infection, on the other hand, is somewhat paradoxical. In volunteer studies, individuals that developed illness on initial challenge also developed illness on rechallenge, 2 to 4 years later (117). Further, those that were resistant to initial infection were also resistant on rechallenge. The resistant individuals also had a lower prechallenge serum antibody level than those that became ill, and they did not develop a significant serologic response postchallenge. Individuals that did become ill showed a serologic response after each challenge. Interferon does not play a significant role in immunity to NV (118). More recent studies have indicated similar rates of infection for individuals with or without preexisting serum antibodies (98). Another recent study has suggested that several challenges must occur to generate immunity (119). In this study, all subjects with a high prechallenge titer of serum antibodies became ill upon challenge, whereas approximately 60% of those with a low titer of serum antibodies became ill. On rechallenge six months later, only four individuals became ill. All of these individuals had low prechallenge titers before the initial challenge, but three had high titer serum antibodies before the second challenge. Upon a third challenge after an additional six months, no individual became ill.

High concentrations of maternal antibody can be detected in the sera of neonates (97,120). Recent studies using sensitive enzyme immunoassays (EIAs) have documented maternal antibody in 96% of neonates during their first month of life (97). Studies show that maternal antibodies to NLV may be detected at 6 to 8 months of age (97,121).

The immune response to recombinant Norwalk-like virus particles (rNLV) was studied in mice and human volunteers (122,123). In mice the rNV were immunogenic with or without adjuvant. Higher levels of antigen were necessary to generate an intestinal IgA response than was necessary to generate a serum IgG response (123). IgG responses were dose dependent and observed earlier than IgA. Tolerance was not induced with oral immunization. IgG and IgA response were noted after each oral dose (123). Similar results were observed in humans. IgG responses were dose dependent. Most individuals showed a serologic response of greater than fourfold increase after one dose, but no increase in IgG titer after a second dose three weeks later (122). Both rNVLPs and NLVs stimulate dominant IgG1 subclass and serum IgA antibodies. However, significantly higher elevations in antibody titer were observed in volunteers infected with live virus (122).

CONTROL AND PREVENTION

Treatment

NLVs typically cause a mild, self-limited illness that resolves without complications. Oral rehydration therapy is usually sufficient treatment. Occasionally, parenteral rehydration may be necessary in cases of severe dehydration (21). Administration of bismuth subsalicylate as a treatment for NLV infection has been shown to help mitigate symptoms of cramping and shorten the duration of the gastrointestinal symptoms (124,125). However, no effect was demonstrated on diarrhea and viral shedding.

Vaccines

Vaccine studies using recombinant Norwalk virus particles (rNV-VLP) are in the early stages. A systemic and mucosal antibody response is induced by the oral administration of rNV-VLP to mice or humans (122,123). An immunogenic response is observed with or without coadministration of adjuvant (126). However, it has not yet been determined whether rNV-VLPs protect against infection or illness when delivered orally.

EPIDEMIOLOGY

Transmission

Volunteer studies and outbreak investigations have indicated that transmission of human caliciviruses (NLVs and SLVs) is by the fecal-oral route (13,18,80,98,119). There is a high rate of secondary spread associated with the NLVs. Fecally contaminated food and water may serve as vehicles of transmission (127–132). Transmission by fomites is also possible. Person-to-person spread is common (24,133). Respiratory transmission is unlikely, although transmission by aerosolization of vomitus has been suggested for several outbreaks in hospitals, aboard ships, and from food (134–137).

A high secondary attack rate is a characteristic of NLV outbreaks. NLV outbreaks have been associated with a number of relatively confined settings, where presumably person-to-person transmission is likely. Norwalk virus was first isolated from a community wide outbreak beginning in an elementary school (14). Outbreaks have occurred at camps (Snow Mountain virus), in hospitals (Tauton virus), in hotels, and within families (Hawaii and Montgomery County viruses) (137–141). NLV outbreaks have also been described in nursing homes, on cruise ships, and at universities or colleges (142–146).

NLV outbreaks are often explosive and linked to a common source of contamination. Common or point source outbreaks may affect thousands of people (147). Water and food are commonly incriminated. Municipal water supplies, private wells, and commercially produced ice are all linked to common source outbreaks of NLVs (132,148–151). Recreational contact with water has also been associated with NLV outbreaks. Several outbreaks have resulted from primary contact (swimming) in contaminated lakes or swimming pool water (152–154). Even secondary recreational contact with contaminated water, such as canoeing, has been linked to NLV outbreaks, although capsizing and eating before changing clothing was associated with a greater risk than canoeing (155,156).

NLVs are estimated to be the leading cause of food-borne illness attributable to a known agent (24,157). The number of estimated annual cases of NLV gastroenteritis in the United States is 23,000,000 (out of an estimated 38,629,641 total cases of illness from known food-borne pathogens), 40% of which are food-borne (158). It is estimated that 50,000 hospitalizations will be caused by NLVs, 20,000 of which will be attributed to food. Additionally, researchers estimate 310 deaths will result from NLV illness, of which 124 will be food-related (158). However, it is acknowledged that these morbidity and mortality figures were estimated from hospital and community studies and are difficult to verify (158). The most common contributing factors to food-borne NLV outbreaks were poor personal hygiene, food from an unsafe source, and inadequate cooking (159).

Numerous food-borne outbreaks of NLVs are well described and a wide range of foods have been implicated as the contaminated vehicle. Raw and minimally processed fruits and vegetables are frequently implicated in NLV outbreaks (143,160–163). Additionally, sandwiches and pre-cooked meats have been implicated (111,164,165). Even more complex food items, such as bakery items (wedding cake with frosting), pasta, spring rolls, potato salads, coleslaw, and raspberry mousse, have been linked to outbreaks (166–172). Perhaps the most common food types associated with epidemic NLV infection are shellfish, in particular, bivalve mollusks. Each year numerous outbreaks of shellfish associated viral gastroenteritis are reported worldwide (173–176). Shellfish are typically filter feeders that retain and accumulate particles from the large volumes of water they pump through their bodies. Hence, sewage contamination of shellfish beds may lead to contamination of the shellfish meat as viruses are taken up, retained, and concentrated by the animals.

Generally, contamination of food may be distinguished into two groups; contamination by an infected food handler

and contamination by exposure to fecally contaminated water. Vegetables and fruits may be contaminated both by infected food handlers or washing or irrigating with fecally contaminated water (177). More complex or heated food items are typically contaminated by infected food handlers having poor personal hygiene and sanitation (178–180), although a community level outbreak associated with consumption of custard slices may have been caused by reconstitution of a dried custard mix with contaminated water (181). Outbreaks have been traced to pre-and post-symptomatic food handlers, and those that were sick on the job (166,178,182).

Incidence and Prevalence

Worldwide, NLVs are the most important causes of epidemic nonbacterial gastroenteritis (110,183). In the late 1970's, only a remote Equadorian Indian tribe, of those populations screened, did not have antibodies to NV (184). In the United Kingdom in 1995 and 1996, NLVs were responsible for more outbreaks of infectious gastroenteritis (42%) than Salmonella (15%) (24). In 1992 and 1993, Salmonella were responsible for slightly more outbreaks of infectious gastroenteritis (32%) than were NLVs (27%) (133). Person-to-person transmission and food-borne outbreaks were the primary mode of transmission (24,133). Between 1990 and 1994, the majority of reported cases, with known age, fell into two age groups: children from age 1 month to 4 years and adults over 65. However, cases were reported in all age groups (38). From 1990 to 1995, there is an apparent increasing trend in the number of reported cases of viral gastroenteritis associated with NLVs. Additionally, there appears to be a winter seasonality to the reported cases (38).

Molecular evidence indicates that the predominant strains of NLVs now in circulation are genogroup II viruses. Further, a naturally occurring recombinant virus between two distinct clusters of genogroup II has been identified (185). Although genogroup I viruses are still detected, they are considerably more rare (186–188). Mixed genogroup infections have been documented (156).

Early seroprevalence studies of NVs in the United States suggested that antibodies are acquired gradually through childhood. However, more recent evidence suggests that antibody acquisition to HuCVs varies with several factors, including age, geographic location, and development status of the country or region. The rate at which antibodies to Norwalk virus are acquired appears related to how developed a country may be. In lesser developed countries, antibodies are acquired very early (67). Reported seroprevalence data is summarized in Table 1.

At least four distinct antigenic types of SLVs have been described, although all share a common antigen detectable by radio-immunoassay (RIA) (189). SLVs have worldwide distribution with a seroprevalence of 30% at six months, increasing with age to greater than 90% for older children (>5 years old) and adults (190–192). In the United Kingdom, SLVs are responsible for approximately 1% of cases of viral diarrhea, with 90% of those detected occurring in young children (193).

Reservoirs

Humans are thought to be the only reservoir of HuCVs. However, recent studies identifying NLVs genetically (by nucleotide sequence analysis) in farm animals suggest that animal reservoirs cannot be completely ignored (75–78).

Age, Sex, Race, and Occupation

Traditionally, NLVs are thought to affect primarily older children and adults, particularly affecting the elderly, and only rarely the neonates and young children. However, recent advances in methods of detection (RT-PCR and sensitive enzyme immunoassays based on recombinant virus like particles) have indicated that NLVs are more widespread than previously thought, even infecting infants and young children (194–197). Geriatric facilities, adult-care facilities, and nursing homes seem particularly susceptible to NLV outbreaks (142,198–201). This may be related to the relatively confined setting of these institutions, the waning immunity, and the declining health of their resident populations. No significant differences in susceptibility have been documented between the sexes. Sexual preference apparently also does not have an effect on seroprevalence to NV because male and female homosexuals have comparable antibody levels as other adults (21,184). Studies determining the effects of race and occupation on NLV epidemiology are lacking.

Seasonality

As the term "winter vomiting disease" implies, NLVs were originally thought to have a winter seasonality. Later studies indicated that in developed countries, NLV outbreaks occur year-round (110,202). Despite year-round occurrence, a recent analysis of eight surveillance studies and unpublished data from four researchers confirm that peak incidence of cases of NLVs occurs in winter (203).

Other Risk Factors for Hucv Infection and Illness

Several studies have investigated the prevalence of diarrheal viruses, including NV, in individuals with HIV-infection (204–208). The prevalence of NV in the stools of HIV-infected children with chronic diarrhea in Tanzania was significantly greater than in HIV-negative children, also with chronic diarrhea (204). In a Venezuelan study of HIV-positive individuals with or without diarrhea, NV was not observed in stool samples (205). Another study in the United States documented a slightly elevated prevalence of caliciviruses in stool samples (6–1%) of HIV patients with diarrhea versus those without diarrhea. However, no seroconversion to NV was observed (207).

Investigations indicate that NV is rarely associated with exacerbation of Crohn's disease and ulcerative colitis (209). Other studies found no difference in antibody prevalence or titer between Crohn's patients and controls (210,211). Antibody levels to NV were also similar in individuals with cystic fibrosis and controls (212).

CONCLUSION

Human caliciviruses, including the NLVs and SLVs, are among the most important and widespread causes of viral gastroenteritis in the world. Illness is characterized by a short incubation period, acute onset, and short duration, with typical symptoms of diarrhea, vomiting, nausea, and abdominal pain. NLVs cause illness in all age groups, whereas SLVs infect mostly infants and young children. Immunity to HuCVs is short-lived and repeated infections probably occur throughout life, with increasing severity in elderly populations. HuCVs are transmitted

by the fecal-oral route, including direct and indirect contact, fecally contaminated water, food and fomites, and possibly by aerosolized vomitus. The infectious dose of HuCVs has been demonstrated to be low for those that have studied, and based on epidemiological investigations suggest that it is low for the others. HuCVs have not been propagated in cell cultures or other animals, and this has hampered progress in understanding their biology and in developing prevention and control measures. However, the cloning and molecular characterization of HuCVs, including the expression of HuCV proteins, has led to the availability of nucleic acid detection and serologic methods that have greatly facilitated characterization of these viruses, the understanding of their epidemiology, including their detection in infected people, and various vehicles of exposure.

HYDROPHOBICITY OF MICROORGANISMS: METHODOLOGY

HENNY C. VAN DER MEI
HENK J. BUSSCHER
University of Groningen
Groningen, The Netherlands

Hydrophobicity is by definition and meaning of the word the degree of dislike of a surface for water (1), but since the pioneering work of Rosenberg and coworkers (2), it was invariably associated with the ability of microorganisms to adhere to hydrocarbons in an aqueous suspension. Adhesion, however, whether to hydrocarbons in aqueous suspension or any other surface, is always an interplay of all factors involved in the process (3) including not only hydrophobicity but also electrostatic charge interactions (4) and influences of structural cell surface properties (5,6). Table 1 lists currently used assays to determine microbial cell surface hydrophobicities.

In the past, there has been extensive debate in the literature about the extent to which the results of different hydrophobicity assays correspond (23–25). The general consensus seems to be at present that the results of different hydrophobicity assays do not correspond (26–27) unless confined to a collection of closely related strains (28–29). Strictly speaking, hydrophobicity is an acid–base phenomenon (30) that can only be measured by water droplets on carefully prepared and dried microbial lawns (8,31). If water molecules have a greater preference to surround each other than to contact a microbial cell surface, the surface appears as hydrophobic (see Fig. 1) and water droplets do not spread, whereas if water molecules favor a microbial cell surface rather than each other, the surface appears hydrophilic. Contact angles with liquids on microbial lawns can be measured without an intervening influence of electrostatic charge, but it must be realized that drying of the lawns is a critical step as it determines the degree of collapse of microbial surface appendages and therewith the contact angle (8,31–32). Usually, contact angles measured on microbial lawns increase as a function of drying time until a so-called plateau is reached (Fig. 2). Note that the duration of the plateau state may also vary. As long as the lawns are dried to the plateau for water contact angles, relevant microbial contact angles can be measured. Theoretically, cell surface hydrophobicity cannot be measured solely by water contact angles, as this does not allow accounting for acid–base interactions as occurring between water molecules and between water molecules and the microbial cell surface. Full surface thermodynamic analysis of the cell surface hydrophobicity requires contact angle measurements, with at least three different liquids with varying acid–base properties (33).

The formal surface thermodynamic analysis of contact angles with liquids on microbial lawns yields one value for the so-called thermodynamic cell surface hydrophobicity of microbial cell surfaces, ΔG_{mwm}, whereas the term intrinsic cell surface–hydrophobicity is used for the contact angle (θ)–based hydrophobicity. Microbial adhesion to hydrocarbons (MATH) is, however, still the most widely used assay for cell surface hydrophobicity and, for that reason, will be described here in its so-called kinetic mode forwarded by Lichtenberg and coworkers (34) as a more quantitative and reproducible variant of the

Table 1. Summary of Different Assays to Measure Microbial Cell Surface Hydrophobicity

Description of the Assay	Comments	References
Contact angle measurements	Quantitative, intrinsic property, but overall property	7–9
Microbial adhesion to hydrocarbon (MATH)	Qualitative, interplay of more than one property	2,10–12
Microbial adhesion to solvents (MATS)	Qualitative, interplay of more than one property	13
Salt aggregation test	Indirect	14,15
Hydrophobic interaction chromatography	Interplay of more than one property	16
Two-phase partitioning system	Qualitative, interplay of more than one property	17
Direction of spreading	Qualitative, but contact angle based	18
Hydrophobic microsphere attachment	Mostly used for yeast cells, interplay of more than one property	19
Adhesion to polystyrene	Interplay of more than one property	20
Adsorption of nonionic and anionic surfactants	Qualitative, interplay of more than one property	21
Image analyses technique	Interplay of more than one property	22

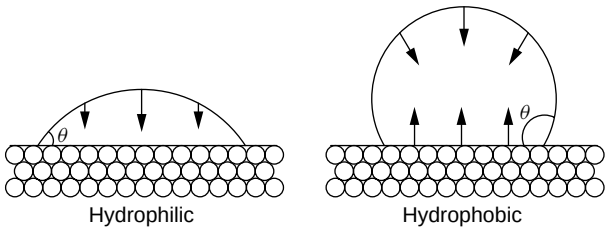

Figure 1. The contact angle equilibrium for a hydrophobic and a hydrophilic microbial cell surface, with the strongest interaction indicated by arrows in each diagram.

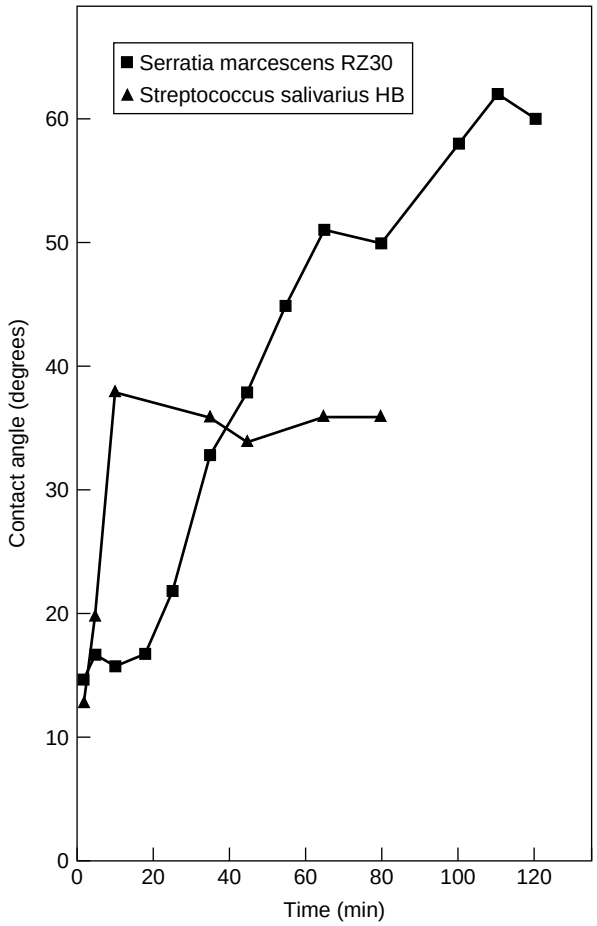

Figure 2. The water contact angle on different microbial lawns as a function of the drying time of the lawn. Note that the plateau angle arises after different drying times for different strains.

assay as originally described by Rosenberg and coworkers (2). Because microbial adhesion to hydrocarbons does not involve acid–base interactions between the hydrocarbon and the microbial cell surface, Bellon-Fontaine and coworkers (13) have suggested replacing the hydrocarbon phase by an organic solvent capable of direct acid–base interactions and proposed the acronym microbial adhesion to solvents (MATS) for this assay. MATS is included in this chapter, as a comparison of MATH and MATS results give an estimate of the acid–base character of a cell surface. Finally, it will be demonstrated that MATH and MATS disqualify as measures for cell surface hydrophobicity, predominantly because of the intervening effect of electrostatic charge interactions.

MICROBIAL CELL SURFACE HYDROPHOBICITY FROM MEASURED CONTACT ANGLES AND SURFACE THERMODYNAMIC ANALYSIS

Microbial lawns for contact angle measurements with liquids can be prepared by slowly depositing approximately 50 layers of bacteria suspended in water, on a membrane filter (pore size 0.45 μm) placed on a fritted glass support while applying negative pressure. These wet filters with bacteria can then be attached on sample holder plates with double-sided adhesive tape and dried at room temperature till the so-called plateau contact angles can be measured. The plateau is indicated by stable water contact angles in time, as can be seen in Figure 2 (31). To determine whether the cells are homogeneously deposited, scanning electron micrographs can be made. Contact angles can be measured with a variety of liquids. For a surface thermodynamical analysis that accounts for acid–base interactions contact angles should be measured with water, formamide, methyleneiodide, and/or α-bromonaphthalene. These liquids have varying Lifshitz-Van der Waals (LW) and acid–base (AB) surface free energy components, whereas in addition, their electron-donating and electron-accepting surface free energy parameters differ (Table 2). The Young equation describes the contact angle equilibrium (Eq. 1) as

$$\gamma_{\mathrm{lv}} \cos\theta = \gamma_{\mathrm{sv}} - \gamma_{\mathrm{sl}} \tag{1}$$

where θ is the contact angle and γ_{ij} is the surface free energy of the liquid (l)-, solid (s)- or the vapor (v)-interface. In a surface thermodynamical analysis, the measured contact angles with the different liquids are inserted in Equation 1, while using

$$(\cos\theta + 1)\gamma_{\mathrm{l}} = 2(\gamma_{\mathrm{mv}}^{\mathrm{LW}}\gamma_{\mathrm{l}}^{\mathrm{LW}})^{1/2} + 2(\gamma_{\mathrm{mv}}^{+}\gamma_{\mathrm{l}}^{-})^{1/2} + 2(\gamma_{\mathrm{mv}}^{-}\gamma_{\mathrm{l}}^{+})^{1/2} \tag{2}$$

to eliminate γ_{sl} from the equation. Details about this mathematical procedure have been given in several papers (30,33,36).

The surface free energy data of the microbial cell surface thus derived G can be employed to calculate a free energy balance ΔG_{mwm}

$$\Delta G_{\mathrm{mwm}} = -4\left(\sqrt{\gamma_{\mathrm{mv}}^{\mathrm{LW}}} - \sqrt{\gamma_{\mathrm{wv}}^{\mathrm{LW}}}\right)^2 - 4\left(\sqrt{\gamma_{\mathrm{mv}}^{+}\gamma_{\mathrm{mv}}^{-}} + \sqrt{\gamma_{\mathrm{wv}}^{+}\gamma_{\mathrm{wv}}^{-}} - \sqrt{\gamma_{\mathrm{mv}}^{+}\gamma_{\mathrm{wv}}^{-}} - \sqrt{\gamma_{\mathrm{mv}}^{-}\gamma_{\mathrm{wv}}^{+}}\right) \tag{3}$$

in which γ^{LW} is the Lifshitz-Van der Waals surface free energy component, γ^{+} and γ^{-} are the electron-accepting and electron-donating surface free energy parameters, and ΔG_{mwm} is a thermodynamic measure for the cell surface hydrophobicity that accounts for acid–base interactions and is negative for hydrophobic organisms and positive for hydrophilic organisms. Table 3 present some examples of microbial contact angles and thermodynamic cell

Table 2. Total Surface Tension (TOTAL), Lifshitz-Van der Waals (LW) and Acid–Base (AB) Components and Electron-Donating (−) and Electron-Accepting (+) Parameters for Water, Formamide, Methyleneiodide, α-Bromonaphthalene, and Different Hydrocarbons and Organic Solvents used in MATH and MATS, Respectively (35)

Liquid	γ^{Total}	γ^{LW}	γ^{AB}	γ^-	γ^+
Water	72.8	21.8	51.0	25.5	25.5
Formamide	58.0	39.0	19.0	47.0	1.92
Methyleneiodide	50.8	50.8	0	0	0
α-bromonaphthalene	44.4	44.4	0	0	0
n-octane	21.6	21.6	0	0	0
n-hexadecane	27.5	27.5	0	0	0
p-xylene	28.4	28.4	0	1.8	0
Toluene	28.5	28.5	0	2.3	0

Actinomyces naeslundii T14-J1	64	37	43	29	−34.9
Lactobacillus plantarum RC20	79	43	45	30	−60.7
Staphylococcus epidermidis 3081	87	50	49	32	−72.4
Streptococcus mitis T9	91	47	55	36	−64.6
Lactobacillus acidophilus T13	102	47	55	38	−36.6

Note: Note that for hydrophobic organisms $\Delta G_{mwm} < 0$, whereas for hydrophilic organisms $\Delta G_{mwm} > 0$.

surface hydrophobicities, taken from a recently published reference guide (37).

The cell surface hydrophobicity as derived here from a surface thermodynamic analysis of contact angles describes an overall surface property, whereas the hydrophobicity of surface appendages, such as fibrils or fimbriae may be substantially different. Handley and coworkers (5), for instance, demonstrated that hydrophobic, colloidal gold particles only adsorbed to the tip of *Streptococcus sanguis* CR311 and PSH and concluded that the cell surface hydrophobicity was confined to the ends of the fibrils. Contact angles measured with liquid droplets on a microbial lawn are essentially representative of a fuzzy coat of cell surface material collapsed into a lawn. Therewith these results are useful to interpret the long-range interactions between an organism and a substratum surface, but not necessarily the short-range interaction, which may be dominated by structural and chemical cell surface heterogeneities (6).

MATH AND MATS ASSAYS

The hydrocarbons employed in MATH are essentially nonpolar, that is, they have a zero acid–base surface free energy, as can be seen from Table 2. By replacing the hydrocarbons by an organic solvent, acid–base interactions between the microorganisms and the solvent droplets in the assay can be introduced because these solvents have a nonzero acid–base surface free energy (Table 2). MATH and MATS are experimentally identical.

MATH and MATS can be carried out as originally proposed by Rosenberg and coworkers (2), but Rosenberg himself criticized the assay five years after its first publication as not being sufficiently quantitative (34). The preferred kinetic mode of the assay is still not widely used, as it is slightly more time-consuming. However, because the quality of the data superior as compared with the original assay has been considered, the kinetic assay will be described here.

Microorganisms are suspended in 3 ml of a buffer solution to an OD_{600} of between 0.4 and 0.6, generally referred to as OD_0. Subsequently, 150-μl hexadecane or another solvent is added to the suspension. The suspensions are vortexed for 10 s and left to settle for 10 min to allow separation of the two-phase system, when the water phase of the OD_{600} is again measured and referred to as OD_t. Vortexing and measuring are repeated until the total vortexing time is 60 s. Log $(OD_t/OD_0 \times 100)$

is plotted against the vortexing time, in which the negative slope yields the initial removal rate (R_0) as a measure of the adhesion of the bacterial cells to hexadecane or the other solvent.

Figure 3 illustrates the determination of the initial removal coefficient for *Streptococcus salivarius* HB adhering to hexadecane in 10-mM potassium phosphate with pH 7. Sometimes MATH (or MATS) is performed at various pH values to determine the degree of involvement of electrostatic interactions in the adhesion process (38,39) and interestingly, the initial removal rates by hexadecane are dependent upon pH, as can be seen in Figure 4. Although not all strains show a pH-dependent removal by hexadecane, the occurrence of a maximum removal coefficient at a certain pH value is common for many strains. Initial removal rates by the electron-accepting solvent chloroform (Table 2) are also pH-dependent and generally greater than the removal rates by hexadecane (Fig. 5) when the organism has a strongly electron-donating character. In contrast, Bellon-Fontaine and coworkers (13) showed that strains with electron-accepting character adhered less to chloroform than to hexadecane, but preferred diethylether above hexadecane. Comparison of MATH and MATS data can thus be useful to obtain an impression of the acidity or the basicity of the cell surface.

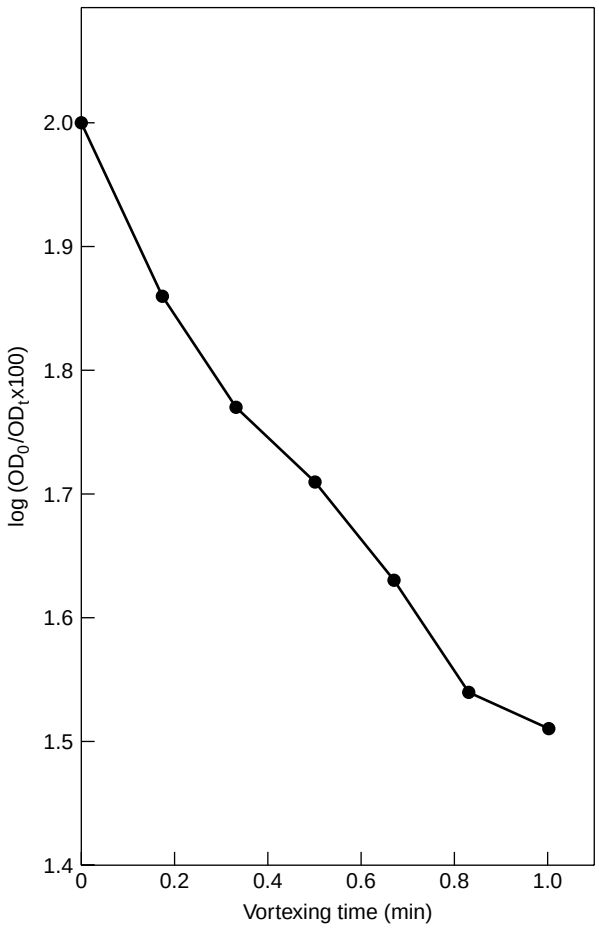

Figure 3. Illustration of the determination of an initial removal coefficient in the kinetic MATH assay for *S. salivarius* HB in 10 mM potassium phosphate at ph 7.

Mechanism of MATH and MATS

Adhesion-based hydrophobicity assays measured an interplay of all factors involved in microbial adhesion (28–29,38–39), which is actually confirmed by the pH-dependence of MATH results (see Fig. 4). The suspension pH dictates the protonation of ionizable groups on the cell surface and the degree of collapse of surface appendages (40) and a pH-dependence of adhesion results may point to electrostatic charge interactions. Several years ago, hydrocarbon droplets in aqueous suspensions have been found to be negatively charged (41). More recently, ζ-potentials of the different hydrocarbons in aqueous solutions used in MATH have been measured as a function of pH and were found to be highly negative above a pH of 3, whereas being slightly positively charged below a pH of 3 (38–39,41). The electrostatic interaction between hydrocarbons and microorganisms arising from this charge can be calculated in a DLVO (Derjaguin-Landau-Verweij-Overbeek) approach (4)

$$\pi\varepsilon a(\zeta_1^2+\zeta_2^2)\left[\frac{2\zeta_1\zeta_2}{\zeta_1^2+\zeta_2^2}\ln\frac{1+\exp(-\kappa d)}{1-\exp(-\kappa d)}+\ln\{1-\exp(-2\kappa d)\}\right] \quad (4)$$

in which ε denotes the dielectric constant of the medium, a is the radius of the microorganism, ζ, ζ-potential, κ^{-1}, double layer thickness and d, the separation distance between the interacting surfaces. If calculated for a separation distance of 1.57 Å, i.e. the distance of closest approach between two surfaces (42,43), the electrostatic contribution per adhering organism, ΔG_{el}, can be directly compared with the thermodynamic cell surface hydrophobicity per unit area, ΔG_{mwm}, although closest approach does not necessarily occur, and both measures have different units.

Figure 6 presents MATH (hexadecane) data for 23 different strains and species as a function of ΔG_{el} and ΔG_{mwm}, as determined in potassium phosphate solutions with varying pH. From Figure 6 it becomes apparent, that microorganisms adhere to hexadecane in MATH only in the absence of strong electrostatic repulsion, that is, ΔG_{el} needs to be negative, and when ΔG_{mwm} is negative too, that is, the organisms need to be hydrophobic (see also Table 3).

Synthesis: Thermodynamic Hydrophobicity, Electrostatic Interactions, and MATH(S)

Table 4 summarizes the observations from Figure 6. Hydrophilic organisms will always prefer the aqueous phase over adhesion to hydrocarbons and organic solvents, regardless of electrostatic repulsion. For hydrophobic organisms, whether adhesion to the hydrocarbons and organic solvents will occur depends on the electrostatic interaction. Hydrophobic organisms clearly adhere only in the absence of electrostatic repulsion. Close to the isoelectric points of the organisms, adhesion in MATH or MATS assays is consequently maximal. Therewith, MATH and MATS disqualify as assays for microbial

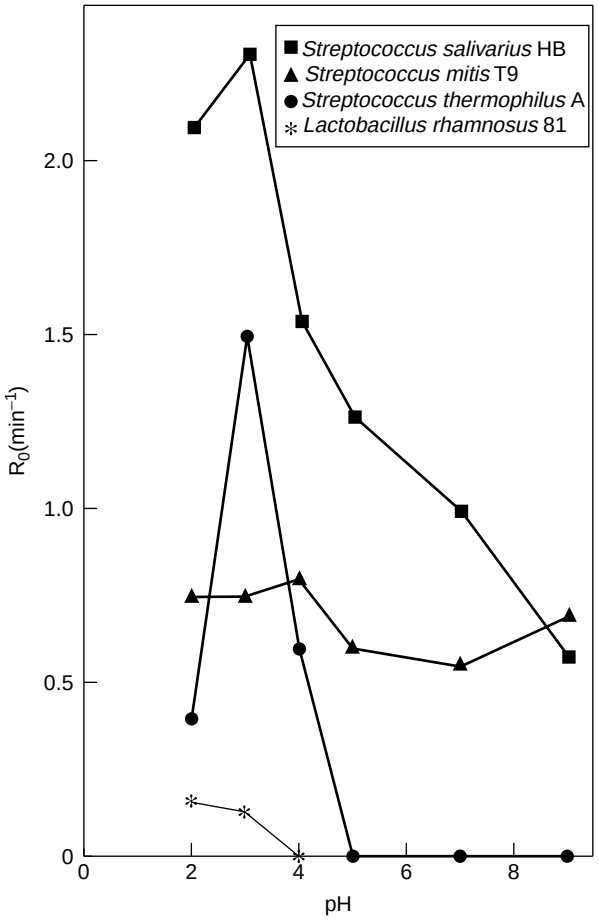

Figure 4. pH-Dependence of the removal by hexadecane in MATH for a variety of different strains.

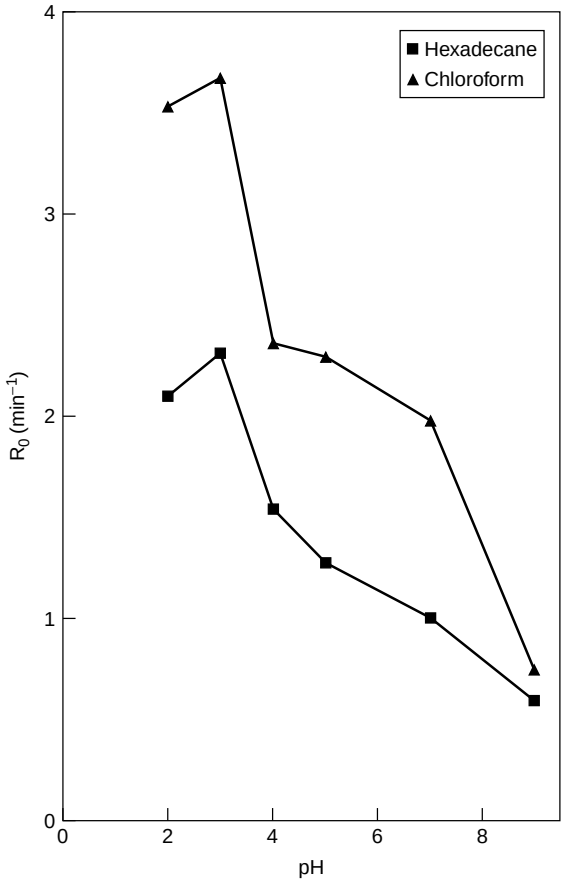

Figure 5. pH Dependent removal by hexadecane and chloroform for *S. salivarius* HB in MATH and MATS, respectively.

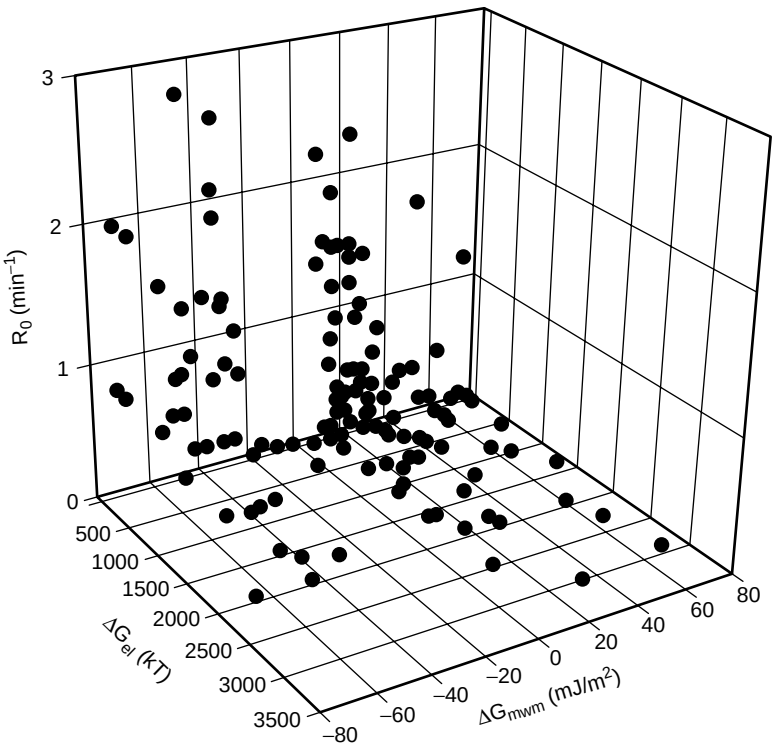

Figure 6. Removal by hexadecane of 23 strains as a function of ΔG_{mwm}, derived by thermodynamic analysis of measured contact angles, and the electrostatic interaction energy at closest approach. Note that adhesion of hydrophobic organisms to hexadecane only occurs in the absence of strong electrostatic repulsion.

Table 4. Schematic Summary of the Relations Between the Hydrophobicity of Microbial Cell Surfaces by Contact Angles or Surface Thermodynamic Analysis, Electrostatic Surface Charge and Adhesion to Hydrophobic Surfaces in Aqueous Suspensions, like in MATH

Cell Surface Hydrophobicity	Microbial Zeta Potential	Adhesion in MATH
Hydrophilic	Highly negative	Low
Hydrophilic	Approaching zero	Low
Hydrophobic	Highly negative	Low
Hydrophobic	Approaching zero	High

cell surface hydrophobicity. However, these assays provide excellent tools for studying microbial adhesion to smooth and homogeneous model interfaces in aqueous suspensions. Microbial cell surface hydrophobicity must be inferred intrinsically from (water) contact angles and can be further evaluated thermodynamically to include acid–base interactions.

HYDROTHERMAL VENTS: BIODIVERSITY IN DEEP-SEA HYDROTHERMAL VENTS

KEN TAKAI
YOSHIHIRO FUJIWARA
Japan Marine Science and Technology Center
Yokosuka, Japan

The discovery of deep-sea hydrothermal vents along the East Pacific Rise (EPR) has provided an expanded view of the deep sea, which was long believed to be a cold, dark, high-pressure, and nutrient-poor environment (1,2). Unexpectedly, a dense, abundant, and diverse population

of animals was found in and around the venting of geothermally superheated water, and it soon became apparent that these macrofaunal populations were strongly dependent on the primary production of symbiotic and free-living microorganisms in the ecosystems (3–5). Since the first discovery, a number of deep-sea hydrothermal vents have been explored in the Pacific and Atlantic Oceans and, very recently, in the Indian Ocean (Fig. 1; 6).

In the microbial ecosystems of the deep-sea hydrothermal vent environments, at least three generic microbial habitats and communities have been identified: (*1*) free-living microbial population associated with the discharged vent fluids and presumably growing and reproducing within the subvent system, (*2*) free-living microbial population associated with the geochemical and physical gradients formed in the range between the discharged vent fluids and the ambient seawater and containing the greatest physiological and genetic diversity, and (*3*) endo- and exosymbiotic microbial population associated with vent fauna.

For a long time, studies of the microbial diversity in the deep-sea hydrothermal vent environments have been performed by microscopic observation of samples and isolation of a restricted number of mesophiles. Because microbial habitats falling within the temperature range for mesophiles (15–50 °C) are probably abundant, mesophilic microorganisms may have the greatest impact on the microbial communities in the deep-sea hydrothermal vent environments. Nevertheless, a greater number of thermophilic microorganisms have been isolated from these environments because of the increasing interest of microbiologists in the evolutionary traits, novel biochemistry, and industrial potential of such extremophiles (7). It is now generally accepted that conventional laboratory cultivation and isolation have substantial limitations for understanding the naturally occurring microbial communities, including most culture-resistant microorganisms (8,9). Yet, conventional, culture-dependent surveys of microorganisms inhabiting deep-sea hydrothermal vents have revealed their great phylogenetic and physiological diversity in these extraordinary environments.

In addition, recent culture-independent, molecular, phylogenetic approaches have demonstrated much greater phylogenetic diversity of microorganisms in the deep-sea hydrothermal vent environments than previously indicated by culture-dependent approaches (8,10–17). Using molecular techniques, the localization of invertebrate-associated endo- and ectosymbionts, the quantification of uncultivated dominant phylotypes in low-temperature communities, and the distribution of thermophilic microorganisms in the vent fluids and chimneys have been determined. The combined use of culture-dependent and independent techniques may allow us to elucidate the occurrence and distribution of microbial communities in deep-sea hydrothermal vent environments and their significance for the circulation of substances and the geochemical processes associated with hydrothermal activities. In this review, microbial diversity is summarized focusing on the invertebrate-associated population, the uncultivated low-temperature population, and the thermophilic population. The possible existence of a subvent

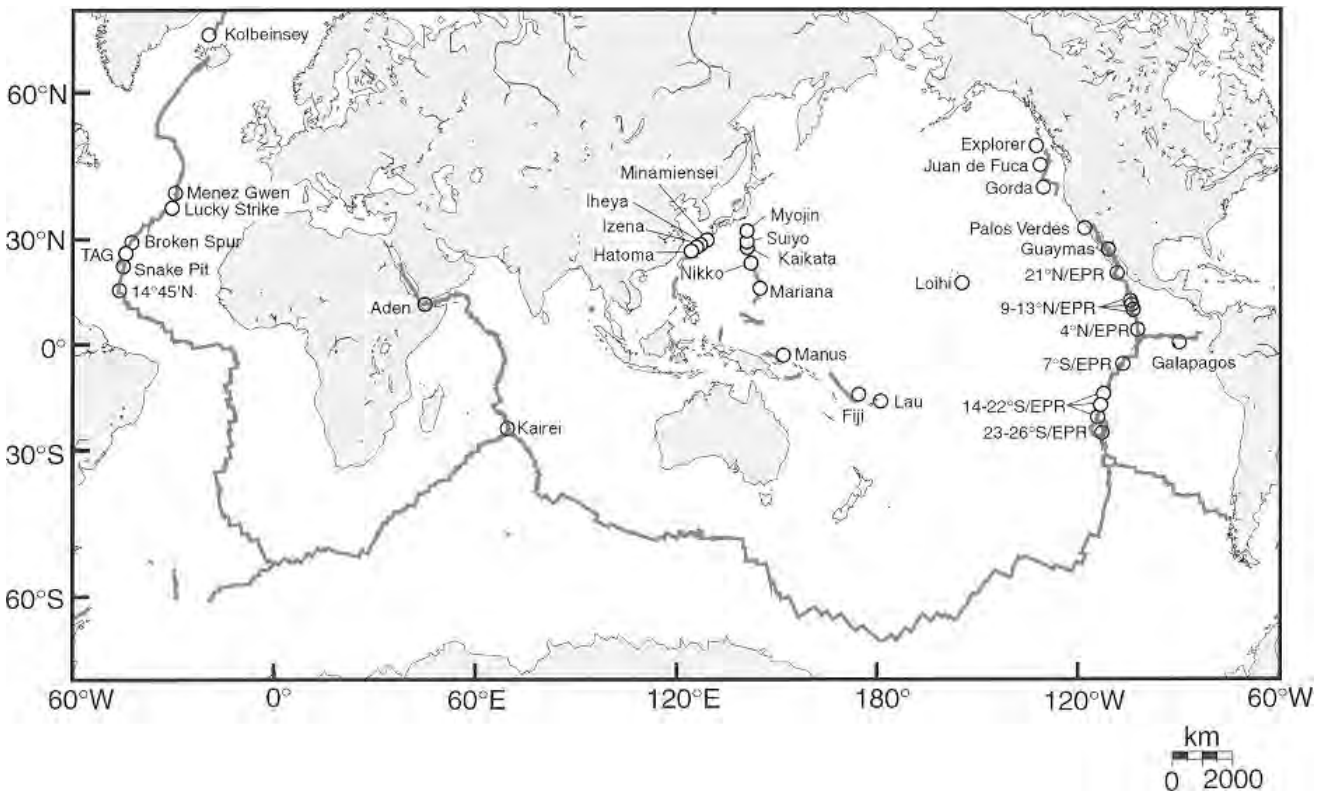

Figure 1. Location map of deep-sea hydrothermal vent sites found so far.

biosphere populated with extremophilic microorganisms and extensive distribution of deep-sea hydrothermal vent microorganisms in global subseafloor environments are also discussed.

INVERTEBRATE-ASSOCIATED MICROBIAL POPULATIONS

Chemoautotrophic and Methanotrophic Endosymbionts

The first conclusive discovery of endosymbiosis between chemoautotrophic bacteria and deep-sea hydrothermal vent invertebrates was in the trophosome of the vestimentiferan tubeworm, *Riftia pachyptila* (18,19). Many other symbiotic associations have since been reported to occur in hydrothermal vents and cold seeps around the world (Table 1). The diversity of invertebrate taxa harboring chemotrophic bacterial symbionts is quite broad (20,21). Chemotrophic symbioses are abundant in five families of bivalves, two of which (Vesicomyidae and Mytilidae) are endemic to hydrothermal vents and cold seeps. Lucinacean bivalves (families Lucinidae and Thyasiridae) are widely distributed in a variety of habitats with access to reduced sulfur compounds, including many seeps and some vents. Symbiosis with chemoautotrophic bacteria is also characteristic of bivalves in the family Solemyidae, and these bivalves are found in a wide variety of reducing habitats. Two hydrothermal vent gastropods of the family Provannidae are also known to harbor chemotrophic symbionts. Similar symbionts are also found in association with several phyla of worms including annelids, nematodes, and platyhelminthes. All currently examined members of the phylum Pogonophora, which includes vestimentiferan tubeworms, harbor chemoautotrophic symbionts. In some of the associations outlined earlier, the symbionts are extracellular, but even in those cases the associations appear to be very specific. Most chemotrophic symbionts are thioautotrophs. However, the first documented methanotrophic (methane-oxidizing) symbiosis in a deep-sea mussel was reported in 1986 (22).

Characterization of endosymbionts has been difficult because of their resistance to cultivation when they are removed from their hosts. As a result, the chemoautotrophic endosymbioses were initially confirmed by electron microscopic observation, stable isotope analysis, lipid analysis, and enzymatic characterization. These techniques revealed the physiological aspects of the symbioses and suggested the energy conversion and carbon assimilation systems of symbionts. They were classified into two types: one using sulfide, oxygen, and carbon dioxide as an electron donor, acceptor, and carbon source (thioautotrophy); and another using methane as an energy and carbon source (methanotrophy). However, the taxonomic and phylogenetic identification and the host specificity of the symbionts was unclear. Molecular phylogenetic analyses based on the 16S rDNA sequences have revealed that most host species contain a single phylotype of endosymbionts belonging either to thioautotrophic or methanotrophic bacteria, and a few have both (Table 1).

Phylogenetic analyses for 16S rDNA of symbionts demonstrated that most symbiotic bacteria in vent/seep species belonged to a limited domain of the γ-subdivision of *Proteobacteria*, despite the wide taxonomic range of their hosts (Fig. 2). All previously reported endosymbionts of vesicomyid clams (representative genera: *Calyptogena*, *Vesicomya*, and *Ectenagena*) are thioautotrophs and are located in host gills. Phylogenetic analyses of 16S rDNA sequences of the symbionts showed that these sequences formed a monophyletic clade that is closely related to the thioautotrophic symbionts of deep-sea mussels (Fig. 2). Deep-sea mussels (representative genus: *Bathymodiolus*) harbor thioautotrophs and/or methanotrophs as endosymbionts in their gills. *Bathymodiolus thermophilus* (East Pacific Rise) and *B. septemdierum* (western Pacific) have thioautotrophic endosymbiotic bacteria, *B. japonicus* (western Pacific) and *B. platifrons* (western Pacific) have methanotrophic bacteria, and *B. puteoserpentis* (Mid-Atlantic Ridge) has both (Table 1). Each trophic type of bacteria forms an independent monophyletic clade (Fig. 2). Methanotrophic symbionts of deep-sea mussels are more closely related to many free-living methanotrophs than to thioautotrophic symbionts in hydrothermal vent hosts (Fig. 2).

Endosymbionts of vestimentiferan tubeworms (representative genera: *Riftia*, *Escarpia*, and *Lamellibrachia*) are also thioautotrophs, located in trophosomes. Unlike the endosymbionts of vesicomyid clams and deep-sea mussels, the symbionts of the tubeworms form a paraphyletic group with thioautotrophic symbionts of solemyid clams (representative genus: *Solemya*) and clams belonging to the superfamily Lucinacea (representative genera: *Codakia*, *Lucinoma*, *Thyasira*, and *Anodontia*) (Fig. 2).

The causes of these differences in phyletic characteristics are still unclear. One possible explanation is a difference in the symbiont transmission mechanism. Direct evidence of symbiont transmission is rare, but three possible paths of transmission are recognized for chemotrophic symbiont-harboring species from deep-sea vents and seeps (23). These include vertical transmission from parent to progeny, horizontal transmission involving the spread of symbionts between contemporary hosts, and environmental reinfection of each generation of hosts from an environmental stock of microorganisms. The operational distinction between the last two is that a free-living form of the symbiont is required for the latter mechanism.

Vesicomyid clams and deep-sea mussels are reported to have a horizontal transmission mechanism. The vesicomyid clam *C. soyoae* contained bacteria within primary oocytes and follicle cells (24). Symbiont 16S ribosomal RNA genes (16S rDNA) were consistently amplified from the ovarial tissue of three species of vesicomyid clams, namely, *C. magnifica*, *C. phaseoliformis*, and *C. pacifica* (25). In situ hybridization showed that the symbionts were located in follicle cells surrounding the primary oocytes (25). Hybridization within oocytes was not observed, but several sections showed follicle cells invaginating and developing oocytes, thereby indicating a possible infection mechanism. The authors also mentioned a similar transovarial transmission mechanism in the symbiont of the deep-sea mussel *B. thermophilus* (25). The symbiont genealogy, based on bacterial 16S rDNA sequences, had a strong affinity with the host genealogy, which was based on clam mitochondrial cytochrome

Table 1. Symbiont-Harboring Invertebrates

Species	Location	Habitat	Depth (m)	Symbiont Symbiont Type	16S rDNA Accession No. of Symbionts

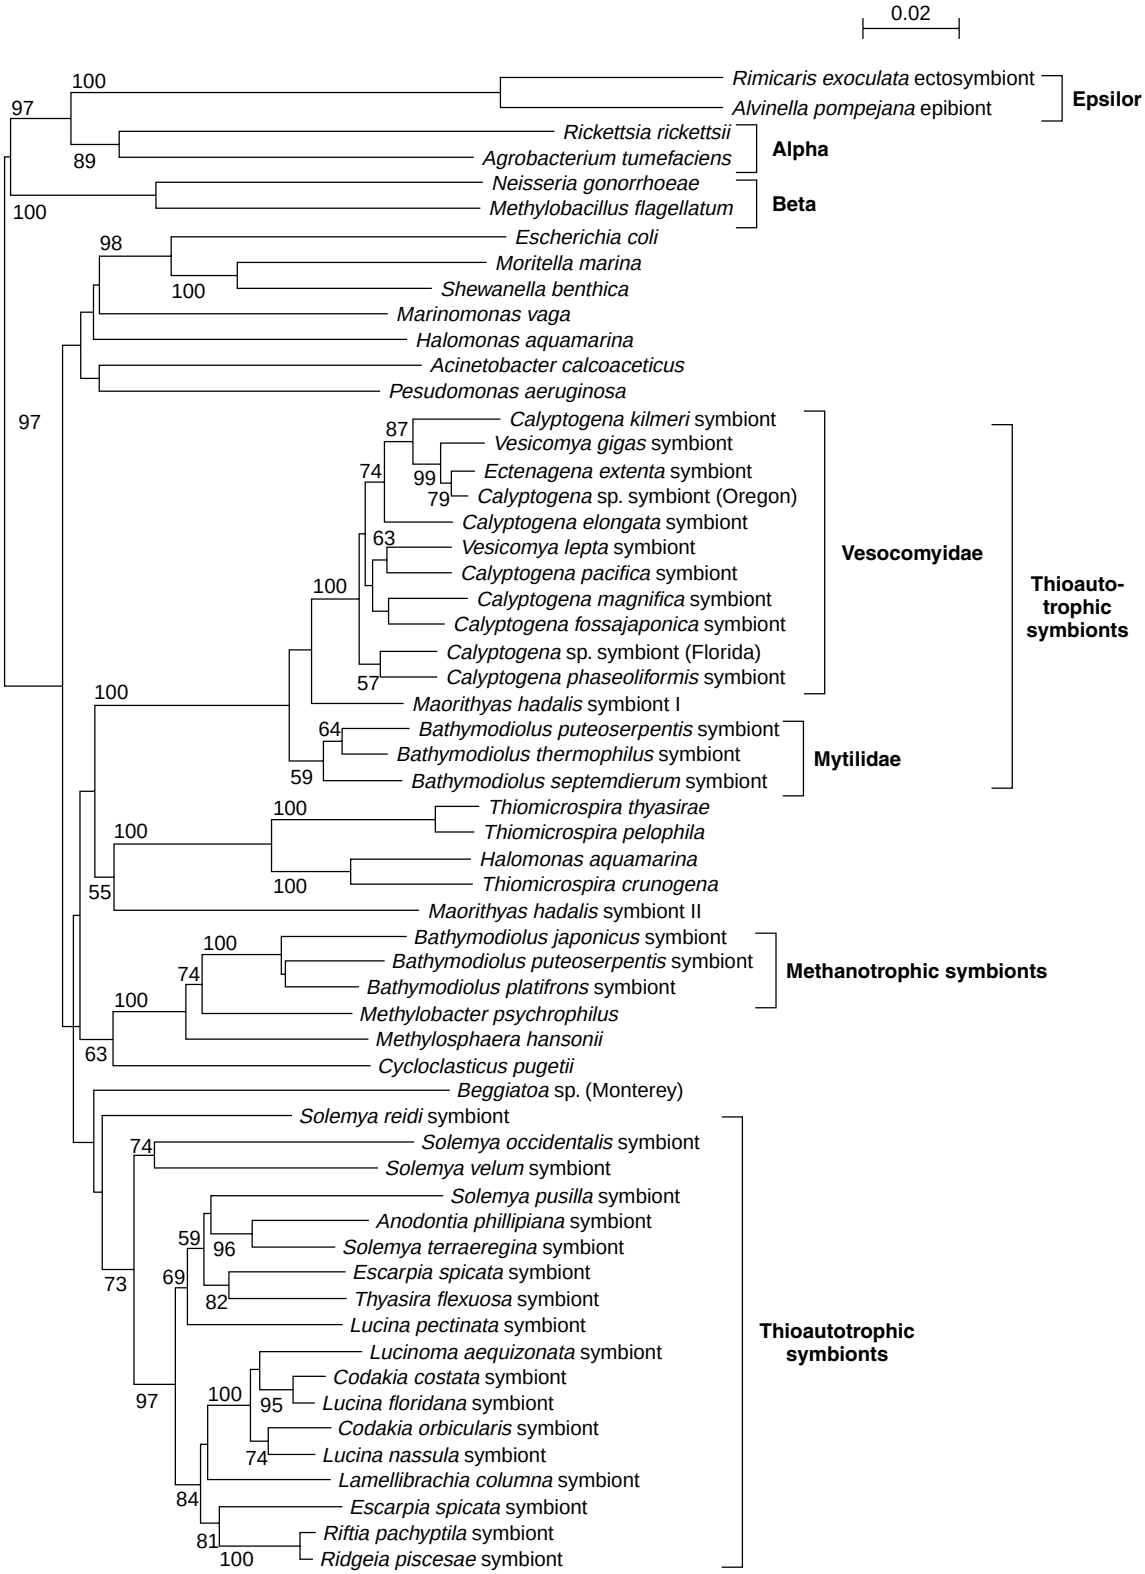

Figure 2. Phylogenetic tree based on small subunit rDNA sequences including various endosymbionts. Neighbor joining (NJ) tree within the members of the χ-subclass of Proteobacteria with the α-, β-, and ε-subclasses of Proteobacteria as an out-group is shown (1,357 homologous positions analyzed). Scale bar represents 0.02 nucleotide substitutions per sequence position. The percentage of 1,000 bootstrap resamplings is indicated. Bootstrap values greater than 50% are shown.

oxidase subunit I and 16S rDNA sequences. This also indicated nearly complete vertical transmission over long-term associations (26).

Evidence is accumulating to suggest that horizontal transmission or environmental reinfection is the mode of transmission in vestimentiferans and lucinid clams. An analysis of restriction fragment length polymorphism (RFLP) was employed on three vestimentiferan symbionts using three symbiont-specific genes, namely, eubacterial 16S rRNA, RuBPC/O Form II, and ATP sulfurylase (27). The results indicated that all of the symbionts from the three different hosts were conspecific and that the *Riftia* and *Tevnia* symbionts were indistinguishable in hosts separated over an 1,800-km range. These results strongly suggest that the symbionts are acquired de novo by each generation of juvenile tubeworms from a common source in the surrounding seawater (27). Feldman and coworkers (28) examined host-symbiont coevolution by comparing phylogenetic trees from symbiont 16S rDNA and host mitochondrial *COI* genes. The endosymbionts comprised two distinct clades, one associated with tubeworms from basaltic vent habitats and the other associated with tubeworms from sedimented seeplike environments. Within each symbiont clade, 16S rDNA sequences were nearly identical, suggesting that vent vestimentiferans share a single endosymbiont species that is distinct from the seep endosymbiont species. In the case of the lucinid clam *C. orbicularis*, amplification of bacterial 16S rDNA sequences using specific primers was unsuccessful in ovaries, eggs, veligers, and metamorphosed juveniles cultivated in sterile sand. Successful amplifications were obtained from gill tissues of adult specimens and from metamorphosed juveniles cultivated in sand from an unsterilized sea-grass bed (29). Hybridization using specific probes and observation of endosymbiotic bacteria in the gills of numerous juveniles cultivated in this sand demonstrated that the sulfur-oxidizing endosymbionts of *C. orbicularis* are environmentally transmitted to the new generation after larval metamorphosis.

In the case of solemyid clams, several lines of evidence seem to be contradictory. Krueger and Cavanaugh (30) showed that the symbiotic associations of solemyid clams appear to have multiple evolutionary origins on the basis of comparative sequence analysis of 16S rDNA. However, Cary and Giovannoni (25) reported a transovarial transmission mechanism in the symbiont of *S. reidi*. Cary (31) suggested that the *S. reidi* symbionts are vertically transmitted with the egg according to his molecular and histochemical analyses. Therefore, it is still unclear how such a paraphyletic group might arise.

The influence of bacterial endosymbionts on host distributions seems to be strong in hydrothermal-vent ecosystems. Fujiwara and coworkers (32) reported deep-sea mussels containing only methanotrophs (lacking thioautotrophs) from hydrothermal vents in the Okinawa Trough. Comparison of methane and hydrogen sulfide concentrations in end-member fluids from deep-sea hydrothermal vents indicated that methane concentrations were much higher at habitats containing *Bathymodiolus* that harbored only methanotrophs than at other hydrothermal-vent mussel habitats. The known distribution of other mussels containing only methanotrophs has till now been limited to cold-seep environments with high methane concentrations from the interstitial water. Therefore, the authors concluded that the distribution of methanotrophic symbioses between deep-sea mussels and methanotrophs is strongly influenced by the methane or hydrocarbon concentrations provided by hydrothermal-vent and cold-seep activities or that methanotrophic symbionts are required for the survival of host mussels in methane-rich environments. Selection of host habitats as related to symbionts might be an important process in the diversification of both hosts and symbionts.

Epibionts

The most extensively studied epibiotic microbial populations are of a tube-dwelling annelid polychaete *Alvinella pompejana* and of a highly motile alvinocaridid shrimp *Rimicaris exoculata*, which are endemic in the deep-sea hydrothermal vent fields of the East Pacific Rise and the Mid-Atlantic Ridge, respectively. On the basis of microscopic observations, it has been concluded that morphologically diverse microbial populations are present in the surface and subsurface of the epidermal organs of these animals. In the case of *A. pompejana*, dorsal epidermal expansions are externally covered by filamentous morphotypes that dominate the worm-bacteria association. Rod-shaped, prosthecate, spiral-curved, and filamentous sheathed or unsheathed bacteria are scattered on the surface of the worm integument, whereas clumplike assemblages of rod-shaped, coccoid, and filamentous bacteria are associated with cuticular protrusions in the intersegmental spaces (33). The extremely dense ectobacterial population consisting of rod-shaped and filamentous morphotypes with varying thickness is also noted on the anterior appendages, especially the hypertrophied gill-bailer, of the hydrothermal vent shrimp *R. exoculata* (34,35). Although culture-dependent approaches have been attempted to characterize the epibiotic microorganisms of these polychaete and shrimp, several nonfilamentous heterotrophic mesophiles have been successfully cultured from *A. pompejana*'s dorsal integument alone (36–40). Most of these heterotrophic strains are probably substantial components of epibiotic microbial communities. However, the most dominant filamentous epibionts have eluded all attempts at culturing, and so molecular phylogenetic techniques based on 16S rRNA sequences were applied to characterize the epibionts of these animals (41–43).

Several molecular phylogenetic analyses have revealed that most of the phylotypes recovered from rDNA assemblages of the epibiotic microbial populations are within the ε-subclass of *Proteobacteria*. This group of bacteria encompasses the genera *Arcobacter*, *Campylobacter*, *Helicobacter*, *Sulfurospirillum*, *Thiovulum*, and *Wolinella*, and the majority of these genera are known to be involved in multiple metabolic pathways regarding oxidation and/or reduction of sulfur compounds under microaerophilic and/or anaerobic conditions (44,45). In phylogenetic trees of the ε-subclass of *Proteobacteria*, the epibiotic phylotypes obtained from *A. pompejana* and *R. exoculata* are closely

related to each other, indicating certain evolutionary biases for the selection of epibionts. In situ hybridization and epifluorescence microscopy demonstrated that these phylotypes might represent the predominant morphotypes found on the surface and subsurface organs of the animals. In addition, epibiotic phylotypes and their close relatives were detected in considerable proportions in the total microbial rRNA assemblage, not only on the exterior surfaces of other invertebrate genera (*Paralvinella* sp. and *Riftia* sp.), but also on the surfaces of the rocks and sulfide blocks around the habitats of the hosts.

The epibionts within the ε-subclass of *Proteobacteria* may be sulfur-oxidizing chemoautotrophs contributing the trophic and sulfide-detoxifying roles in the gradients formed in the mixing zone of the reduced and oxidized waters. A combined use of culture-dependent and culture-independent techniques will shed light on the exact function and role of the epibionts for their hosts and surrounding microbial ecosystems.

MICROBIAL COMMUNITIES IN LOW-TEMPERATURE HABITATS

In low-temperature habitats that are probably formed in the steep geochemical and physical gradients between the discharged vent fluids and the ambient seawater, the availability of dissolved free oxygen renders aerobic or microaerobic oxidation of the reduced sulfur compounds, methane, and hydrogen the predominant energy-conversion systems. Sulfur-oxidizing bacteria colonizing rocks, chimneys, sediments, and animal surfaces exposed to vent emissions have been studied most extensively. With the exception of endosymbiotic chemolithoautotrophs, the sulfur-oxidizing microbial population identified in deep-sea hydrothermal vent environments include (*1*) uncultivated large filaments, probably consisting of *Beggiatoa* and *Thiothrix* in dense bacterial mats (46,47), (*2*) numerous base-producing facultative chemolithotrophs and heterotrophs (48,49), (*3*) rather few acid-producing obligately chemolithotrophic bacteria limited to two fully described species, *Thiobacillus hydrothermalis* (50) and *Thiomicrospira crunogena* (51–53), and (*4*) filamentous, sulfur-excreting species of the ε-subclass of *Proteobacteria* (54). As often observed in the endosymbiotic microbial population, methanotrophs are also probably dominant microorganisms in the mixing zone of the reduced vent water and the oxidized seawater. However, very few cultures have been obtained from the free-living methanotrophic population in the deep-sea, hydrothermal-vent environments. Hydrogen-oxidizing chemolithoautotrophs are very often cultivated from terrestrial hot springs and shallow marine hydrothermal vents. Although it was not fully described, the first hydrogen-oxidizing thermophilic bacterial strain EX-H1 was cultivated from chimney fractions in the East Pacific Rise (55).

On the basis of culture-independent molecular techniques, the bacterial rDNA community structures have been determined in several deep-sea, hydrothermal-vent environments. Muyzer and coworkers (56) found that the members of *Thiomicrospira* and *Desulfovibrio* belonging to the α- and δ-subclass *Proteobacteria*, respectively, were the possible dominant bacterial components in the microbial rDNA assemblages of two independent chimney samples using a denaturing gel gradient electrophoresis (DGGE) technique. This result indicated that not only sulfur-oxidizers, but also sulfate-reducing bacteria (SRB), predominantly occurred in the deep-sea, hydrothermal-vent environments, which was consistent with the evidence of sulfate-reduction activity in the sediments at the Guaymas Basin (57,58). In addition, the isolation and dominant occurrence of SRB within the δ-subclass *Proteobacteria* have been reported from different hydrothermal-vent sites [(59,60), Takai and coworkers, unpublished data].

Enrichment cultures and molecular signatures of typical deep-sea aerobic heterotrophs (61) belonging to the genera of *Alteromonas*, *Pseudoalteromonas*, *Vibrio*, *Pseudomonas*, *Halomonas*, *Marinobacter*, *Shewanella*, and *Colwellia* are often retrieved from deep-sea, hydrothermal-vent environments. Most of these genera of bacteria are probably derived from the ambient seawater. However, the high primary production and relatively high concentration of organic compounds in the seawater around the deep-sea, hydrothermal-vent emissions might harbor such ubiquitous deep-sea heterotrophs at much higher community density than in the typical deep-sea water and provide suitable habitats for certain populations of heterotrophs that specifically adapt to the deep-sea, hydrothermal vent environments.

The dominant occurrence and remarkable genetic diversity of the members of the *ε-Proteobacteria* have been demonstrated by a number of molecular phylogenetic surveys. Moyer and coworkers (14,62) reported that approximately 60% of the total bacterial clones constructed from a bacterial mat at a deep-sea hydrothermal vent in the Loihi Seamount was closely affiliated with *Thiovulum* sp. within the *ε-Proteobacteria*. As described in the previous section, the members of the *ε-Proteobacteria* represent major components in the epibiotic habitats and the surface area of the deep-sea, hydrothermal-vent animals.

Similarly, the deep-sea, hydrothermal-vent fluids and plumes may be niches for various members of the *ε-Proteobacteria*. To analyze the bacterial and archaeal diversity over time in the habitats just adjacent to vent emissions, an in situ titanium growth chamber (vent cap) was designed and deployed over several vents at the Snake Pit site in the Mid-Atlantic Ridge. During the deployment of the vent cap, the temperature was observed to decrease to approximately 20 °C (16). The rDNA clone analysis indicated that the most abundant bacterial rDNA sequences were of the *ε-Proteobacteria*, with a great phylogenetic diversity. These experiments did not necessarily demonstrate the community structures in the vent fluids, although the lower temperatures of vent fluids and plumes mixing with ambient seawater are able to provide suitable environmental settings for growth of the *ε-Proteobacteria*. In fact, a number of rDNA clones phylogenetically associated with the *ε-Proteobacteria* were found in a water sample directly collected from black smoker vent water at a temperature greater than 300 ° in the Okinawa Trough (Takai and coworkers unpublished data). The high abundance of rDNA sequences of the

ε-Proteobacteria was also observed in the surface layer (3 mm inside from the surface) of a black smoker chimney emitting vent fluid at a temperature greater than 300° in the Suiyo Seamount, Japan (Takai and coworkers unpublished data).

Archaea, the other domain of the prokaryotes, are substantial components even in low-temperature microbial communities occurring in deep-sea, hydrothermal-vent environments. As described in the next section, a great number of archaeal thermophiles have been isolated from the vent fluids, chimneys, rocks, sediments, and animals. Considering the hydrogen and carbon dioxide–rich environmental settings and the presence of mesophilic sulfate-reducing bacteria, it seems very likely that a certain population of psychrophilic or mesophilic methanogens occur in the anoxic zones of low-temperature habitats. However, no mesophilic or psychrophilic archaea have been cultivated from deep-sea, hydrothermal-vent samples. On the basis of recent molecular phylogenetic analyses, a great phylogenetic diversity of archaea containing possible psychrophilic and mesophilic entities have been identified in deep-sea, hydrothermal-vent environments (15–17,63). Most often, recovered archaeal phylotypes are classified into marine crenarchaeotic group I (MGI) (Fig. 3a). This group of phylotypes is an uncultivated, cosmopolitan archaeal group that is found in the global ocean environment (64–66). Cultivation of MGI is probably one of the greatest challenges for marine microbial ecologists because of their largest biomass potential within the domain of Archaea in the global ocean environment. Very limited but significant information on their physiology has been obtained from the vertical and seasonal distribution profiles in the coastal and oceanic waters (67,68), the molecular traits of some proteins restored from their DNA fragments (69), and the nutritional signatures using radioisotope-labeled substrates (70). At present, it is widely accepted that MGI might be in a category between psychrophiles to mesophiles, microaerobes to aerobes, and oligotrophs to heterotrophs. These predictions may lead to a simple answer that the ubiquity of MGI in deep-sea, hydrothermal-vent environments results from contamination from the ambient seawater; nevertheless, the formation of certain environmental optimums for their growth in the mixing zone of the vent emissions and the deep-sea water is not completely excluded.

Putative nonthermophilic archaeal phylotypes are noted within the euryarchaeotic kingdom as well (Fig. 3b). Marine euryarchaeotic group (MGII in Fig. 3b) and marine benthic group (MGIII in Fig. 3b) are also cosmopolitan nonthermophilic archaea widely distributed in the global ocean environments (64–66,74). Highly divergent uncultivated euryarchaeotic phylotypes [deep-sea euryarchaeotic group (DSEG) and miscellaneous euryarchaeotic group (MEG) in Fig. 3b] were obtained from sediments of a simmering point in the Okinawa Trough (17). The deep-sea, hydrothermal-vent systems located along the spreading Backarc axis are attributed to methane- and hydrocarbon-rich vent fluids by means of several geochemical surveys (89–91). Several archaeal phylotypes (pISA14 and pISA16 in Fig. 3b) recovered from the hydrothermal-vent systems are relatively abundant in the archaeal rDNA population (17) and had close phylogenetic relationship with the archaeal phylotypes found in subseafloor methane hydrate samples and methane-seep sediments (84,92,93). It is suggested that these archaeal phylotypes are derived from possible methanogenic archaea probably involved in anoxic methane oxidation syntrophically associated with sulfate-reducing counterparts (84,92,93). The anoxic oxidation of methane and hydrocarbon forms may play an important role in the primary production and energy conversion of the deep-sea, hydrothermal-vent ecosystems.

MICROBIAL COMMUNITIES IN HIGH-TEMPERATURE HABITATS

Cultivation and Isolation

Thermophiles have been isolated from various deep-sea, hydrothermal-vent sites since immediately after the discovery of deep-sea hydrothermal vents (94). These thermophiles are physiologically and phylogenetically diverse groups of microorganisms and include members of both the bacterial and archaeal domains (7,95–113). Among them, the members of *Thermococcales* are the most frequently isolated thermophiles, and these organisms are regarded as the major decomposers of organic matter within marine hot water ecosystems (99,100,104–107,109–117). They are strictly anaerobic, obligately heterotrophic microorganisms capable of using complex substrates for growth. Their growth is also strongly associated with the reduction of elemental sulfur (S^0). Within the order *Thermococcales*, three genera are known. The members of *Thermococcus* most predominantly occur as a culturable thermophilic population in the global deep-sea, hydrothermal-vent environments and are also obtained from oceanic and terrestrial oil reservoirs (118–120). Only two species of *Pyrococcus*, (*Pyrococcus horikoshii* and *Pyrococcus abyssi*), and one species of *Palaeococcus* have been cultured from the deep-sea vents and described (110,113).

The other thermophilic archaeal isolates are the sulfate-reducer *Archaeoglobus profundus*, the sulfite-reducer *A. veneficus* (101,121) and chemolithoautotrophic methanogens including the genera *Methanopyrus* (98,122) and *Methanococcus* [(95,123–126), Takai and coworkers unpublished data] within the Euryarchaeota. The thermophilic species of genera within the Crenarchaeota, such as *Desulfurococcus* (97), *Pyrodictium* (103), and *Staphylothermus* (96), are also listed in the culture collection of deep-sea, hydrothermal-vent archaea. A facultatively aerobic, obligate chemolithoautotroph *Pyrolobus fumarii* (108) is a deep-sea, hydrothermal-vent crenarchaeotic hyperthermophile currently representing the life-form with the highest temperature limit (113 °C) for growth.

Although relatively few of the fully described thermophilic isolates are classified as the domain Bacteria, the presence of various thermophilic genera is evident in deep-sea hydrothermal ecosystems. The occurrence of aerobic, heterotrophic thermophiles represented by *Bacillus*, *Thermus*, and *Thermaerobacter* has been reported till now (111,127,128). The bacterial chemolithoautotrophic thermophiles, consisting of

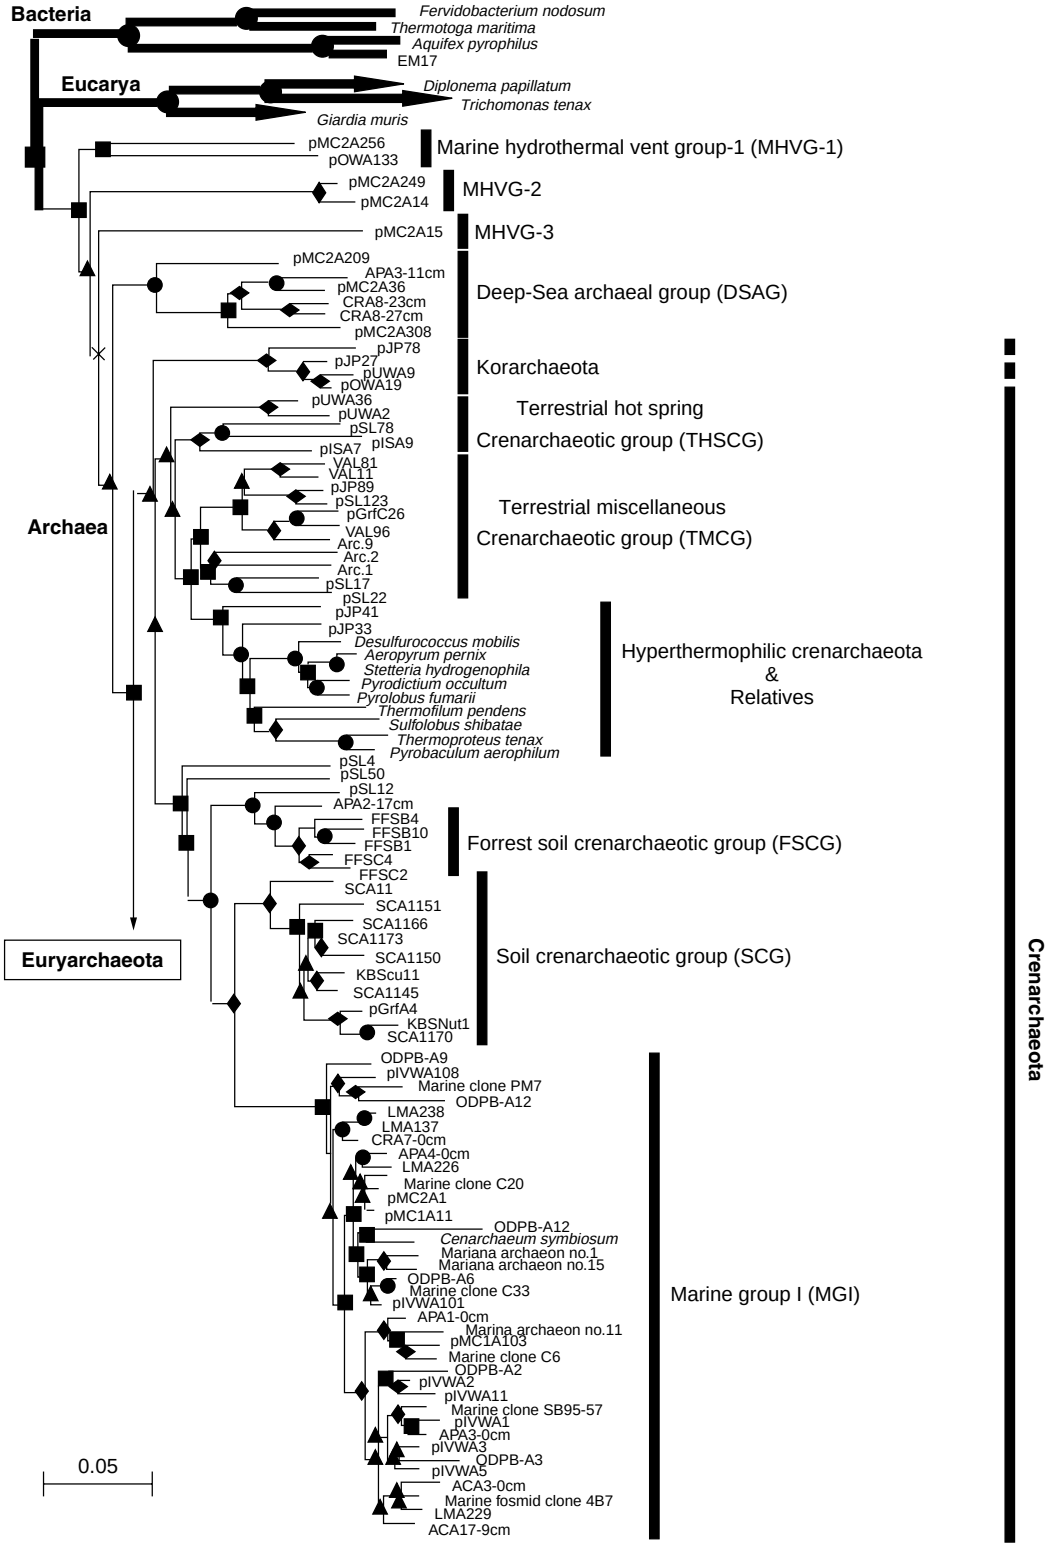

Figure 3. Phylogenetic tree based on small subunit rDNA sequences including various rDNA clones obtained from deep-sea, hydrothermal-vent environments. The tree was inferred by neighbor-joining analysis. (**a**) The tree indicates the phylogenetic relationship among the domains of Bacteria and Eukarya, the deep branches of uncultivated Archaea and the crenarchaeotic kingdom. (**b**) The tree indicates the phylogenetic organization within the euryarchaeotic kingdom. The marks on the branches represent the bootstrap confidence values: (●) greater than 80%, (■) 60 to 80%, (▲) 40 to 60%,(×) less than 40%. The scale bars indicate the expected changes per sequence position. (*Figure legend continues to next page*)

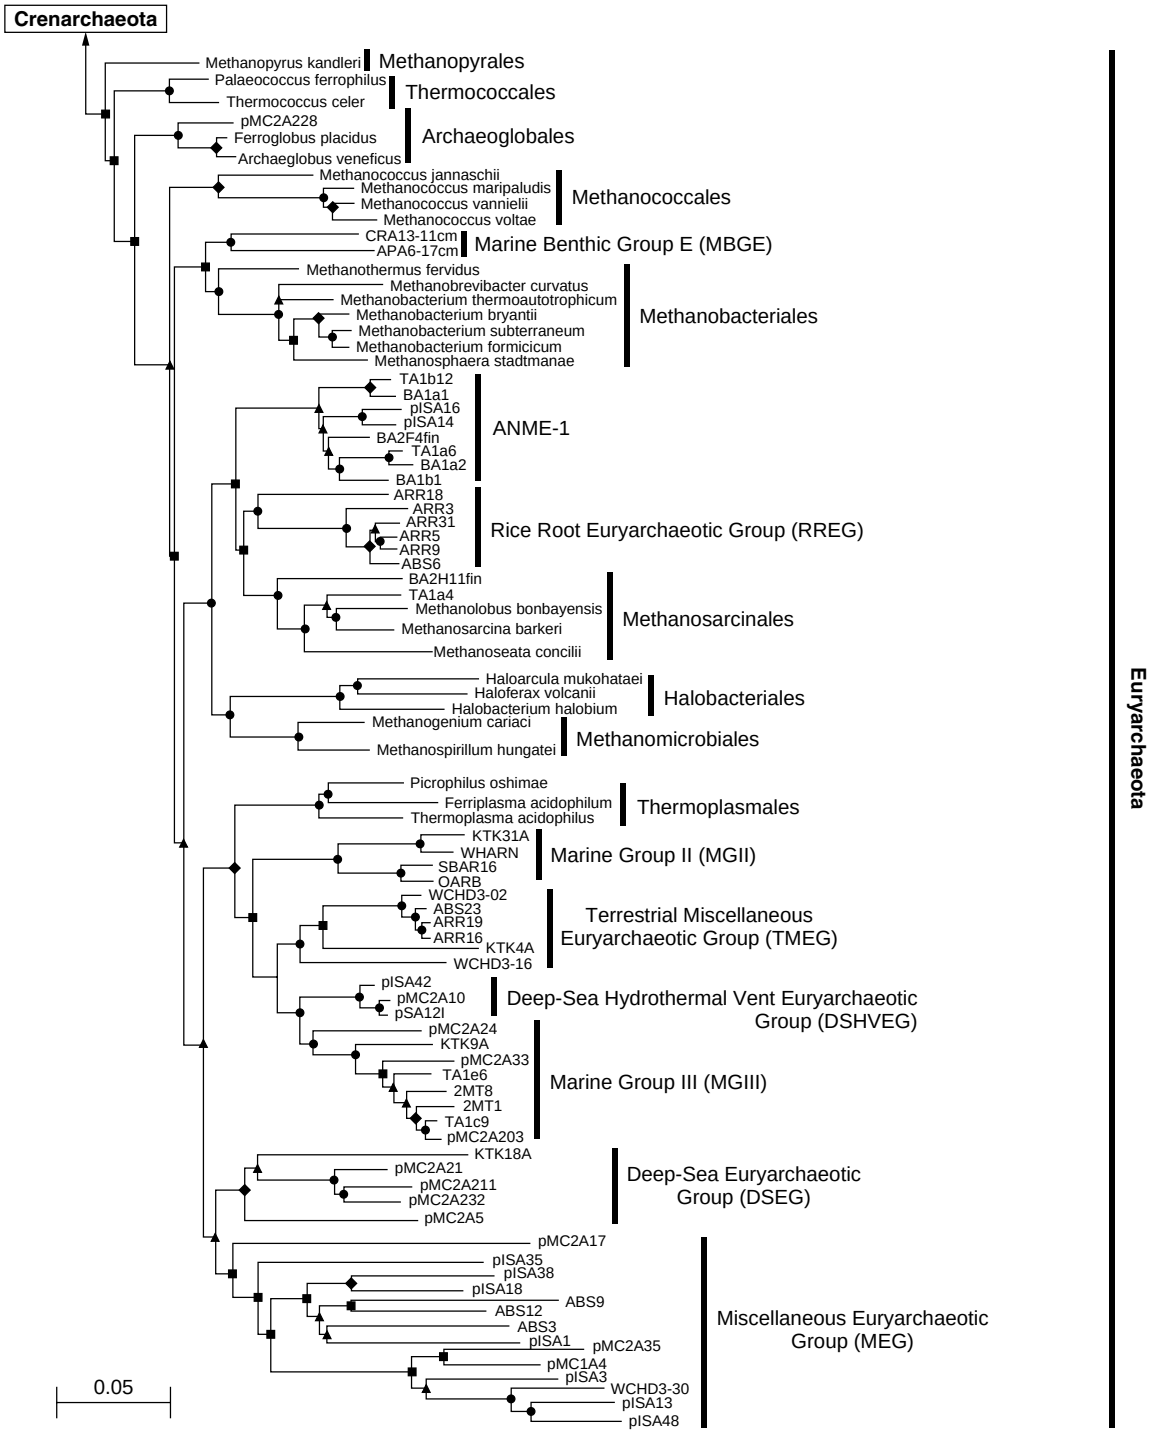

Figure 3. (*Figure legend continued from previous page)* Abbreviations indicate rDNA clones corresponding to uncultivated organisms derived from the following environments: bold pMC1A, pMC2A, pISA, and pIVWA from deep-sea, hydrothermal-vent environments (17); pOWA and pUWA from shallow-marine, hydrothermal-vent water and terrestrial acidic, hot spring water, respectively (71); pJP and pSL from sediments in Yellowstone National Park hot springs (72,73); CRA, APA, ACA, and LMA from deep-sea sediments (74); VAL from boreal forest lake water (75); soil clone SCA from agricultural soil (76); KBScul and KBSnat from soils (77); pGrifA and LMA from freshwater lake sediments (78,79); Arc from a subsurface paleosol (80); marine clones C and PM from ocean water samples (81); ODPB-A from subseafloor sediments and water (82); Mariana archaeon from sediments in Mariana Trench (83); TA and BA from marine anoxic methane-oxidizing layers (84); ARR and ABS from rice roots and paddy soils (85); KTK from deep-sea brine sediments (86); SBAR, OARB, and WHARN from coastal water (64); 2MT from salt marsh sediment (87); and WCHD from a subsurface soil (88).

microaerobic hydrogen-oxidizers of deeply branched *Aquificales* [(55), Sako pers. comm.] and anaerobic sulfur-reducing hydrogen oxidizers of *Desulfurobacterium* [(129), Sako pers. comm.], might partially sustain the deep-sea, hydrothermal-vent microbial communities as primary producers with thermophilic methanogens and hydrogen-oxidizing archaea. The facultatively sulfur-reducing, fermentative strains of *Thermosipho* (107,112) are isolated from various deep-sea, hydrothermal-vent samples. *Thermosipho* species are physiologically similar to *Thermococcales* members despite lower temperature ranges for growth of *Thermosipho*, and are often cocultivated in early enrichment cultures from the same inocula (112). It seems likely, therefore, that the thermophilic strains of the orders *Thermococcales* and *Thermotogales* share almost identical microhabitats in the deep-sea, hydrothermal-vent environments. Recently, a strain of dissimilatory iron (III)-reducing thermophiles has been successfully isolated from a black smoker chimney in the Suiyo Seamount (Takai and coworkers unpublished result).

Molecular Phylogenetic Approach

Compared with the number of culture-dependent approaches, only a few investigations have been made using molecular phylogenetic techniques for high-temperature microbial communities in deep-sea, hydrothermal-vent environments. The genetic diversity of thermophilic bacteria and archaea have been characterized using rDNA clone analyses in the microbial rDNA assemblages obtained from the vent cap system deployed in the Mid-Atlantic Ridge (16) and from vent fluids, chimneys, and sediments around Japan (17). In the vent cap experiments, most of the archaeal and bacterial phylotypes had strong phylogenetic associations with known cultivated groups of thermophiles such as *Thermococcales*, *Archaeoglobales*, *Aquificales*, and the *Desulfurobacterium* group, although several novel phylotypes having no apparent phylogenetic similarity with any other rDNA sequence were also recovered (16). Considering the deep branching and the short branch length of these novel phylotypes, they may represent uncultivated thermophilic populations in deep-sea hydrothermal vents. However, further phylogenetic analysis and its use in combination with enrichment cultivation will be required to determine their thermophily and physiological properties. The detailed analysis of archaeal diversity in the vent chimneys has provided greater genetic diversity of archaea in high-temperature microbial communities (17). It was demonstrated that several, at least division- or order-level novel, ancient lineages of archaeal phylotypes [marine hydrothermal vent group I (MHVG-1), MHVG-2, MHVG-3, and deep-sea archaeal group (DSAG) in Fig. 3a] were obtained from the distinct deep-sea, hydrothermal-vent chimneys in the Izu-Bonin Arc. The relatively high G + C content of the rDNA sequence and their limited occurrence in marine hydrothermal-vent systems strongly suggested that these ancient lineages of archaea were thermophiles. The occurrence of putative thermophilic, deep branches of archaea was partially supported by in situ whole-cell hybridization (FISH) (17). The occurrence of some of these phylotypes was detected from another deep-sea, hydrothermal-vent system in the Manus Basin (130).

The distribution of discrete thermophilic microbial communities in the deep-sea, hydrothermal-vent environment was reported by Harmsen and coworkers (131), by applying enrichment culture and whole-cell fluorescence in situ hybridization (FISH) techniques (132) to analysis of black smoker chimneys obtained from the Mid-Atlantic Ridge. The microbial-community density varied in subsamples obtained from different parts of a chimney structure, with the top part having the highest density (131). In addition, the increased density of the total archaeal population in the top part of the chimney was observed by the FISH technique. The preferred colonization patterns of potential *Thermococcales* members in the surface area and of potential *Igneococcales* members in the top parts and the vent area were also indicated by enrichment-culture techniques (131). A similar distribution pattern of microbial communities was also observed in the analysis of archaeal community structures in different microhabitats of a black smoker chimney from the Manus Basin, which is geologically and geographically distinct from those in the Mid-Atlantic Ridge (130). These results suggest that fine and detailed analyses of microhabitats dispersed a few centimeters apart, by using a combination of culture-dependent and culture-independent techniques, is necessary for future investigations on the diversity and function of microbial communities in the deep-sea, hydrothermal vent environments.

Subvent Biosphere

On the basis of several microbiological, geochemical, and geophysical observations, Deming and Baross (133) proposed the possible existence of a subvent biosphere, a viable microbial ecosystem populated with hyperthermophilic microorganisms beneath the active hydrothermal seafloor. Positive enrichments of hyperthermophiles from cold plume water shortly after an eruption event (134,135) also support the hypothesis for the subvent biosphere. This biosphere is now recognized as one of the most important research targets for elucidating the global terrestrial and oceanic subsurface biosphere. A direct approach to the subvent biosphere using a submarine drilling system, boring machine system (BMS), is now being undertaken to obtain samples from the subvent environment of active deep-sea, hydrothermal-vent sites in the Suiyo Seamount by a Japanese research team (136). This project will involve a multidisciplinary study of the subvent biosphere and may give direct evidence of its existence. However, an effective approach indirectly accessing the biosphere can also give great insight.

A deep-sea. hydrothermal-vent chimney is formed by chemical interaction between cold seawater and hot vent water. In the chimney structures and the underlying sulfide mounds, steep geochemical and physical gradients can be formed by equilibration between the vent water and the seawater, and similar environmental gradients are evidently formed in the subvent environments. Microbial rDNA showing substantial diversity was recovered from black smoker vent water in the Okinawa Trough, at a temperature greater than 300 °C which is far above the

upper temperature limit for growth of even the most hyperthermophilic archaeon, *P. fumarii* (113 °C) (17). The microbial rDNA may serve as a genetic signature indicative of the microorganisms thriving in the subvent habitats, conveyed there by vent water. It is probable, therefore, that a hydrothermal vent chimney is an environment analogous to the subvent biosphere, and elucidation of its microbial community structure will serve to characterize the features of the subvent microbial ecosystem.

The microbial population probably occurring in the subvent biosphere is believed to share similar habitats in the vent fluids and the interface between the vent fluids and the inside structures of chimneys. In these microhabitats, it was demonstrated that hyperthermophilic and extremely halophilic archaeal phylotypes were present (130). The hyperthermophilic rDNA population of the interface between the vent fluid and the chimney consisted largely of members of *Ignicoccales*, including the facultatively chemolithoautotrophic members with the highest temperature range for growth. This might indicate that these hyperthermophilic archaea thrive lithotrophically, using the reduced chemicals provided by hydrothermal activity in the extraordinary high-temperature environment. The discovery of extremely halophilic archaeal rDNA and the subsequent cultivation of halophilic microorganisms revealed the hypersaline microhabitats in the subvent biosphere. In fact, the formation of brines or salt deposits in deep-sea hydrothermal systems has been proposed (137–139). These brines or salt deposits provide suitable microhabitats for the extremely halophilic archaea. The global distribution of extremely halophilic archaea and hyperthermophilic *Thermococcales* members has been observed in nonhydrothermal pelagic subseafloor sediments (140) and in subseafloor methane hydrate core samples (Komatsu and coworkers, unpublished data). The widespread distribution patterns of *Thermococcales* in the terrestrial and oceanic subsurface oil reservoirs are other examples (118–120). The distribution of archaeal components found in the deep-sea hydrothermal or the subvent environments in global subsurface microbial communities may shed light on the origin of subsurface microorganisms and the biogeographical propagation of hyperthermophiles and extreme halophiles.

CONCLUSION

Since the first discovery of deep-sea hydrothermal vents, the investigations on deep-sea hydrothermal vents, with the dense, abundant, and diverse populations of animals and microorganisms, have fascinated numerous ocean biologists and microbiologists. With the recent development of technology and machinery for approaching deep-sea hydrothermal vents, a number of microorganisms composed primarily of thermophiles and hyperthermophiles have been isolated by cultivation techniques. In addition, advanced, culture-independent, molecular techniques have extended our view to deep-sea, hydrothermal vent microbial communities, with a great physiological and phylogenetic diversity. The microbial populations found in deep-sea hydrothermal vents were initially considered to be very limited, unusual, and specific microbial ecosystems. However, it has become apparent that microbial activities associated with these vent systems have great impact on the global microbial ecology, and on the geologic and geochemical processes of the earth, past and present. We believe in the future, because the discovery of deep-sea hydrothermal vents in the Mid Ocean Ridge revolutionized the oceanography in the twentieth century with the establishment of active plate tectonics; this knowledge of deep-sea, hydrothermal-vent ecosystems led to the elucidation of the origin of life and the exploration of extraterrestrial life in the 21st century.

Acknowledgments

We gratefully appreciate Koki Horikoshi for his overall support. We would also like to thank Fumio Inagaki, Tetsushi Komatsu, Yoshihiko Sako, and Satoshi Nakagawa for their important contributions.

HYDROTHERMAL VENTS: PROKARYOTES IN DEEP-SEA HYDROTHERMAL VENTS

Daniel Prieur
I.U.E.M. Technopole
Bresg-Iroisg
Plouzane, France

The exploration of the deep-sea, from a microbiology point of view, started with the expedition of the "Travailleur" and the "Talisman" between 1882 and 1883, which demonstrated the occurrence of living bacteria in marine sediments at a depth of 5,000 m (1). After this pioneer work, deep-sea microbiology interested only a rather small part of the marine microbiologist community, although the deep sea (oceanic waters >1,000 m deep) represents 75% of the total volume of the oceans and 62% of the Earth's biosphere (2). The cost of deep-sea technologies may probably partially explain this situation.

The deep sea is mostly characterized by low temperature, low nutrient concentration, and elevated hydrostatic pressure. For these reasons, deep-sea microbiologists focused on psychrophilic bacteria, the degradation of organic matter under in situ conditions, and responses to hydrostatic pressure (3). Barophiles and obligate barophiles, in particular, have been isolated and studied for their physiology and molecular adaptations (4). Despite several very fascinating discoveries, the deep sea remained, for many scientists, a cold, dark, almost desert-like remote environment where all processes are very slow.

This view of the deep oceans was totally modified by the discovery of the first deep hydrothermal vent fields in the Galapagos Rift (5). In February 1977, the pilot and passengers of the manned submersible Alvin were faced with totally unexpected luxuriant animal communities at a depth of 2,500 m. Two years later, at 21°N on the East Pacific Rise, another Alvin dive led to the discovery of the now famous "black smokers," sulfide chimneys from which

hot fluids vented at temperatures up to 350 °C (6). This was a new departure for deep-sea biology and microbiology, which heralded further developments in the fields of biochemistry, molecular biology, biotechnology, or even astrobiology.

PRESENTATION OF HYDROTHERMAL VENTS

Hydrothermal Processes and Fluid Composition

Physiochemical processes that occur at deep-sea hydrothermal vents have been well documented by several authors (7,8). Briefly, in areas exposed to tectonic activity, seawater penetrates through cracks of the oceanic crust, to a depth of several kilometers below the sea floor, where it interacts with hot basaltic rocks. The seawater becomes an acidic solution enriched with minerals and metallic elements. This superheated solution (kept liquid because of high hydrostatic pressure) rises up through the ocean floor. The mixing of this solution with cold oxygenated seawater at discharging points results in the precipitation of calcium sulfate and polymetallic sulfides (the black smoke) and subsequent construction of the sulfide chimneys from which fluids vent at temperatures up to 350 °C. However, it is also possible that the hot fluid may mix with cold water before reaching the sea bottom. In this case, fluids vent out at rather low temperatures (10 to 30 °C) and the surrounding areas may be colonized by invertebrate communities.

Because of rock leaching by heated seawater, vent fluids have a chemical composition different from seawater and are characterized by low pH and high concentrations of dissolved gases (hydrogen sulfide, methane, carbon monoxide, carbon dioxide, hydrogen) and minerals (silicon, iron, manganese, zinc, etc.). However, the chemical composition and the temperature of the fluid, and, consequently, smoker wall minerals, may vary according to the vent site location. Also, speed of emission may vary from several centimeters per second to 2 m/second. Recent analysis for a Mid-Atlantic Ridge hydrothermal vent (9) reported concentrations of 3 to 12 mM kg^{-1} for H_2S, 25 μM kg^{-1} for CH_4, 750 to 6,500 μM kg^{-1} for iron, or 360 to 1,140 μM kg^{-1} for manganese, all these not being detected in seawater. Also, lead, copper, and zinc had concentrations of 10 to 360 nM kg^{-1}, 10 to 40 μM kg^{-1}, and 40 to 100 μM kg^{-1}, for an enrichment factor, compared to seawater, of 1,000, 1,500, and 4,000, respectively. On the contrary, magnesium and sulfate ions are absent from vent fluids.

Distribution of Vent Fields

Hydrothermal vent fields have been discovered and explored in many parts of the oceans, but are all located along oceanic ridges or in back-arc basins. About 40 active sites have been listed (10), from which about 30 are located in the Pacific Ocean (Guaymas Basin, East Pacific Rise at 21°, 17°, 13°, 11°, 9.5°N and 13°, 20°, 23°, 26°S and the Galapagos Rift for the eastern side; Marianna Basin, Lau Basin, North Fiji Basin, and Okinawa Basin for the western side). In the Atlantic, eight sites have discovered on the Mid-Atlantic Ridge between 14°45′ and 37°51′ N. The less and more deep sites known are located in the Atlantic at depths of 800 and 3,650 m, respectively.

Deep-sea hydrothermal vents represent very complex ecosystems inhabited by complex microbial communities. However, it is usual to distinguish three main categories: nonsymbiotic mesophiles, invertebrate-associated microorganisms, and thermophilic prokaryotes.

NONSYMBIOTIC MESOPHILES

Abundance and Activity in Surrounding Waters

As is common in aquatic microbial ecology, the abundance of bacteria in the waters surrounding vent biotopes has been estimated by several methods. Direct counts indicate numbers ranging from 6×10^4 to 10^9 cells/mL, whereas viable counts are in the range of 10 to 2×10^6 cells/mL for autotrophs and 10^2 to 2×10^7 cells/mL for heterotrophs (3). Both autotrophic and heterotrophic bacterial activities were also measured, but data obtained indicated a great variability between vents and even between samples from the same vent. However, all data indicate that the rate of bacterial production in seawater was too low to support the invertebrate biomass present. Several studies also considered the bacteria present in vent plumes (some plumes are detectable several kilometers away from the vent), and particularly manganese-metabolizing bacteria (11,12). Manganese oxidizers are rather abundant in vent waters but some plume bacteria can also bind manganese in their capsular polysaccharides.

Inert Surfaces and Bacterial Mats

Early reports from dives at hydrothermal vents mentioned heavy bacterial colonization of the sea bottom and the existence of spectacular bacterial mats, particularly at the Guaymas Basin, where they may be several centimeters thick. Scanning and transmission electron microscopic observations revealed not only a diversity of morphotypes but also the presence of some metabolic types, such as nitrifying and methane-oxidizing bacteria, identified thanks to their intracellular membranes (3). Most of the morphotypes observed were filaments with or without sulfur granules. Those sulfur granules were assigned (from morphological observations only) to either *Beggiatoa* or *Thiotrix* (13,14).

The exposure of artificial surfaces (glass, stainless steel) at vent sites indicated that the rate of bacterial colonization was similar to the rate observed in coastal waters. More recently, the use of vent caps (in situ growth chambers) exposed for several days at the Mid-Atlantic Ridge has allowed us to analyze the molecular diversity of the surface microbial communities from low-temperature vents (about 20 °C). In one instance, after a 5-day exposure, 47 phylotypes were determined by restriction fragment length polymorphism on a 87 clone library, all belonging exclusively to the epsilon subclass of Proteobacteria (15). In another study of a second vent at the same Atlantic site, Epsilon Proteobacteria were found, but also phylotypes corresponding to thermophilic bacteria and Archaea (16).

Cultivated Species

Among mesophilic bacteria isolated from hydrothermal vents, some were obtained from water samples and from various surfaces or pieces of invertebrate tissues when attempting to isolate symbionts (3). It is not possible to fully describe mesophilic microbial communities from the data found in the literature. However, all reports agree that there is a wide metabolic diversity (autotrophs, heterotrophs, sulfur-oxidizers, methane-oxidizers, nitrifiers, denitrifiers, sulfate reducers, etc.) of these communities. This is not surprising if one considers the density and complexity of the animal assemblages. It is worthy of noting that mesophilic halotolerant (16 to 27% NaCl) bacteria have been found in different vent plume samples collected at the Juan de Fuca Ridge, where they may form up to 28% of the total microbial community, as estimated by means of most probable number viable counts. Several isolates have been assigned to the genus *Halomonas* and *Marinobacter*, but these have not been fully identified. These organisms may have originated from sub–sea floor brine environments (17).

From all the strains isolated, only a small number have been fully characterized and identified (Table 1).

These strains do not reflect the real biodiversity of free-living mesophiles but were obtained from experiments dedicated to autotrophy and sulfur oxidation (18,19), surface colonization (20), or specific enrichment and screening for exopolysaccharide production (21–23).

INVERTEBRATE-ASSOCIATED BACTERIA

Vestimentifera Symbionts

The large tube worm *Riftia pachyptila* is probably the most fascinating invertebrate living in the East Pacific Rise deep-sea vents, but other species of Vestimentifera have also been described, such as *Tevnia jerichonana* and *Ridgea piscesae*. The lack of a digestive tract is a characteristic they all have in common. They obtain their nourishment, instead, through a special organ called the *trophosome*, which is full of autotrophic sulfur oxidizers. Despite several attempts at cultivating them, these symbionts have so far only been characterized by their 5S and 16S ribosomal RNA (rRNA) sequences. It was demonstrated that a single endosymbiont, belonging to the gamma subclass of Proteobacteria, inhabited each host. Further experiments using DNA/DNA hybridization indicated that the symbiont did not vary in different geographical areas, but was also identical for *R. pachyptila* and *T. jerichonana*. (24). Specific nucleotidic probes have been constructed to elucidate the mode of transmission of the symbionts. No signal was detected through the polymerase chain reaction amplification of DNA from gonad or oocytes, suggesting that the bacteria might be acquired from the environment after metamorphosis and settlement of the larvae (25).

Table 1. Mesophilic Bacterial Species Isolated from Deep-Sea Hydrothermal Vents

Genus	*Species*	Metabolism	Reference
Thiomicrospira	*crunogena*	Sulfur-oxidizer	18
Thiobacillus	*hydrothermalis*	Sulfur-oxidizer	19
Hyphomicrobium	*hirschiana*	Heterotroph	20
Hyphomicrobium	*jannaschiana*	Heterotroph	20
Alteromonas	*macleodii/jijiensis*	Heterotroph	21
Alteromonas	*infernos*	Heterotroph	22
Vibrio	*diabolicus*	Heterotroph	23

Mollusc Symbionts

Independent of the functionality (*Bathymodiolus thermophilus*) or nonfunctionality (*Calyptogena magnifica*) of their digestive tracts (3), bivalve molluscs harbor monospecific assemblages of endosymbionts (gamma subclass of the Proteobacteria) within their gill filaments. Whereas sulfur-oxidizing endosymbionts are found in most cases, it appears that some Mytilid populations can also harbor methanotrophic endosymbionts (26). It has also been demonstrated for Mytilids from the Snake Pit vent site on the Mid-Atlantic Ridge, that both metabolic types can coexist within the bacteriocytes in the gill filaments of the same mussel (27). Symbiont transmission was investigated for *C. magnifica* and *B. thermophilus* using specific 16S rRNA probes. Symbionts were detected in the follicle cells surrounding the oocytes, providing strong evidence for the vertical transmission between parents and progeny (28).

Crustaceans

Dense clouds of shrimps swarming close to the active chimneys and beehive-like structures are typical of the Mid-Atlantic Ridge vent sites. *Rimicaris exoculata*, one of these shrimps, has been shown to harbor dense epibiotic bacterial populations composed of rods and different-sized filaments on their hypertrophied mouth appendices (29). Again, attempts at cultivation were not successful, but the epibionts were characterized from their 16S rRNA. In fact, the different morphotypes appeared to correspond to a single phylotype belonging to the epsilon subclass of the Proteobacteria (30). Data obtained from sequence analysis were confirmed by in situ hybridization, which indicated that the epibionts could correspond to either a single pleomorphic species or very similar species with similar 16S rRNA. Interestingly, it was found that this phylotype was also abundant on the sulfide rocks within the same vent area. Although the relationship between the shrimps and their epibionts has not been completely elucidated, the most probable significance of this association is nutritional (31).

Polychaetes

Whereas Vestimentifera and molluscs live in warm (10 to 20 °C) waters and the shrimps swarm around active chimneys, Polychaetous annelids (*Alvinella pompejana*) build their tubes onto the wall of active smokers and are exposed to rather elevated temperatures and high concentrations of toxic compounds (32). Measurements of temperatures for the worm are not so easy, and temperatures ranges of 25 to 40 °C and 40 to 50 °C or

even 70 to 80 °C have been reported for the opening of the tubes and within the worm colonies, respectively. A single individual of *A. pompejana* has even been observed twisted on the temperature probe of the submersible Nautile, whereas the probe indicated a temperature of 100 °C. Although the true optimal temperature for the life cycle of this organism has not yet been determined, it is probably the most eurythermal or thermotolerant metazoan species presently known (33).

Zoologists who first described this novel species, using scanning electron microscopy for fine observation, were surprised by the abundance of epibiotic microorganisms living on the dorsal parts of the worm integuments. Rod-shaped, prosthecated, spiral-curved, sheathed, and unsheathed filaments were scattered on the worm surface, whereas more specific filamentous epibionts were found associated with cuticular extensions in the intersegmental spaces (34). Following these morphological studies, culture methods revealed a very metabolically diversified community, particularly adapted to elevated heavy metal concentrations, and displaying resistance to arsenate, cadmium, silver, zinc, or copper (35). About 20% of the isolates (*Acinetobacter, Alteromonas, Pseudomonas*, or *Vibrio*) harbored one to five plasmids of sizes ranging from 4.6 to 157 kb. Hybridization experiments indicated that plasmids of identical sizes existed within different genera, indicating a probable transfer of genetic elements (36,37). However, the dominant filamentous morphotypes again escaped attempts of being cultured and so are only characterized by their 16S rRNA. Four dominant clone families (32) represented 65% of the clone library. These were placed into two different clades within the epsilon subclass of Proteobacteria (38). Only few genera are known for this subclass. These are mostly adapted to low oxygen concentration environments, and are involved in several types of sulfur compounds' metabolisms, under both microaerophilic and anaerobic conditions. The two dominant phylotypes were detected from worm specimens collected in different geographical areas. In situ hybridizations indicated that they represented the dominant forms living on the dorsal integument of the worm. These two phylotypes were also detected on *Paralvinella* sp. integument, *R. pachyptila* tube and rock surfaces, and on *Alvinella caudata* integuments, indicating that these epibionts are not obligate companions of *A. pompejana* (39). The role and significance of this association are yet to be fully elucidated.

THERMOPHILIC PROKARYOTES

Abundance and Distribution

As it will be shown in what follows, hyperthermophilic Prokaryotes have been isolated mostly from debris or pieces of active smokers or hot sediments. Although the real habitat of these organisms is not totally known (see the section on Hydrostatic pressure), it is well documented that thermophilic and hyperthermophilic organisms are present within the mineral walls of the active black smokers. Their abundance has been evaluated using various methods, including lipid analysis, direct counts, cultures, and molecular probes.

Membrane lipids are often used as biomarkers to estimate bacterial abundance, or even to detect specific taxa. Lipids have been detected in all sections of a flange structure collected from the Juan de Fuca Ridge (40). Because Archaea typically possess lipids with ether bonds, the ether/ester lipid ratio is an indication of Archaea versus Bacteria abundance. In this example, archaeal lipids were present in all layers of the flange, with an exception of the external layers; the highest concentration was found in the middle parts. The ratio of diether to tetraether lipids increased from the coolest to the hottest sections analyzed. From the lipid concentrations measured, the abundance of prokaryotic cells within the flange was estimated at 10^6 to 10^8 cells per gram (41). Another set of measures indicated bacterial densities above 10^5 and archaeal densities in the range of 10^7 to 10^9 cells per gram of smoker wall (dry weight) (42). All these data are consistent with a distribution of bacteria mostly in the outer parts (cooler) of the smoker walls and archaea in the inner (warmer), with a decrease in the central parts (too hot).

Other estimations were based on direct cell counts using fluorochromes such as acridine orange or DAPI. Cell densities of about 10^9 to 10^{10} per gram (d.w.) were obtained for the outer parts of the walls, but only 10^5 per gram within the chimney wall; densities decreased below the level of detection (10^3 to 10^4) in the very inner parts of the samples (43).

Viable counts for anaerobic heterotrophic sulfur-reducing cocci were also performed and gave densities up to 3×10^6 cells per gram (d.w.) for heterotrophic sulfur-reducing cocci (44). These results were consistent with those obtained by the same research team using whole-cell hybridization with domain- and kingdom-specific oligonucleotide probes. The upper and outer parts of the sample appeared to be the most heavily colonized. Bacteria and Archaea cell numbers were almost similar and Crenarchaeota, when detectable, remained at a rather low level (maximum 19% of Archaea for the inner outer part of the sample).

Probes specific to the genus *Bacillus*, different *Thermus* species, the genus *Thermotoga*, and the order Aquificales were also used on the same samples (45). Although the two first genera had been detected by culture methods, no positive signals were noted using their specific probes, and only one sample appeared to contain cells hybridizing with the *Thermotoga* probe (also confirmed by enrichment cultures). The combination of the Aquificales-specific probe and a Bacteria-specific probe (that does not hybridize with the described species of Aquificales) made it possible to estimate that cells responding to these two probes (including cells of the genus *Desulfurobacterium* (46), see subsequently) may represent up to 40% of the bacterial population.

The Bacteria Domain

As has been reported earlier, the temperature gradient at deep-sea hydrothermal vents is particularly steep, between 350 °C within the active smokers to 2 °C, some decimeters away, for the cold deep-sea water. It is also estimated that the boundary between the oxic and

anoxic zones occurs at about 30 °C, which eliminates the possibility of a niche for aerobic (or facultative) thermophiles. However, certain active smokers (beehives), particularly at the Mid-Atlantic Ridge, have a porous structure that allows some entry of cold oxygenated water, and consequently the existence of some warm (60 to 70°C) oxygenated habitats within the beehives. These structures allowed us to isolate the first aerobic thermophiles from deep-sea vent habitats.

***Bacillus* sp.** Spore-forming facultative aerobic bacilli have been isolated from Mid-Atlantic Ridge smoker samples, from sediments collected in the Guaymas Basin, and from smoker samples from the Lau Basin (47). Although not completely characterized, these organisms were assigned to the genus *Bacillus*. They appear to differ from reference strains of thermophilic bacilli (with the exception of several strains from the Lau Basin) when compared by means of numerical taxonomy. Although it is always difficult to come to a conclusion regarding the real origin of spore-forming bacteria, particularly from aquatic habitats, the results of the numerical taxonomy study lead us to conclude the existence of novel and distinct thermophilic spore-forming communities at least in the Mid-Atlantic Ridge and Guaymas samples.

***Thermus* sp.** Bacteria belonging to the genus *Thermus* have been isolated from all thermal environments of the world, including man-made systems. For reasons reported earlier, aerobic thermophiles were not expected in the black smoker habitats until the beehive structures with potential habitats for such organisms were described. Non–spore-forming bacteria, growing aerobically and heterotrophically with a maximum temperature range from 70 to 80 °C, were isolated from the Mid-Atlantic Ridge beehives and Guaymas Basin sediments (48). From a numerical taxonomy study, several strains were assigned to the genus *Thermus*; one of them was later identified by means of DNA/DNA hybridizations as *Thermus thermophilus* (49), extending to the deep sea the already ubiquitous distribution of this organism.

***Thermotoga* sp.** Several species of Thermotoga (50) have been described from coastal hot springs and from other hot habitats such as oil reservoirs. This genus has rarely been reported from deep-sea vent habitats, and the strains, enriched or isolated, never identified.

Thermosipho melaniensis. *Thermosipho melaniensis* 5(51) has been isolated from the gills of a vent mussel *Bathymodiolus brevior* collected in the Lau Basin (1,887 m). This organism cannot be considered as a commensal of the mussel, rather it is an organism trapped within the particles collected by the filtration organs of this bivalve. The cells are gram-negative rods (0.4 to 0.6/1 to 3.5 μm), surrounded by a sheathlike structure and ballooning over the ends. They occur singly, in pairs, or in short chains of up to five cells. They are strict anaerobes and grow heterotrophically on complex organic substrates such as yeast extract or brain-heart infusion. Growth can be also supported by malt extract, tryptone, or carbohydrates, if supplemented with yeast extract. Hydrogen is a growth inhibitor, but inhibition is overcome by elemental sulfur respiration, and consequently hydrogen sulfide production. Growth occurs between 45 and 80 °C, with an optimum at 70 °C (doubling time 10 minutes). Optimum pH and salt concentration are 6.5 to 7.5 and 3%, respectively. DNA base composition is 30.5 mol% G + C. Type strain BI429 has been deposited at the Collection of Institut Pasteur (CIP 104,789).

Thermosipho japonicus. *Thermosipho japonicus* (52) was isolated from deep vents located in the Okinawa area (972 m). Cells are slightly curved nonmotile rods (0.5/3 to 4 μm), surrounded by a sheathlike structure. This organism is a chemoorganotroph and uses yeast extract, peptone, tryptone, or casein as carbon and energy sources. In addition to these complex substrates, this organism also uses maltose, glucose, galactose, starch, and so on. Growth is enhanced in the presence of sulfur or thiosulfate and is inhibited by hydrogen. The temperature range for growth is 45 to 80 °C with an optimum at 72 °C. The optimum pH is 7 to 7.5, and the optimum salt concentration is 4%. The DNA base composition is 31.4 mol% G + C. Type strain IHB1 has been deposited at the Japan Collection of microorganisms (JCM 10,495).

Desulfurobacterium thermolithotrophicum. This novel genus (46) was isolated from a smoker sample collected at the Mid-Atlantic Ridge (3,500 m). Cells are gram-negative and occur singly or in pairs as small highly motile rods (0.4 to 0.5/1 to 2 μm). They are obligate chemolithoautotrophs that use hydrogen as electron donor and sulfur, thiosulfate, or sulfite as electron acceptors. Growth occurs between 40 and 75 °C (optimum 70 °C, doubling time 135 minutes). The optimum pH is about 6.25, and the optimum salt concentration is 3.5%. The DNA base composition is 35 mol% G + C. Type strain BSA has been deposited at the German collection of microorganisms (DSM 11,699).

Marinitoga carminata. *Marinitoga* (53) represents a novel genus within the Thermotogales. It was obtained from a chimney sample collected at the Mid-Atlantic Ridge (980 m). Cells are rod-shaped with a sheathlike structure (0.5 to 1/1 to 3 μm). They are obligate anaerobes and chemoorganotrophs, fermenting gluten, peptone, brain-heart infusion, tryptone and saccharose, glucose, fructose, maltose, and cellobiose in the presence of yeast extract. Carbon dioxide, hydrogen, acetate, isovalerate, and isobutyrate are formed during glucose fermentation. Growth occurs between 25 and 65 °C with an optimum at 55 °C. The optimum pH is 7, and the NaCl concentration 2%. The DNA base composition is 29 mol% G + C. Type strain MV 1,075 has been deposited at the Collection of Institut Pasteur (CNCM I-2,413) and the German collection of microorganisms (DSM 13,578).

Caloranaerobacterazorensis. This novel genus (54) was obtained from a Mid-Atlantic Ridge chimney (1,650 m). Cells appear as motile rods (0.3 to 0.5/0.5 to 2 μm) by means of peritrichous flagella. They stain gram positive, but heat-resistant spores were never observed,

and cultures do not survive to heat exposure. 16S ribosomal DNA (rDNA) sequence analysis placed this organism within cluster XII of the genus *Clostridium*. This organism is strictly anaerobic and chemo-organotrophic, and ferments gluten, brain-heart infusion, glucose, starch, xylan, and pyruvate. Acetate, isovalerate, butyrate, and propionate are formed during glucose fermentation. The temperature range for growth is 40 to 70 °C (optimum 65 °C). The optimum pH is 7, and the optimum salt concentration is 2% NaCl. The DNA base composition is 27 mol% G + C, one of the lowest for a thermophilic anaerobic bacterium. Type strain MV 1,087 has been deposited at American Type Culture Collection (ATCC) and the German collection of microorganisms (DSM).

The Archaea Domain

Because of the very elevated temperatures of hot fluids recorded at deep-sea hydrothermal vents, many microbiologists focused on hyperthermophilic organisms and were rather successful with the isolation of novel genera and species of Archaea.

Methanopyrus kandleri. *Methanopyrus kandleri* (55) was isolated from sediment samples collected in the Guaymas Basin (2,000 m) and from a shallow marine hydrothermal system at Kolbeinsey Ridge (106 m, Iceland). Cells are rod-shaped with a gram-positive structure, 0.5 μm in diameter, and 2- to 14-mm long (average 8 to 10) occurring singly or in chains of up to 70 cells. Polar tufts of flagella make the cells motile. They are strictly anaerobic and form methane from hydrogen and carbon dioxide. Growth is stimulated by yeast extract and bacterial cell homogenates. H_2S is formed in the presence of sulfur, but cells tend to lyse. 16S rRNA sequence analysis indicated that this organism was not related to any of the three methanogenic lineages already known. Growth occurs between 84 and 110 °C with an optimum at 98 °C (doubling time: 50 minutes). The optimum pH and salt concentration are 6.5 and 2%, respectively. The DNA base composition is 60 mol% G + C. The type strain AV 19 has been deposited at the German collection of Microorganisms (DSM 6,324).

Methanococcus jannaschii. *Methanococcus jannaschii* (56) was obtained from a smoker collected on the East Pacific Rise at 20°50′ (2,600 m). Cells are irregular cocci, motile, with a complex flagella system. They are obligate anaerobes that produce methane from hydrogen and carbon dioxide. No organic compound is required, and do not stimulate growth. But selenium stimulates growth significantly, and sulfide is required. The temperature range for growth is 50 to 86 °C with an optimum at 85 °C for a doubling time of 25 minutes. The optimum pH is 6.0, and the optimum salt concentration is 0.5 M. The DNA base composition is 31 mol% G + C. The type strain JAL-1 has been deposited at the German collection of microorganisms (DSM 2,661).

Methanococcus infernus. *Methanococcus infernus* (57) is an autotrophic methanogen isolated from a hydrothermal chimney collected at the Mid-Atlantic Ridge (14°45′N, 3,000 m). Cells are coccoids (1 to 3 μm), single or in pair, and highly motile, with tufts of flagella. This organism is strictly anaerobic, and uses hydrogen and carbon dioxide as energy and carbon sources to produce methane. Growth is stimulated by selenate, tungstate, and yeast extract; sulfur is reduced to H_2S in the presence of carbon dioxide and hydrogen. Growth occurs between 55 and 91 °C with an optimum around 85 °C and a doubling time of 35 to 40 minutes. The optimum pH and salt concentration are 6.5 and 2.5%, respectively. The DNA base composition of the type strain is 33 mol% G + C. The type strain has been deposited at the German collection of microorganisms (DSM 11,812).

Methanococcus vulcanius. *Methanococcus vulcanius* (58) has been isolated from an active smoker collected on the East Pacific Rise (13°N, 2,600 m). It is an autotrophic methanogen, showing coccoid cells (1 to 3 μm), motile by means of three tufts of flagella. It is a strict anaerobe that produces methane from hydrogen and carbon dioxide as energy and carbon sources. Growth is stimulated by arsenate, tungstate, and yeast extract; hydrogen sulfide is produced from sulfur in the presence of hydrogen and carbon dioxide. Growth occurs between 49 and 89 °C, with an optimum at 80 °C (doubling time 45 minutes). The optimum pH and salt concentration are 6.5 and 2.5%, respectively. The DNA base composition of the type strain is 31 mol% G + C. The type strain has been deposited at the German collection of microorganisms (DSM 12,094).

Methanococcus fervens. This species (58) was first described as strain AG86, and was isolated from hot sediments collected in the Guaymas Basin (2,003 m). It was assigned to a novel species when chosen as a reference strain for the description of *M. vulcanius*. Cells are regular or irregular motile cocci. They use hydrogen and carbon dioxide to produce methane, and growth is stimulated by yeast extract, casamino acids, trypticase, selenite, and tungstate. Growth occurs between 48 and 92 °C, with an optimum at 85 °C (doubling time 20 to 30 minutes). The optimum pH and salt concentration are 6.5 and 3%, respectively. The DNA base composition of the type strain is 33 mol% G + C. Strain AG 86 is deposited at the German collection of microorganisms (DSM 4,213).

With the description of *Archaeoglobus fulgidus*, a novel lineage within the Euryarchaeota was reported, and was presented as a tentative missing link between the methanogens and the sulfur-metabolizing Archaea. Two novel species have been isolated from deep-sea vents.

Archaeoglobus profundus. *Archaeoglobus profundus* (59) was isolated from smokers and hot sediments collected at the Guaymas Basin (2,000 m). Similarly to *A. fulgidus, A. profundus* is a sulfate reducer which shows a blue-green fluorescence at 420 nm. Cells are nonmotile irregular cocci (about 1.3 μm). This species is mixotrophic: H_2 is required as an electron donor, but acetate, lactate, pyruvate, yeast extract, meat extract, or peptone can be used as organic carbon sources. Thiosulftate and sulfite may also serve as electron acceptors. Elemental sulfur is reduced, although it inhibits growth. The temperature range for growth is

65 to 90 °C with an optimum around 82 °C. The optimum pH and salt concentration are 6.0 and 1.8%, respectively. The DNA base composition is 41 mol% G + C. The type strain, AV18 has been deposited at the German collection of microorganisms (DSM 5,631).

Archaeoglobus veneficus. *Archaeoglobus profundus* (60) was isolated from black smoker samples collected at the Mid-Atlantic Ridge (3,500 m). Cells are very irregular cocci to triangular plate–shaped lobes (0.5 to 1.2 μm), and are motile with polar flagella. They show a blue-green fluorescence at 436 nm. They grow chemolithoautotrophically with molecular hydrogen as the electron donor and sulfite or thiosulfate as the electron acceptors. They show organotrophic respiration with sulfite as the electron acceptor, and formate, acetate, pyruvate, isopropanol, ethanol, fumarate, and glucose as the electron donors and carbon sources. They never use sulfate, nitrate, or nitrite as electron acceptors; elemental sulfur inhibits growth. End products are hydrogen sulfide and, to a lesser extent, methane. Growth occurs between 65 and 85 °C (optimum 80 °C), and optimally at pH 7 and 2% NaCl. The DNA base composition is 45 mol% G + C. The type strain SNP6 has been deposited at the German collection of microorganisms (DSM 11,195).

Among all thermophilic and hyperthermophilic organisms isolated so far, Thermococcales are represented by a large number of species. Several reasons may be suggested to explain this situation. Thermococcales are probably abundant within geothermally heated systems where they show a great specific diversity; they are relatively easy to handle in the laboratory (although strict anaerobes, they resist to exposure to oxygen at temperatures below temperatures allowing growth), they are organotrophic, grow rather quickly and represent a great potential for thermophilic enzymes, and consequently have been enriched intensively by microbiologists. They are distributed within three genera: *Pyrococcus, Thermococcus*, and *Palaeococcus*.

Pyrococcus abyssi. *Pyrococcus abyssi* (61) was isolated from a fluid sample (more probably a chimney particle contained in the sample) collected in the North Fiji Basin (2,000 m). Cells are slightly irregular cocci (0.8 to 2 μm), motile by means of a polar tuft of flagella. They are obligate anaerobes, fermenting organic compounds (tryptone, gelatin, amino acids). H_2 produced during fermentation inhibits growth, but addition of elemental sulfur, cystine, or polysulfides in the medium prevents inhibition. In that case, H_2S and mercaptans are produced. Growth occurs between 67 and 102 °C (optimum 96 °C, 33 minutes doubling time). The optimum pH and salt concentration are 6.8 and 3%, respectively. The DNA base composition is 45 mol% G + C. Type strain GE5 has been deposited at the Collection of Institut Pasteur (France) (CNCM I-1,302).

Pyrococcus horikoshii. *Pyrococcus horikoshii* (62) was isolated from hydrothermal fluids collected at the Okinawa Trough vents at 1,395 m. Cell morphology, motility, and metabolism are rather similar to *P. abyssi*. However, *P. horikoshii* requires tryptophan for growth. Growth occurs between 80 and 102 °C, with an optimum at 98 °C. The optimum pH and salt concentration are 7 and 2.4%, respectively. Elemental sulfur is not essential, but greatly stimulates growth. The DNA base composition is 44 mol% G + C. The type strain has been deposited at the Japanese collection (JCM 9,974).

Pyrococcus glycovorans. This species is very similar to the two other deep-sea *Pyrococcus* with respect to its morphology and metabolism. However, in addition to proteinaceous compounds, *Pyrococcus glycovorans* (63) ferments carbohydrates, particularly glucose. Growth occurs between 75 and 104°C, with an optimum at 95 °C. The optimum pH and salt concentration are 7.5 and 3%, respectively. The DNA base composition is 47 mol% G + C. Type strain AL 585 has been deposited in the Institut Pasteur collection with the number CNCM I-2,120.

Thermococcus profundus. This strain (64) was isolated from a vent system at the middle Okinawa Trough (1,395 m). Morphologically this organism is very close to the earlier-mentioned species of *Pyrococcus* (coccoid motile cells of 1 to 2 μm). It is also an anaerobic chemorganotroph that ferments organic compounds (tryptone, peptone, casein, gelatin, yeast extract or pyruvate, maltose, starch). Growth was observed between 50 and 90 °C, with an optimum at 80 °C. The optimum pH and salt concentration are 7.5 and 2 to 4%, respectively. The DNA base composition is 52.5 mol% G + C. Type strain is numbered DT 5,432.

Thermococcus chitonophagus. This species (65) was obtained from a sample collected at 20°50′N on the East Pacific Rise, containing smoker material and vestmentifera tube pieces, inoculated into a chitin-supplemented medium. In addition to features common to the Thermococcales described earlier, *Th. chitonophagus* ferments chitin with hydrogen, carbon dioxide, NH_3, acetate, and formate as end products, plus hydrogen sulfide when grown in the presence of sulfur. Growth occurs between 60 and 93 °C (optimum at 85 °C). The optimum pH and salt concentration are 6.7 and 2%, respectively. The DNA base composition is 46.5 mol% G + C. The type strain GC74 has been deposited at the German collection (DSM 10,152).

Thermococcus peptonophilus. *Thermococcus peptonophilus* (66) was isolated from hydrothermal systems in the western Pacific Ocean (Izu-Bonin and South Mariana Trough Areas). The species is distinct from other *Thermococcus* as it only grows on complex protein compounds and peptides, and cannot use amino acids, organic acids, or carbohydrates. Temperature range for growth is 60 to 100 °C (optimum 85 °C). The optimum pH and salt concentration are 6 and 3%, respectively. The DNA base composition is 52 mol% G + C. Type strain OG-1 is registered at the Japanese collection of microorganisms (JCM 9,653).

Thermococcus fumicolans. *Thermococcus fumicolans* (67) was isolated from the North Fiji Basin (2,000 m).

Although rather similar by certain features to the *Thermococcus* species described earlier, *Th. fumicolans* exhibits some specific physiological features: temperature range for growth is 73 to 103 °C (optimum 85 °C); the optimum pH is 8, and the optimum salt concentration varies from 1.3 to 2.6% NaCl. The DNA base composition is 54 to 55 mol% G + C. Type strain ST557 has been deposited at the Collection of Institut Pasteur (CIP 104,680).

Thermococcus hydrothermalis. *Thermococcus hydrothermalis* (68) was obtained from a smoker sample collected at 21°N on the East Pacific Rise. The strain was selected among other Thermococcales for the presence of a nicotinamide adenine dinucleotide phosphate–dependent alcohol dehydrogenase activity. Although close to other known *Thermococcus* species, *Th. hydrothermalis* was assigned to a novel species that grows between 55 and 100 °C (optimum 85 °C); the optimum pH is 6, and the optimum salt concentration is 3 to 4%. The DNA base composition is 58 mol% G + C. Type strain AL662 is registered at the Insitut Pasteur Collection (CNCM 11,319).

Thermococcus guaymasensis. This species (69) has been isolated from hot marine sediments at the Guaymas Basin hydrothermal vent site (2,000 m depth) in the Gulf of California. Cells are coccoids (1.0 to 3.0 μm), nonmotile, and occur mainly as single cells or as diploid forms. They are strict anaerobes and use proteinaceous substrates (yeast extract, and trypticase, but also casein, dextrose, maltose, and starch) in the presence of elemental sulfur. With yeast extract, trypticase, and sulfur, the end products are acetate, propionate, isobutyrate, isovalerate, carbon dioxide, and H_2S, whereas with the other substrates, only acetate, carbon dioxide, and H_2S are formed. Growth occurs from 56 to 90 °C, with an optimum at 88 °C. The optimum pH and salt concentration are 7.2 and 3.0%, respectively. The DNA base composition is 46.0 mol% G + C. The type strain has been deposited at both the German and the Japanese collections of microorganisms (DSM 11,113 and JCM 10,136, respectively).

Thermococus aggregans. *Thermococcus aggregans* (49) was isolated from a hot sediment sample collected in the Guaymas Basin (2,000 m). Cells are coccoid (1.0 to 1.5 μm), nonmotile, occur as single cells or as diploid forms, but may produce aggregates of up to 50 cells. Substrates and end products are similar to those used and produced by *Th. guaymasensis*. Growth occurs from 60 to 94 °C with an optimum at 88 °C. The optimum pH and salt concentration are 7.0 and 2.5%, respectively. The DNA base composition is 42.0 mol% G + C. The type strain has been deposited at the German and the Japanese collections of microorganisms (DSM 10,597 and JCM 10,137, respectively).

Thermococcus barossii. *Thermococcus barossii* (70) was obtained from rock fragments of a hydrothermal vent flange formation located at the Juan de Fuca Ridge. Cells have the typical coccoid morphology of Thermococcales but are apparently nonmotile. For this species elemental sulfur is required whereas it only stimulates growth of other deep-sea *Thermococcus* species. Temperature range for growth is 60 to 92 °C, with an optimum at 82.5 °C. The optimum pH varies from 6.5 to 7.5, and cell density was not affected by salt concentrations between 1 and 4% NaCl. The DNA base composition is 60 mol% G + C.

Thermococcus siculi. *Thermococcus siculi* (71) was obtained from the Mid-Okinawa Trough hydrothermal vents (1,394 m). Although it may resemble several already described species of *Thermococcus* in some criteria, *Th. siculi* features do not totally match with those species, and this has been confirmed by DNA/DNA hybridizations with close species. Growth only occurs on proteinaceous substrates in the temperature range 50 to 93 °C, with an optimum at 85 °C. The optimum pH is 7.0, and salt concentrations between 1 and 4% NaCl are required (lysis occurs for concentrations below 1%). The DNA base composition is 55.8 mol% G + C. The type strain has been deposited at the German collection (DSM 12,349).

Thermococcus barophilus. *Thermococcus barophilus* (72) has been isolated from a smoker sample collected at the Mid-Atlantic Ridge (3,500 m). Morphologically and metabolically it is a very classic *Thermococcus* species. However, it has been purified after enrichment and subcultures, all performed under elevated hydrostatic pressure (40 MPa). Although it also grows under atmospheric pressure in a temperature range of 48 to 95 °C, with an optimum at 85 °C, its growth rate under hydrostatic pressure is twofold higher, for the same optimum at 85 °C. Hydrostatic pressure is required for growth between 95 and 100 °C. The DNA base composition is 37.1 mol% G + C. Type strain MP has been deposited at the Collection of Institut Pasteur (CNCM I-1,946).

Palaeococcus ferrophilus. This strain (73) representing a novel genus within the Thermococcales was isolated from a smoker collected in Ogasawara-Bonin Arc (1,388 m). Although it closely resembles to other Thermococcales, it is physiologically different by its requirement for sulfur, especially ferric iron. In the latter case, H_2 is produced during fermentation of proteinaceous substrates. It is noticeable that contrary to other microorganisms, including several hyperthermophilic Archaea that utilize ferrous iron as an electron donor or ferric iron as an electron acceptor, *Palaeococcus ferrophilus* does not use iron in such a way. Although the role of iron has not been totally elucidated, it has been suggested that "relatively high concentrations of ferrous iron might be required for proper operation of the iron(II)-regulated fermentation pathways of *P. ferrophilus*." Temperature range for growth of this species is 60 to 88 °C, with the optimum being 83 °C. The optimum pH and salt concentration are 6.0 and 4.3%, respectively. The DNA base composition is 53.5 mol% G + C. Type strain DMJ has been deposited at the Japan Collection of microorganisms (JCM 10,246).

***Desulfurococcus* sp.** Four species of *Desulfurococcus* (74) have been isolated from nonabyssal hot environments, but deep-sea strains assigned to this genus have never been identified fully. Cells are irregular cocci and

may or may not be motile. They have been reported from various vent sites in the Atlantic and Pacific oceans. They are strictly anaerobes, chemoorganotrophs, and only ferment complex proteinaceous substrates, preferentially but not obligately in the presence of sulfur. They grow in the range of 50 to 95 °C with an optimum at 85 or 90 °C.

Staphylothermus marinus. *Staphylothermus marinus* (75) has been isolated from coastal geothermal areas, but also from the East Pacific Rise at 11°N (2,500 m). Cells are slightly irregular cocci, nonmotile, occurring singly, in pairs or in chains and aggregates up to 100 cells. Cell size may vary from 0.5 to 15 μm according to culture conditions. They are strictly anaerobes and sulfur dependent. They grow heterotrophically on complex proteinaceous substrates, forming carbon dioxide, acetate, isovalerate, and H_2S. Growth occurs between 65 and 98 °C with an optimum at 92 °C and a doubling time of 270 minutes. The optimum pH is 6.5, and the optimum salt concentration is 1.5%. The DNA base composition is 35 mol% G + C. Type strains F1 and Al2 have been deposited at the German collection of microorganisms (DSM 3,639 and DSM 3,666, respectively).

Pyrodictium abyssi. This novel species of *Pyrodictium* (76) was isolated from hot sediments and smokers collected in the Guaymas Basin (2,000 m) but also from hot sediments collected at the Kolbeinsey Ridge (Iceland, 103 to 106 m). Cells are polymorphous disk-shaped (1 to 2 μm) with flat protrusions. This species is strictly heterotrophic and ferments proteins, carbohydrates, cell extracts, acetate, and formate, growth being stimulated by H_2. Fermentation products from yeast and meat extracts and H_2 are isovalerate, isobutyrate, butanol, and carbon dioxide. In the presence of H_2, H_2S is formed from S^0 or $S_2O_3^{2-}$. Growth occurs between 80 and 110 °C (optimum 97 °C); the optimum pH is 5.5, and the optimum salt concentration is 2% NaCl. The DNA base composition is 60 mol% G + C. Type strain AV2, isolated from the Guaymas Basin, has been deposited at the German collection of microorganisms (DSM 6,158).

Pyrolobus fumarii. *Pyrobolus fumarii* (77) was isolated from a chimney sample collected at the Mid-Atlantic Ridge (3,650 m). Cells are nonmotile, irregular coccoid-shaped (0.7 to 2.5 μm). This novel genus is a strict chemolithoautotroph using H_2 as the electron donor under microaerophilic conditions or anaerobic conditions with NO_3^- or $S_2O_3^{2-}$ as the electron acceptors. Growth is not stimulated by organic compounds and is even inhibited by acetate, pyruvate, glucose, starch, or elemental sulfur. Growth occurs between 90 and 113 °C with an optimum at 106 °C (doubling time 60 minutes). The optimum pH is 5.5, and the optimum salt concentration is 1.7%. *Pyrobolus fumarii* tolerates a pressure of 25 Mpa, and exponential cultures survived 1 hour autoclaving at 121 °C. The DNA base composition is 53 mol% G + C. Type strain 1A has been deposited at the German collection of microorganisms (DSM 11,204).

Molecular Diversity

It is a well-known fact that despite the best efforts and imagination of microbiologists, culture methods do not permit us to obtain a pure culture of all of the living microbial species within a single sample. The list of organisms reported earlier does not reflect the total and true diversity of hydrothermal vent microbial communities (78). The ability to extract total DNA from a sample, and then to amplify 16S rDNA genes is considered as an alternative method for the estimation of microbial diversity.

This approach has been used in the case of smoker samples, but not very successfully until recently. The main problem encountered was the extraction of DNA from smoker samples, which failed in part because of the patchy distribution of the microbial communities within the mineral structures, but also because of the strong attachment of cells to minerals and/or chemical interactions (78). However, it was recently reported that some authors were successful in extracting and measuring up to 80 μg of DNA per gram of chimney (42), and in detecting novel methanogens using amplification of the *mcrA* gene from DNA extracted from freshly collected samples of an active smoker (79). Takai and Horikoshi were able to obtain DNA from hydrothermal water and chimney samples collected in the Ogasawara and Okinawa areas and conduct a molecular phylogenetic analysis of the archaeal communities (80). Novel phylotypes distinct from other cultivated archaea or environmental clones were obtained. These clones were mostly placed in the Euryarchaeota, but a few were placed in the Crenarchaeota. Interestingly, several clones were placed close to *Picrohilus* and *Thermoplasma*, two acidophilic thermophiles.

An alternative to DNA extraction from chimney samples involved the deployment of the "vent caps," in situ growth chambers, on the top of active smokers with intermediate temperatures (81,15). This approach allows the investigator to extract DNA from coupons exposed within the growth chamber and colonized by microorganisms. Again unique novel rRNA sequences were obtained. These corresponded to members of the Thermococcales or Archaeoglobales, well known from the vent environments, and also to members of the Thermoplasmales, confirming that thermoacidophiles may be present in the vent ecosystems, although they have so far escaped all attempts at being cultured.

Genetic Elements

The first genetic elements found in deep-sea hyperthermophiles were plasmids from the methanogen *Methanococcus jannaschii* and a relative strain AG-86, with sizes of 64, 18, and 20 kb (82). Plasmids of sizes ranging from 3.5 to 24 kb were also found when screening a collection of 57 strains of Thermococcales (83). The plasmid pGT5 from *P. abyssi* has been studied more intensively (84). As it was the first discovered within a phylogenetic group studied intensively for basic and biotechnological research, this plasmid presently serves as a base for the construction of shuttle vectors. It is a

3.5-kb cryptic plasmid that has been sequenced fully. Two open reading frames were detected, one of them coding for a protein involved in the replication through a rolling circle mechanism (85). This plasmid has also been used for DNA topology experiments (84) where it was shown to be in the relaxed state at physiological temperatures despite the presence in this archaeon of a reverse gyrase that was expected to favor a positively supercoiled DNA. Further experiments showed that the plasmid topology hyperthermophilic archaea may vary from a relaxed to a positively supercoiled state (all mesophiles, including Archaea, have their DNA in a negatively supercoiled state), depending on growth phase and temperature variations (86). However, the plasmid pGS5 from *A. profundus* (87) was found negatively supercoiled, probably because of the coexistence of histones, reverse gyrase, and gyrase in this organism.

Responses to Hydrostatic Pressure

Deep-sea hydrothermal vents have been documented at depths ranging from 800 to 3,500 m (10). At each of these vents, hydrostatic pressure is 80 to 350 bars or 8 to 35 MPa. The responses of some continental mesophiles (such as *Escherichia coli*) or deep-sea psychrophiles to elevated hydrostatic pressure have been well documented. However, very little is known about the response of thermophiles and even deep-sea thermophiles to this parameter. Different types of responses have been observed by several authors (88). For instance, it was shown that elevated pressure increased the maximum temperatures for growth of several Thermoccoccales strains, including *Pyrococcus abyssi*, from 1 to 4 °C. The optimum temperature for growth was also shifted up from 2 to 4 °C; the growth rate increased as well (61). Similar experiments were carried out for a few methanogenic strains, with the added difficulty that these organisms require a CO_2/H_2 headspace that prevents the efficient pressurization of the liquid medium. (A common technique for pressure studies consists in culturing the cells within a glass syringe, without head space above the liquid medium. The syringe is immersed into a high-pressure reactor, filled up with water, and connected to a pump. Pressurization of water within the reactor transmits the pressure to the culture through the piston of the syringe.) It was noted that a pressure of 200 bars decreased the growth rate of deep-sea thermophilic methanogens strains CS1 and FS (89). However, pressure of up to 750 bars was shown to increase growth rate and methanogenesis of *M. jannaschii* at 86 and 90 °C, when helium was used as the pressurizing gas (90). Using argon or H_2/CO_2 as the pressurizing gas, methanogenesis did not occur above 86 °C. After an examination of the studies dealing with responses of deep-sea hyperthermophiles to hydrostatic pressure, Deming and Baross (91) distinguished four different behaviors. For barosensitive strains, high pressure reduces growth rate; for barotolerant organisms, growth rate is unaffected by pressure; for barophilic strains, growth rate is stimulated by high pressure. The fourth category, obligate barophiles, corresponds to organisms that can grow only under elevated pressure. For instance, *P. abyssi* is an obligate barophile between 102 and 106 °C, as it cannot grow above 102 °C under atmospheric pressure; its maximum temperature for growth is shifted up under elevated pressure, and growth for this supraoptimal temperature is only possible when elevated hydrostatic pressure is applied.

It must be noted that all deep-sea hyperthermophiles exposed to elevated hydrostatic pressures had been isolated previously under atmospheric pressure (or under a slight gas pressure that prevents boiling of the culture medium). Recently, *Th. barophilus* was isolated after enrichment and subcultures were all carried out under elevated pressure (40 MPa) (72). This organism, which can grow also under atmospheric pressure, showed an interesting behavior. The maximum temperature (but not the optimum) for growth was enhanced by pressure, and, in particular, the growth rate was increased twofold. The total protein profiles of the cells grown either under atmospheric or under hydrostatic pressures were studied and compared (92). Under pressure, a 60-kDa protein was expressed, which is still unknown. But under atmospheric pressure, a 35-kDa protein was expressed, which appeared to be close to a heat shock protein reported previously for the hyperthermophilic archaeon *Desulfurococcus* strain SY. This would indicate that this organism is in a stress situation when it grows under atmospheric pressure. Deming and Baross (91) also noted that for most of the strains showing a barophilic behavior, the optimum pressure for growth was above the pressure existing where the sample from which the strains had been isolated were collected. For instance, *P. abyssi* was obtained from a North Fiji Basin vent site at 2,000 m (pressure: 200 bars), but its optimum pressure for growth was 400 bars. This is in contrast to the situation with deep-sea psychrophiles, where it has been shown that the optimum pressure for growth was always below the pressure existing at the sampling depth (93). From these observations, it was suggested that black smokers could represent "windows to a deep biosphere." If such a subterranean biosphere really exists, its inhabitants would be exposed to an elevated pressure (hydrostatic and lithostatic), higher than the pressure existing at the sea floor. Arguments for the existence of this novel biotope were given in the report of thermophilic and hyperthermophilic microorganisms in moderate temperature hydrothermal fluids (3 to 30 °C) following a deep-sea volcanic eruption (94,95).

FUTURE RESEARCH

Thirty years ago, deep-sea hydrothermal vents were unknown. Since then, 40 sites have been discovered and explored, which is a lot, but also very few if one is aware of the fact that oceanic ridges have a total length of 60,000 km. Although many of these sites, but not all, have been studied by microbiologists, a significant level of research effort is still needed to fully understand these fascinating ecosystems. It is obvious that low and moderate temperature habitats have been studied very little. About the microbiological aspects of symbiosis, several points must be clarified, including symbiont transmission, ecology and physiology of free-living states of the symbionts, cell recognition

mechanisms, or prokaryotic cell division control by the host.

Apparently much more is known about thermophilic prokaryotes. But despite a rather long list of novel species, the first attempts at a molecular approach to thermophilic microbial diversity indicate that many novel phylotypes exist, whose whole organisms are yet to be cultured (for instance thermoacidophiles). Novel culture techniques (with imaginative sets of electron donors, acceptors, and carbon sources) must be developed (continuous cultures, mixed cultures, nutrient gradients, immobilized cells, etc.).

An exploration effort also must be encouraged to investigate other sites, particularly deeper sites that certainly exist, where more barophilic organisms may exist. The hypothesis of a deep sub–sea floor biotope also will require many efforts to be supported. Deep drilling in areas surrounding active vents should be organized in the future. Though the active exploration of the solar system is presently scheduled for the twenty-first century, the exploration of microbial diversity of planet Earth is not yet completed, and must go on.

HYPERTHERMOPHILES

JUN GAO
DONALD F. WARD
ROBERT M. KELLY
North Carolina State University
Raleigh, North Carolina

Over the past few decades, hyperthermophilic microorganisms (those with optimum growth temperatures of 80 °C and above) have been isolated from a number of geothermally heated habitats, including shallow terrestrial hot springs, deep wells, sediment from volcanic islands, and deep-sea hydrothermal vents (Table 1; 1–5). A significant number of isolates, representing a broad spectrum of growth physiologies (e.g., methanogens, fermentative anaerobes, sulfur-reducers, sulfate-reducers, microaerophiles), have successfully been propagated in laboratory pure culture (6). This capability has facilitated metabolic studies and efforts to examine scientific and technological issues associated with the intrinsically thermostable and thermoactive proteins produced by these unique microorganisms (4,7,8). Because of their small genome sizes (typically ~2 Mb), interest in their evolutionary significance (9) and biotechnological potential (3,10,11), a relatively large amount of genome sequence information currently exists for these organisms (see Table 2). In fact, efforts are underway to further expand these databases (12). This situation presents some important opportunities. Although genetic systems for these organisms are currently unavailable in forms that would be readily useful for physiological studies, other approaches, including DNA microarrays and proteomics (13) coupled with genome sequence data, could be used to help decipher novel features underlying high-temperature microbial lifestyles (14). No doubt such efforts will also lead to the identification of interesting biocatalysts whose function in extreme environments is an important technological attribute (7). Paramount to such efforts to utilize genomic data is the capability of culturing hyperthermophiles in experimentally meaningful ways. This is particularly important because nearly half of the ORFs in hyperthermophilic genomes sequenced to date cannot be linked to a particular function (Table 2; 12).

HYPERTHERMOPHILIC ENVIRONMENTS

The natural habitats from which hyperthermophiles have been isolated often contain steep thermal gradients and have distinctive chemical and physical characteristics. Biotopes that have provided hyperthermophiles may be shallow or deep, terrestrial or marine (Table 1; 5). Shallow terrestrial environments, including hot springs, mud holes and solfaterras, are usually located in proximity to regions of significant geothermal activity and are widespread geographically. Such biotopes can be found in, for example, Iceland, New Zealand, Russia, Japan, Italy and the United States. An interesting feature of some hot, shallow terrestrial biotopes is the variation in pH encountered. For example, in Yellowstone National Park in the northwestern United States, hyperthermophiles can be isolated from sites with moderately alkaline pH (up to approximately pH 9) and from extremely acidic pH (down to approximately pH 1) (88). Hyperthermophiles have also been found in the deep, terrestrial subsurface while drilling oil reservoirs in places such as Alaska (89). Many hyperthermophiles have been isolated from readily accessible, shallow marine springs in locations such as Vulcano Island, Italy (62), and the Azores. Probably the most intriguing source of hyperthermophiles has been deep-sea hydrothermal vent environments that give rise to temperatures ranging from cold seawater at 2 °C to superheated hydrothermal fluids at more than 400 °C. Within this temperature gradient, a complex, nonphotosynthetic ecosystem operates that not only includes hyperthermophiles but a variety of microscopic and macroscopic life forms. Although new high-temperature habitats continue to be discovered, both marine and terrestrial, a relationship between geographic diversity and biodiversity has yet to be established.

ISOLATION AND CULTIVATION OF HYPERTHERMOPHILES

Discovering new hyperthermophiles and obtaining them in pure cultures for further study continues to be a central focus in this field. Although it is clear from phylogenetic fingerprinting that the biodiversity of hyperthermophiles in samples collected from natural environments is extensive (90), extracting selected species from these samples for further microbiological study can be an elusive undertaking. Whether many such members of the hyperthermophilic communities are viable but not culturable remains to be seen (91).

Table 1. Hyperthermophilic Archaea and Bacteria

Order	Genus	Species	Ref	Sample Site	Morphology	T_{opt} (°C)	pH Range (opt.)	Aerobic/ Anaerobic	G/C Content
Bacteria									
Thermotogales	*Thermotoga*	*T. maritima*	15	Marine mud	Rods with sheath	80	5.5–9 (7)	An	46
		T. neapolitana	16	Submarine hot springs	Rods with sheath	80	5.5–9 (7)	An	41
Aquificiales	*Aquifex*	*A. pyrophilus*	17	Hot marine sediments	Rods	85	5.4–7.5 (6.8)	Ae	40
		A. aeolicus	17	Hot marine sediments	Rods	85	N/A	Ae	43.4
	Thermocrinis	*T. ruber*	18	Pink filaments of Octopus Spring	Rods	80	7–8.5	Ae	47.5
Archaea									
Sulfolobales	*Sulfolobus*	*S. acidocaldarius*	19	Acid hot springs	Lobed cocci	75	1–5.9 (2)	Ae	37

Isolation

Given the difficulty in accessing certain high-temperature habitats, isolation of hyperthermophiles from natural settings into pure culture presents a number of challenges (5). Not only are plating techniques problematic because of the scarcity of solid media that function at hyperthermophilic temperatures (92), but the obligate anaerobicity and sulfur requirement of many of these organisms are additional complications. There has been some success reported using solid media for hyperthermophile cultivation (93), but the method of choice has been serial dilution in liquid media (94). Despite potential problems with ensuring the presence of a pure culture, serial dilution techniques have been used to isolate most of the hyperthermophiles listed in Table 1. However, although initially the serial dilution approach led to the isolation of a host of hyperthermophiles with unique physiological and phylogenetic features, the pace of discovery of new organisms with distinctive characteristics has slowed considerably in recent years. High-temperature marine enrichment cultures at neutral pH consistently yield rapidly growing heterotrophic hyperthermophiles, such as those from the orders *Thermococcales* and *Thermotogales* (29). New isolation methods are needed to tap the extensive biodiversity in geothermal habitats inferred from the morphological variability under the microscope and from molecular phylogenetic analysis (Fig. 1). Stetter and colleagues have recently reported using an optical tweezers trap (95,96) for single cell isolation from mixed cultures (5,6). This method used in conjunction with specific whole-cell hybridization using 16S rRNA phylogenetic probes is especially promising for isolating yet to be isolated hyperthermophiles into pure culture from natural enrichments (90,91).

Cultivation

Before the availability of genome sequence information for selected hyperthermophiles, efforts to examine their physiology and enzymology relied to a great extent on the ability to grow these microorganisms in pure culture in laboratory and pilot plant settings (97). Many different reactor systems have been developed in this regard (4,98). Until efforts to clone and express genes encoding hyperthermophilic enzymes in mesophilic hosts, such as *Escherichia coli* (10), were successful, hyperthermophilic enzymes studied in purified form were obtained from hyperthermophilic biomass. Cultivation of hyperthermophiles on a scale sufficient to provide biomass for protein purification efforts presents many challenges (97,99). In short, lack of knowledge of microbial physiology, low biomass yields, generation of copious amounts of hydrogen sulfide, explosive substrate and product gases, salt-laden media, anaerobic conditions and cell sensitivity to shearing are all potential obstacles. A few heterotrophic hyperthermophiles, e.g., *P. furiosus* (62), *T. litoralis* (50) and *T. maritima* (15), can be cultivated without sulfur (albeit, anaerobically) and have, thus, been the primary focus of direct purification efforts. These organisms can be grown to biomass yields of 1 kg (wet) or higher in 600-liter fermentation systems (100) and can also be grown for long periods of time in

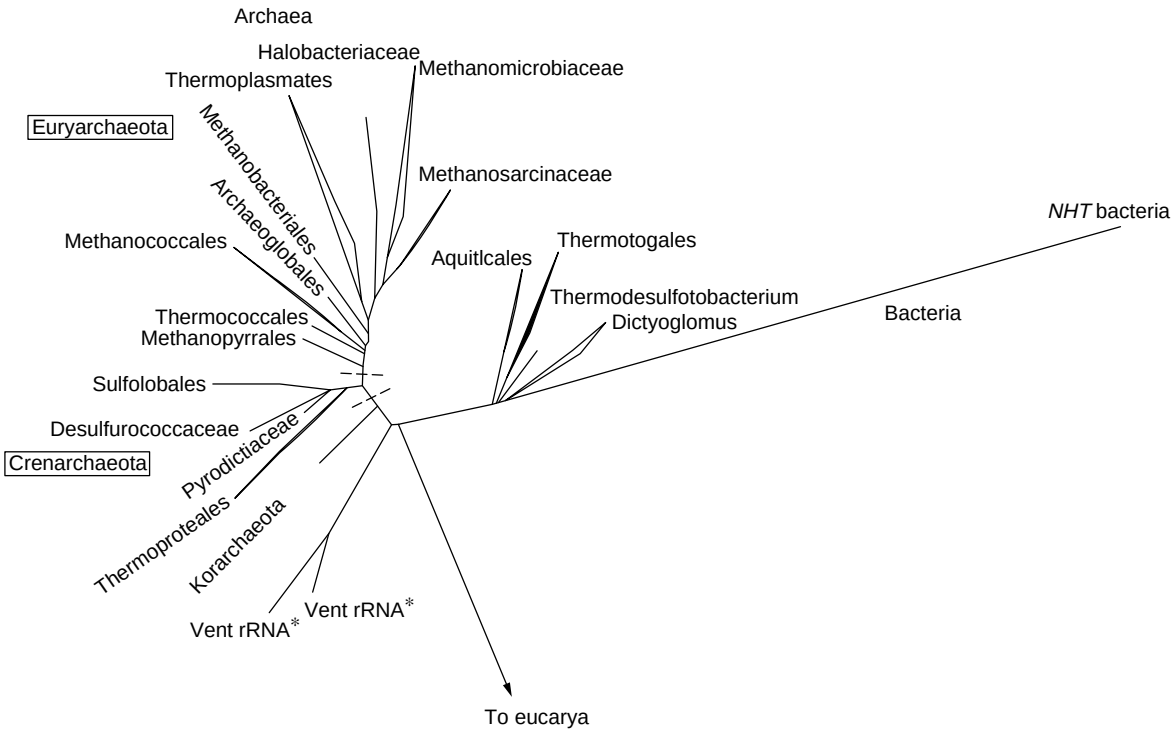

Figure 1. Families and orders of hyperthermophilic Archaea and Bacteria (9). Hyperthermophilic groups are indicated in bold text. Korarchaeota represents rRNA sequences cloned from hot springs. Vent rRNA represents cloned rRNA sequences from submarine hydrothermal vents. NHT, nonhyperthermophilic bacteria.

continuous culture (101,102). However, although sulfur is unnecessary for the growth of these organisms, their cultivation still presents significant challenges (101). The advent of genome-sequence data overcame an important barrier to the study of specific hyperthermophilic proteins. Using amino acid sequence homology, genes encoding candidate proteins could be identified, cloned and expressed in mesophilic heterologous hosts. The fact that a heat treatment step could be used to facilitate purification is an additional advantage of this approach. Of course not all genes from hyperthermophiles can be converted into actively expressed proteins in mesophilic hosts, thereby still necessitating direct purification methods be pursued. This is important given the significant fraction of genes in hyperthermophilic genomes with unidentified function (Table 2).

Unraveling the functional genomics of hyperthermophiles will need to be pursued through a combination of approaches, namely, examining the physiological response of genes to changes in growth environment (e.g., media formulation, temperature, pH, etc.) and relating these to variations in bioenergetic parameters, differential expression of genes, and protein production patterns and metabolic products. The combination of classical methods for studying microbial physiology with molecular techniques can be an advantage when used to determine the relationship of the genome to the proteome to the physiome. However, it is critical that the response of a particular organism to environmental changes be interpreted in an unequivocal way so that cause and effect relationships can be established. A particularly valuable tool for this is continuous culture, which can be used to provide biomass resulting from steady-state operation or transients in cultivation conditions. This approach works particularly well for hyperthermophilic microorganisms, given the reduced chances for contamination at elevated temperatures and, thus, the prospect of long periods of stable cultivation (101,103,104). For example, Han and coworkers (104) showed that continuous culture in conjunction with two-dimensional gel electrophoresis was useful for studying heat shock in the extreme thermoacidophile *Metallosphaera sedula*. Transcriptional (i.e., differential gene expression) and translational (i.e., two-dimensional gel electrophoresis in conjunction with mass spectrometry) responses of the organism to changes in growth environment can be related to specific genes and proteins, thereby contributing to elucidation of physiological and metabolic patterns. This information, taken together with insights into cellular bioenergetics arising from classical approaches developed for continuous culture, can be used to further the knowledge of biological function in extreme environments.

METABOLISM OF HYPERTHERMOPHILES

Hyperthermophiles as a group represent a diverse set of metabolic features reflecting to some extent the various environments from which they are isolated (5,105–112). Lithotrophic metabolism, utilized by most anaerobic or microaerophilic hyperthermophiles, involves oxidation of H_2 or S, coupled to the reduction of S, SO_4^{2-}, CO_2 and NO_3^-. Autotrophic hyperthermophiles use CO_2 as the sole carbon source via reductive tricarboxylic acid (TCA) cycle or reductive acetyl CoA/carbon monoxide dehydrogenase pathway, whereas heterotrophic hyperthermophiles metabolize carbohydrates or peptides, by either oxidation to CO_2 or fermentation to free acids such as acetate and other metabolic products. In sugar catabolism, glucose is converted to pyruvate through either a modified Embden-Meyerhof (EM) or a nonphosphorylated Entner-Doudoroff (ED) pathway, although members of the genus *Thermotoga* appear to use the typical EM and phosphorylated ED pathways. Some hyperthermophiles can utilize complex peptides as a source of carbon and energy, with S, $S_2O_3^{2-}$, SO_4^{2-}, O_2 or NO_3^- as possible electron acceptors, producing H_2S or CO_2 by respiration or acetate and other free acids, such as isobutyrate and isovalerate, by fermentation. Hyperthermophiles with completed genome sequences (Table 2) represent the metabolic variety found in this group of microorganisms, aspects of which are discussed later for particular species. Two hyperthermophilic bacteria, *A. aeolicus* and *T. maritima*, represent among the deepest lineages of Bacteria in the 16S phylogenetic tree, and the early divergence indicates that they are closely related to the universal common ancestor (Fig. 1). Their metabolic functions may represent those of early life on earth (87,113). The other eight organisms are from the domain Archaea. *Aeropyrum pernix* and *Pyrobaculum aerophilum* are aerobic hyperthermophiles with optimum temperatures above 95 °C, and their metabolic functions provide insight into the origin of oxygen respiration on earth (84,85). *Pyrobaculum aerophilum* can also carry out denitrification, a metabolic function that is unique in genus *Pyrobaculum* (32). *Archaeglobus fulgidus* is the first sulfur-metabolizing microorganism with its genome information available, and its sulfate-reducing pathway can help us understand the global sulfur cycle (82). *Methanococcus jannaschii*'s genome is the first sequenced archaeal genome. As a methanogenic autotroph, its metabolic function is to synthesize all cellular materials from CO_2, and form methane (83). Three closely related *Pyrococcus* species, *P. horikoshii* (79), *P. furiosus* (81) and *P. abysii* (direction submission to NCBI), have also been sequenced recently, and their different metabolic functions are reflected in their genome sequences. Along with *P. furiosus*, *Sulfolobus solfataricus* is one of the most studied hyperthermophiles. Originally isolated from high temperature (75 °C–90 °C) solfataric field, it is an aerobic acidophile, and its sugar metabolism enables it to utilize a wide range of carbohydrates from the environment (86,114).

Aquifex aeolicus

Aquifex aeolicus is a hydrogen-oxidizing, microaerophilic, chemolithoautophic bacterium, with an optimum growth temperature of 85°C (113). Incapable of growing on organic substrates, it uses CO_2 as the sole carbon source for biosynthesis by reductive tricarboxylic acid (reverse TCA) cycle, using two CO_2 molecules to form acetyl coenzyme A (Acetyl-CoA) and other intermediates for biosynthesis. Different from the conventional TCA cycle in aerobic bacteria, two important enzymes are required for the

process: a ferredoxin-dependent 2-oxoglutarate synthase, which catalyzes reductive carboxylation of succinyl-CoA to 2-oxoglutarate, and an ATP citrate lyase, which cleaves citrate to oxaloacetate and acetyl CoA (115). In *A. pyrophilus*, a close relative of *A. aeolicus*, both enzyme activities were detected in the cell extracts using H_2, CO_2, O_2 and thiosulfate; other enzymes involved in the reverse TCA cycle were also detected (115). In *A. aeolicus*, ferredoxin oxidoreductase, which can catalyze the reversible carboxylation/decarboxylation of 2-oxoglutarate, pyruvate, or 2-isoketovalerate with different specificities, is found in the reverse TCA cycle. Two distinct sets of ferredoxin oxidoreductase gene clusters, encoding two enzymes with 4 subunits each, were identified in its genome (113). The citrate synthase gene (*gltA*), along with other required genes encoding various enzymes to complete the reverse TCA cycle, have also been identified in the genome. From the genome sequence, it is clear that the reverse TCA cycle is essential for *A. aeolicus* metabolism. A number of key enzymes in the pathway have two copies of genes, resembling similar functions, but with varied specificities, such as two ferredoxin oxidoreductase gene clusters, two fumate hydratase genes, and two succinate-CoA ligase genes (113). Also, there is an absence of any other enzymes essential for other CO_2 fixation pathways, such as would be found in the Calvin cycle or reductive acetyl CoA pathway. *Aquifex pyrophilus* contains neither ribulose1,5-bisphosphate carboxylase, an essential enzyme for Calvin cycle, nor two enzymes, CO dehydrogenase and formate dehydrogenase, which are key enzymes in reductive acetyl CoA pathway (115). The energy metabolism of *A. aeolicus* is based on O_2 respiration, gaining energy by Knallgas reaction with H_2 as electron donor. Although the solubility of O_2 is low at high temperatures, *A. aeolicus* can grow at oxygen levels as low as 7.5 ppm (17,113). Its highly developed oxygen-respiration system is similar to those found in less thermophilic bacteria, causing speculation that aerobic respiration had either originated before the phylogenetic lineage including members of the genus *Aquifex*, or been laterally transferred, and acquired by *Aquifex* later on (113). When grown under strictly anaerobic conditions, *A. pyrophilus* was able to reduce nitrate to N_2 as an end product (nitrate respiration) (17,32). However, despite the presence of nitrate reductase (*nasA*) and nitrate transporter (*narB*) genes in the genome of *A. aeolicus*, nitrate respiration has not been observed, leading to the speculation that the two genes may be involved in nitrogen catabolism rather than respiration (113).

Aeropyrum pernix

Aeropyrum pernix, an archaeon with an optimum growth temperature of 95 °C, is a strictly aerobic hyperthermophile (42). It metabolizes peptides and gains energy by aerobic respiration, completely oxidizing peptides to CO_2. Although not essential for growth, thiosulfate stimulates the growth of *A. pernix* eightfold, without producing H_2S. Other hyperthermophiles, such as *P. aerophilum* and *T. tenax*, can also oxidize peptides to CO_2, with sulfur or thiosulfate as electron acceptor, either aerobically or anaerobically (28,31). The *A. pernix* genome contains all genes involved in TCA cycle, with the genes coding for a dimeric 2-oxoacid:ferredoxin oxidoredactase replacing alpha-ketoglutarate dehydrogenase found in bacterial TCA cycle (84). A homologous 2-oxoacid:ferredoxin oxidoredactase was previously purified from a *Sulfolobus* sp., with broad substrate specificity toward 2-oxoglutarate, 2-oxobutyrate, and pyruvate (116). *Aeropyrum pernix* cannot survive under any anaeorobic condition (42), yet three genes in its genome encode a nitrate reductase enzyme complex typically involved in nitrate respiration. Phylogenetic analysis showed that the nitrate reductase subunit A was closely related to several bacterial oxidoredutase genes, but not archaeal or eukaryotic genes, indicating that the genes are probably laterally transferred between Archaea and Bacteria (117).

Archaeoglobus fulgidus

Archaeoglobus fulgidus, a strict anaerobe, can grow both chemolithoautophically in the presence of H_2, CO_2, and thiosulfate, and chemoorganotrophically on various organic carbon sources, such as lactate, glucose, formate, starch, peptone, with sulfate, sulfite, and thiosulfate, but not sulfur, as electron acceptors (67). Because of its anaerobic natural environment, *A. fulgidus* carries out sulfate respiration as its energy metabolism (109,118). Similar to the pathway found in mesophilic sulfate-reducing bacteria, sulfate is first activated to adenylylsulfate (adenosine-5′-phosphosulfate; APS) by ATP sulfurylase, followed by reduction of APS to sulfite by adenylylsulfate reductase, before final conversion to sulfide by sulfite reductase (109,119). All the enzymes in the pathway have been identified in *A. fulgidus* (118,120–122). Reduction of adenylylsulfate to sulfite is an essential step of this metabolic pathway. The adenylylsulfate reductase from *A. fulgidus* is composed of two subunits, encoded by two genes separated by 17 base pairs in the genome, and arranged in order of *agrB-agrA*. Subunit A, a 73-kDa protein, is closely related to subunits of several bacterial succinate dehydrogenases and fumarate reductases. Subunit B, with M_r of about 17 kDa, is an iron-sulfur protein, and its seven cysteine residues form two clusters, assisting in the formation of an ion-sulfur center with eight ions and six sulfide atoms in the protein (118). Chemoautotrophically, *A. fulgidus* can fix CO_2 via a reductive acetyl CoA/carbon monoxide dehydrogenase pathway (123). When grown organotrophically, the organism utilizes various organic carbon sources, such as formate, lactate, and methanol, oxidizing them to CO_2 (67). The presence of 57 β-oxidation enzyme genes and five types of ferredoxin-dependent oxidoreductase genes in its genome further confirmed *A. fulgidus*' ability to use organic carbon sources (82). In a proposed lactate catabolism, a membrane bound lactate dehydrogenase and pyruvate:ferrodoxin oxidoredutase oxidized lactate to Acetyl CoA and CO_2. The acetyl CoA from both chemoautotrophic and organoheterotrophic pathways undergoes modified acetyl CoA/carbon monoxide dehydrogenase pathway by acetyl CoA decarboxylate/synthase (ACDS) complex (119,123). The acetyl CoA decarboxylate/synthase complex (ACDS) catalyzes reversible conversion of CO_2 and Acetyl CoA, carrying out acetyl CoA synthesis and

CO-dependent of methyl-tetrahydromethanopterin (CH_3-H_4MPT) reduction simultaneously. It is composed of five subunits with total M_r of 2.0 MDa, and resembles an ACDS complex from *Methanosarcina thermophila* (124), not only in overall and α-, γ-, ε-subunit molecular weights, but also immunologically (125). Two genes, clustered as *cdhA2B2* under one operon in the genome, encode acetyl CoA synthases, which are α- and ε- subunits of the complex, and are homologous to *M. thermophila*'s ACDS α- and ε- subunits genes (125). It is still unclear whether the gene sequences encode β-, γ-, δ-subunits of the ACDS complex, although two carbon monoxide dehydrogenase genes, *CooF* and *CooS*, are identified in the genome (82). The genome sequence has also resulted in some conflicting results about other metabolic functions of *A. fulgidus*. Although glucose was listed as a carbon source (67), no glucose uptake- or transport-genes, or its route of catabolism can be identified in the genome. On other hand, there are multiple clusters of acetyl CoA synthase genes, *cdhE-cdhD-cdhC*, *cdhA1-cdhB1*, *cdhA2-cdhB2*, although *A. fulgidus* cannot grow on acetate (82).

Methanococcus jannaschii

Methanococcus jannaschii is a strictly anaerobic, obligate autotrophic methanogen, utilizing H_2 and CO_2 as food and energy sources (74). Its energy metabolism is methanogenesis, involving the stepwise reduction of CO_2 to CH_4 (see recent reviews for detail mechanism discussion (109,112,126). As a critical enzyme in methanogenesis, formylmethanofuran (formyl-MF) dehydrogenase reduces carbon dioxide to formylmethanofuran with H_2. Formyl-MF dehydrogenase in *M. jannaschii* has seven subunits, A, B, C, D, E, F, G, encoded by a gene cluster *fwdEFGDAXC*, in which *fwdX* encodes a hypothetical protein with no homology to any function-known enzymes. All subunits contain only tungsten as a cofactor (83,112). Formyl-MF dehydrogenase from a thermophilic methanogen, *Methanobacterium thermoautotrophicum*, has four subunits, all of which have both tungsten and molybdenum as cofactors (127). By comparing with other mesophilic and hyperthermophilic methanogens, it was believed that the use of tungsten cofactor in this enzyme is unique to hyperthermophiles (112). Formylmethanofuran:tetrahydromethanopterin formyltransferase exogenetically catalyzes the transfer of formyl group from formyl-MF to H_4MPT, which is encoded by one gene cluster, *mtrEDCBAFGH*, in *M. jannaschii* genome, compared to two copies of such gene are present in *M. thermoautotrophicum* (128). Methyl-coenzyme M reductase catalyzes the release of methane from coenzyme M. In *M. jannaschii*genome, there are two clusters of genes, *mrtBGA* and*mcrBDCGA*, encoding for two three-subunits methyl-CoM reductases. Two homologous methyl-CoM reductases, MCRI and MCRII, are characterized in *M. thermoautotrophicum*; both enzymes consist of three subunits, with native M_rS of about 300 kDa, but differ in kinetic properties and pH optima (129,130). Fixation of CO_2 in *M. jannaschii* is through the reductive Acetyl-CoA-carbon monoxide dehydrogenase pathway (83), similar to that of *A. fulgidus* (see earlier discussion). Gluconeogenesis and glucose metabolism are not present in *M. jannaschii*, yet there are two genes encoding polysaccharides-degrading enzymes in the genome, an α-amylase and a glucoamylase. These genes are clustered around a portion of the genome in which the G + C content is less than 95% of rest of the genome, suggesting they were laterally transferred from other organisms (83).

Pyrobaculum aerophilum

Pyrobaculum aerophilum is capable of utilizing a variety of metabolic pathways (32). It grows aerobically on organics, such as peptides or acetate, or inorganic compounds, such as CO_2, H_2, and thiosulfate. It carries out denitrification as its energy metabolism under strict anaerobic conditions, a mechanism that has not been identified in its close relatives *P. islandicum* (31), *P. organotrophum* (31), *P. oguniense* (33), or *P. arsenaticum* (34). *Aquifex pyrophilus* is the only other hyperthermophile capable of denitrification (17). When grown under anaerobic conditions with complex carbon sources, *P. aerophilum* requires tungstate, but not molybdate, and nitrate reductase, nitrite reductase, and nitric oxide reductase activities were detected associated with cellular membranes (131). Although nitrite reductase and nitric oxide reductase were not affected, nitrate reductase activity was inhibited by high level of tungstate concentrations, decreasing fourfold from tungstate concentration of 0.1 μM to 5.0 μM and indicating that tungstate is involved in a complex metabolic pathway of *P. aerophilum* (131). In the partially (95%) completed genome sequence, a nitrate transporter gene and three genes (*narZ*, *narY*, *narG*), encoding for α-, β-, γ-subunit of nitrate reductase, are cotranscribed under one operon; a ferredoxin-nitrite reductase was also identified (85). Heterotrophically, *P. aerophilum* completely oxidized complex peptides to CO_2, similar to *A. pernix*. The presence of genes encoding pyruvate-flavodoxin oxidoreductase and malate oxidoreductase indicate that TCA cycle is involved. Recently, it was shown that under anaerobic conditions, *P. aerophilum* grew organotrophically in the presence of arsenate (34). As a close relative *P. arsenaticum* grows chemolithoautotrophically on CO_2, H_2, and arsenate, or heterotrophically on complex peptides and arsenate, both anaerobically (34). An enzyme system for the arsenate respiration has yet to be characterized.

Pyrococcus sp.: *P. abyssi, P. horikoshii,* and *P. furiosus*

The three *Pyrococcus* species have similar growth physiologies in that they have comparable optimum growth temperatures, are all strict anaerobes, grow fermentatively on peptides, and reduce sulfur. *Pyrococcus furiosus*, isolated from shallow marine sediments, can grow on a number of carbohydrates, such as starch, maltose, cellobiose and barley glucan, without sulfur, and on complex peptides with sulfur (62,110,132). *Pyrococcus abysii* and *P. horikoshii*, both isolated from deep hydrothermal vent environments, grow on complex peptides with sulfur, but not carbohydrates (64,66). *Pyrococcus furiosus* possess a wide range

of glycosyl hydrolases, many of which have been identified and characterized: a β-glucosidase (*celB* gene) (133,134), two α-amylases (135–137), a β-mannosidase (138), a pullulanase (139), a laminarinase (140), an endoglucanase (141), and two chitinases (Gao et al., unpublished results). These endo- and exo-acting enzymes synergistically hydrolyze complex carbohydrates into glucose, providing *P. furiosus* with carbon and energy sources (142). In the *P. abysii* genome, six putative glycosyl hydrolases can be identified (*http://www.genoscope.cns.fr/cgi-bin/Pab.cgi*). Although at least 12 putative glycosyl hydrolases are found in *P. horikoshii* genome, only two are endo-acting enzymes. The difference in glycosyl hydrolases among the three *Pyrococcus* species might be indicative of their natural habitats. *Pyrococcus furiosus* was isolated from shallow marine sediments, which contain high carbohydrate but low protein content, whereas *P. horikoshii* and *P. abysii* may have more limited access to carbohydrates in deep hydrothermal vent environments (81). *Pyrococcus furiosus* uses a modified EM pathway for glucose degradation to pyruvate, using ADP-dependent hexokinase and ADP-dependent 6-phosphofructokinase (109,143), which might be related to the higher stability of ADP over ATP at or near 100 °C (110). The ADP-dependent hexokinase has been purified and exists as a dimer, exhibits high substrate specificities toward glucose and ADP, which cannot be replaced by fructose or ATP/GTP molecules; K_m values for ADP and glucose are 0.033 mM and 0.73 mM, respectively (144). The ADP-dependent phosphofructokinase, a tetramer, exhibited lower specificities to its substrates with K_m values of 0.11 mM for ADP and 2.3 mM for fructose-6-phosphate; ADP can be replaced by ATP, GP, or GDP (145). *Pyrococcus horikoshii* and *P. abysii* probably obtain pyruvate through degradation of peptides, although the metabolic pathways responsible are still unclear. In *P. horikoshii*, many seemingly essential metabolic enzymes are still unidentified (80,81). Pyruvate has two possible metabolic fates in *P. furiosus*. It can be further oxidized to acetyl CoA by pyruvate:ferredoxin oxidoreductase (POR) and subsequently converted to acetate and ATP via substrate level phosporylation by the acetyl CoA synthase (109). In *P. furiosus*, POR is a 4-subunits protein with thiamine pyrophosphate and two ferredoxin-like clusters; unlike the same enzyme from *T. maritima* (146), it does not contain a copper ion, resulting in different catalytic mechanism (147). The homologous genes encoding the pyruvate:ferredoxin oxidoreductase are identified in the other two *Pyrococcus* species. The second metabolic fate of pyruvate is to serve as an alternative electron sink by its conversion to alanine through the coordinated action of the glutamate dehydrogenase and alanine aminotransferase (148,149). *Pyrococcus furiosus* cannot use a TCA cycle to further oxidize acetyl CoA to CO_2, due to absence of two important enzymes for the TCA cycle, succinyl-CoA hydrolase and 2-oxoglutarate synthase. Instead, acetyl CoA is fermentated to acetate, via acetyl CoA synthase, coupled with phosphorylation of ADP, a mechanism present only in Archaea (150,151). An entire operon, containing three enzymes of TCA cycle, is missing in *P. horikoshii* (81).

Sulfolobus solfataricus

Sulfolobus solfataricus is a microaerophilic heterotroph, capable of utilizing a number of simple carbohydrates, including glucose, xylose, maltose, sucrose, as carbon and energy source (20,114). With the availability of its genome sequence, other complex carbohydrates, such as starch, cellulose, and xylans, can also be listed as potential growth substrates for the microorganism (86). Two genes, encoding a xylanase and a cellulase homologous to glycosyl hydrolase family 11 and 12, have been identified; the presence of signal peptide sequences indicate that both genes are secreted in the media, degrading polysaccharides into oligosaccharides. These two genes, along with a putative β-xylosidase gene encoding an intracellular xylosidase, are cotranscribed under one operon. Another gene cluster identified in the genome involves an α-amylase and a pullulanase gene, presumably degrading α-linked polysaccharides into oligo-, disaccharides. After being carried into the cytoplasmic membrane by a number of transporters, the oligo- and disaccharides are degraded into glucose and xylose by intracellular glucosidase and xylosidase (86). A family 1 β-glucosidase, encoded by *lacS* gene, has been studied extensively and its crystal structure has been solved (152–154). Recently, an α-xylosidase (XlyS) was characterized (155). The enzyme was exo-acting, and exhibited high hydrolytic activity on the xylose-containing disaccharides, releasing xylose from oxyloglucan oligosaccharies at optimum temperature of 90 °C. It acted synergistically with the β-glucosidase (LacS) on the xyloglucan oligosaccharides, releasing glucose and xylose shortly after incubation. No glucose and only trace amounts of xylose were observed when the substrate was incubated with LacS or XlyS alone. These genes, along with a major facilitator superfamily of transporter gene, and a gene with an unknown function, are cotranscribed as a polycistronic message (155). *Sulfolobus solfataricus* then degrades glucose to pyruvate via non-phosphorylated ED pathway (86,109,114). Glucose dehydrogenase ($NAD(P)^+$-dependent) oxidizes glucose to gluconate, which is then oxidized to 2-keto-3-deoxygluconate (KDG) by gluconate dehydratase. KDG aldolase then degrades KDG to pyruvate and glyceraldehyde, which is further oxidized to glycerate by glyceraldehyde dehydrogenase. Finally, a kinase phosphorylates glycerate to 2-phosphoglycerate, which is then converted to pyruvate by enolase and pyruvate kinase. A number of genes encoding these glycolytic enzymes are clustered in the genome, such as a cluster containing phosphoglycerate kinase and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) genes, and a cluster with NADP-dependent glyceraldehyde-3-phosphate dehydrogenase, fructokinase, 2-keto-3-deoxy-gluconate aldolase genes (86). Pyruvate that is generated by sugar metabolism is utilized by *S. solfataricus* via the TCA cycle involved a 2-oxoglutarate:ferredoxin oxidoreductase (105).

Thermotoga maritima

Thermotoga maritima is a strictly anaerobic bacterium, growing fermentatively on peptides and many simple and complex carbohydrates, including glucose,

sucrose, starch, cellulose and xylan (15). A number of glycosyl hydrolases involved in sugar catabolism have been characterized, including amylases (156), xylose isomerase (157), two β-glucosidases (158,159), a β-galactosidase (158), two xylanases (160), two cellulases (161,162), and a α-galactosidase (163). Other glycosyl hydrolases genes, encoding for a pullanase, a laminarinase, four α-glucosidases, two α-mannosidases and two β-mannosidase, have also been identified in its genome (87). Many of these genes are under the same operon with ATP-binding cassette (ABC) transporter genes, indicating that metabolizing and transporting carbohydrates are coregulated in *T. maritima*. Overall, 7% of the total function-identified genes are involved in sugar metabolism, significantly more than for any other genomes sequenced so far (87). There are several unique features about *T. maritima*'s metabolic functions. Unlike other anaerobic hyperthermophiles, *T. maritima* produced two moles of acetate, CO_2, four moles of H_2 and 2 moles of ATP per mole of glucose, without other minor metabolic products, such as lactate, ethanol (164). Its metabolism, like those of other anaerobic bacteria, involves an EM pathway with ATP-dependent hexokinase and ATP-dependent-6-phosphofructokinase, whereas other hyperthermophiles, such as *Pyrococcus* and *Thermococcus* species, use ADP-dependent hexokinase/phosphofructokinase (109,165). *Thermotoga maritima* also uses a phosphorylated ED pathway in addition to the EM pathway. With ^{13}C-labeling experiments, it was found that two pathways operated simultaneously, with the majority (85%) of glucose undergoing the EM pathway, and the rest undergoing the ED pathway. Two key enzymes for the phosphorylated ED pathway, glucose 6-phosphate dehydrogenase and 2-keto-3-deoxy-6-phosphogluconate (KDPG) aldolase (but not KDG aldolase), were detected in the cell extract (165). *Thermotoga maritima* was also found to be able to utilize Fe^{+3} as a terminal electron acceptor, thus avoiding the production of toxic sulfide end-products and H_2 (166). Additionally, a flavoprotein, consisting of α- and β-subunits, and multiple ion-sulfur identified in the genome as potential electron transporter (87). The last step of metabolism in *T. maritima* involves the conversion of acetyl CoA to acetate ATP by the coordinated action of the phosphate acetyltransferase and acetate kinase, in contrast to the single enzyme system of acetyl CoA synthase found in *P. furiosus* (109).

GENETICS OF HYPERTHERMOPHILES

The hyperthermophiles represent a diverse group of microorganisms that display a range of metabolic and genetic properties and span both the bacterial and archaeal domains. Accordingly, the genetics, transcription, translational, and genetic elements, of the hyperthermophiles are equally as diverse. From an evolutionary standpoint the hyperthermophiles cluster at the base of the 'tree of life' and many of their branches are short. Also, hyperthermophiles may represent the closest relatives to our last universal common ancestor(s), and by studying the genetics and molecular biology of these unique microorganisms we may gain insight into early evolution. Furthermore, a solid understanding of the genetics will be necessary to develop genetic systems for the hyperthermophiles.

Transcription and Translation

The transcriptional and translational apparatus of the hyperthermophilic bacteria *Thermotoga* and *Aquifex* is similar to that of *E. coli* and for this reason this review will only briefly address the hyperthermophilic bacteria. The three subunits (α, β, β') of the core RNA polymerase (RNAP) are present in the genome sequences of both *T. maritima* (87) and *A. aeolicus* (113). In addition, four sigma (σ) factors that determine promoter specificity, have also been identified in both organisms. The promoter elements consist of -35 and -10 regions as found in *E. coli* and in *T. maritima* have the consensus TTGAC and TATAAT (167). Similar to *E. coli* and *Bacillus subtilis*, the AUG triplet is used as the translational start codon. However, to a lower extent both the GUG and UUG triplets are also used as the translational start codon.

The hyperthermophilic archaea, however, display a chimeric transcriptional and translational apparatus with features from both eukaryotic and bacterial organisms (for recent reviews see 168–172). Similar to transcription in bacteria, archaeal genes are often located on the chromosome in clusters and can be transcribed as polycistronic messages. Further, there does not appear to be significant posttranscriptional modification of the mRNA such as poly-A tailing or a 5′ cap. However, the archaeal DNA is complexed with histones into nucleosome-related structures similar to eukarya (173). The archaeal RNAP also resembles the eukaryotic RNAP II in its complexity possessing at least 10 subunits as opposed to the four-subunit bacterial enzyme (174). This complexity was also observed in the genome sequences of *A. fulgidus*, *M. jannaschii*, *A. pernix*, and *P. horikoshii* with the identification of the individual subunits and subsequent comparison to their eukaryal homologs (80,82–84). The archaeal RNAP is unable to recognize promoters unaided and requires two additional *trans*-acting factors: the TATA-binding protein (TBP) and transcription factor B (TFB), which are homologs of the eukaryal TBP and transcription factor IIB. These three elements have been found to be sufficient to drive transcription in vitro (175,176). However, it cannot be ruled out that in vivo there are other factors yet to be identified that are also involved. The archaeal promoter element consists of two *cis*-acting elements, which include the TATA Box, and the TFIIB-responsive element (BRE). The TATA box is centered around $-25/-26$ relative to the transcription initiation site, and the BRE immediately precedes the TATA box with a AA doublet found at approximately -33 and -34 (177–180). A comparison of mapped promoters from *P. furiosus* is given in Figure 2. An analysis of the transcriptional start sites reveals a slight bias for a purine base. The TATA box is readily identified and is centered around -25 relative to the transcription start site and is preceded by an A-rich stretch of bases that make up the BRE.

Figure 2. Promoters from the hyperthermophilic archaeon *P. furiosus* Mapped promoter of *P. furiosus*. *celB* and *adhA* (181), *gdh* (175), *aat* (Ward et al., unpublished results), *lrp* (182), *aroQ* and *tyrB* (Ward et al., manuscript submitted), *nox1* (Ward et al., manuscript submitted), *gor* (183), *pfpI* (184), *pls* (185), *pol* (186), *pdk* (187), *hydB* (188), and *argF* (189).

Archaeal transcription is initiated by binding of the TBP to the 8-base pair TATA box, which is followed by the binding of the TFB to the BRE element. It has been shown that it is the BRE/TFB complex that determines the polarity of transcription in Archaea (190). The crystal structure of the archaeal preinitiation complex containing TBP, TFB, and the promoter region, including the TATA box and BRE has also been determined, which identified the sequence specific interactions between the C-terminal helix-turn-helix domain of the TFB and the BRE (191). It is this final ternary complex that is required for recruitment of the RNAP. Similar to eukaryotes, the N-terminal domain of TFB contains a zinc-finger, and is essential for recruitment of the archaeal RNAP to the promoter and subsequent promoter clearance (192,193). Although there has been significant focus on transcription initiation in the Archaea, this is not the case so far for transcription elongation and termination, and little is known about the factors involved. Posttranscriptional modification of messenger RNA (mRNA) does not appear to be as significant in the Archaea and 5′-capping of mRNA has never been observed. Transcription termination appears to resemble the bacterial Rho-independent mechanism, and probably involves an inverted repeat followed by a stretch of T-residues between four to thirty nucleotides in length.

Efforts to elucidate the mechanisms behind transcriptional regulation have focused on the identification and characterization of regulators identified through genome sequences. Analysis of archaeal genomes identified a large number of transcriptional regulatory proteins that were more closely related to bacterial sources than eukaryal (170). Three regulators from hyperthermophilic archaeons have been characterized in detail: the LrpA from *P. furiosus* (182), Lrs14 from *S. solfataricus* (194), and MDR1 from *A. fulgidus* (195). Both LrpA and Lrs14 belong to the Lrp/AsnC family of transcriptional regulators and were found to bind to their own promoters and repress transcription in vitro. The Lrs14 was found to bind the promoter region including the TATA and BRE sequences and it was proposed that inhibition may be via direct competition between the TBP and Lrs14 (194). The LrpA from *P. furiosus* binds from position −22 to +24 of its promoter and although it may not exclude binding of TBP it is possible its mechanism of repression is through the inhibition of the RNAP recruitment (182). The addition of possible effector molecules such as leucine did not have an effect on the binding of either LrpA or Lrs14. The crystal structure of the LrpA from *P. furiosus* was recently elucidated and could provide a great deal of insight into the how Lrp binds DNA thereby effecting transcription (196). Despite the similarity of these two regulators to the global regulator Lrp from *E. coli*, their roles as activators or global regulators is still purely speculation, and the actual genes, besides themselves, that they regulate is currently unknown. The LrpA is found just downstream of the gene encoding the glutamate dehydrogenase (*gdh*) and was originally thought to possibly play a role in its regulation. However, binding of the LrpA to the *gdh* promoter region has never been observed in vitro even in the presense of various potential effectors. The MDR1 (metal-dependent repressor 1) from *A. fulgidus* is located within a gene cluster that also encodes a metal-importing ABC transporter and is expressed as a polycistronic message (195). Transcription was found to respond to the availability of metal ions in the growth medium and MDR1 bound in a metal-dependent manner to repress transcription. It was also shown that binding of MDR1 to the promoter region did not inhibit TBP and TFB binding, but did block recruitment of the RNAP. The majority of regulators identified in the genomic sequences appear to be of a bacterial origin and are repressors. A transcriptional activator (GvpE) has been identified in a halophilic archaeon that activates genes involved in the formation of gas vesicles (197). The GvpE resembles the eukaryal basic leucine zipper proteins, but the precise mechanism of activation remains to be elucidated.

Very little is known about translational initiation in Archaea other than that the mRNAs can be found as either mono- or polycistronic messages, are usually preceded by Shine-Delgarno (SD) sequence, and the initiation usually begins with a AUG codon, although

GUG and UUG can also serve as the initiation codons. Analysis of genomic sequences reveals a combination of bacterial and archaeal features (for reviews see 168,169). Recently, it has been shown that two mechanisms exist for translation initiation in *S. solfataricus* (198). It was found that the SD-like ribosome binding motif was essential for efficient initiation and that disruption of the SD resulted completely blocked translational initiation. However, this could be overcome by the removal of the entire 5′ untranslated region. This leaderless mRNA was correctly translated, suggesting that a secondary mechanism for translational initiation exists in the hyperthermophilic archaea. The translation of leaderless mRNA's has now been observed in *Pyrobaculum* (199). It was found that genes that were expressed as a monocistronic message or were the first gene in an operon utilized a leaderless mRNA for translation. However, genes that were internally located within operons required the presense of a SD-like sequence for translation.

Genetic Elements

In recent years genetic elements have been found throughout the hyperthermophilic archaea and bacteria, including plasmids, viruses, and IS elements (for recent reviews see 200–202). These plasmids and viruses can serve as excellent models to study DNA replication, gene expression, and have great potential to serve as templates to build genetic systems for the hyperthermophiles. Furthermore, the study of genetic diversity could provide insight into the genetic variation, biodiversity, and evolution of these ancient organisms. With the completion of a number of genomes from hyperthermophiles horizontal transfer of genes has been shown to play a role in the genetic diversity of prokaryotes. The transfer of genes are often linked to genetic elements such as parts of prophages, transposases, integrases, and recombinases (203,204).

Mobile elements such as insertion sequence (IS) elements are integral parts of the bacterial genome and are also found in eukaryotic organisms (205). These elements are generally less than 2.5 kb and only contain the elements necessary for transposition, which usually involves a set of terminal inverted repeats (IR) flanking the element and a gene encoding a recombinase/transposase. The activity of these mobile elements can result in numerous genomic rearrangements such as deletions, inversions, and gene fusions. IS elements were found to be responsible for the spontaneous generation of β-galactosidase-deficient mutants (ISC1217), and uracil-auxotrophic mutants (ISC1058, ISC1217, ISC1359, and ISC1439) in *S. solfataricus* (206). The activity of these mobile elements probably plays a significant role in genomic rearrangements in this organism. IS elements have also been found in the genomes *P. furiosus* (*http://comb5–156.umbi.umd.edu/genemate/*), *P. abyssi* (*http://www-archbac.u-psud.fr/Projects/Pab_r/Pab_r Genome.html*), *T. maritima* (87), and *A. fulgidus* (82). In *P. furiosus*, a 16 kb region of the genome was found to be identical to 16 kb of the genome of *T. litoralis* with exception of 153 bp (207). This 16 kb region in *P. furiosus* is flanked by two IS elements and, on the basis of this, was given to be evidence of a recent lateral transfer between these two organisms.

Many hyperthermophilic bacteria and archaea have been found to harbor endogenous plasmids varying in size from 0.8 to 41 kb (Table 3). The presence of multiple plasmids within an organism is also common, as it has been observed in both the Euryarchaeota and Crenarchaeota. Most of the reported plasmids appear to be cryptic, despite significant effort to link the plasmids to phenotypic traits. Only one plasmid has been identified and characterized in detail in the hyperthermophilic bacteria: the 846-bp cryptic plasmid pRQ7 from *Thermotoga* sp. strain RQ7, which is one of the smallest replicons described in any organism (208). The plasmid has been sequenced and a single open reading frame (ORF) was identified that encodes a protein of 25.4 kDa and probably encodes the Rep protein necessary for plasmid replication. Sequence analysis of the Rep protein and putative origin of replication suggested that the plasmid replicated via a rolling-circle mechanism and single-stranded DNA intermediates of pRQ7 were identified confirming that the plasmid replicates via this mechanism (209). This plasmid has been found in three other strains of *Thermotoga* isolated from distantly located hydrothermal vent systems suggesting that the plasmid is both highly conserved and widely distributed among the *Thermotogales* (210). An extrachromosomal element (ECE) of 39.4 kb was identified in *A. aeolicus* and is present at approximately twice the copy number of the chromosome (113). The ECE encoded 32 coding regions of which only one could be assigned a function, a transposase. One coding region was also present on the chromosome in two identical copies suggesting that there has been transfer of genetic material between the ECE and the chromosome.

In the hyperthermophilic archaea, a large number of genetic elements have been identified, sequenced, and characterized in detail. The two model organisms of study are the aerobic, acidophilic Crenarchaeote *Sulfolobus* and the strictly anaerobic, heterotrophic Euryarchaeotes *Pyrococcus* and *Thermococcus*. A study was carried out to determine the distribution of plasmids in the *Thermococcales*, and of the 57 strains tested, 11 harbored plasmids that ranged in size from 3 to 24 kb suggesting that plasmids are diverse and widely distributed among the *Thermococcales* (212). Three of the strains isolated contained two plasmids, one of 3 kb and a second larger plasmid of 24 kb. On the basis of the relatedness of these three strains and that the 3 kb plasmids cross-hybridized, as did the 24 kb plasmids, they are probably closely related. To date, only the small cryptic plasmid pGT5 from *P. abyssi* has been characterized in detail (211). The plasmid is 3.4 kb and contains 2 ORFs with the larger ORF encoding the Rep protein necessary for plasmid replication, and was also found to replicate via the rolling-circle mechanism. The function of the second smaller ORF is unknown, but may play a role in copy number control. A second plasmid has been isolated recently and sequenced from *Pyrococcus* sp. strain JT1 and was found to be distinct from pGT5. The 3.4 kb plasmid (pRT1) was sequenced and encoded two proteins, both of which are

expressed. Similar to pGT5, the plasmid replicated using the rolling-circle mechanism (Ward et al., manuscript in preparation).

The distribution and diversity of genetic elements has been best characterized in *Sulfolobus*, and this is largely due to the work of Zillig and coworkers. They have now discovered more than 25 plasmids and 30 novel viruses (202). The plasmids have been divided into two groups; conjugative and nonconjugative. The nonconjugative plasmids range in size from 4.7 to 35 kb and similar to the plasmids described in the Thermococcales appear to be cryptic (202). A number of these plasmids have been sequenced and five of them, pRN1, pRN2, pHEN7, pDL10, and pSSVx, are closely related and are grouped together as the pRN family of plasmids (216). These plasmids exhibited significant sequence identity in three ORFs and in two noncoding regions. Two of the ORFs appear to be involved in plasmid replication and its control, as one ORF encodes the putative Rep protein involved in plasmid replication and the other appears to be a CopG homolog and has been proposed to be involved in copy number control. It has been suggested that the pRN family of plasmids replicate via the rolling-circle mechanism. The ORF encoding the CopG homolog of pRN1 (ORF56) has been expressed and the recombinant protein binds its own promoter (226). In all 5 plasmids, the gene encoding the CopG homolog lies immediately upstream of the gene encoding the Rep protein and it is possible that these two genes are cotranscribed and binding of the CopG to its own promoter could affect expression of the Rep protein and control the copy number of the plasmid (226). The plasmid pSSVx of this family is especially intriguing in that it appears to be a cross between a plasmid and a virus (216). The plasmid was isolated from *S. islandicus* strain REY15/4, which also contains a novel virus SSV2. The plasmid could be spread to *S. solfataricus* but only in combination with SSV2 either during infection or with purified virus. Despite the similarity of pRN1 and pRN2 with pSSVx, neither plasmid could be spread, even the presence of the viruses SSV1 or SSV2.

Conjugation has been found to be a more frequent event in the Crenarchaeota than previously thought. From 300 novel strains of *Sulfolobus* 11, conjugative plasmids were identified and range in size from 24 to >40 kb (227). These plasmids were found to efficiently spread from donor to recipient cells by direct contact of the cells. The transfer of DNA was not mediated by pili

as is found in some bacterial conjugation systems, but instead contacts involving large sections of the cell surface were observed (227). The authors believe that the high frequency of these plasmids in isolates could in part be attributed to the self-spreading nature of these plasmids. The copy number of these plasmids is generally low in the host cell, but on transfer into the recipient strain, the copy number increased to at least 35 c.c., which resulted in inhibition of growth (220,227). Another characteristic of these plasmids is significant genetic variation that results after prolonged growth of the recipient cells. This was most pronounced with pNOB8, where a 10-kb deletion event occurs resulting in formation of pNOB8–33 (220). The complete nucleotide sequence of the conjugative plasmids pNOB8, pING1, pING4, and pING6 have been determined and the sequence of pSOG2/4 is in progress (219,228). The pING, pNOB, and pSOG plasmids were found to contain regions of extensive identity across the three subfamilies. These regions included ORFs that may be involved in plasmid replication, maintenance, and conjugative transfer, and noncoding regions (219,228). IS elements were also identified in both pNOB8 and the pING plasmids, which appear to play a significant role in the genetic variation of these plasmids and could possibly be involved with the transfer of genetic material between the plasmids and the host chromosome.

Approximately 35 viruses have been found in the archaea and in the hyperthermophiles they so far have only been isolated in the Crenarchaeotes *Thermoproteus* and *Sulfolobus* (reviewed in (202,229). These viruses have been found to be morphologically unique and resulted in the formation of three novel virus families. All the genomes have been found to be dsDNA and were either linear (SIFV, SIRV1, and TTV1) or circular (SSV1, SSV2, and SNDV) and the genomes of SSV1 and TTV1 have been completed. All of these viruses, with the exception of SNDV1, integrate into the genome of its host. The spreading and subsequent integration of these viruses could be a significant source of gene disruption or replacement, and a mechanism for lateral gene transfer.

MICROBIAL ECOLOGY OF HYPERTHERMOPHILES

On the basis of the information gained from 16S rRNA phylogenetic probes (90) and from visual inspection of samples from geothermal sites using electron microscopy, it is clear that only a small fraction of the hyperthermophile world has been captured in laboratory pure culture (5). One of the current challenges is to relate information gained from phylogenetic analysis to physiological and ecological phenomena. The fact that hyperthermophiles participate in a complex ecosystem in high temperature environments is beginning to be examined more carefully. Stetter and coworkers, for example, have tried to relate phylogenetic and physiological information gained from samples taken from regions within the Pisciarelli Solfatara near Naples, Italy (5). Consistent with what is known about hyperthermophile physiology, they noted that the distribution of previously studied hyperthermophilic species was consistent with their expected pH growth ranges as determined in laboratory pure culture. At the same time, phylogenetic analysis and microscopic examination revealed the presence of numerous organisms unrelated to known hyperthermophiles.

Significance of Polysaccharides in Hyperthermophile Microbial Ecology

Over the past decade, the enzymology and physiology of carbohydrate utilization by hyperthermophiles has been examined (110,111,230–234). These efforts, in conjunction with genome sequence data, have revealed that hyperthermophiles produce a wide array of glycosyl hydrolases (GH), representing a number of GH families (235). Genome sequence information has been enlightening in view of the expanded list of carbohydrates that may be substrates for actual and putative GHs in a given organism. For example, *P. furiosus*, once thought to only grow on starch and cellobiose, has in fact the enzymatic inventory to utilize a wide array of complex β-linked carbohydrates, including lamanarin, barley glucan and chitin (236). Whereas *P. furiosus* that normally grows best near 100 °C, can grow on simple sugars such as glucose, maltose and cellobiose, polysaccharide utilization by this hyperthermophile and others offer the advantage given the apparent stabilization of sugar moieties conferred by the polymeric structure (142).

The use of complex carbohydrates by heterotrophic hyperthermophiles raises questions about the sources of these compounds in their natural environments. Very little has been done to this point to address this issue, although it is clear that polysaccharides are found in extreme environments. For example, *S. acidocaldarius*, an extreme thermoacidophilic aerobe, produces a sulfated, exocellular, glucose-, mannose-, and galactose-containing polysaccharide (237), whereas the archaeon *Haloferax mediterranei*, a mesophilic halophilic aerobe, produces a sulfated, exocellular polysaccharide (238). Anaerobic archaea have been less studied in this regard, but the moderately thermophilic *M. thermophila* produces a heteropolysaccharide outer layer (239) that may aid in colonization (240), and hyperthermophilic *Thermococcus* species typically produce glycogen, apparently as an intracellular storage polymer (241). Unusual extracellular polysaccharides have also been identified in hydrothermal vent mesophilic bacteria (242–244). Complex carbohydrates typically associated with higher plants are good growth substrates for certain hyperthermophiles. *Thermotoga maritima*, for example, grows extremely well on carboxymethylcellulose and guar galactomannan; synergistic enzyme systems in this organism are indeed present to hydrolyze such material for transport and utilization (Chhabra et al., submitted). However, except for shallow marine and terrestrial geothermal vents, hyperthermophiles are usually found in the deep-sea hydrothermal vent settings, which lack any photosynthetic life. The question arises as to how these compounds are made available to hyperthermophiles and how have these organisms acquired the enzymatic machinery to use them.

The answer to the aforementioned question may lie, at least in part, in the recently discovered capability

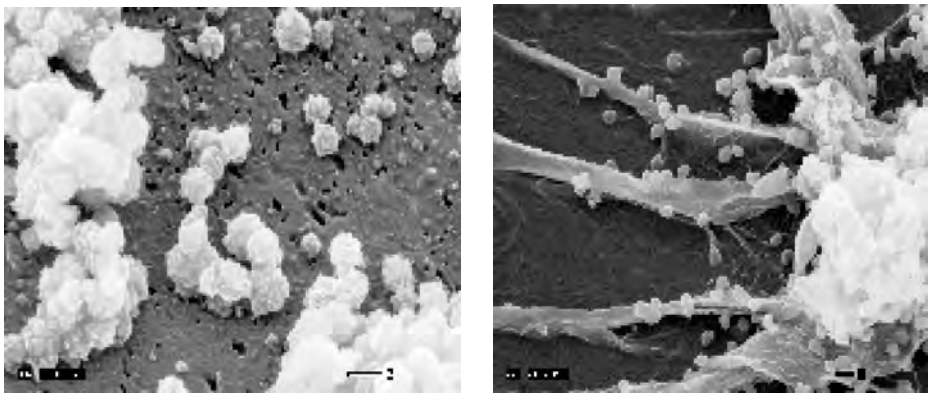

Figure 3. *Pyrococcus furiosus* grown on cellobiose (left) and maltose (right) in batch culture at 98 °C. Note formation of capsular polysaccharide (left) and exopolysaccharide (right) (Pysz and Kelly, unpublished data).

of hyperthermophiles to produce exocellular and capsular polysaccharides. It has been reported, for example, that the hyperthermophile *M. jannaschii* forms a biofilm based on exopolysaccharides it produces (245). Rinker and Kelly (99) showed that *T. litoralis* was able to produce large amounts of a mannan-based exopolysaccharide under certain growth conditions. Furthermore, this organism was also able to form biofilms with this material. Rinker and Kelly (246) have shown that *T. litoralis* forms copious amounts of polysaccharide in chemostat culture, as does *T. maritima*. It is possible that stress induces polysaccharide formation; Rinker and Kelly (246) revealed that exopolysaccharide formation by *T. litoralis* was induced at elevated NH_4Cl concentrations, which at the same time served to inhibit growth. Indeed, Laplagia and Hartzell (245) reported that stress induced polysaccharide formation by the hyperthermophile *A. fulgidus*. We have recently been able to establish growth conditions that induce exocellular and capsular polysaccharide formation by the hyperthermophile *P. furiosus* (Pysz and Kelly, unpublished data) (see Fig. 3). These two types of polysaccharides may play different roles in microorganisms (247). The genes and enzymes regulated in the formation of polysaccharides in hyperthermophiles are currently being investigated.

Interspecies Interactions at High Temperatures

The focus so far in the study of hyperthermophiles has been on isolating organisms in pure liquid culture for subsequent characterization. However, in natural settings, microorganisms are typically not planktonic but rather associated with surfaces and biofilms that offer higher concentrations of nutrients and protection from predators and toxic agents (248). It has been proposed that the concept of communities existing and interacting within microbial biofilms represents a more unifying theory of ecology and that evolution may have been more of a proliferative and associative process than competitive and selective (249). Certainly, geothermal systems are now known to harbor a diverse set of microorganisms, which may be difficult to separate into pure cultures (90,250). Although much can be learned from the analysis of electron flux from donor to acceptor in pure culture, such processes in natural settings take place within a web of other organisms and may be much different. The difficulties typically encountered in establishing and maintaining certain hyperthermophiles in pure culture probably stem from the elimination of cell to cell interactions that occur in natural consortia. Hence, there are likely to be synergistic relationships within hyperthermophilic consortia, which may be an important factor in establishing stable ecosystems containing these microorganisms. For example, it has been shown that many heterotrophic hyperthermophiles are positively affected in coculture with hyperthermophilic methanogens (251,252). Muralidharan and coworkers have shown that *T. maritima* and *M. jannaschii* in hyperthermophilic coculture results in a 10-fold increase in cell densities of the heterotroph as a result of removing H_2 inhibition through methanogenesis (253). Also, although H_2 levels in the headspace in these cocultures are negligible, *M. jannaschii* was able to grow to in excess of 2×10^7 cells/ml on the CO_2 and H_2 generated by the fermentative anaerobe. Cell sorting and electron microscopy revealed that these organisms form very tight interactions in the coculture. Using a mathematical model to describe coculture interactions, it was shown that the high growth rates of hyperthermophilic methanogens relative to mesophilic methanogens led to an increased dependence on H_2 availability, hence the close physical interaction observed experimentally (Fig. 4).

CONCLUSION

Much has been learned about the enzymology and physiology of hyperthermophilic microorganisms over the past two decades. In many respects, not many new rules have been uncovered that underly the biological mechanisms enabling life to thrive at such biologically extreme temperatures. On the other hand, genome sequences for these organisms have only been partly diciphered and thus may include information and insights not fully appreciated at this point. In any case, hyperthermophiles have expanded the scope of the biosphere and presented the intriguing possibility that life, extant or extinct, may be associated with other solar bodies that are just beginning to be explored.

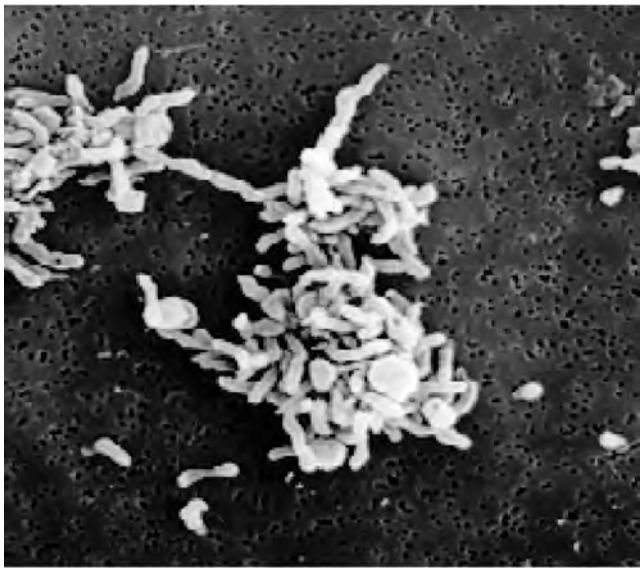

Figure 4. *Thermotoga maritima* (rods) and *Methanococcus jannaschii* (cocci) coculture (252).Interactions within hyperthermophilic consortia may also help explain the presence of a diverse set of glycosyl hydrolases produced by these organisms. For example, *T. neapolitana* and *T. maritima* both produce a set of hemicellulases that act together to hydrolyze galactomannans (254). One of these hemicellulases, β-mannanase, is produced extracellularly, and is effective in hydrolyzing the mannan-based exopolysaccharide produced by *T. litoralis* (99). Thus, one can envision a consortium. The importance of biofilm-based consortia in hydrothermal environments cannot be overlooked and such structures may in fact be the defining framework of any ecosystems that exist in these niches. However, at present, little is known about mixed culture dynamics at high temperatures, especially with respect to intra- and inter-consortial processes. The central importance of polysaccharide-forming and–hydrolyzing enzyme systems cannot be overlooked in this regard.

IDENTIFICATION OF AIRBORNE FUNGI

PATRICIA CRUZ
University of Nevada
Las Vegas, Nevada

The fungal kingdom consists of macroscopic and microscopic organisms that can be parasitic, symbiotic, or saprophytic. A fungus made of filaments forming a colony is defined as a *mold*. Mold colonies are generally visible to the naked eye; however, the individual filaments (hyphae) and spores forming the colony are visible only with the aid of a microscope. Mold spores can become airborne, because many fungi use air currents for dispersing their spores. In addition, their small size and weight makes transportation through the air possible. Fungi are known to occupy natural and artificial habitats in both indoor and outdoor environments. Dead or living plants, decaying or freshly cut wood, food, grains, soil, and building materials such as paint, wallpaper, and cellulose products can be colonized and damaged by fungi, especially under humid or wet conditions. Certain molds growing on environmental surfaces can produce toxins that can cause disease when inhaled, ingested, or on direct contact with skin. Therefore, it is important to sample and accurately identify fungi to properly remediate or treat the contamination. Fungi are identified by observing the colony morphology and the color, shape, and arrangement of the spores they produce. Difficulties surrounding fungal identification include the lack of appropriate references and trained personnel, the inability of certain fungi to produce classical structures in the laboratory, and variations in the colony morphology that is observed, depending on the culture medium used. Fungal identification is achieved after a sample is collected, processed, and/or cultured. Types of samples that can be analyzed for fungal identification are tape samples of visible colonies on building materials or surfaces, microscope slides coated with an adhesive film used for air sampling, and colonies growing on fungal media in the laboratory. This chapter summarizes the criteria and techniques used for identifying environmental fungi and the characteristics of the fungal genera that are most often found in environmental samples.

CLASSIFICATION OF FUNGI

Molds and yeasts are eukaryotic organisms that belong to the kingdom Fungi. Approximately 60,000 species of fungi have been described (1). They are characterized by being nonmotile, having a cell wall, lacking chlorophyll, and developing by means of spores (2). Like any other kingdom, fungi are classified into divisions, classes, orders, and families (3). Classification of microscopic fungi is based on their reproduction and on the type and characteristics of the spores they produce. Fungi can reproduce sexually or asexually. Organisms showing both types of reproduction (at different times in their life cycles) are given two names [e.g., *Aspergillus* (asexual form) and *Emericella* or *Eurotium* (sexual forms)]. Asexual fungi are also referred to as "microfungi" or "Fungi Imperfecti" and belong to the phylum Deuteromycota (4). Sexual fungi that are common in indoor environments are classified into three phyla: Zygomycota, Ascomycota, and Basidiomycota (5).

TERMINOLOGY AND DEFINITIONS

Microscopic fungi can be either yeastlike or filamentous in nature. Yeastlike microscopic fungi are referred to as *yeasts*, whereas filamentous microscopic fungi are referred to as *molds*. Some fungi, referred to as "dimorphic," present both as a yeast or a mold at different stages in their life cycles. Colonies vary in texture. They may be cottony, powdery, woolly, velvety, leathery, or granular. In addition, their color may be white, brown, black, green, yellow, or other colors (5,6). Molds forming black dots on clothing, books, or damp materials are referred to as "mildew"; however, true mildews are parasitic fungi growing on plants (7).

Spores are reproductive fungal structures that can be produced either sexually or asexually. Depending on the type of reproduction or function, spores are referred to with names such as *arthroconidia*, *ascospores*, *basidiospores*, *sporangiospores*, *blastoconidia*, or *chlamydoconidia*. However, the name most commonly used is "spore" or "conidium" (pl. conidia). In addition, when a fungus produces both large and small conidia, these are referred to as "macroconidia" and "microconidia," respectively. Spores generally form on the side or at the end of hyphae (long chains of cells comprising the mold) or conidiophores. Conidiophores are specialized hyphae that serve as a structure that bears conidia. The size, color, shape, and arrangement of spores are generally constant for each genus, thus making them a very useful tool for identification (8). The combined characteristics of the conidiophores and spores are unique to the genus. Several characteristics such as the arrangement of spores around the conidiophore, spore pigmentation, roughness or smoothness of the conidiophore and spores, and length

of the conidiophore need to be considered in the speciation of fungi.

Fungi that are capable of reproduction are said to be viable. Fungi that grow under laboratory conditions are said to be culturable and can de detected by culture analysis of air or bulk samples. Certain fungi that are viable may not grow in culture under laboratory conditions for various reasons such as sampling stress or lack of proper nutrients. These fungi are referred to as viable but nonculturable and can be detected by genetic amplification or microscopic analysis of air samples such as those collected onto an adhesive-coated slide.

FUNGAL HABITATS

Molds are ubiquitous in nature and are essential in nutrient cycling, the decomposition of dead or dying matter. However, molds have specialized nutritional requirements (see the following text). Fungi can live in a symbiotic relationship with other organisms, can be parasitic, saprophytic, or both (5). The habitat that a mold occupies depends on several factors such as the kind and availability of nutrients, competition, and spore dispersal (8). Fungi occupy natural and artificial habitats in both indoor and outdoor environments (9). Among the habitats molds occupy are dead or living plants, decaying or freshly cut wood, food, grains, water, and soil. In addition, artificial products such as paint, wallpaper, and cellulose products (e.g., paper, cardboard, and wood derivatives) can be colonized and damaged by fungi especially under humid or wet conditions. In the process, certain molds can produce toxins (mycotoxins) that can cause disease on direct contact with skin, inhalation, or ingestion (5).

NUTRIENTS

Fungi need sources of energy (i.e., organic carbon), nitrogen, minerals, and occasionally vitamins. Many fungi can be grown in the laboratory; however, some may not produce spores (or toxins) when cultured away from their natural habitat (10,11). In the laboratory, molds and yeasts are grown in a substance called a *medium* (pl. media) that can be semisolid or liquid. Semisolid media are generally preferred for identification purposes (8). Growth media can be made by diluting all the necessary nutrients and a solidifying agent (i.e., agar) in water. Otherwise, growth media in dehydrated form or poured into ready-to-use plates are available from commercial sources. Regardless of the source, media should be inspected for the appropriate appearance, pH, sterility, and performance (12).

CULTURE MEDIA AND INCUBATION CONDITIONS

There are several publications that provide recommendations on microbiological media for the isolation of fungi (5,13). A list of common fungal media and their formulations is presented in Table 1. For the primary isolation of fungi, a general culture medium such as malt-extract agar (MEA) should be used. In samples in which a large number of bacteria are anticipated, a bactericidal agent such as chloramphenicol (100 μg/ml final concentration) should be used (5). Dichloran glycerol-18 (DG-18) (14) is useful for the isolation of xerophilic fungi (13). In addition, DG-18 and 2% MEA without glucose or peptone have been recommended for the inhibition of fast-growing fungi (e.g., *Rhizopus* and *Trichoderma*) (5). Cellulose agar (CA) contains rose bengal that retards growth of fast-growing fungi and allows slower-growing organisms to be detected. Because rose bengal is light-sensitive, this medium should be protected from light (5). Cellulose agar is useful for the isolation of cellulolytic fungi such as *Stachybotrys* species. Water agar (20 g agar/L of water) overlaid with sterile filter paper has also been suggested for the isolation of *Stachybotrys* from environmental samples (5). For promoting sporulation, potato dextrose agar (PDA) is recommended. Czapek solution agar (CZA) has proven useful for the identification of certain *Aspergillus* species (3).

Light is not required for fungal growth; however, periods of light and darkness necessary for normal sporulation are usually provided by the normal handling of the cultures during incubation (2). Environmental fungi are generally incubated at 23 to 25 °C for up to 10 days. Preliminary identification of fast-growing organisms can usually be performed after three days of incubation by using a stereoscope and the methods discussed in the following text. Plates should be reincubated and checked periodically to observe the organism at the proper stage of sporulation. Higher incubation temperatures should be used if special interest in thermophilic fungi exists. Although incubation at 45 °C (5,13) is not necessary for the isolation of *Aspergillus fumigatus*, it is useful for speciation. For the detection of *Stachybotrys* on MEA plates, samples should be checked periodically and incubated for 10 days. However, if fast-growing or numerous other fungi are present, detection of this organism on MEA will be difficult if not impossible. Therefore, it is recommended that for the isolation of *Stachybotrys* species, CA plates be used in conjunction with a primary isolation medium. Care must be taken in handling the plates because spores can be dislodged from the original colonies, forming satellite colonies that produce an overestimation of the quantity of colonies on the plate. Plates with numerous colonies, toxigenic fungi, or fast-growing fungi such as *Rhizopus* should be taped or sealed to prevent accidental exposure to the organism(s).

SPORE DISPERSAL

Mold spores can become airborne, because many of the fungi use air currents for dispersing spores. In addition, their small size and weight makes transportation through the air possible (5). Several mechanisms exist for spore dispersal by air currents, such as exposure of spores to the air, shooting spores into the air, and droplet adhesion (8,15). Fungal spores are subjected to both seasonal variations and daily fluctuations that are influenced by several factors including wind velocity and rain (1,16,17).

Table 1. Summary of Commonly Used Fungal Growth Media and Stain Formulations

Malt-Extract Agar (MEA)[a]

1.275% maltose
0.275% dextrin
0.235% glycerol
0.078% peptone
1.5% agar
Final pH = 4.7

Potato Dextrose Agar (PDA)[a]

20% potato infusion
2% dextrose
1.5% agar
Final pH = 5.6

Sabouraud Dextrose Agar (SDA)[a]

1% neopeptone
4% dextrose
1.5% agar
Final pH = 5.6

Cellulose Agar (CA)[b]

0.2% sodium nitrate
0.1% potassium phosphate, dibasic
0.05 % magnesium sulfate
0.05 % potassium chloride
2 % cellulose powder[d]
0.005 % rose bengal
1.5 % agar
Final pH = 8.0

Lactophenol Cotton Blue[e]

20% concentrated phenol
20% lactic acid
40% glycerol
20% distilled water
0.05% cotton blue

Corn Meal Agar (CMA)[a]

5% corn meal infusion
1.5% agar
Final pH = 6.0

Czapek Solution Agar (CZA)[a]

3% saccharose
0.2% sodium nitrate
0.1% potassium phosphate, dibasic
0.05% magnesium sulfate
0.05% potassium chloride
0.001% ferrous sulfate
1.5% agar
Final pH = 7.3

Rose Bengal Agar (RBA)[a]

0.5% soytone
1% dextrose
0.1% potassium phosphate, monobasic
0.05% magnesium sulfate
0.005% rose bengal
1.5% agar
Final pH = 7.2

Dichloran Glycerol-18 (DG-18)[c]

1.0% glucose
0.5% peptone
0.1 % potassium phosphate, monobasic
0.05% magnesium sulfate
1.5% agar
18% (wt./wt.) glycerol
0.0002% dichloran (in ethanol)
0.0005% chlortetracycline (in water)
Final pH = 5.6

[a] MEAC can be prepared by adding chloramphenicol (100 μg/ml final concentration) to the MEA formulation [chloramphenicol is added to the cooled media (51°C) after autoclaving]; formulation obtained from Difco Manual, 10th ed., Difco Laboratories, Detroit, 1985.
[b] Formulation courtesy of W. Sorenson, NIOSH, Morgantown, West Virginia, and B. Jarvis, University of Maryland, Maryland.
[c] Filter-sterilized chlortetracycline is added to the cooled media after autoclaving; formulation obtained from A. D. Hocking and J. I. Pitt, *Appl. Environ. Microbiol.* **39** (3), 488–492 (1980).
[d] Sigmacell type, Cat. No. S-6790, Sigma Chemical Co., St. Louis, Missouri.
[e] Formulation obtained from D. H. Larone, *Medically Important Fungi. A Guide to Identification*, 3rd ed., ASM Press, Washington, 1995.

METHODS OF IDENTIFICATION

Air sampling is the traditional method used for the collection of spores for identification of airborne fungi. Two approaches exist for air sampling: collection of viable spores onto growth media for the culture of colonies and collection of total spores (viable and nonviable) onto an adhesive-coated glass slide for the microscopic examination of fungal spores (8). Chemical analyses for ergosterol and glucans have been developed as a means to measure fungal biomass. In addition, immunological analyses that can detect certain fungal allergens and mycotoxins have also been developed. However, both chemical and immunological assays have relatively low sensitivity of detection (5). Of increasing interest is the detection of environmental fungi using molecular techniques such as polymerase chain reaction (PCR). However, the limited number of published unique nucleic acid sequences and the similarities between closely related genera have made this approach difficult. A more detailed discussion on alternative methods of sampling and analysis of airborne microorganisms can be found elsewhere in this Encyclopedia.

IDENTIFICATION CRITERIA

Fungal (mold) identification is achieved by the observation of temperature requirements in combination with both macroscopic and microscopic characteristics. Macroscopic

characteristics include colony appearance and growth rate. Colony appearance and growth rate can vary, depending on the culture medium that is used and the age of the colony. Therefore, it is important to note the culture medium being used by the reference text of choice, especially if the manual includes color pictures of the fungal morphology. The colony appearance refers to the color of the surface and the reverse of the colony, the texture, configuration, margin, and elevation (18). The growth rate refers to the diameter of the colony and can be recorded periodically for identification purposes. Most reference books for fungal identification give emphasis to the surface and reverse colors of the colony, indicating growth rate in a subjective manner rather than by measurements. Microscopic characteristics include septation of hyphae, size, color, shape and arrangement of spores, and specialized structures. Microscopic characteristics can vary, depending on the age of the colony. Hyphae may be septate, with cross walls, or aseptate (coenocytic) with no cross walls. They can appear with or without color; however, colorless hyphae will tend to absorb the stain being used for mounting (i.e., structures appear blue when stained with lactophenol cotton blue). The size, shape, arrangement, and color of the spores are the most important determinants of fungal identification. The presence of specialized structures should also be noted because it may be important for the identification of some genera such as *Bipolaris* sp. and in the identification of *Aspergillus* to the species level. Taxonomic, dichotomous, and illustrated keys are generally used for the identification of fungi (3,6,12) and the the easiest one is probably that of the dichotomous or illustrated key, in which a flowchart approach guides the user in the identification process (6). Beginning with a fungal colony and a microscopic slide preparation of the organism of interest, this approach focuses initially on the macroscopic morphology (especially surface and reverse colors) before guiding the user to microscopic drawings of the possible matches and to more detailed information on each possible match. This approach narrows down the possibilities until a match is found for the organism of interest.

PROCESSING AND IDENTIFICATION OF SAMPLES

Fungal identification is achieved following four steps: (*1*) sample collection, (*2*) sample processing, (*3*) culture and incubation, and (*4*) analysis. A detailed discussion on sampling for airborne microorganisms can be found elsewhere in this Encyclopedia.

Analysis of Air Samples

The approach suggested for the identification of culturable fungi present in air samples is summarized in Figure 1. Following collection and incubation of an air sample, observation of the colonies through a stereoscope often reveals the presence of spores. With the interchangeable use of the top and bottom lighting on the stereoscope, it is often possible to visualize both the spores and their arrangement. With experience, fungi such as *Alternaria*, *Cladosporium*, *Penicillium*, *Epicoccum*, *Aspergillus*, *Paecilomyces*, *Chaetomium*, and *Rhizopus* can be identified to the genus level without the need for further microscopy work. Care must be taken to avoid misidentification of organisms with similar spore shape or arrangement (e.g., *Aspergillus* and *Penicillium*; *Bipolaris* and *Curvularia*; *Alternaria* and *Ulocladium*). If observation of the colony through a stereoscope does not reveal the presence of spores or if the spores observed cannot be identified with absolute certainty, it is necessary to prepare a mount of the colony (see the following text) for observation through a light microscope. The fungal mount is stained with a dye and observed through a light microscope at low magnification (100 X total magnification). Although several dyes are available for the staining of fungal structures, lactophenol cotton blue (Medical Chemical Corporation., Santa Monica, California) (Table 1) is the one that is most often used. This dye is both a staining and a mounting agent that preserves at the same time that it kills the fungal elements present in the sample (6). Scanning the mount at low magnification will reveal the areas containing spores. Certain areas may be too dense with spores impeding proper visualization, whereas others may be ideal for closer observation. Once fungal spores are located, increasing the total magnification to 400 X will reveal details of the spore shape and arrangement that will aid in identification. With the aid of dichotomous or taxonomic keys present on fungal manuals, it is possible to identify the fungus to the genus (and sometimes species level) by combining the colony morphology with the microscopic observations. Also, the use of selective culture media and incubation temperature will aid in the speciation of certain fungi such as *A. fumigatus*. In cases in which the spores cannot be identified because they are not present in any of the fungal manuals available, the organism is called an unknown. If no spores can be

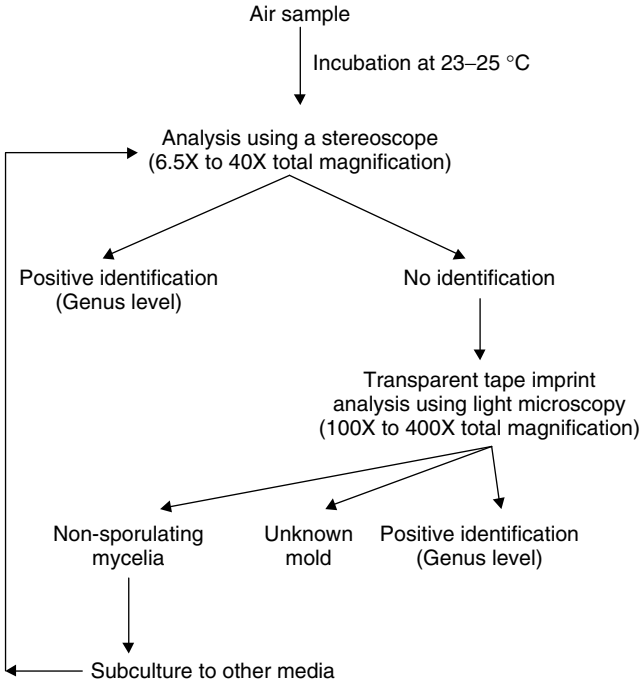

Figure 1. Flowchart summarizing the approach suggested for the identification of culturable fungi in air samples.

found, the organism should be subcultured onto other microbiological culture media such as PDA or CZA. Both the original culture and the subcultures should be incubated and examined periodically for up to 10 days. If the organism does not produce spores after these attempts, the organism is identified as nonsporulating mycelia or mycelia sterilia.

Impaction sampling onto an adhesive-coated surface [e.g., Burkard personal sampler (Burkard Manufacturing Co. Ltd., Rickmansworth, England), Air-O-Cell air sampling cassette (Zefon Analytical Accessories, St. Petersburg, Florida)] is often used for the detection of airborne fungi. It is particularly useful in the detection of fungi that would otherwise be missed by culturable sampling, either because the fungi are nonculturable or because they are dormant or slow growers that do not compete well with fast-growing fungi. Slides are mounted by placing a drop of lactophenol cotton blue on top of the adhesive portion of the sample and examined using a microscope. Similar to tape sampling (discussed in the following text), spores often have to be differentiated from debris. It is usually impossible to differentiate between organisms with similar spore shape. Also, because the spores observed cannot be cultured, there is usually only one opportunity to identify the fungi present. In addition, once the slide is stained, it must be analyzed within a few hours because air bubbles will form in the slit area under the cover slip, making analysis and quantitation difficult. This effect is of special concern with heavy samples showing a wide slit. In contrast to tape sampling, Burkard and Air-O-Cell sampling are volumetric methods and therefore quantitative.

Analysis of Surface Samples

Airborne fungi can settle on surfaces that can promote growth and amplification when sufficient water and nutrients are available. Therefore, identification of fungi present on surfaces is included in this review. The approach suggested for the identification of culturable and nonculturable fungi present in surface samples is summarized in Figure 2. Agar contact plates are incubated and analyzed in the same manner as culturable air samples (described earlier). However, they must be checked often because of the chance for overgrowth in the reduced area available on the sample surface of small agar plates. Swab, bulk (e.g., ceiling tile, wallboard, carpet, and air filter), and dust or vacuum samples require processing followed by incubation before identification. Fungal identification of the processed samples is achieved in the same manner as culturable air samples. Transparent tape imprints are often used as a sampling method for suspect fungal growth, especially of water-stained or visibly moldy building materials. Identification of fungi present in tape imprints involves mounting the tape on a drop of lactophenol cotton blue and examining with a light microscope. Examination of this type of sample is often lengthy because the spores and fungal elements must be discriminated from the debris present in this type of sample. Unless spore arrangement and critical identification structures are present in the sample, it will be difficult to differentiate between organisms with similar spores. Therefore, spores of the genus *Aspergillus* that resemble *Penicillium* spores are identified as belonging to the *Aspergillus or Penicillium* group; the same applies for *Bipolaris or Dreschlera* and *Alternaria or Ulocladium*. This method is only qualitative and there is usually only one opportunity to identify the fungi present because the spores observed cannot be cultured. In addition, once the tape is stained, it must be analyzed within a couple of hours because the adhesive in the tape will begin to dissolve with prolonged contact with the dye.

SAFETY PRECAUTIONS

It is important that safety precautions be used when handling fungal colonies and fungal contaminated material. A biosafety cabinet is necessary whenever fungi-containing samples are examined. Surfaces on which samples have been placed should be decontaminated often with a 10% bleach solution or other biocide such as 70 to 75% isopropanol solution. Discards should be properly wrapped and autoclaved before disposal or washing. In addition, gloves should be worn and hands should be washed thoroughly with soap and water after handling fungal plates and slides. Under no circumstance should fungal colonies or fungal contaminated materials be smelled. For a more comprehensive list of safety precautions, mycology books (especially medical mycology books) should be consulted (3,6).

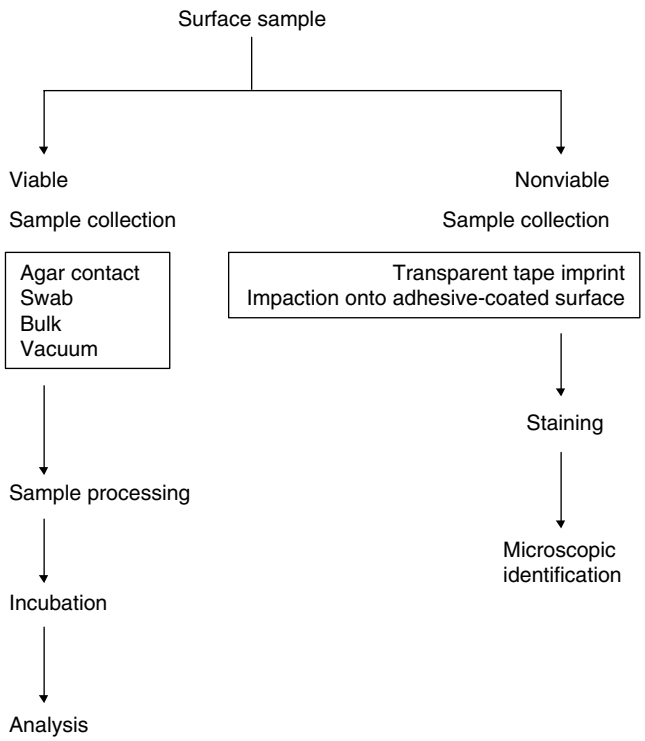

Figure 2. Flowchart summarizing the approach suggested for the identification of culturable and nonculturable fungi in surface samples.

TOOLS OF IDENTIFICATION

Several methods are available for the preparation of fungal mounts: transparent tape imprint, cover slip culture, and slide culture (6).

Transparent Tape Imprint

This is the fastest and easiest way to prepare a microscopic mount for fungal identification. Imprints are generally made of colonies growing on fungal media in the laboratory but they can also be used as a field-sampling method (as described earlier). It is important to use transparent rather than frosted cellophane tape to obtain a clear mount. It is a matter of personal choice, whether the $\frac{1}{2}$" or $\frac{3}{4}$" tape width is used; however, the wider tape is easier to handle. Following the safety precautions already mentioned, a piece of tape approximately 1.5"long is cut and looped with the adhesive toward the outside. Care must be taken to handle the tape only by the edges. The adhesive part of the tape is pressed lightly against the surface of the colony. If required, a finger or a disposable swab can be used to press down on the tape. Fungal colonies growing on agar are circular, growing from a central point toward the outside; both the center and edge of the colony should be sampled because these areas will contain old and new fungal growth, respectively (2). When pressing the tape, one must avoid pressing too hard because this will produce a sample that is too dense and difficult to analyze; when in doubt, a second (less dense) sample should be prepared. Touching adjacent colonies should be avoided because this can lead to misidentification of fungal colonies. When sampling very small colonies, the region of the tape containing the sample should be noted to make analysis easier. The tape is unlooped and mounted on a drop of lactophenol cotton blue on a glass slide, avoiding air bubbles or wrinkles in the mount. Using too much lactophenol should be avoided or cleaned up immediately. Dye on top of the tape will make visualization impossible, and any dye on top or sides of the tape can damage the microscope objectives. Once the tape is stained, it must be analyzed within a couple of hours because the adhesive in the tape will begin to dissolve with prolonged contact with the dye. Observation through a microscope using 100 X total magnification will reveal the areas with spores that are not too dense for observation at higher magnification. Slides should be discarded (e.g., inside empty slide boxes and taped when full) and autoclaved before disposing. When using this method for field sampling, the sample is collected and mounted onto a glass slide without the dye. At this stage, the sample can be stored indefinitely until it can be stained and analyzed. Therefore, it is important to label the slide properly and to store it in a cool, dry place. In addition, it is best to store each slide individually on collection either in a plastic slide holder or inside a Whirlpack bag (Nasco, Fort Atkinson, Wisconsin) to prevent cross-contamination. Staining and analysis is performed in the same manner as for imprints taken off a colony in the laboratory.

Cover Slip Culture

This is a method used for the identification of fungi on subculture and/or for the preparation of microscope mounts that can be used for taking pictures when a microscope with a camera setup is available. This method is a modification of the traditional slide culture method, in which hyphae and spores grow on the surface of a cover slip. The colony of interest is subcultured on the media of choice using a three-point inoculation. A swab usually works better than an inoculating loop for this purpose. Using sterile forceps, sterile cover slips are positioned over the inoculum at a 45° angle and inserted halfway into the agar. Up to three cover slips can be inserted on a plate; however, it is best to do only two while the third colony is left untouched to observe macroscopic fungal characteristics better and to prepare a tape imprint in case it is necessary. The plate is incubated with the agar side down and examined periodically until sporulation begins; this examination can generally be done by using a stereoscope. Hyphae and spores will grow on the glass surface of the cover slip, producing an intact arrangement of the spores. The cover slip is pulled gently using forceps and mounted on a drop of lactophenol cotton blue on top of a glass slide. Very often, fungal growth will be present on both sides of the cover slip. Therefore, the side of the cover slip away from the dye should be cleaned with an alcohol-moistened swab (70% isopropanol or 70% ethanol). This is difficult to achieve because the cover slip is already mounted on the dye. Alternatively, a second drop of lactophenol is placed on top of the cover slip that has already been mounted and a second cover slip is applied on top; this traps the fungal growth in between two layers of dye. This approach will produce a mount that although sharp and clear needs to be visualized in two planes of focus. The mount is observed under a microscope at low and high magnification and analyzed as indicated previously. If no spores are visible, the plate can be reincubated and a second cover slip can be removed and mounted later. Cover-slip preparations can be sealed around the cover slip edges with clear nail polish and stored flat in a slide holder. However, with time, the seal may start to break and the dye can start leaking out or the mount will start drying out. A commercially available dye that contains lactophenol cotton blue with an adhesive (Mycoperm, Scientific Device Laboratory, Inc., Glenview, Illinois) can be used for the preparation of permanent slides.

Slide Culture

Slide culture has been used traditionally for the preparation of fungal microscope mounts, especially for those organisms with fragile spore chains (8). It provides an undisturbed arrangement of the fungal colony of interest; however, the macroscopic morphology cannot be appreciated with this method. For this technique, a sterile glass petri dish is preferred because of the depth they provide over the disposable type. The petri dish is lined with a sterile piece of filter paper and sterile water (~2 mL) is added to the bottom of the plate. A U-shaped glass tube is placed on top of the filter paper and a glass slide is positioned on top of the glass tube. An agar square of approximately 1 cm × 1 cm is aseptically cut and removed from an agar plate (poured 4-mm deep with the media of choice) and transferred to the center of the glass slide

inside the petri dish. The agar block is then inoculated with the organism of interest by using an inoculating loop to touch the sides of the square. A cover slip is placed on top of the inoculated agar block and slight pressure is applied. The petri dish is incubated and checked periodically for signs of sporulation. It is important that water be added as required to the bottom of the petri dish to prevent the agar block from drying out. Once ready to analyze, the cover slip is removed gently with forceps and mounted on a drop of dye on a glass slide. The mount is observed using a microscope at low and high magnification and analyzed as indicated previously. If no spores are visible, a clean cover slip should be placed on top of the inoculated agar block and the plate should be reincubated until sporulation occurs. It is also possible to prepare an additional mount by removing the agar block from the top of the glass slide and disposing it in a biohazard bag. The slide should be stained by placing a drop of dye followed by a cover slip. Like cover slip culture, this type of preparation can also be sealed around the cover slip edges with clear nail polish and stored flat.

COMMON ENVIRONMENTAL FUNGI

Although mold populations are seasonal and vary from one region to another, certain environmental fungi are present throughout the world (2). Generally identified to the genus level because of the difficulties discussed previously, the fungi included in this section comprise the majority of the organisms that are generally encountered in environmental samples. A description of the general macroscopic and microscopic characteristics of each genus has been summarized from several mycology books (6,12,19). These descriptions are based on morphologies observed on Sabouraud dextrose agar. The following genera (arranged in alphabetical order) are discussed: *Alternaria, Aspergillus, Bipolaris, Chaetomium, Cladosporium, Curvularia, Epicoccum, Fusarium, Paecilomyces, Penicillium, Rhizopus, Stachybotrys*, and *Trichoderma*. A brief description on yeasts is also included.

Alternaria

There are approximately 50 known species with some having spores measuring up to 200 μm in length. Generally, spores are 23 to 34 μm in length by 7–10 μm in diameter at the widest part. Sporulation occurs in approximately five days. Macroscopic morphology is characterized by a woolly colony with a surface that starts as pale gray and becomes olive/black or brown and with a black reverse. Microscopic characteristics (Fig. 3a) include (*1*) brown (dematiaceous) hyphae and conidia; (*2*) muriform (longitudinally and transversely septate) conidia; (*3*) chains of elongated conidia; and (*4*) a beaklike apical cell. The presence of elongated conidia in chains is the characteristic that distinguishes *Alternaria* from the genus *Ulocladium* (Fig. 3b). *Ulocladium* spores also have septate conidia; however, these are usually smaller, rounder, and their arrangement is in an alternate fashion rather than in chains.

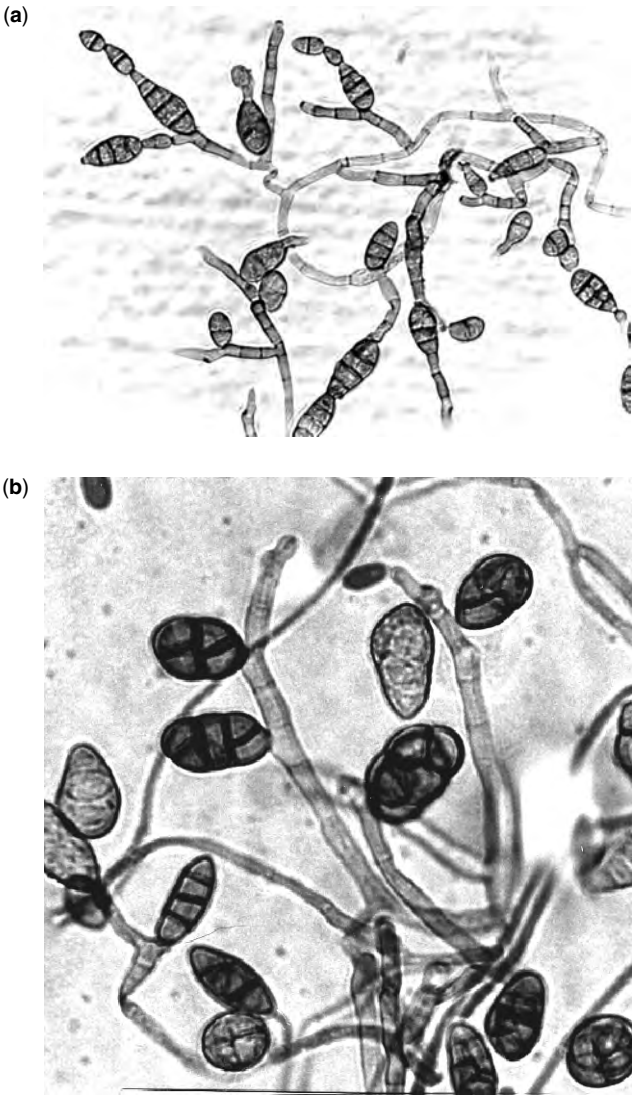

Figure 3. (**a**) Alternaria spores in chains. (**b**) Ulocladium spores and hyphae.

Aspergillus

There are approximately 185 known species, with spores generally measuring 2 to 5 μm in diameter. Most species are rapid growers, showing sporulation in approximately three days. Some species such as *A. niger* have conidiophores completely covered with spores that in culture are visible with the naked eye. Macroscopic characteristics include a velvety, powdery, or cottony colony with a surface color that starts as white and becomes yellow, green, brown, or black and a reverse that can be white, gold, or brown. Microscopic morphology is characterized by (*1*) foot cells (merging of hypha with the base of the conidiophore forming an inverted letter T) (Fig. 4a); (*2*) vesicles (swollen structures at the end of a conidiophore) that are partially or completely covered by

phialides (cells that produce conidia) and conidia (Fig. 4b); (*3*) the presence of round or oval conidia in chains; and (*4*) conidia with smooth or rough walls. Single spores of *Aspergillus*, such as those encountered in impaction sampling onto an adhesive-coated surface, cannot be distinguished from those of the genus *Penicillium*. The arrangement of spores around the vesicle, its size, and shape are the main characteristics used in the speciation of *Aspergillus*.

Many of the *Aspergillus* species produce both an asexual and sexual (teleomorph) stage. The species is generally identified by the asexual name because of the difficulty in obtaining the sexual stage in the laboratory (12). However, if the sexual stage is observed, many mycologists identify the species by the sexual name (e.g., *A. glaucus* and *A. nidulans* are the asexual forms and *Eurotium* and *Emericella* are the sexual forms, respectively). There are several publications that aid in the speciation of *Aspergillus* (20,21).

Bipolaris

There are approximately 52 known species. Generally, spores measure 16 to 35 μm in length by 6 to 12 μm in diameter. Sporulation occurs in approximately five days. Macroscopic morphology is characterized by a downy colony with a gray or brown surface becoming black, and a black reverse. Microscopic characteristics (Fig. 5a) include (*1*) brown hyphae; (*2*) knobby conidiophores, curved at the end bearing conidia; (*3*) spores born in an alternate fashion on the conidiophore; (*4*) black scars on the spores at points of attachment to the conidiophore; (*5*) brown, thick-walled conidia; and (*6*) oblong to cylindrical conidia containing four or more cells. The absence of curved conidia and a darker central cell distinguishes *Bipolaris* from the genus *Curvularia* (described in the following text). Two other genera (*Drechslera* and *Exserohilum*) also resemble *Bipolaris*. *Drechslera* produces germ tubes (germination of hyphae from a spore) emerging from any cell of the conidium, perpendicular to the long axis, whereas the germ tubes of *Bipolaris* are polar and in the direction of the long axis of the conidium. In addition, *Drechslera* isolates tend to become sterile in the laboratory. Therefore, when unable to differentiate between these two organisms, they should be reported as *Bipolaris* or *Drechslera*. Conidia produced by the genus *Exserohilum* are longer (14 by 80 μm in length), have a protuberant hilum (scar remaining at point of attachment), and the end cells of some species are delimited by dark septa (Fig. 5b). The hilum of *Bipolaris* is scarcely protuberant.

Chaetomium

There are approximately 81 known species. Spores (ascospores) generally measuring 6 to 11 by 3.5 to 8.5 μm in diameter are contained within asci (cells producing and containing ascospores) in a saclike structure called a perithecium (pl. perithecia) that measures approximately 100 to 150 by 110 to 225 μm in diameter. Perithecia are often visible in a culture with the naked eye. Sporulation occurs in approximately five days. Macroscopic characteristics include a cottony colony with a surface, which starts as white and becomes tan/gray or gray/olive with age, and an orange/tan

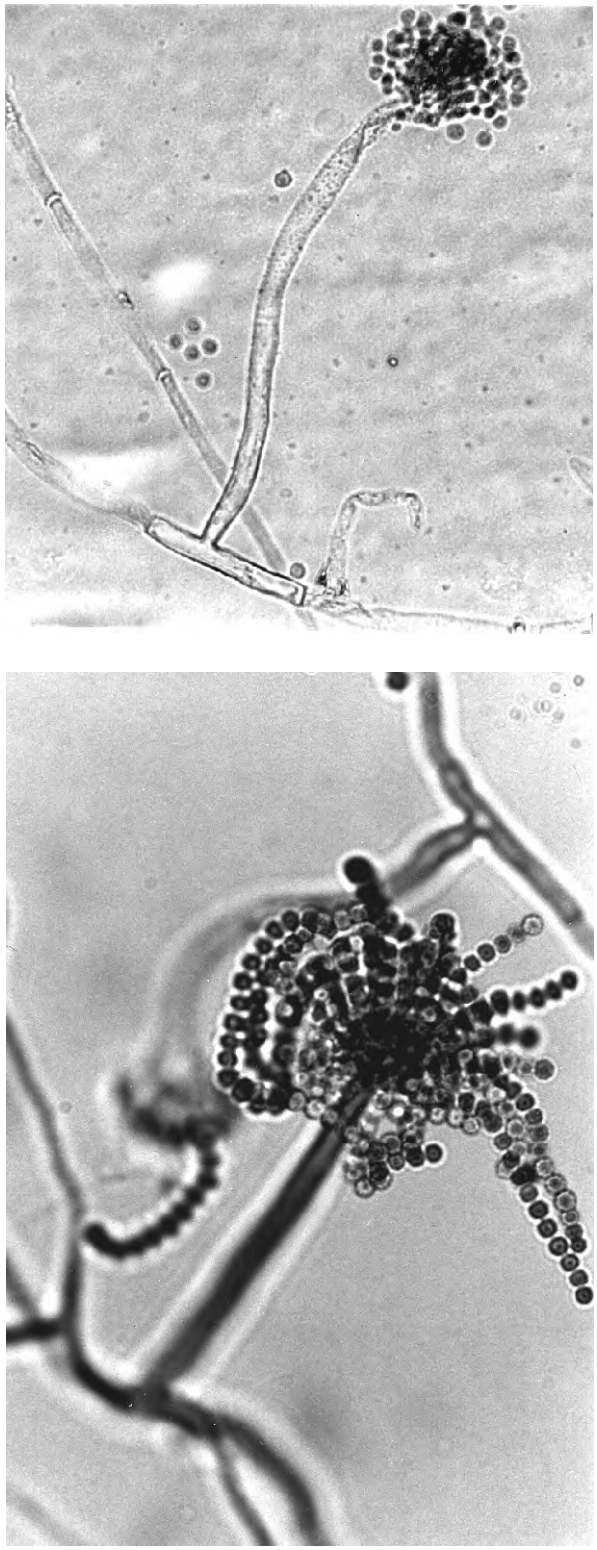

Figure 4. (**a**) Aspergillus conidiophore with visible foot cell. (**b**) Aspergillus vesicle covered with spores.

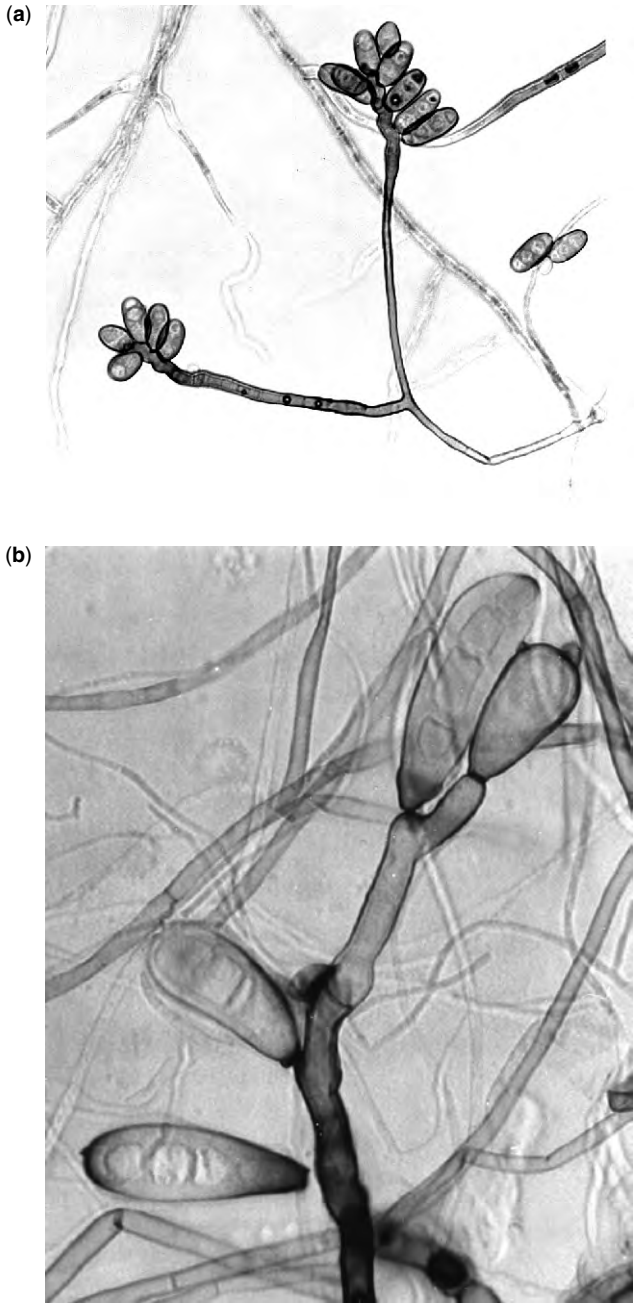

Figure 5. (**a**) Bipolaris conidiophores. (**b**) Exserohilum conidiophore.

or brown to black reverse. Microscopic morphology is characterized by (*1*) round to ovoid, olive to brown perithecia; (*2*) perithecia surrounded by spinelike hairs (Fig. 6a); (*3*) long, undulant, helical and/or erect hairs; (*4*) asci containing four to eight ascospores that readily dissolve on release from the perithecia; and (*5*) brown, unicellular, oval to lemon-shaped ascospores (Fig. 6b). One feature that distinguishes *Chaetomium* from the genus *Phoma* is the presence of spinelike hairs (Fig. 6c). In addition, *Phoma* produces large fruiting bodies (pycnidia) that have an opening (ostiole) from which spores are released. The ostiole produced by *Phoma* is usually more readily visible than that produced by *Chaetomium*. Also, the spores produced by *Phoma* tend to be slimy, smaller (3 to 5 by 2 to 3 μm in diameter), are oval to round, and are lighter in color than those of *Chaetomium*. In cases in which the pycnidia produced by *Phoma* cannot be distinguished from the perithecia produced by *Chaetomium*, it is recommended that the microscopic mount be pressed (e.g., with the eraser of a pencil) to break open these structures and visualize its contents. *Arthrinium* also produces spores that resemble those produced by *Chaetomium*. Single ascospores of *Chaetomium* such as those encountered in impaction sampling onto an adhesive-coated surface can be confused with those of the genus *Arthrinium*. Characterized by caramel-colored hyphae with swollen cells, *Arthrinium* produces conidia with an equatorial germ slit (Fig. 6d).

Cladosporium

There are approximately 50 known species. Generally, spores measure 4 to 12 μm in length by 3 to 6 μm in diameter. Sporulation occurs in approximately seven days. Macroscopic morphology is characterized by a velvety colony with very short hyphae. The surface color can be olive/brown or black and the reverse is black. Microscopic characteristics (Fig. 7) include (*1*) brown hyphae; (*2*) brown spores resembling very pointy rice grains with black scars at points of attachment; (*3*) very fragile branching treelike spore chains; and (*4*) shield-shaped cells at the base of the chains.

Curvularia

There are approximately 33 known species, with spores generally measuring 8 to 14 μm in length by 21 to 35 μm in diameter. Sporulation occurs in approximately five days. Macroscopic characteristics include a pink-gray woolly colony with an olive-green, brown, or black surface and a dark reverse. Microscopic morphology (Fig. 8) is characterized by (*1*) brown hyphae; (*2*) curved conidia usually with 3 to 4 cells; and (*3*) central cell that is typically expanded and is darker than the other cells. The spores of *Curvularia* can be confused with those of *Bipolaris* (Fig. 5a). However, the curved spores and the darker central cell distinguish *Curvularia* from the genus *Bipolaris*. In addition, the spores of *Curvularia* are septate, whereas those of *Bipolaris* are distoseptate (cells contained within sacs, lacking conventional septations).

Epicoccum

There are two known species. Generally, spores measure 15 to 30 μm in diameter. Sporulation occurs in approximately seven days. Macroscopic morphology is characterized by a cottony colony that starts with a yellow to orange surface becoming brown to black. The reverse color can be red, with some species producing a yellow, brown, orange, or red pigment that diffuses into the medium. Microscopic characteristics (Fig. 9a,b) include (*1*) hyaline (clear) to brownish hyphae;

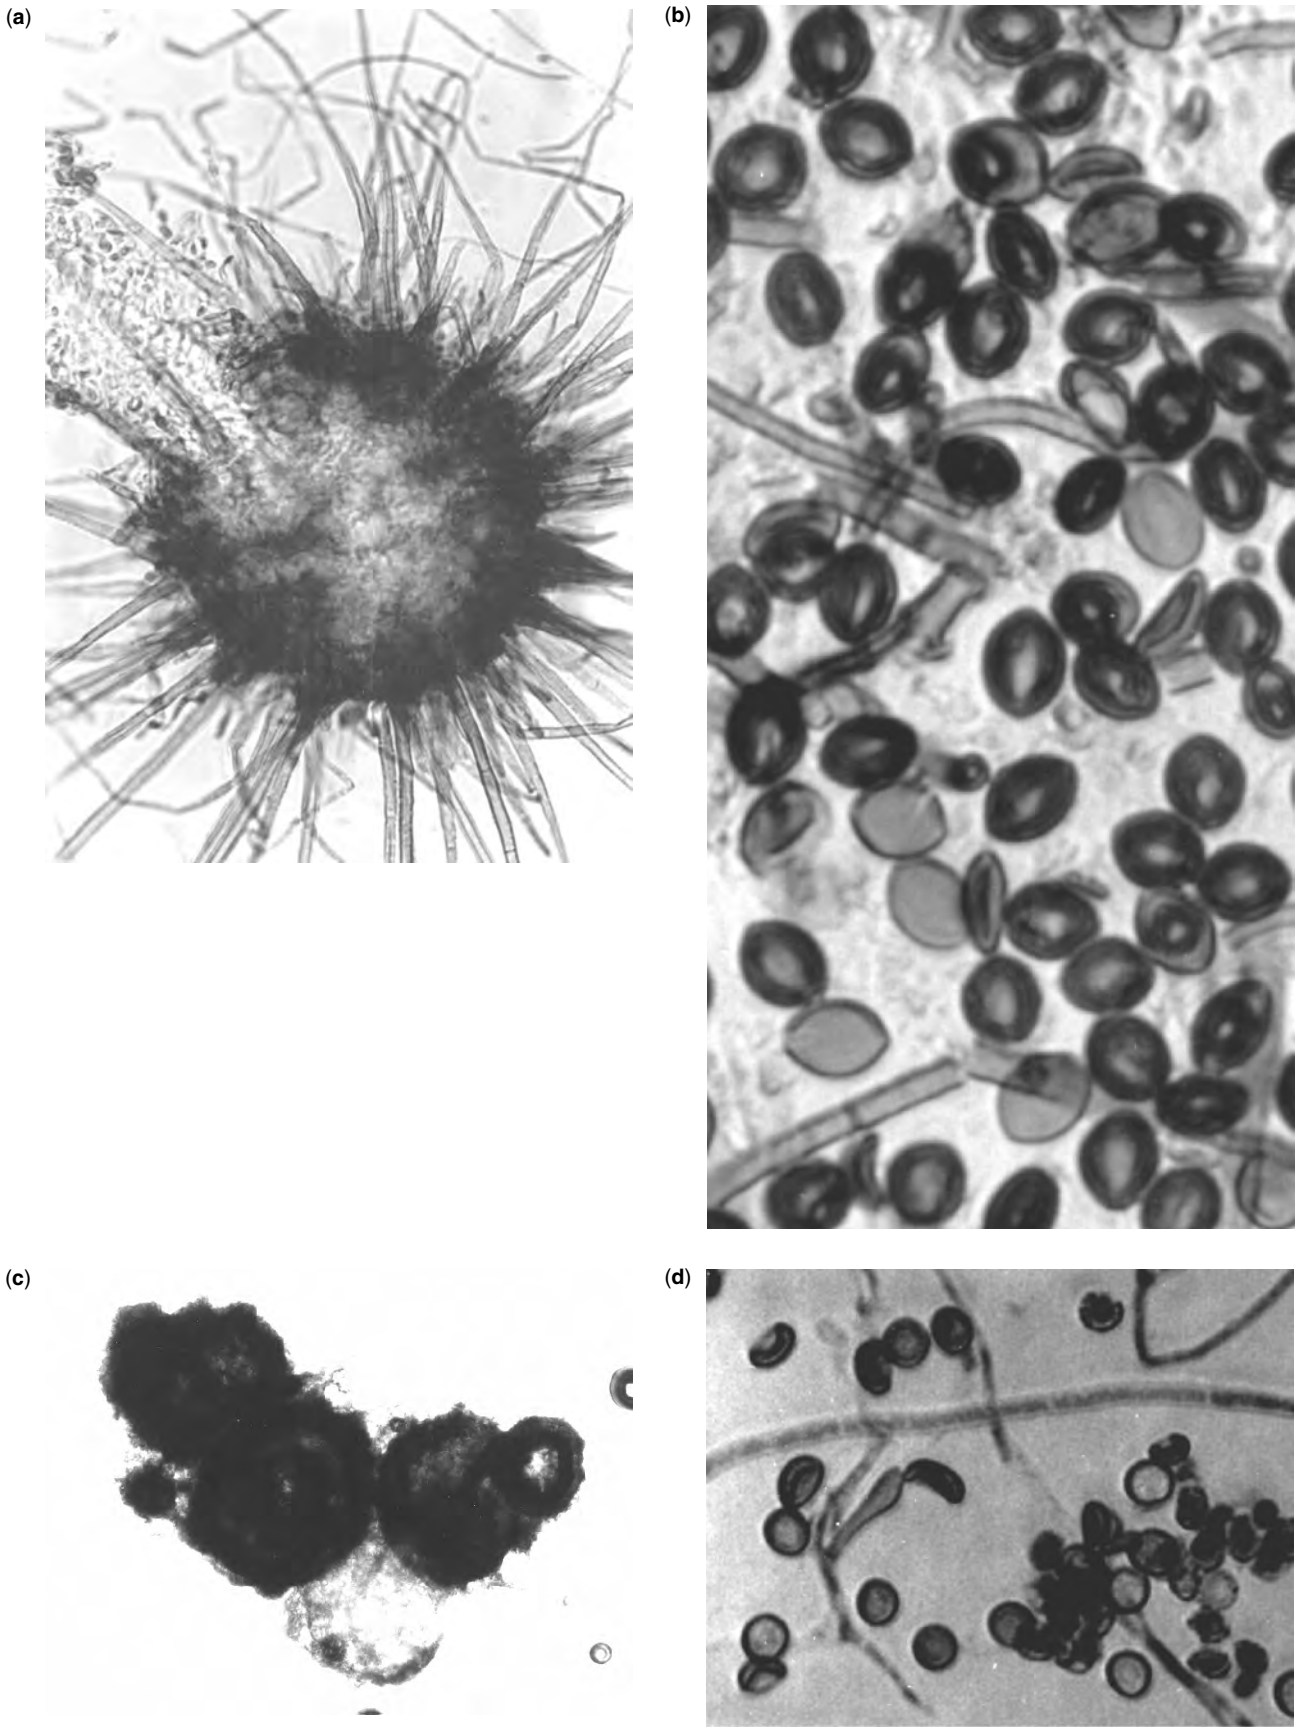

Figure 6. (**a**) Chaetomium perithecium. (**b**) Chaetomium ascospores observed at high magnification. (**c**) Phoma pycnidia. (**d**) Arthrinium spores and conidiophore.

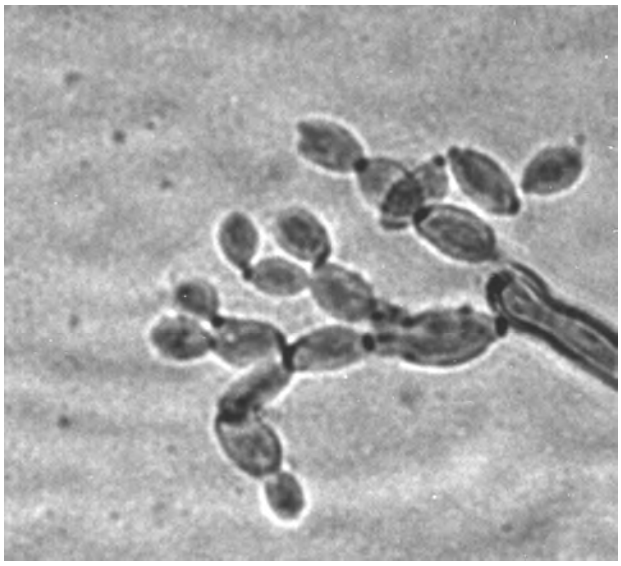

Figure 7. Cladosporium conidiophore.

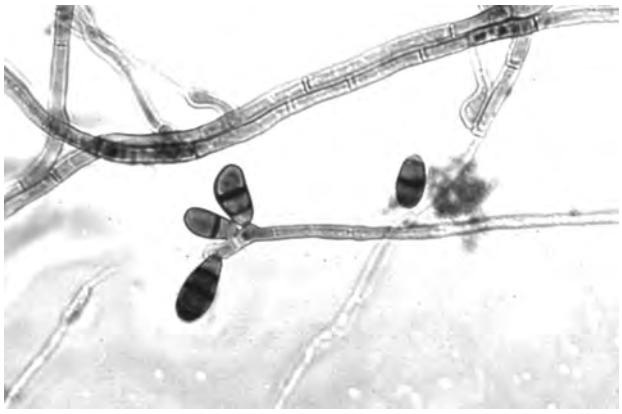

Figure 8. Curvularia conidiophore and hyphae.

(*2*) short conidiophores bearing more or less round conidia; (*3*) brown-black mature conidia with rough walls; (*4*) conidia with both transverse and longitudinal septations; and (*5*) conidia grouped in clusters. Mature clusters of spores are often visible in a culture with the naked eye. For isolates suspected of being *Epicoccum* that do not produce spores in the laboratory, sporulation may be stimulated by incubation under ultraviolet (UV) light alone or in combination with growth on 2% water agar (12).

Fusarium

There are approximately 50 known species; in which large (macroconaidia) and small (microconidia) spores are produced. Macroconidia generally measure 11 to 70 μm in length by 3 to 8 μm in diameter. Microconidia measure approximately 4 to 8 μm in length by 2 to 4 μm in diameter. Sporulation occurs in approximately four days. Macroscopic characteristics include a cottony, sometimes mucoid, colony with a surface that

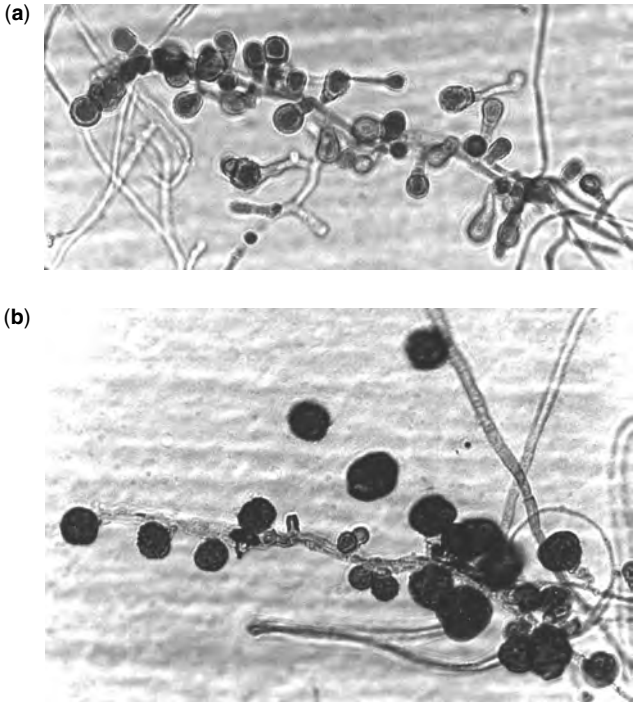

Figure 9. Epicoccum young (**a**) and mature (**b**) spores.

starts as white and becomes pink or violet in the center and with a light reverse. Microscopic morphology is characterized by (*1*) hyaline hyphae; (*2*) macroconidia that are curved and multiseptate; (*3*) foot cells present at the base of the conidiophores; and (*4*) microconidia that are unicellular, sometimes bicellular, ovoid to ellipsoid in slimy heads or in chains (Fig. 10a,b). The microconidia of *Fusarium* can be confused with the spores of *Acremonium* (Fig. 10c). However, the presence of macroconidia and foot cells distinguishes *Fusarium* from the genus *Acremonium*. The genus *Cylindrocarpon* resembles *Fusarium* by producing macroconidia and microconidia; however, the macroconidia produced by *Cylindrocarpon* have rounded ends, whereas those produced by *Fusarium* have pointed ends. In addition, the absence of foot cells distinguishes *Cylindrocarpon* from *Fusarium*.

Paecilomyces

There are approximately 41 known species. Generally, spores measure 2 × 3.5 μm in diameter. Sporulation occurs in approximately three days. Macroscopic morphology is characterized by a powdery or velvety colony with a surface that is yellowish-brown, lilac, or another color (except green), and an off-white to brown reverse. Microscopic characteristics (Fig. 11a,b) include (*1*) hyaline hyphae; (*2*) brushlike clustered phialides elongated at the tips; (*3*) conidia oval to fusoid in long chains; and (*4*) phialides/conidial chains that bend away from the axis of the conidiophore. The brushlike appearance of the conidiophores of *Paecilomyces* may be confused with that of the genus *Penicillium* (Fig. 12a). However, the phialides

Figure 10. (**a,b**) Fusarium macroconidia. (**c**) Acremonium conidiophores and hyphae.

of *Paecilomyces* are swollen at the base and slender at the top that bears the conidia. In addition, *Paecilomyces*

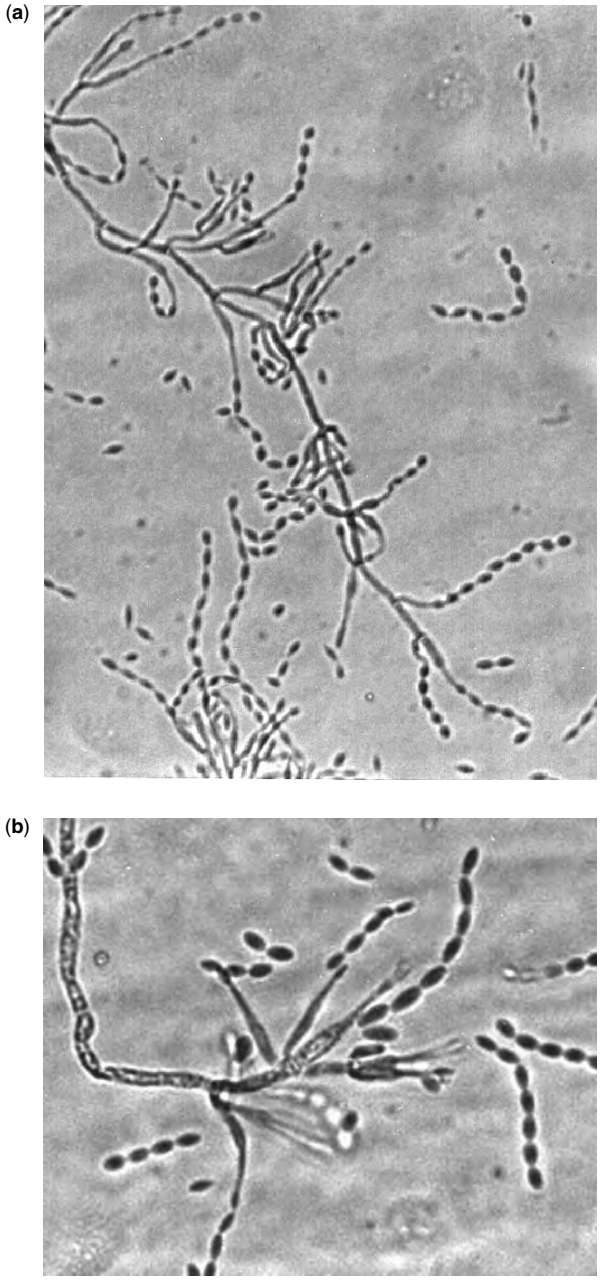

Figure 11. (**a**) Paecilomyces spores and hyphae. (**b**) Detail of Paecilomyces phialides.

produces spores that are oval as opposed to those produced by *Penicillium* that are round to oval.

Penicillium

There are approximately 223 known species. Conidia generally measure 2.5 to 5 μm in diameter. Sporulation occurs in approximately four days. Macroscopic characteristics include a powdery colony with a surface that starts as

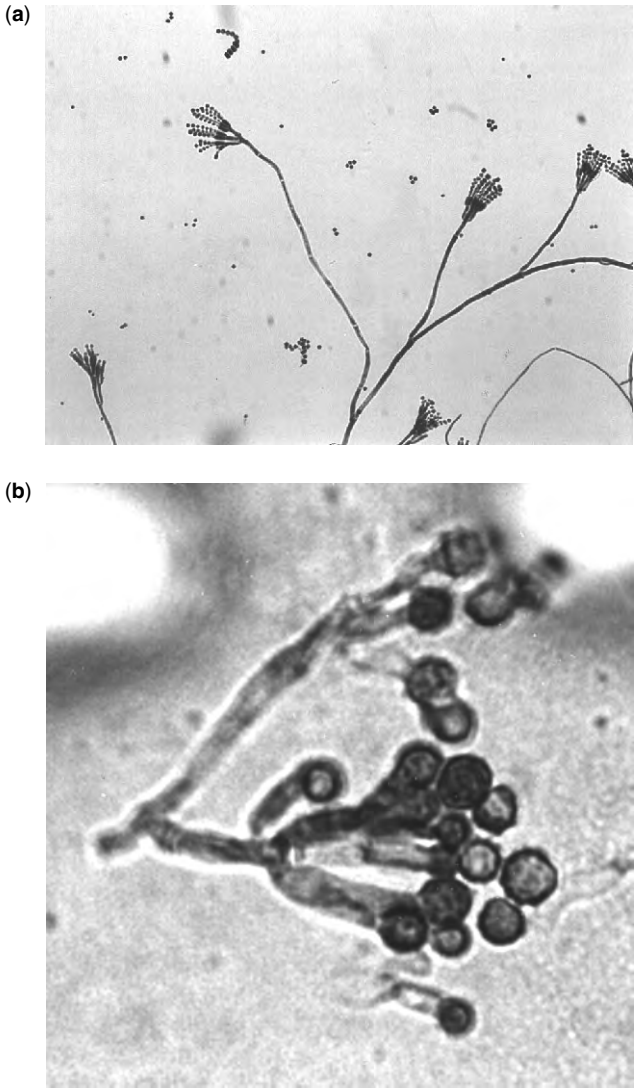

Figure 12. (**a**) Penicillium conidiophore and spores. (**b**) Scopulariopsis conidiophore.

white and becomes blue green with a white margin. However, other surface colors and textures have been observed in less common species. The colony reverse is white, sometimes red or brown. Microscopic morphology (Fig. 12a) is characterized by (*1*) hyaline hyphae; (*2*) brushlike conidiophores; (*3*) round to oval spores in chains; (*4*) hyaline or pigmented spores; and (*5*) spores with smooth or rough walls. The spores of *Penicillium* can be confused with those of at least four genera, namely, *Paecilomyces* (described in the previous section) (Fig. 11a,b), *Trichoderma* (described in the following text) (Fig. 15), *Scopulariopsis* (Fig. 12b), and *Gliocladium*. Conidia produced by *Scopulariopsis* are round to lemon-shaped, thicker-walled, larger (4 to 9 μm in diameter), and cut off at the base (truncate base). In addition, their mature spores often have spiny walls and their conidiophores generally are shorter than those of *Penicillium*. *Gliocladium* produces brushlike conidiophores containing masses of sticky conidia at their tips that (unlike *Penicillium*) tend to clump.

Some *Penicillium* species produce both an asexual and sexual stage. The sexual stage is characterized by the presence of sexual fruiting bodies. Many mycologists identify these species by their sexual name (i.e., *Eupenicillium* or *Talaromyces*) (23). Several publications exist that aid in the speciation of *Penicillium* (4,24).

Rhizopus

There are approximately 10 known species. Spores (sporangiospores) generally measuring 4 to 11 μm in diameter are contained within a saclike structure called a *sporangium* (pl. sporangia) that measures approximately 40 to 350 μm in diameter. Mature sporangia are visible in a culture with the naked eye. Sporulation occurs in approximately four days. Macroscopic morphology is characterized by a cottony colony that grows very rapidly. The surface of the colony starts as white and becomes gray or yellow/brown and the reverse is white. Microscopic characteristics include (*1*) hyaline hyphae; (*2*) wide hyphae with few or no septations; (*3*) long sporangiophores (the equivalent of a conidiophore, approximately 4-mm long); (*4*) dark, round sporangia; (*5*) ovoid spores; (*6*) hyaline or brown spores; and (*7*) rhizoids (rootlike hyphae opposite the sporangiophore that are submerged in the growth medium) (6) and stolons (horizontal hyphae often connecting sporangiophores and bearing rhizoids) are present (Fig. 13). The microscopic morphology of *Rhizopus* can be confused with that of three genera, namely, *Mucor*, *Absidia*, and *Rhizomucor*, *Mucor* lacks rhizoids and stolons and produces branched and unbranched sporangiophores that are mostly hyaline. *Rhizopus* produces sporangiophores that are mostly brown. In addition, it is reported that *Mucor* has a maximum growth temperature below 37 °C, whereas that of *Rhizopus* is approximately 45 °C (6). *Absidia* produces indistinct rhizoids that form between stolons and not directly opposite to a rhizoid. It is often useful to use a stereoscope to visualize the rhizoids formed by *Absidia* isolates. *Absidia* also produces pear-shaped sporangia and finely branched sporangiophores that are almost hyaline. Its maximum growth temperature is the same as that of *Rhizopus* (6). *Rhizomucor* produces branched, dark brown sporangiophores. In

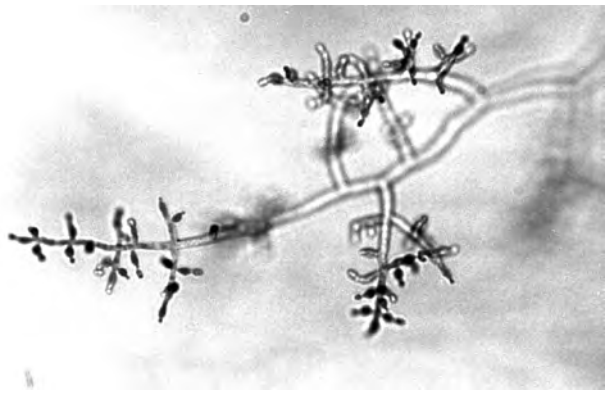

Figure 13. Trichoderma conidiophores (young).

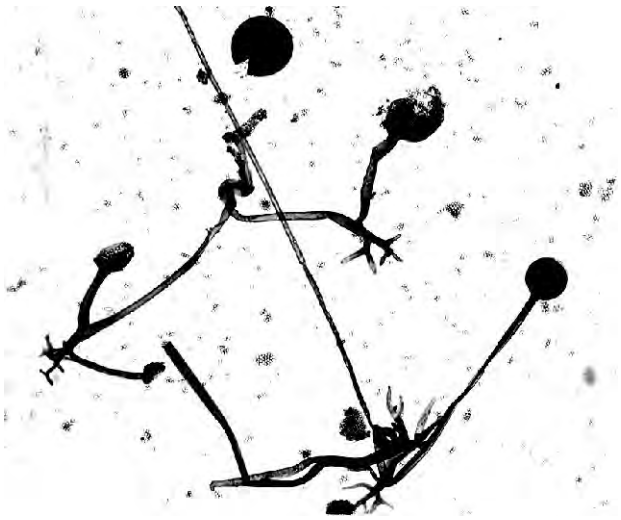

Figure 14. Rhizopus conidiophores with visible sporangiospores and rhizoids.

addition, short rhizoids forming between stolons are produced. Its maximum growth temperature is approximately 54 °C (6).

Stachybotrys

There are approximately 15 recognized species of *Stachybotrys* (22). Conidia generally measure 4.5 to 9 μm in diameter. Sporulation in laboratory media occurs in approximately four days in pure culture. However, up to 10 days may be required when other competing fungi are present. Macroscopic characteristics include a yeast-like colony surface that starts as white to beige. As the colony matures, cottony mycelia develop that become covered with black, oily droplets. The reverse of the colony starts with a light color that becomes dark. Microscopic morphology (Fig. 14a,b) is characterized by (*1*) hyaline to dark hyphae; (*2*) hyaline or pigmented conidiophores; (*3*) hyaline or pigmented phialides; (*4*) ellipsoidal phialides in groups of 3 to 10; (*5*) dark unicellular conidia; (*6*) oval conidia forming slimy masses; and (*7*) conidia with smooth to rough walls. The conidiophores of *Stachybotrys* can be confused with those of the genus *Memnoniella* (Fig. 14c). However, the spores produced by *Memnoniella* are smaller, round, and are produced in chains rather than in clumps.

Trichoderma

There are approximately nine known species. Spores generally measure 3 μm in diameter. Sporulation occurs in approximately five days. Macroscopic morphology is characterized by a rapidly spreading white fluff becoming woolly. As sporulation occurs, the surface of the colony is covered by scattered green patches often forming concentric rings. The reverse of the colony can be pale or light orange/tan to yellow. Microscopic characteristics (Fig. 15) include (*1*) hyaline hyphae; (*2*) branched conidiophores; (*3*) conidiophores bearing phialides attached at right angles; (*4*) phialides swollen at the base; and (*5*) round or oval conidia forming clusters at tips of phialides.

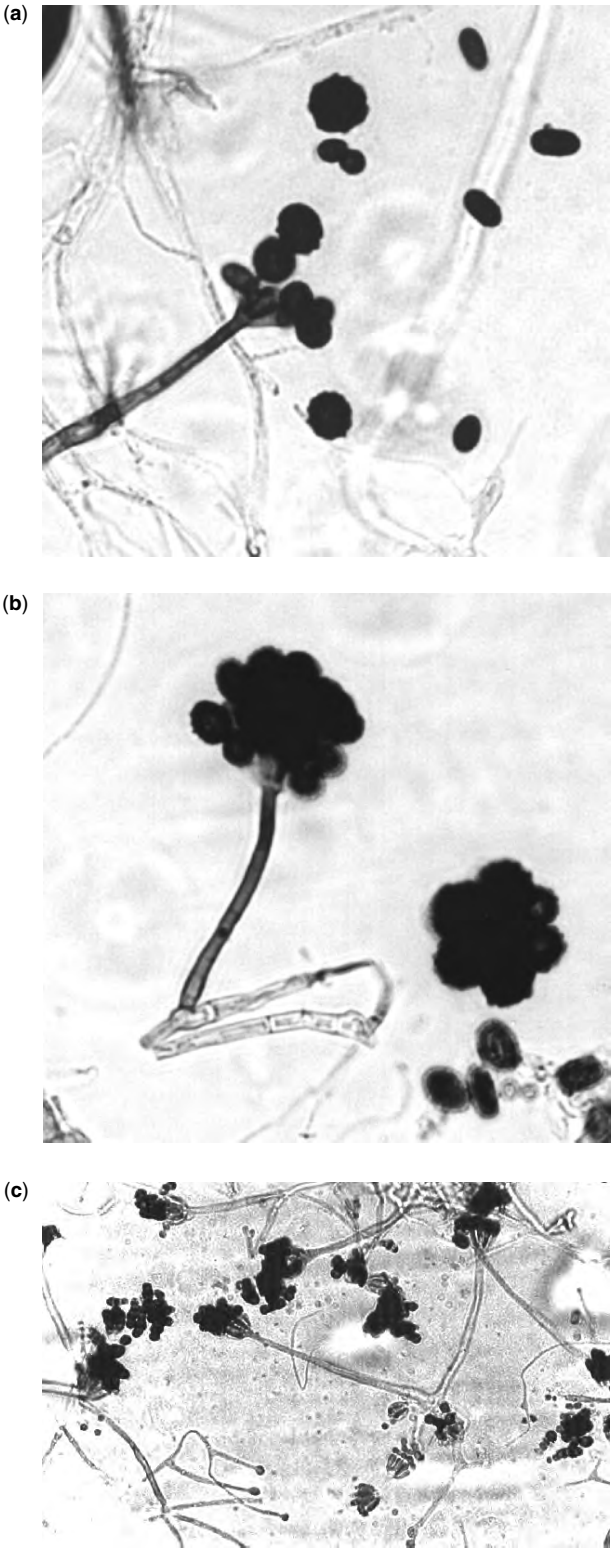

Figure 15. (**a**) Stachybotrys conidiophore and different shaped spores. (**b**) Stachybotrys spores covering conidiophore. (**c**) Memnoniella conidiophores and spores.

Yeasts

Macroscopic morphology is characterized by smooth, moist, or mucoid colonies that resemble bacterial colonies. Colony color is usually white to cream but can also be orange, pink, or tan. Reproduction occurs by budding or binary fission, a type of reproduction in which parent cells divide to produce two identical cells. Yeasts are characterized by the presence of buds, small outcroppings present in parent cells. Microscopically, yeasts are characterized by (*1*) single cells; (*2*) oval or round cells; (*3*) budding cells; (*4*) large cells observable at low magnification (100 X total magnification); and (*5*) sometimes pseudohyphae or elongated buds (2,12). Some organisms can produce true hyphae or no hyphae at all, and few can produce ascospores. Because it is necessary to perform biochemical and physiological tests for their classification into genus and species, yeasts generally are not identified but reported as the number of yeasts per sample (5). Yeast-identification procedures include determination of the presence of pseudohyphae or true hyphae, the germ tube test, carbohydrate assimilation or fermentation, the Dalmau test, capsule production, cycloheximide resistance, and temperature studies. There are several manuals (6,24) that can provide the reader with a more detailed description of yeast-identification methods.

CONCLUSION

With an increased awareness of the health effects associated with exposure to environmental fungi, there is also an increased interest in the identification of these microorganisms. Traditionally, mycology has emphasized on the study of pathogenic or opportunistic fungi and treated environmental (saprophytic) fungi as contaminants that can be encountered during routine analysis of medical specimens. It is the purpose of this review to give an overview of the culture media and methods that can be useful in environmental mycology and to present the reader with the basic methodology for identification of the genus level of several of the most common environmental fungi. Although identification of environmental fungi has its difficulties and requires practice, building a large reference library and acquiring and maintaining stock cultures can make identification easier and more accurate.

IGNEOUS ROCK AQUIFERS MICROBIAL COMMUNITIES

KARSTEN PEDERSEN
Göteborg University
Göteborg, Sweden

Independent scientific work has unambiguously demonstrated life to be present in most deep geological formations investigated, down to depths of several kilometers (1,2). Sub-seafloor environments (3,4), sedimentary rocks (5), and igneous rocks (6) all harbor life. The distribution of

underground life is conceptually restricted only by temperature. The temperature limit for life is, as far as is known, 113 °C (7). This temperature is reached at very different depths around the earth, from the seafloor surface at marine hot springs to 10 km or deeper in massive sedimentary rock formations. In the Fennoscandian Shield, the temperature typically increases between 1 and 2 °C per 100 m, implying that at igneous rock sites in Scandinavia, microbial life may extend as far as 10 km underground. Such rocks are penetrated by humans for a variety of purposes such as mining for metals, drilling boreholes for the extraction of groundwater and rock heat, and building tunnels and vaults for communication, transport, defense, storage of hazardous waste, and radioactive waste disposal. Microbial processes should, if possible, become an integral part of preinvestigations of such sites. This review presents research record from the last decade of microbiological research performed on microbial communities in deep igneous, Fennoscandian rock aquifers, the ultimate aim being to contribute to a safe disposal of high-level nuclear waste (8).

EXPLORATION METHODOLOGY

Eleven subterranean sites in Fennoscandian igneous rocks have been explored down to a depth of 1,700 m for diversity and activity of microbial communities (Table 1). A total of 75 specific borehole positions in 53 different boreholes have been investigated for geology, chemistry, total numbers of viable microorganisms, and microbial diversity and activity.

Drilling and Sampling of Rocks and Groundwater

All sampling of igneous hard rock aquifer material and groundwater require penetration of the rock to reach the target aquifers. There is only one main way of achieving this goal and that is via the drilling of holes (Fig. 1). The detailed procedure may be modified in many ways, but there are two main drilling approaches, namely, from the ground surface and from an underground tunnel. Drilling in hard rock is done either with percussion-boring or with core-drilling. The percussion drill does not recover any rock material and may introduce air into intersected aquifers. The debris, created during drilling, and groundwater, once an open fracture has been intersected, are forced to the surface by air. This type of drilling depends on the use of compressed air with a pressure higher than groundwater pressure. This sets a limit of about 150 to 200 m, at which depth the pressure needed will be too high for normal percussion drilling machines. Deeper boreholes must instead be drilled by core-drilling producing a core, which can be used for mapping the geological strata penetrated. The retrieval of rock aquifer material during drilling in igneous hard rock always requires core-drilling. Triple-tube drilling (Fig. 2) is the best available method

Table 1. Site Information Comprising All Boreholes in Fennoscandian Igneous Rock Investigated for Microbiology Since 1987

SITE	Year	Borehole	Geological Situation	Depths (m)	Levels
Hålö (S)	1992–1996	HBH01, HBH02	Porphyritic monzo-granite	10–45	(2 levels)
Hästholmen (F)	1997–1998	HH-KR1, H-KR2, HH-KR3, H-KR4, HH-KR5, HH-KR6	Rapakivi-type granite	65–943	(6 levels)
Kivetty (F)	1997–1998	KI-KR5, KI-KR13	Granodiorite and granite	497–721	(2 levels)
Laxemar (S)	1988–2000	KLX01, KLX02	Småland granites	100–1700	(7 levels)
Olkiluoto (F)	1998–1999	OL-KR3, OL-KR4, OL-KR8, OL-KR9, OL-KR-10	Gneisses, schists, grandiorite, and granites	248–863	(7 levels)
Palmottu (F)	1998–1999	R302, R337, R387	Supracrustal volcanic and sedimentary rock	32–309	(5 levels)
Romuvaara (F)	1998–1999	RO-KR10, RO-KR11	Gneisses, granodiorite, and metadiabase dykes	543–564	(2 levels)
Stripa (S)	1987–1991	V1, V2	Granite	799–1,240	(4 levels)
Ävrö (S)	1987	KAV01	Porphyritic granite-grandiorite	420–924	(4 levels)
Äspö (S)	1988–1996	KAS02, KAS03, KAS04	Porphyritic granite-grandiorite	129–1,002	(11 levels)
Äspö Hard Rock Laboratory (HRL) tunnel (S)	1992–2001	KR0012, KR0013, KR0015, SA813B, SA923A, SA1062A, HA1327B, SA1420A, KA2511A, KA2512A, KA2858A, KA2862A, KA3005A, KA3010A, KA3067A, KA3105A, KA3110A, HD0025A, KA3385A, KA3539 G, KA3548A01, KA3600F, KJ0050F01, KJ0052F02, KJ0052F03	Porphyritic granite-grandiorite	68–450	(25 levels)
11 sites	1987–2001	53 boreholes		10–1,700	(75 levels)

Detailed information about the boreholes and the rock formation studied can be obtained from Reference 9.
F = boreholes in Finland; S = boreholes in Sweden.

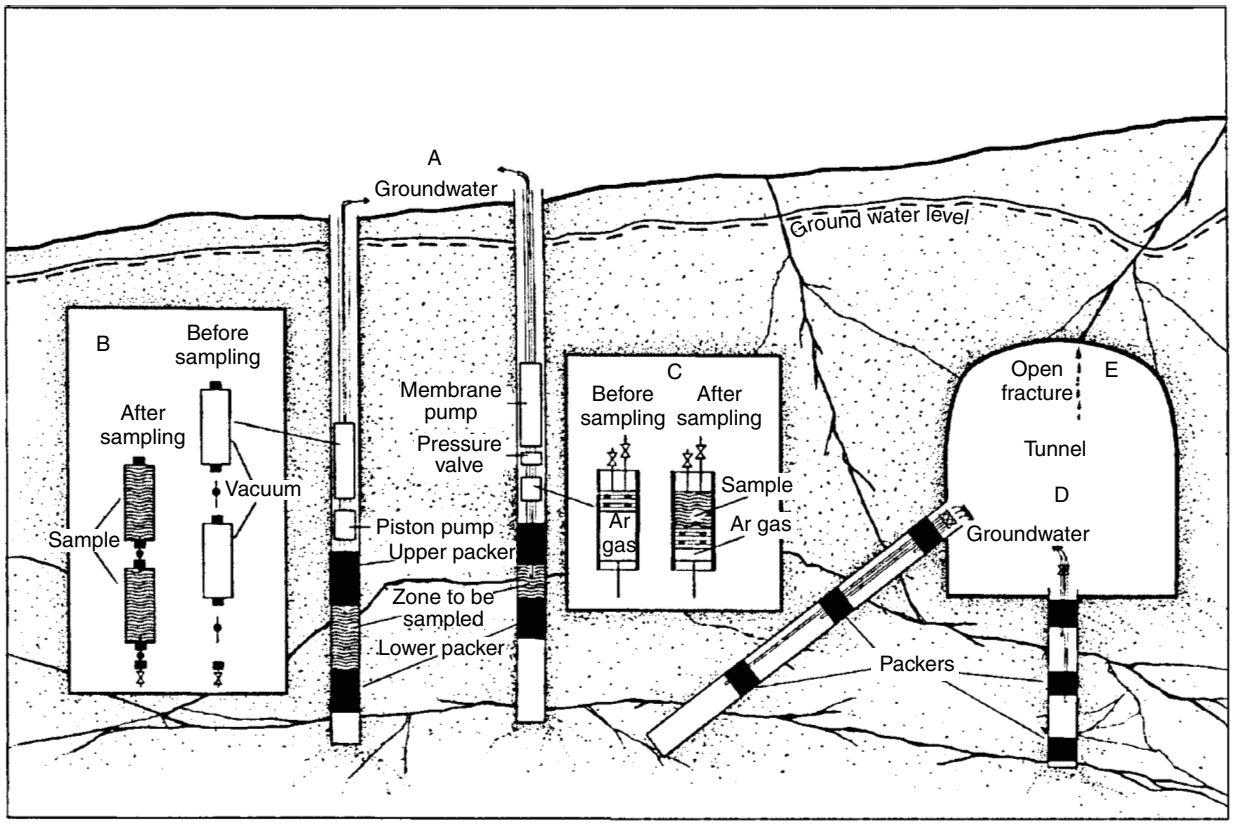

Figure 1. Access to aquifer material and groundwater occurs via the drilling of boreholes from the ground surface or tunnels. After retrieval of drill core material, the boreholes are packed off in one or several sections, each of which isolates one or more specific aquifers. A. Down-hole pumps of various types force groundwater from the aquifer to the ground surface for subsampling. B. Borehole BAT sampler, which can be opened and closed from the surface and is designed for gas-sampling (10). C. The PAVE borehole sampler, which can be opened and closed from the surface, is designed for gas and microbiological sampling (11), and allows one or more sample vessels to be used simultaneously. D. Tunnel boreholes do not require pumps when the tunnel is below the groundwater table. Aquifers can be packed off and connected to sampling devices in the tunnel with pressure-resistant tubes. It is important, however, to understand the potential danger and technical problems connected with the high hydrostatic pressure, which occurs at depth and increases by approximately 1 atmosphere per 10-m depth penetration. E. Open fractures in tunnels can be sampled directly and represent groundwater with minimal disturbance except for the pressure decrease caused by the tunnel.

for obtaining cores with the smallest possible disturbance to the rock environment.

Evaluation of the Contamination Risk During Drilling and Excavation

The risk of contamination of an intersected aquifer during drilling is obvious. Drill water may penetrate aquifers. Therefore, control of drill water contamination is done by the addition of one or more tracers to the drill water. Fluorescent stains may be employed on a routine basis for drilling of the boreholes. The stains used for the boreholes listed in Table 1 were fluorescein and uranin (Aldrich, Germany). Drilling in tunnels reduces the risk of drill water contamination of aquifers when drilling at tunnel depths more than about 60 to 70 m. The risk decreases with the depth because of an increasing aquifer pressure that is higher than the pressure used for the drill water, at least in water-conducting fractures. Pumping or flushing of boreholes to measure the maximum hydraulic water capacity will concurrently clean aquifers and the borehole from drill water, mud, and cuttings, provided there is enough water inflow for intense pumping.

An investigation of the potential risk of microbial contamination of hard rock aquifers has been performed during drilling of boreholes in a hard rock tunnel, using 16/18S ribosomal DNA (rDNA) sequencing and culturing methods (12). It was found that the tubing used for drill water supply constituted a source of bacterial contamination to the aquifers via the drilling equipment. The sequencing results showed that although large numbers of contaminating bacteria were introduced into the boreholes during drilling, they did not establish at detectable levels in the aquifers. The number of microorganisms in drill water introduced into the boreholes varied from 10^5 to 10^6 cells ml^{-1}. Drill water contamination of the studied boreholes was below 1 part

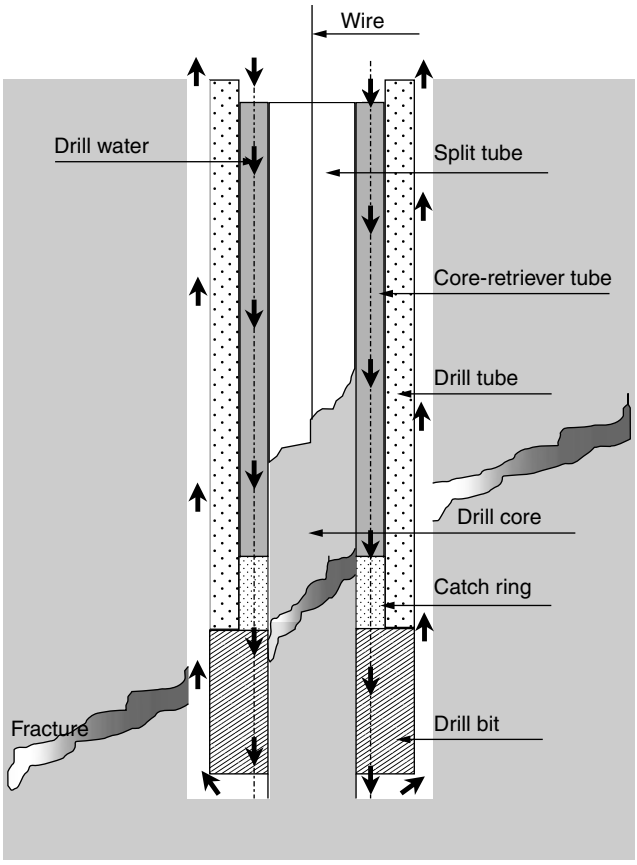

Figure 2. The triple-tube drilling principle. The use of a core retriever minimizes the exposure of the core to drill water and delivers the core intact to the surface, even when multifractured rock is penetrated. The drill tube protects the drill core from contact with aquifer systems intersected during drilling. This is of great importance when layers with contaminants, such as hydrocarbons, are penetrated. The split tube keeps intersected fractures intact with small pieces of rock in their original place.

per 1,000, so that fewer than 10^3 cells ml^{-1} in the aquifers of the drilled boreholes could be expected to originate from contamination during the drilling operation. This number was more than one order of magnitude less than that found directly after drilling and could, therefore, not explain the origin of the observed total cell numbers in the new boreholes. Thus, microorganisms appear to have been present in the aquifers before the drilling operation was undertaken.

Groundwater-Sampling

Surface boreholes generally require pumping for the retrieval of groundwater, whereas tunneling below the groundwater level offers access to artesian water that can be sampled without pumps, thereby reducing the risk of contamination. It is easy to collect samples with a retained in situ pressure. Most tunnels used for igneous rock microbiology research are found in mines at various stages of mining. Some, such as the Stripa mine in Sweden (Table 1) and the Kamaishi mine (13) and Tono uranium mine (14) in Japan, have been closed for mining and are only used for research, whereas others, such as the Witwatersrand gold mines in South Africa (15), are being researched while mining is still going on. Mines generally penetrate large bodies of rock, depending on the age of the mine and the rock formation of interest. This fact, together with the extensive pumping needed to keep the mines dry, will after some period of operation alter the surrounding groundwater system in a way that makes it difficult to assure that the observations made reflect a pristine groundwater. These disturbances can be decreased significantly when underground facilities are built specifically for research. A few tunnels, such as the Äspö Hard Rock Laboratory (HRL) tunnel (6), Grimsel in the Swiss Alps (16), and the Underground Research Laboratory in Pinawa, Canada (17), have been built for the purpose of research only. Data on changes in the hydrodynamic situation and the biogeochemical record during construction are obtained and can be used as a baseline when interpreting information obtained at a later stage.

Pumping from the surface and all withdrawal of groundwater via tubes may introduce unwanted effects. These include degassing because of a pressure decrease and the possibility of microbial biofilm formation on tube walls during prolonged pumping over periods of several weeks. Such long pumping times are commonly needed before the geochemical situation, especially redox potential, becomes stable in the groundwater. Most of these effects can be avoided by the application of down-hole samplers. The suitability of two types of down-hole samplers has previously been tested, in addition to that of sampling via pumping. The samplers used were the BAT (10) and the PAVE (11) samplers (Figs. 1b and c, respectively). The BAT sampler was constructed with gas-sampling as a major aim and consists of two sterile cylindrical tubes or one larger tube made of stainless steel. The tubes are supplied with nitril rubber stoppers and evacuated. In the study testing the BAT sampler the tubes were opened and closed at sampling depths by penetration of the stoppers with hypodermic needles by means of a mechanical device controlled from the ground level. For several reasons, however, this sampler was not a reliable microbiology-sampling tool. The piston pump, which was very difficult to clean, was placed before the sample containers and the sudden decrease in pressure, when the sample containers opened, ripped biofilms from the pump into the sample container. Also, the pressure difference between the evacuated sample cylinders and the groundwater at depth (up to 100 atmospheres) may have caused a "French press" effect on cells in the groundwater, disrupting some of the cells by a sudden drop in pressure when they passed out of the narrow hypodermic needle orifice, penetrating the sampling containers. The BAT sampler (Fig. 1b) never came into routine use for microbiology-sampling. The boreholes at ground level at Hålö, Laxemar, Palmottu, Ävrö, and Äspö (Table 1) were sampled by the borehole pump technique (Fig. 1a). A mobile chemistry laboratory was used at ground level for sample retrieval and preparations (18).

The PAVE system was designed with both gas and microbiological sampling as major objectives. The system consists of a rubber membrane pump placed above a

sample container with two sterile, evacuated, and closed pressure vessels filled with argon gas so that the piston moves to the top of the pressure vessel (Fig. 1c). The argon pressure is set just below the hydrostatic pressure at the sample depth, which makes the pressure-drop during sampling negligible. In experiments conducted by Haveman and coworkers (11) the complete PAVE system was disinfected before sampling by rinsing for 30 minutes. with a 10-mg l^{-1} chlorine dioxide water solution (Freebact, Wecantech AB, Märsta, Sweden), then flushed with sterile water for 10 minutes. Control samples were analyzed to ensure the efficiency of sterilization, and growth could not be detected (11). The section of the borehole to be sampled with PAVE was packed off with inflatable rubber packers, as with the BAT system (Fig. 1b). Groundwater was pumped from the packed-off zone, past the closed-pressure vessels, and out of the borehole. Until they stabilized, groundwater parameters (pH, E_h, conductivity, and temperature) were monitored in N_2-shielded flow through cells in the field laboratory at the surface. At this point, samples for field and laboratory analysis for hydrogeochemical characterization were collected. Thereafter, the pressure valve of the PAVE was opened. Groundwater pressure pushed down the piston in the sampler to fill the sampler with groundwater. The valve was left open for several hours to allow water to pump through the sampler, and then the PAVE sampler was closed again and raised out of the borehole. This system was employed to sample the Hästholmen, Kivetty, Olkiluoto, and Romuvaara sites in Finland (Table 1).

Sampling from tunnels below the groundwater table (Fig. 1d) significantly reduces sampling difficulties. Boreholes become artesian, and packers and pressure-resistant tubes with valves are all that are needed for successful sampling. The high pressure encountered as the tunnel gains depth requires very robust anchoring and packer systems but such equipment is readily available. This sampling method was used for all the Äspö HRL tunnel boreholes (Table 1).

A final possibility is to sample open fractures that enter tunnels underground (Fig. 1e). These are free from drilling effects but may reflect some disturbance encountered during the blasting operations used for tunnel construction. Parts of the Äspö HRL tunnel have been drilled with a tunnel-boring machine (diameter of drill = 5.5 m) and the disturbance on the surrounding rock mass is minimal in those (lower) parts of the tunnel.

The Groundwater Environment

The groundwater environment in igneous rock aquifers is generally anaerobic, normally with a pH of between 7 and 8. The pH is seldom below 7 but may approach 10 in some water (19). The presence of ferrous iron and sulfide attests to reduced and anoxic conditions (Fig. 3). The content of organic carbon is generally low, being in the range of 0.1 to 10 mM. The content of dissolved solids is usually dominated by chloride, sodium, and calcium (Fig. 3), but these vary in concentration by four orders of magnitude. Such variability in groundwater composition makes it difficult to interpret chemical information of the type presented in Figure 3. Multivariate-mixing and mass balance calculations, so-called "M3 modeling", can be used to trace the effect from present and past groundwater flow with fair accuracy (20). This technique has identified five end-members, so-called "reference waters", that mix to form most types of groundwaters found in the Fennoscandian Shield aquifers. These waters have meteoric (i.e., through precipitation), glacial, marine (from the Baltic Sea), altered marine, or deep brine characteristics.

Attempts to correlate cultivable and total numbers directly with groundwater characteristics have not been very informative. Except for some correlation between total numbers and DOC, no correlation could be found. However, when all groundwater characters were taken into consideration in an M3 plot, it was found that, as the water tends toward brine, sulfate-reducing bacteria (SRB) and iron-reducing bacteria (IRB) can no longer be cultured. Other physiological types, such as heterotrophic acetogens, could be cultured from almost any groundwater type in the M3 plot. The complexity in deep groundwater

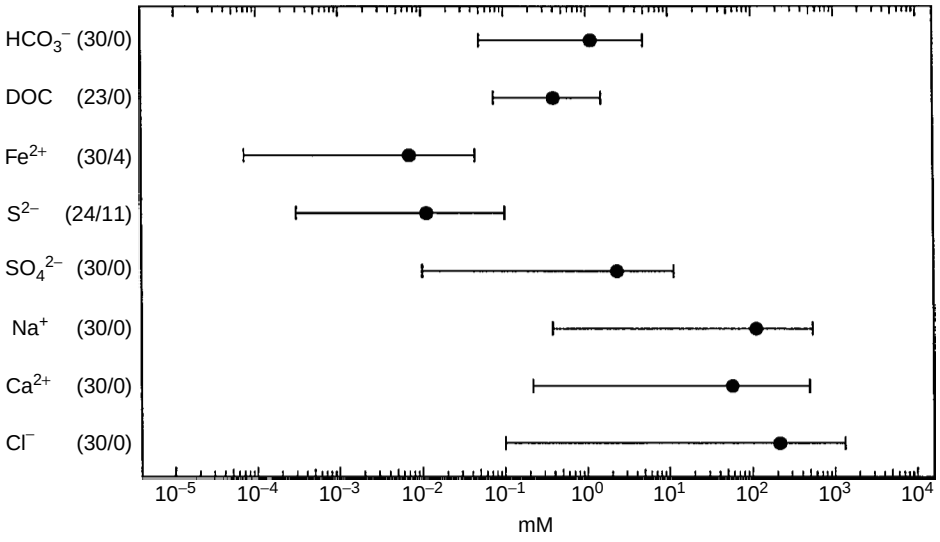

Figure 3. Chemical data observed at investigated sites. The figure shows the average concentration of the chemical species measured; the bar gives the range of data used to calculate the average. The numbers in parentheses following the site name give the sum of observations for the site/sum of observations below the detection limits for the respective analytical procedure. DOC = dissolved organic carbon.

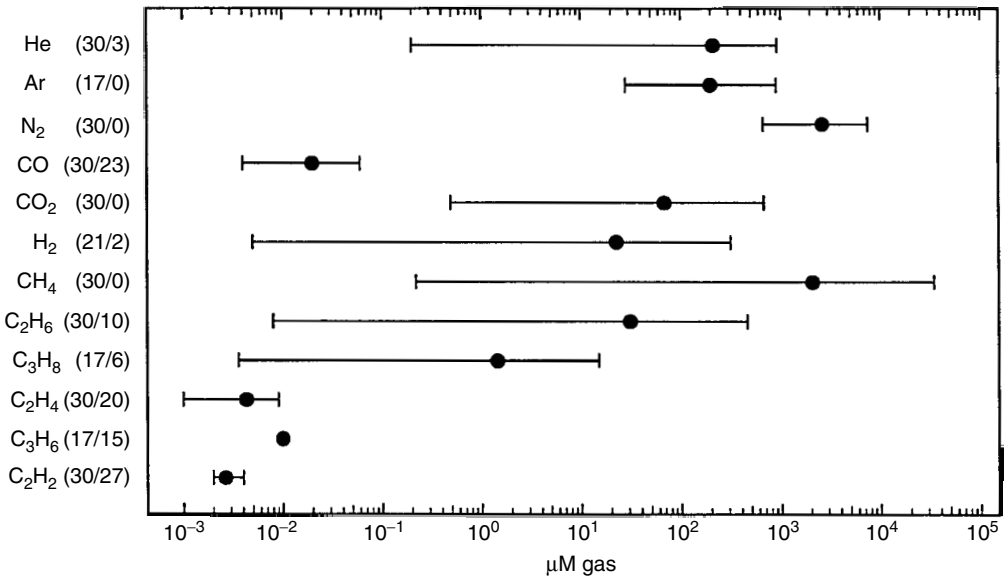

Figure 4. The composition of the gas observed at investigated sites. The data have been extracted from Haveman and coworkers (11) and Pedersen (6). The figure shows the average amount of the gas measured; the bar gives the range of data used to calculate the average. The numbers in parentheses following the site name give the sum of observations for the site/sum of observations below the detection limits for the respective gas.

hydrogeochemistry suggests that many different ecological niches may exist because each point in an M3 plot represents a more or less unique mix of different groundwaters. If this is correct, then a significant microbiological diversity (see "Diversity and Phylogeny of Aquifer Communities" in the following text) with many different species should be expected, each adapted to one or several of the observed hydrogeochemical conditions.

Several gases occur in the studied groundwaters (Fig. 4). Nitrogen generally dominates, followed by helium and argon. Traces of carbon monoxide are found, whereas carbon dioxide occurs in much higher concentrations. Hydrogen is almost always present, although it varies significantly in concentration. Methane is always found and, in some of the deep boreholes at Olkiluoto in Finland, it is the dominant gas (11). Ethane and propane occur, suggesting that some of the methane is of mantle origin, as discussed further in the following text (see "Stable Isotope Signatures").

MICROBIAL NUMBERS IN DEEP GROUNDWATER

Total Number of Microorganisms

Total numbers of subsurface microorganisms vary notably, depending on the site studied. Values in the range of 10^3 to 10^8 ml^{-1} groundwater or gram sediment have been reported for deep environments (1,5,21,22). The total number of microorganisms in igneous rock groundwater samples has been examined ever since the first boreholes listed in Table 1 were visited, back in 1987. Unattached microorganisms have been counted with epifluorescent microscopy after filtration on 0.2-μm filters and staining with acridine orange (AO) and/or 4′6-diamidino-2-phenylindole (DAPI) (23,24). Generally, the

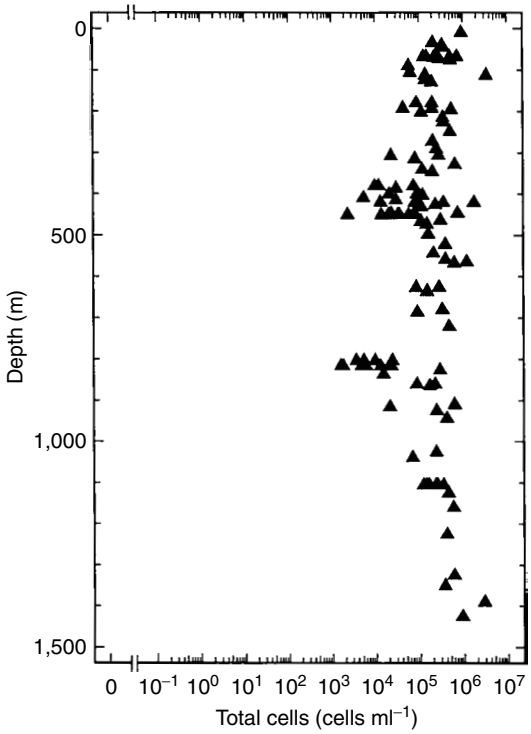

Figure 5. Total number of cells observed at the sites listed in Table 1. At least one determination was done on each level in each borehole. The number of observations depicted in the figure is 112.

average total number of cells commonly registered in the Fennoscandian igneous rock aquifers is within the interval of 10^5–10^6 cells ml^{-1} (Fig. 5), although the range of single observations is from 1×10^3 to 5×10^6 cells ml^{-1}. A large

set of boreholes examined at a site results in a larger range of total cell numbers than does a small set of boreholes. This correlation can be expected if there are large local variations between the aquifers examined at one site, which indeed seems to be the case for Laxemar, Stripa, and Äspö HRL, showing ranges in total cell numbers of almost three orders of magnitude. The total number of cells in specific boreholes was studied extensively at Stripa and Äspö and the variability was found to be remarkably small. The Stripa borehole V2 delivered reproducible and nonvariable numbers for the whole period studied, which was four years (19,25). Four new drilled boreholes in the Äspö HRL tunnel were revisited three times during one year and showed matching total numbers over this period (12), as did seven other boreholes at Äspö HRL revisited three times over a period of six months (26). The variability in total numbers between boreholes and the nonvariability in total numbers within specific boreholes is indicative of stable environments with little or no change in the conditions for microbial life. These conditions may, however, vary considerably between sites and boreholes intersecting the Fennoscandian Shield igneous rock aquifers. This observation compares well with data on the groundwater chemistry in boreholes, which may vary significantly between boreholes, depths, and sites, but is nonvariable within specific boreholes over time (27).

Viable Counts of Microorganisms in Igneous Rock Groundwater

The plate-count technique has been employed for the determination of the number of colony-forming units (CFUs) in deep igneous rock groundwater. The percentage of total numbers that could be cultured from Äspö borehole groundwater with this method ranged from less than 0.1 to 10%, with an average of 1.7% (28). The media used were of general purpose types for heterotrophic bacteria, and further characterization was required for information about the kinds of CFU obtained. *Pseudomonas* and *Shewanella* were typically found. More recent use of this method for Äspö HRL tunnel borehole groundwater resulted in very low CFU percentages of less than 0.1% of the total numbers (12). These low viable count numbers and the inability of the plate-count method to reveal information about the metabolic diversity of the investigated microorganisms motivated the adaptation of more selective media for different predominant physiological groups of microorganisms. A range of anaerobic-culturing media for physiological microbial groups were, therefore, developed and applied to Äspö HRL tunnel groundwater and at the investigated five groundwater sites in Finland. Anaerobic Hungate tubes and serum bottles with aluminum crimp–sealed butyl rubber stoppers (Bellco, U.S.A) were used for most probable number (MPN) determinations with a set of various media (11,29). Figure 6 summarizes the MPN results of IRB and SRB, heterotrophic and autotrophic acetogens, and heterotrophic and autotrophic methanogens.

IRB and SRB in the range of 10^0–10^4 cells ml^{-1} were detected at many of the depths investigated (Figs. 6a–b). An inverse relation between IRB and SRB correlating with the predominating types of fracture minerals at the sites became evident when the Finnish Hästholmen and Olkiluoto sites were compared (11). Olkiluoto has a relatively high average number of SRB and a low number of IRB, whereas the opposite is true for Hästholmen. Hästholmen's groundwaters were found to be rich in iron, containing up to two orders of magnitude more total iron than what is found at Olkiluoto. Fracture minerals at Hästholmen include iron hydroxides but pyrites are only sporadically present, whereas Olkiluoto fracture minerals have pyrite as one of the major components. This indicates that the presence or absence of pyrite as a fracture mineral correlates well with the presence or absence of SRB at the compared sites. Pyrite formation on fractures in these cold aquifers may reflect long-term SRB activity, which is not apparent from groundwater chemistry data. Interestingly, no correlation could be found between sulfate or sulfide concentrations and MPN of SRB. Some of the largest numbers of SRB were found in boreholes with both very low and very high sulfate and generally low sulfide concentrations. This example demonstrates that it is important to identify indicators of microbial activity that are both conservative and insensitive to transport processes because under steady state conditions, the time frames of various processes in hard rock may span millions of years. Even the slowest transport rate may replenish sulfate to SRB within this time frame, resulting in a steady state concentration of sulfate and a buildup of pyrite precipitates. Long-term and very slow processes should be in focus when searching for evidence of subterranean microbial activity. Signatures in fracture minerals seem to be reliable indicators of past and present microbial activity, especially if stable isotope ratios are added to the analysis protocol (30,31).

In most hydrothermally oxidized fractures, IRB have access to an almost unlimited source of ferric iron, provided they can reach it. Humic and fulvic acids are common in most deep groundwaters and these complex compounds have been demonstrated to act as electron shuttles between ferric iron sources and IRB (32). The molecular size of these compounds is small enough to allow penetration of the rock matrix, which then enables iron reduction in parts of the rock that are not directly accessible to the IRB. Attempts to correlate numbers of IRB with amounts of ferric and ferrous iron have not been successful because much more than the sulfur redox couples, the iron redox couple is sensitive to inorganic processes, at least where reduction is concerned. Therefore it is not possible to discriminate between biological and chemical iron redox reactions. Adaptation of mixing models has been demonstrated to be more fruitful (33). The effect of IRB on carbon dioxide and ferrous iron production was demonstrated for a shallow groundwater-intrusion system at the Äspö HRL tunnel. Organic carbon in the groundwater that reached the studied fracture zone was oxidized with ferric iron as the electron acceptor, and this process rapidly reached a steady state that has been sustainable over the measuring period of nine years. A similar approach was taken at the Äspö HRL for the

determination of sulfate reduction along the tunnel. It was found that the MPN of SRB correlated well with geological, hydrological, and groundwater isotope data, indicative of ongoing sulfate reduction (6,34).

Pure cultures and 16S rDNA sequences of acetogenic bacteria from Äspö HRL groundwater indicate that this physiological group of bacteria is important in the subterranean environment (26). Later applications

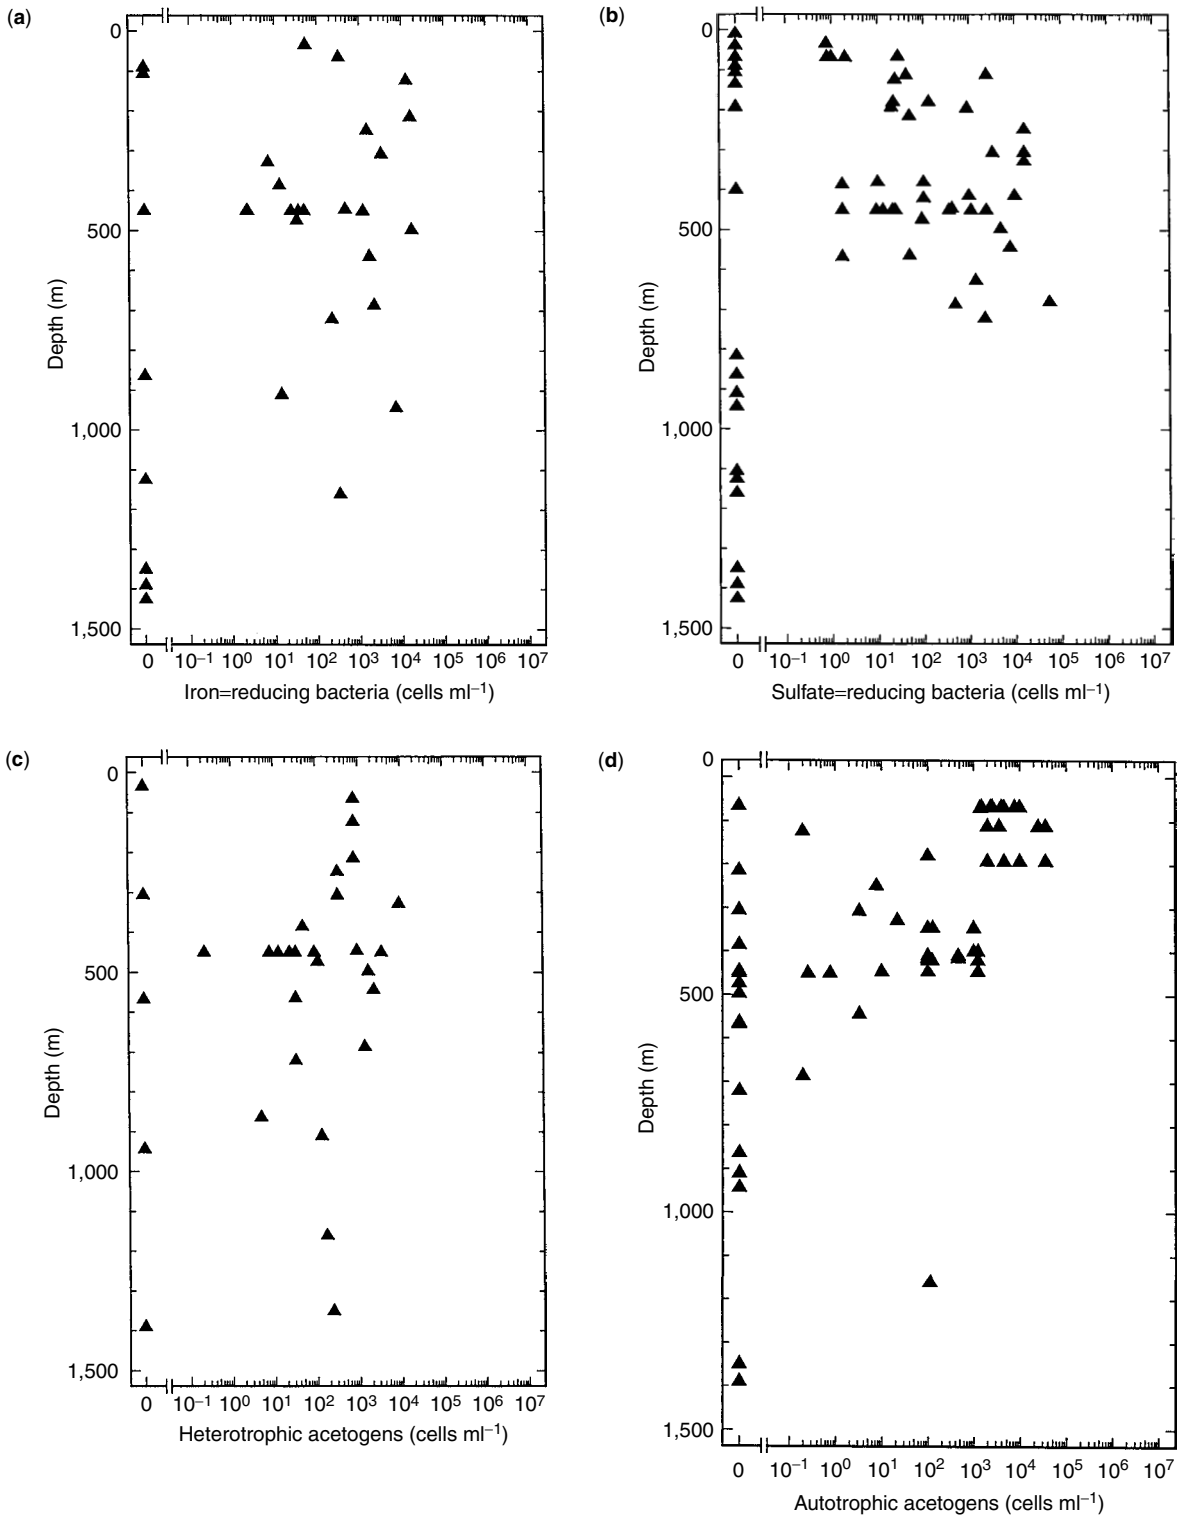

Figure 6(a-f). Most probable numbers of different physiological groups of microorganisms observed at the 11 sites investigated (Table 1). Each observation consists of an MPN determination with three or five parallel tubes in the dilution series.

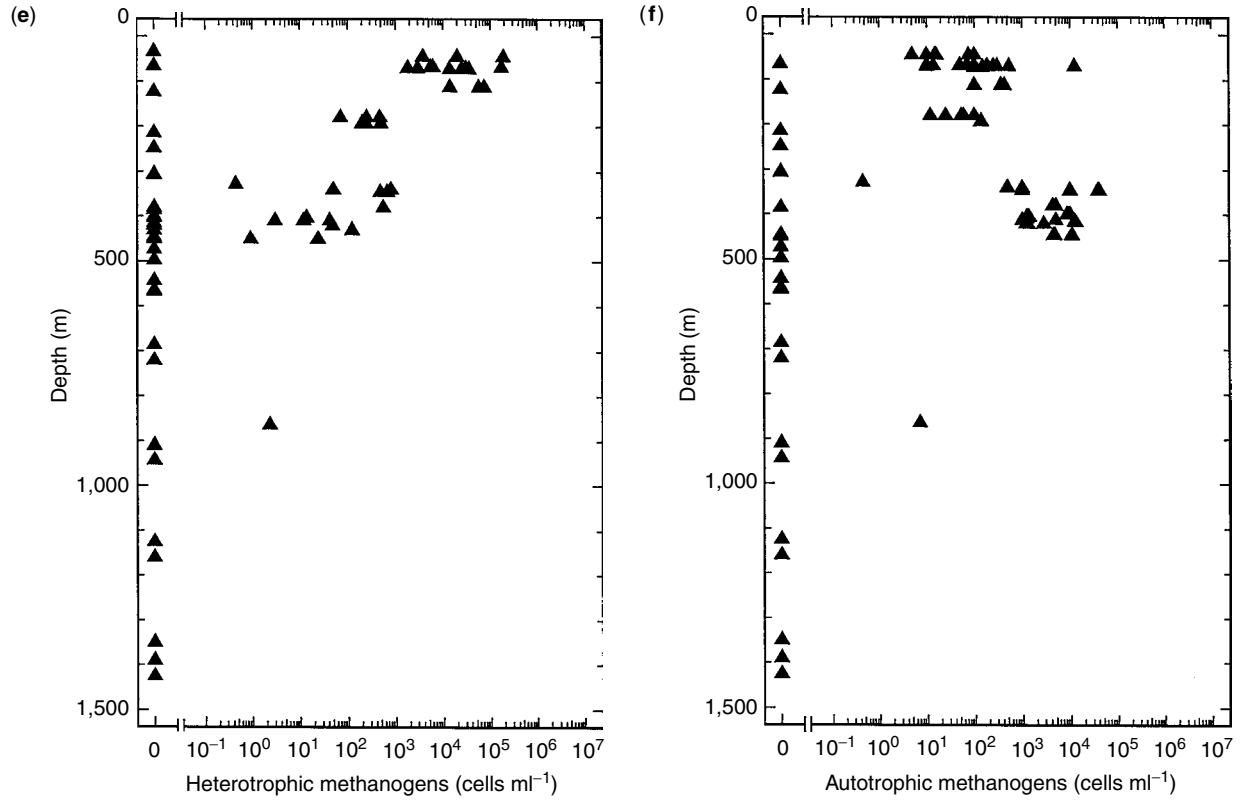

Figure 6(a-f). (*continued*)

of MPN media for heterotrophic and autotrophic acetogens lend support to this hypothesis. Autotrophic acetogens form acetate from hydrogen and carbon dioxide and thereafter the carbon may be further transformed to methane by the acetoclastic methanogens. Heterotrophic acetogens have, with five exceptions, been found at all depths studied (Fig. 6c) and autotrophic acetogens have also been shown to occur frequently (Fig. 6d). The numbers of autotrophic acetate–producing bacteria (Fig. 6d) correlate well with the numbers of heterotrophic methanogens (Fig. 6e) including acetoclastic ones (29).

The presence of hydrogen and carbon dioxide in most deep groundwater examined (Fig. 4) indicates that autotrophic methanogenesis should be possible and the MPN analyses indeed report significant numbers of organisms responsible for this process at Hålö, Äspö HRL, and Olkiluoto (not shown; 11,29). There is no simple explanation for the lack of positive indications of methanogens in most samples from Finland, other than the media used, which were developed and adjusted at Äspö during many repeated sampling occasions in the tunnel. All Finnish samples from boreholes were collected from the ground surface with the PAVE method (Fig. 1), which offers one sample of 300-ml groundwater per level. It is generally not possible economically to repeat such sampling campaigns. However, it cannot yet be excluded that the MPN determinations were accurate and that there were no, or very few, methanogens at most studied Finnish sites.

CARBON-TRANSFORMATION ACTIVITIES

Isotope Techniques

Radioactive compounds for the estimation of microbial activity have been used in microbial ecology for several decades (35). With this technique, samples are incubated with the radiotracer of interest and then examined. Cells, or products, can be separated and examined for radioactivity using standard liquid-scintillation techniques. The method gives average activity results for the whole sample. The activity of individual cells can be examined using a microautoradiography (MARG) technique (36,37). Both liquid-scintillation and the MARG technique have been applied on microorganisms from the Laxemar, Stripa, and Äspö HRL sites (Table 1) with different radiotracers and incubation times. A strong advantage of the MARG technique is that individual cells can be examined and the method can be successfully combined with nucleic acid–probing, offering specific information on selected metabolic activities (38). However, the MARG method is less applicable at very low metabolic rates than is liquid scintillation. In an aquatic sample supplemented with a radiolabeled substrate for a short period an individual cell must have a minimum uptake rate to become sufficiently labeled to produce a positive microradiogram. The lowest radioactivity that resulted in cells sufficiently radioactive to expose the film faster than the background radiation was found to be 10^{-3} disintegrations per minute (19). This level corresponds to $0.1–1 \times 10^{-16}$ mole ^{14}C per bacterium and 2.1×10^{-19} mole ^{3}H per bacterium for the method

used to generate the MARG data. A prolonged incubation for more than a few hours will lower the detection limits but will concurrently increase the background and also allow growth on the added substrates.

Both the Laxemar and the Stripa populations transformed all added compounds, although at varying rates. Carbon dioxide was assimilated at relatively low rates, as were formate, acetate, and glucose. The fastest uptake was reported for lactate. Generally ten times more lactate than other ^{14}C-labeled compounds was transformed, and up to 83% of the deepest population at Laxemar was active in lactate transformation. Lactate appeared to be the preferred carbon source and can be used by SRB and heterotrophic acetogens under anaerobic conditions prevailing in deep groundwater. Figures 6b and 6d shows that these two physiological groups of bacteria are indeed common. The incorporation of acetate was not high but, as ^{3}H was used, the sensitivity of the MARG with this isotope was higher than when ^{14}C was used. The MARG technique revealed that a large proportion of the cells did take up this compound (for a detailed discussion on method sensitivity, see 19). Acetate is used by many SRB and heterotrophic methanogens and both these groups are frequently represented in the MPN data (Figs. 6b,e). Acetoclastic methanogens have also been found to be active in many of the studied Äspö HRL boreholes. Uptake of carbon dioxide by the Stripa and Laxemar populations suggests that autotrophic organisms were present. Later studies (29) confirmed this conclusion and autotrophic acetogens and methanogens have since been enriched, enumerated (Figs. 6d,f), and isolated at many of the studied sites. Autotrophic methane production was common at Äspö HRL, as shown by using the radiotrace- scintillation technique.

A relatively large data set describing carbon transformations has therefore been obtained over a 12-year investigation period. When these data are compared with MPN data, it appears that most of the observed radiolabeled carbon transformations can be correlated with the detected physiological groups of microorganisms that are able to accomplish the observed transformations.

Significant methane and acetate formation rates were obtained in vitro with Äspö groundwater at a temperature (17 °C) close to the in situ temperature of 10 to 17 °C. The general trends for heterotrophic methane formation and acetate formation followed the trends observed with MPN and enrichments (29). The highest activity was found in shallow boreholes (i.e., at 45–68 m), which also had the highest numbers of heterotrophic methanogens and homoacetogens. Autotrophic methane formation did not, however, follow the cultivability trend. This may have occurred because with increasing depth it is more difficult to mimic in situ conditions in vitro for parameters such as pressure and dissolved gases. With this exception, three independent methods, MPN (Fig. 6), enrichments (29), and radiotracer assays, all established the presence of active heterotrophic methanogens and homoacetogens in the examined groundwater.

Stable Isotope Signatures

Microorganisms express a kinetic isotope effect by favoring lighter isotopes over heavier isotopes. Isotope fractionation may, therefore, reflect past and present activity of microorganisms in deep rock environments. The presence of hydrogen, carbon dioxide, and methane in most igneous rock groundwaters examined suggests that methanotrophic microorganisms are present. As discussed earlier, culturing and activity data support this conclusion. Methane of biogenic origin commonly has a $\delta^{13}C$ value that is lower than −50% PDB (Peedee belemnite) (39). Microbial gas is also depleted in higher alkanes so that $C_2H_6 + C_3H_8$ is less than 1% of the amount of methane. A plot of the $\delta^{13}CH_4$ values versus the quotient of methane over alkanes shows biogenic and thermogenic sources of the methane found in Fennoscandian Shield groundwater (Fig. 7). The five values that plot in the biogenic box were obtained with Äspö HRL groundwater, whereas all other data were obtained from Finnish groundwater. Several values plot between the two possible sources, suggesting that a mix of them was observed. The main component seems to be thermogenic for Finnish groundwater and biogenic for Äspö HRL groundwater. This is in line

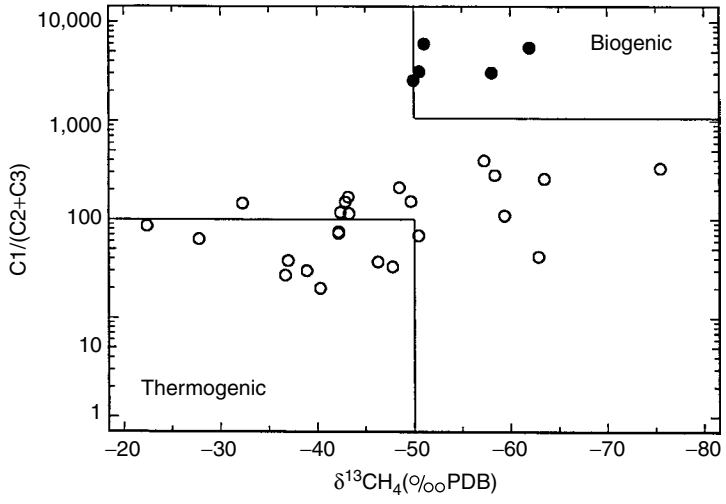

Figure 7. Stable isotope values of ^{13}C in methane dissolved in deep Fennoscandian groundwater versus the quotient of methane gas over the sum of ethane and propane (Fig. 4). Biogenic and thermogenic boxes indicate typical values for methane produced by microorganisms and deep mantle reactions, respectively. Filled circles represent samples from the Äspö hard rock laboratory, Sweden; open circles represent data from boreholes in Finland.

with culturing data, suggesting that methanogens are more active around the Äspö HRL than in the Finnish groundwater examined. Cultivability of methanogens has been significantly higher for Äspö HRL groundwater than for groundwater collected from Finnish igneous rock aquifers.

DIVERSITY AND PHYLOGENY OF AQUIFER COMMUNITIES

Molecular Investigations

The MPN assays and activity measurements described earlier have supplied extensive information about present and viable physiological groups in the examined deep aquifers but these methods do not reveal species diversity and phylogeny. Classical microbiology comprises characterization and species affiliation based on large sets of phenotypic and genotypic data, which is a very time-consuming procedure not suitable as a species diversity–screening technique for environmental samples. The concept of microbial diversity has been changed by the increase in available sequence data on ribosomal 16/18S rDNA. The cloning and sequencing of DNA from microbes living in their natural environments have revealed a genetic diversity way beyond the dreams of past researchers whose tools were limited to culturing and microscopy (40). An early strategy in the study of Fennoscandian rock aquifers was to add 16/18S rDNA sequencing of environmental DNA to the investigations. The DNA was amplified with polymerase chain reaction (PCR) methodology using so-called universal primers. The first site to be thus examined was the Stripa borehole V2 (41). Attached microorganisms were studied and all sequences found among the 72 clones investigated belonged to the Proteobacteria. Two of the major groups of clones fell into the β-group, and the third group fell into the γ-group. Because specific archeal primers were not used in this study, the probability to detect organisms belonging to the domain *Archaea* was strongly reduced.

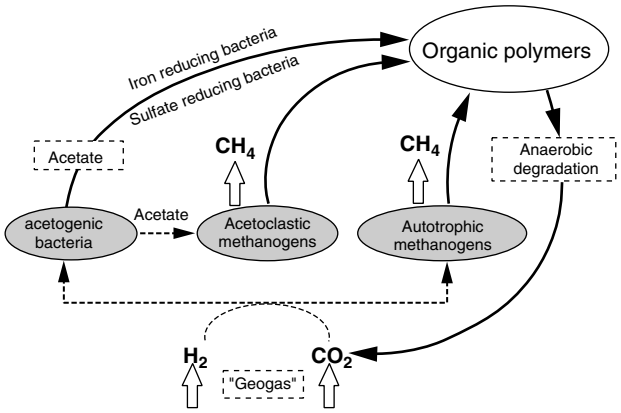

Figure 8. The deep hydrogen-driven biosphere hypothesis illustrated by the carbon cycle. At relevant temperature and water-availability conditions, subterranean microorganisms are theoretically capable of performing a life cycle that is independent of sun-driven ecosystems. Hydrogen and carbon dioxide from the deep crust of the earth or organic carbon from sedimentary deposits can be used as energy and carbon sources. Phosphorus is available in minerals such as apatite. Nitrogen, nucleic acids, and so on can be synthesized via nitrogen fixation, and nitrogen gas is the predominating dissolved gas in most groundwaters (Fig. 4).

The next site to be investigated with 16/18S rDNA studies was the Äspö HRL tunnel. In the first campaign, 155 clones of unattached and attached bacteria from 9 boreholes were sequenced (26). A comparison of predominating 16S rRNA gene sequences with international sequence databases revealed three clone groups that could be identified as bacteria on the genus level, the *Bacillus*, *Desulfovibrio*, and *Acinetobacter* genera. One of the clone groups could be identified as belonging to the fungi. A second campaign was executed during a contamination-control investigation while drilling boreholes in the Äspö HRL tunnel (12) and 158 clones were sequenced. Several clones showed close similarity to 16S rRNA genes from known and sequenced bacteria such as *Bacillus, Desulfovibrio*, *Desulfomicrobium*, *Methylophilus*, *Acinetobacter*, *Shewanella*, and the yeast *Candida*. Archeal primers were not used for those studies.

The diversity size of the bacterial community detected in the Äspö HRL groundwaters is not large compared with the numbers expected in surface soils, for example, 4,000 species in 1 gram of soil (42). Of the total of 385 sequenced clones from Stripa and Äspö HRL, 122 constituted unique sequences, each representing a possible species not reported to the database at the time the comparison was done. On an average, approximately one-third of the sequenced clones represented unique species. In other investigations similar to the Äspö HRL study, a matching molecular biodiversity per total number of sequenced clones was observed. For example, 44 specific clone groups out of 130 sequenced clones from 5 boreholes were observed at the natural nuclear reactor in Bangombé, Gabon, Africa (43), as well as 20 specific clone groups out of 67 sequenced clones from nuclear waste buffer material (44), and 23 specific clone groups out of 87 sequenced clones from alkaline spring water in Maqarin, Jordan (45). These investigations and the Äspö HRL and Stripa studies have clearly not exhausted the sequences to be found because new sequences have been found in nearly every additional sample repetition. The 16/18S rDNA sequence data–collection effort therefore clearly needs to be scaled up significantly for the study of most groundwater sites and furthermore requires automated procedures. Bacteria are very likely to be the first group of organisms for which such automated biodiversity assessment will be available, because as a major constituent of the microbial community, they deserve assessment in their own right in addition to their value as indicators (46).

Characterization and Description of New Species from Deep Igneous Rock Aquifers

The molecular work already described has given a fair insight into the phylogenetic diversity of igneous rock aquifer microorganisms but it does not reveal species-specific information. None of the 122 specific sequences mentioned earlier had 100% identities with

described species. Even if a 100% identity is obtained, there may yet be strain-specific differences in some characters and such differences are not revealed by the 16S rDNA information (47). If species information is required, time-consuming methods in systematic microbiology must be applied to a pure culture, including DNA–DNA reassociation studies. Known genera or species can be identified with these methods. Several isolates from the Laxemar, Äspö, and Äspö HRL sites have been identified as *Shewanella putrefaciens, Pseudomonas vesicularis*, and *Pseudomonas fluorescens* (26,28).

If the target isolate does not match a known genus or species, then the opportunity of describing a new species is provided. Three new subterranean species from deep igneous rock aquifers have been described and published. The isolate Aspo-2 has been characterized in detail and described as a new species, *Desulfovibrio aespoeensis* (48). It is a mesophilic species with growth characteristics that appear well adapted to a life in the aquifers from where it was isolated. Similarly, a methanogenic isolate, A8p, has been studied in detail and placed with the genus of *Methanobacterium*. Phenotypic and phylogenetic characters indicate that the alkaliphilic, halo-tolerant strain A8p represents a new species and the name *Methanobacterium subterraneum* was proposed. Finally, several oxygen-dependent methanotrophic isolates have been obtained during the investigations of microbial methane oxidation in the Äspö HRL tunnel, and a first isolate, SR5, has been successfully described (49). On the basis of phenotypic and genotypic characteristics, the strain SR5 has been proposed as the new species *Methylomonas scandinavica*.

The prospect of anaerobic methane oxidation is an intriguing possibility that has been approached in different environments (50), but absolute evidence in the form of a laboratory culture of an anaerobic methane–consuming species or a consortium is still lacking.

HYDROGEN DEPENDENCY OF DEEP MICROBIAL COMMUNITIES

The repeated observations of autotrophic, hydrogen-dependent microorganisms in the deep aquifers studied (Figs. 6d and f) imply that hydrogen is an important electron and energy source and carbon dioxide is an important carbon source for the subsurface biosphere. Hydrogen and carbon dioxide have been found in μM concentrations at all sites investigated for these gases (Fig. 4) together with methane, which is a major product of autotrophic methanogens and has been shown to be very active in vitro at Äspö HRL. Therefore a model of a hydrogen-driven biosphere in deep Fennoscandian Shield igneous rock aquifers has been suggested with various modifications (6,8,29,51,52). The organism base for this biosphere has been suggested to be composed of autotrophic acetogens that have the capability of reacting hydrogen with carbon dioxide to produce acetate, and autotrophic methanogens that yield methane from hydrogen and carbon dioxide or from acetate produced by autotrophic acetogens (acetoclastic methanogens) (Fig. 8). All components needed for the life cycle in Figure 8 have been shown to be present in deep igneous rock aquifers and the microbial activities expected have been demonstrated at significant rates in vitro. The model has, consequently, convincing support from the qualitative data obtained. It remains to examine in situ rates, a process that will require meticulous experimental conditions because of the expected very slow metabolic rates at nondisturbed conditions. The central question to address during such an experimental endeavor is whether hydrogen-driven microbial chemolithotrophic in situ activities at depth are in balance with renewal rates of hydrogen. An indisputable affirmative answer to this question is crucial for the unequivocal confirmation of a deep hydrogen-driven biosphere in the deep igneous rock aquifers of the Fennoscandian Shield.

The theory of a deep biosphere driven by hydrogen generated in deep geological strata (Fig. 8) requires more research. There are at least six possible processes in which crustal hydrogen is generated: (*1*) reaction between dissolved gases in the carbon-hydrogen-oxygen-sulfur system in magmas, especially in those with basaltic affinities; (*2*) decomposition of methane to carbon (graphite) and hydrogen at temperatures above 600 °C; (*3*) reaction between carbon dioxide, water, and methane at elevated temperatures in vapors; (*4*) radiolysis of water by radioactive isotopes of uranium, thorium and their decay daughters, and potassium; (*5*) cataclasis of silicates under stress in the presence of water; and (*6*) hydrolysis by ferrous minerals in mafic and ultramafic rocks (53). It is important to explore the scale of these processes and the rates at which the produced hydrogen is becoming available for deep microbial ecosystems.

CONCLUSION

Extensive investigations of deep aquifers in Fennoscandian igneous rocks have revealed active microbial life. As the rock is too hot to host any life when formed, this life must have migrated via groundwater-conducting fractures into cooled rock mass and adapted to the environmental conditions prevailing there. The life found represents a large physiological and genetic diversity, reflecting the variability in groundwater chemistry and rock composition of the Fennoscandian shield. These deep microbial communities may be independent of solar energy. Instead, a range of independent results have demonstrated a hydrogen-dependency of the populations, which implies that a deep hydrogen-driven biosphere may exist in the depth of Fennoscandian shield rock.

Jules Verne's famous book *Journey to the Center of the Earth* reports how Prof. Lidenbrock and his nephew, Axel, found advanced life in natural caves and tunnels deep under Europe. At that time the story was genuine science fiction. Now, 135 years later, it is obvious that Jules Verne in a sense was correct because deep under the terrestrial ground and deep under the seafloor, life is very abundant, albeit mostly in smaller cavities than suggested by Verne (2). Possibly, parts of this deep biosphere are self-sustained, without the need of

a surface biosphere. The discovery of a deep biosphere that may be independent of solar energy is of great importance to how we should search for life on other planets and to our theories about the origin of life. The predominant idea that life originated on the surface of the earth, strongly dependent on a hypothetical primordial soup, has recently come up against strong competition. Subsurface environments were relatively stable, calm, and rich in chemical and physical gradients compared to the surface environments that experienced meteoritic impacts, volcanic eruptions, and space radiation. A subsurface place of birth for life, probably very hot, is likely.

Matieland, South Africa

Microbiologists have exploited various forms of light microscopy to directly observe bacteria in pure cultures, waters, soils, sediments, biofilms, and bioaggregates. Microscopy is an important tool in environmental microbiology, providing the only direct approach to the microbial environment. Combining microscopy with an increasing range of reporter molecules such as phylogenetic probes allows observation of which bacteria are where, what they are doing, and what the environment is like at that scale. Various studies suggest that it is critical to study bacteria at this scale through direct observation (1,2). The application of computer-based image analysis to microscope images provides a powerful method to extract quantitative information. Although this technology has been used in a number of studies in applied and environmental microbiology, its potential has not been fully exploited. This review is intended as a point of departure for those interested in applying analytical imaging methods in environmental microbiology.

OBTAINING AN IMAGE

Basic System Requirements

Imaging of bacteria requires the application of various microscope techniques described below, a camera or digital imaging device, suitable connectors and cables, a monitor and computer. Useful image analysis and image processing may be carried out with as little as an Intel 80486 processor, 16-MB RAM, Windows 95 operating system, display of 256 colors, and 800X600 pixel resolution. Manz and associates (3) used a 200-MHz PC running under Microsoft Windows 95 to accomplish deconvolution of image stacks, although operating times were long. In general, a user can never have enough processor speed, RAM, storage memory, or resolution. It is also recommended that image storage systems such as CDs and archiving be considered before venturing into image processing and analyses. There are also many output options, in terms of black and white and color printers, resolution, cost, and so on. Basic manuals such as: 4, 5, 6, 7, 8, and 9 all contain valuable general information, and details with respect to microscopy, digital imaging, and analyses.

Conventional Light Microscopy

Performing effective image analyses of microorganisms requires a high-quality initial or primary image. It is always best to improve the quality of the primary image through sample-preparation steps and selection of the most suitable imaging approach. In addition, regardless of the microscopy technique selected, alignment and cleanliness are important considerations.

The small size of bacteria, often less than 1 micron, presents a challenge to the resolving power of even the highest quality light microscope. As a result, it is important to be aware of the principles of light microscopy and the microscopy options available. In general, all light microscopy techniques can be used with digital imaging methods. These techniques include phase contrast, epifluorescence, dark-field, bright-field, interference contrast, and other less commonly applied approaches (9). Each of these microscope methods serves to magnify the object of interest while enhancing the contrast between the object and its background, allowing small, low contrast objects such as bacteria to be seen. Increasingly, technology-based methods such as confocal laser scanning microscopy (CLSM) and 2-photon laser microscopy (2-PLSM) are also used to obtain high-information-content images of microbes. Basic procedures for each of these microscope methods have been detailed in other publications (9,10), and hence will be briefly discussed in the next section. Furthermore, other imaging techniques, including electron microscopy, acoustic microscopy, and scanning probe microscopy methods can be used to create images of bacteria that are amenable to image processing and analyses.

Light is a wave and therefore a perfect point cannot be imaged. Rather, resolution in a microscope is a function of the wavelength of the light used, the numerical aperture of the objective lens used for observation, and the medium between the lens and the specimen. Objective lenses have their best resolution in the *xy* plane and relatively poor resolution in the *xz* dimension. As a consequence of poor resolution in the *xz*, out-of-focus information recorded by most imaging devices degrades image quality. This *xz* error is a significant problem for *xz* imaging, 3D imaging and reconstruction, and image analysis particularly for thicker biological materials. However, the error can be modeled as a point spread function and mathematically corrected through a process referred to as deconvolution (see discussion next section).

Phase Contrast Microscopy

Phase contrast microscopy remains extremely useful because it provides for high magnification, excellent resolving power, and may be found in many laboratories. It is also a relatively simple and convenient method because it avoids the need for drying, fixation and special staining, it is nondestructive, and slides can be returned to a test system if necessary. It also avoids the problems of under- and overestimation of cell size inherent in bright-field or dark-field and epifluorescence microscopy. This approach can readily be used for making

continuous observations (11–13). Liu and associates (14) used phase contrast microscopy to image suspended bacterial populations. Cells were prepared and mounted on agarose-coated slides (15), a technique that provides a high quality phase contrast image of bacterial cells within a single focal plane. It is, however, limited to use with optically transparent substrata; that is not the case for some other approaches such as epifluorescence or laser microscopy.

Dark-Field–Bright-Field Microscopy

Dark-field microscopy achieves contrast between organisms and their surroundings by scattering light from a point source (10). Relatively inexpensive dark-field condensers and objective lenses are required, but can be used with standard microscopy equipment. Because of the increased contrast between the object and the background, dark-field images are advantageous for analyses where accurate size representation of the objects is not critical. For example, dark-field image analysis has been used to quantify rates of bacterial deposition, quantify the growth and development of bacteria and bacterial microcolonies, and monitor the motile behavior of both bacteria and surface-associated protozoans (1,16,17). In bright-field microscopy, the most common illumination on light microscopes, the object contrasts with the background if they differ in their light absorption. For bacteria to appear in bright-field images they must be stained and are frequently fixed, so continuous observation of bacterial cultures is not possible.

Differential Interference Contrast (DIC)

Another method of obtaining images of bacteria is differential interference contrast, wherein two beams are produced optically; one carrying the image and the second, a reference beam causing interference patterns (10,18). This method exploits the differences in indices of refraction of the specimen. Furthermore, the interference contrast images contain interference colors that are useful for studies of microstructure. Nomarski DIC has been used in a reflected mode to observe bacteria (19).

Hoffman Modulation Contrast

Dark-field, phase contrast, and DIC are all useful for observing unstained bacteria in suspension or on surfaces. Another approach is Hoffman modulation contrast microscopy (20). This method is also useful, although unlike phase contrast and DIC it may produce halos around objects being observed, and so can create problems for subsequent image collection, processing, and analyses.

Epifluorescence Microscopy

Typical laboratory grade microscopes are often equipped for epifluorescence microscopy. Epifluorescence microscopy requires an appropriate light source and filter sets to observe specially stained (see next section) bacterial cells. Epifluorescence microscopy focuses incident light through the objective lens that functions as both a condenser and an objective. The light source may either be a quartz-halogen-tungsten filament lamp, a mercury vapor arc or a xenon arc lamp, each of which provide particular wavelengths of light to excite special fluorescent stains. Epifluorescence approaches have the advantage of allowing analyses to be conducted on solid or opaque surfaces, and when linked with probes specific for certain bacteria, can provide detailed information from within complex microbiological systems. Rost (21,22) has published an excellent two-volume review on fluorescence microscopy that may be referred to for additional details.

Other Light Microscopy Options

Images of bacteria have been obtained using various other techniques, including transmitted, incident, or polarizing light microscopy techniques (23). The use of color infrared photography for microscopic visualization of nonstained microorganisms, modified metallurgical reflected light, continuously variable phase and amplitude contrast system microscope, interval scanning microscopy, polarizing microscopy and interference reflectance microscopy have recently been reviewed by Lawrence and associates (9).

Confocal and 2-Photon Laser Scanning Microscopy

Confocal laser scanning microscopy (CLSM) combines traditional light microscope hardware with a laser light source, photomultiplier detectors, and computerized digital imaging. Two-photon laser-scanning microscopy (2-PLSM) employs a high peak power infrared laser with an extremely short mode–locked pulse in the femto- or picosecond range to produce a high photon density. Laser microscopy is an advanced digital form of fluorescence microscopy that allows optical sectioning of living fully hydrated samples with enhanced xy and xz resolution and quality. During excitation of a fluor-stained specimen with the laser, a confocal pinhole allows only those fluorescence signals that arise from the focused xy plane to be detected by a photomultiplier tube (PMT). Typically, the selection of the fluorescence colors to be detected is accomplished using a beam splitter and filter sets. Other commercial systems allow selection of excitation emission without the need for optical lenses through the application of a filter-free prism-spectrophotometer-based system. The PMT converts the signals to a digital image. With the advent of Krypton-Argon, commercial UV and recently two-photon and multiphoton laser microscopy systems, multiple parameter imaging of samples is practical, allowing the collection of multiple quantitative data sets at a single location (24,25). Laser microscopy provides a digital data base that is highly amenable to image processing and analysis. So the user may obtain quantitative information on a wide variety of parameters including cell numbers, cell area, and object parameters such as minimum–maximum dimensions, orientation, average gray value, and so on. These techniques have been described in detail (9,26,27). In addition, the Handbook of Biological Confocal Laser Microscopy is also an excellent source of information on nearly all aspects of confocal microscopy (5).

FLUORESCENT LABELS FOR EPIFLUORESCENCE, CLSM AND 2-PLSM

Epifluorescence and laser microscopy require that the specimen be stained with special fluorochromes such as acridine orange (AO), 4'6-diamidino-2-phenylindole (DAPI), fluorescein isothiocyanate (FITC), 5-(4,6-dichloroztriazin-2-yl), aminofluorescein (DTAF), tetramethyl rhodamine isothiocyanate (TRITC), other rhodamine stains, and Texas red. Many fluorochromes (fluorescein (FLUOS, FITC) or rhodamine (TRITC) derivatives are used, however, cyanins (CY3, CY5), the blue-fluorescing aminomethylcoumarin (AMCA), or ALEXA dyes, phycoerythrine (PE)) can also be conjugated to molecules that recognize specific structures of the target microorganisms. These fluorescent probe-conjugates include lectins, poly- and monoclonal antibodies, and deoxyoligonucleotides used to detect specific sugars, antigens, or complementary nucleic acid sequences, respectively. See Haugland (28) for a comprehensive listing of commercially available fluorescent probes. Additional technical information is also available in Wang and Taylor (29).

Green fluorescent protein genetic constructs (30,31) may be used in conjunction with laser microscopy and epifluorescence microscopy to monitor gene expression in single cells. Applications of green fluorescent protein have been reviewed by Errampali and associates (32) (see GREEN FLUORESCENT PROTEIN (GFP), this Encyclopedia).

It should be noted that further research and development are required before specific recommendations can be made regarding fluorescent labels for application in 2-Photon microscopy in which excitation and emission spectra for specific fluors may be very different from that seen in traditional epifluorescence or CLSM (33).

In some instances, the application of fade retardants can be useful or necessary to extend the signal life in epifluorescence and laser microscopy. Commercial fade retardants such as Citifluor or those provided by Molecular Probes (Eugene, OR) will reduce bleaching of the fluor and extend working times for fluor-labeled samples.

VIDEO/DIGITAL CAMERA SELECTION

Although photographic film provides a suitable image for subsequent digitization, the video camera (a charge coupled device (CCD)) is the most common instrument used to obtain an analog signal of a microscopic or macroscopic image. This image may be digitized directly or fed to a frame grabber to be digitized and stored in an appropriate format. The fidelity of the primary image is again crucial, as all downstream image processing and analysis steps will vary in difficulty relative to the quality of the primary image. Video cameras vary in terms of their horizontal resolution, light sensitivity, blooming characteristics, geometric distortion, and spectral response. The camera system should be matched with the intended end application in terms of the sensitivity, resolution, and linearity of response. For example, epifluorescence microscopy images often require greater sensitivity and intrascene dynamic range to record detailed images. Manual adjustment of the camera gain and voltage control is preferable, as self-adjusting cameras alter their light sensitivity in response to changes in inter- or intrascene brightness, limiting the quantitative use of the images. In general, the low- to mid-sensitivity CCD (10^{-5} to 10^{-1} lux) cameras, are cost effective, less subject to electronic noise and geometric distortion, have relatively broad intrascene dynamic range and low blooming tendencies. These traits make them applicable for phase contrast, bright field, DIC, and most epifluorescence microscopy. Peltier cooled CCDs also offer RGB color imaging (Optronics Engineering, Goleta, CA.), providing very quiet, or noise-free imaging as a result of extremely low dark current while performing on-chip integration (summation of image information) over extended exposure times (up to 4 minutes). CCD systems, such as these also have a broad exposure range (from 0.0002 to 13,000 lux) and onboard digital contrast control, so weakly fluorescent and bright-field images can be digitized using the same basic system. Highly sensitive, cooled (−40 to −70 °C) CCD cameras having a wider range of gray-level intensities (e.g., 12–16 bit, 4096–65,686 gray-levels) may also be obtained (Photometrics Equipment, Roper Scientific, Tucson, AZ; Astromed Ltd., Cambridge, England; Micro Luminetics, Inc., Los Angeles, CA). Cameras with photon-counting capabilities (limiting low level illuminance, 10^{-11} lux) are suitable only for highly specialized applications (e.g., bio- or chemiluminescence, *lux* gene expression). These systems require specialized support equipment, darkrooms, and are not generally applicable for routine lab use (34).

The selection of peripheral equipment may also influence the quality of primary images. These include the quality of coaxial cables and connectors, random camera noise, and incorrect termination. Analog to digital conversion (ADC) circuitry and the high-frequency clock used for digital time base control may further contribute to signal degradation. Currently, completely digital CCD cameras are available that eliminate the need for ADC circuitry and associated problems.

IMAGE ANALYSIS/PROCESSING SYSTEMS

Many commercial and freeware systems for image analysis and processing are available. It has been found that no single software package offers all the features required by a specific user, so selection of software must be made with care. It is important to note that software will vary in terms of grey level resolution, programming language, capacity for software modification, design of macros or plug-ins, and system memory configuration. Equally important are details that may affect suitable end uses of the system, including their capacity to perform operations on serial image stacks produced in confocal microscopy or to perform object-based image analysis. Commercial systems available include the Quantimet System offered by Leica (Heidelburg, Germany) that has been used to analyze CLSM images of bacteria (35). PC-based three-dimensional imaging/image analysis systems include, MicroVoxel (Indec Systems, Sunnyvale, CA), VoxelView (Vital Images, Fairfield,

Iowa), or VoxBlast (VayTek, Inc., Fairfield, Iowa). The silicon graphics–based software offered by Molecular Dynamics features the 3D image analysis of CLSM image stacks. Additional commercial software suppliers are listed in Lawrence and associates (9) or on the Internet.

There are also excellent software in the published literature or available from web sites (36,37,38). Möller and associates (38) used Cellstat, a program for UNIX workstations (see *http://www.lm.dtu.dk/cellstat/index.html*). There are two excellent freeware programs that may be downloaded over the Internet. NIH Image is a versatile freeware analysis package developed for Apple platforms (*http://rsb.info.nih.gov/nih-image/*) and also compiled for Windows-based systems (ScionImagePC at www.scioncorp.com). This package was specifically designed to deal with confocal images and image stacks. NIH Image 1.62 performs well, is user friendly, and provides a wide range of analysis/enhancement and user-programing functions. ImageTool is a PC-based freeware image analysis package available at *http://ddsdx.uthscsa.edu/dig/itdesc.htlm*. This software offers many excellent object recognition and analysis features. Liu and associates (14) provide an excellent example of the application of ImageTool for studying microbial populations. In this study the authors demonstrated recognition and enumeration of 11 bacterial morphotypes. Image Tool plug-ins for studies of cell morphology are available through the Internet. Neural network systems have also been proposed for analysis of fluorescence images (39).

Specialized software is also available for the removal of out-of-focus haze by mathematical deconvolution (3,40,41). A UNIX based package for this is available over the internet that may be applied to CLSM or other fluorescent images (see *http://ibc.wustl.edu/bcl/xcosm/xcosm.html*). Deconvolution software such as EPR is available from Scanalytics (Billerica, M.A.) and was demonstrated by Manz and associates (3). The Huygens system (Scientific Volume Imaging, B.V., Hilversum, The Netherlands) runs on silicon graphics computers and includes many image-processing features, including deconvolution.

THE BASICS OF IMAGE ACQUISITION

The Primary Image

After the sample is ready to be observed, images may be collected directly (single scan), or the signal to noise (S : N) ratio of the image may be enhanced through application of various mathematical filters during collection. Typical filters include the running average, exponential, or Kalman type mathematical filter. Kalman filtration averages sequentially collected images, reducing the noise level of the image while maintaining edge features. The use of these filters may cause bleaching as a result of high frequency of scanning, and are not recommended during collection of images for applications such as ratiometric imaging.

Image-averaging techniques are best used when light is not limiting and the image is stationary. Averaging functions to eliminate nonimage interference such as pixel dropout and electronic noise. The improvement of image quality (S : N ratio) is proportional to the square root of the number of images averaged. Image-averaging may also be utilized to eliminate objects that are not stationary such as protozoans or motile bacteria (see next section) (17,42).

Another option during image collection is to use image integration, wherein the imaging device integrates images over time, allowing intensification of very faint signals. Other collection methods are available that permit image enhancement through summation of signals or collection to preset maximum signal levels. Image integration is preferred under low-light conditions, most typically during epifluorescence microscopy applications when the fluorescent signal is very weak. An example of image collection using a summation input versus a running average is shown in Figure 1a,b. These functions may be applied during image acquisition through software, or performed "on-chip" in some video cameras. The number of gray levels (e.g., 12 bit or 16 bit cameras) available for on-chip integration also enables the accumulation of low light information over a extended range of measurable brightness without saturating image pixels, a feature especially valuable during low light fluorescence microscopy applications. Subsequent application of functions such as local contrast enhancement, median filters, linear smoothing filters, and gradient filters (5,6) may serve to reduce noise levels in images, smooth the data set, and enhance the edges of objects within the image (see next section).

PRESEGMENTATION PROCESSING STEPS

As noted by Wilkinson (43) there are two types of images; those that are easy where objects stand out from a background with little detail in it and difficult images where the background is confusing or complex. Figure 2 provides an example of easy and difficult images, image A has reasonable contrast and an absence of debris, in contrast B contains problematic non-microbial objects. While it should be emphasized that sample preparation and quality of the imaging system are key factors in the optimization of the primary image, additional processing may be required in order to facilitate the identification of objects to be measured. Processing steps that may be applied before the actual segmentation of object pixels (thresholding) to improve image quality and define the edges of the objects are outlined in the next section. The result of this image-processing is an image that is gray scale, binary, or color that may be subjected to image analyses.

Shading Corrections

Optical imperfections and microscope misalignment frequently result in the uneven illumination of the primary image, often causing difficulties during subsequent image-processing steps (44). So primary images should be corrected for uneven illumination before image-processing. Peters and associates (45) used shading corrections to eliminate uneven lighting and to remove particulate debris

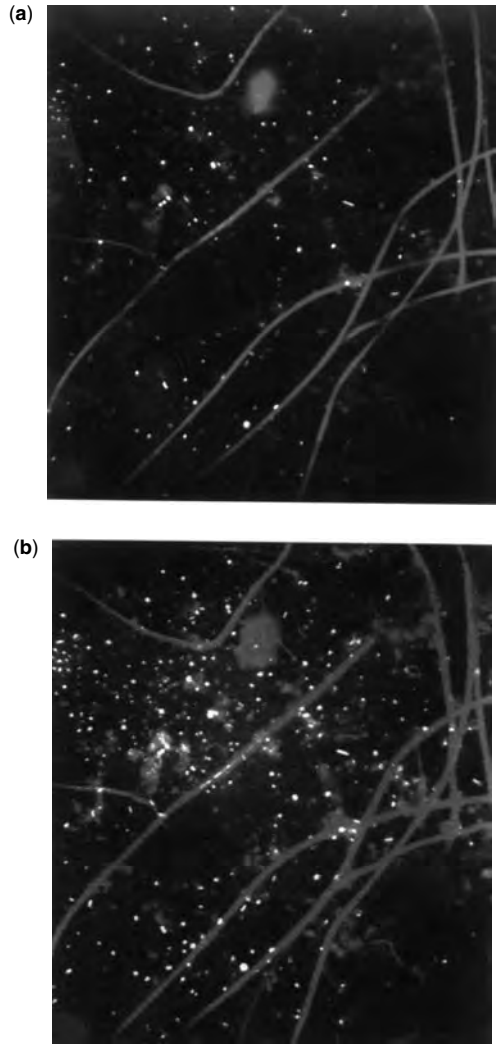

Figure 1. Confocal laser micrographs illustrating the effect of collection method on images of the same location in a river biofilm, (**a**) Kalman or line averaging mode (**b**), and image integration to increase contrast and detect faint objects in the image.

present within the optical system. This is also important for measurements because uneven lighting will result in differential sizing of objects in the image. Increasing contrast from the center to the edge of the image will result in an apparent increase in size of the same objects with distance from the center. Generally, shading corrections involve the digitization and storage of the study surface illuminated under study conditions before the sample is introduced (a reference image). If the system is aligned and no debris is present, the gray level shading correction will have a zero gray level value. If uneven illumination exists, the gray level of the shading correction will be subtracted from the study image, thereby eliminating localized bright spots or surface imperfections but not the cells introduced after collection of the reference image. Shading corrections may also be performed in the event

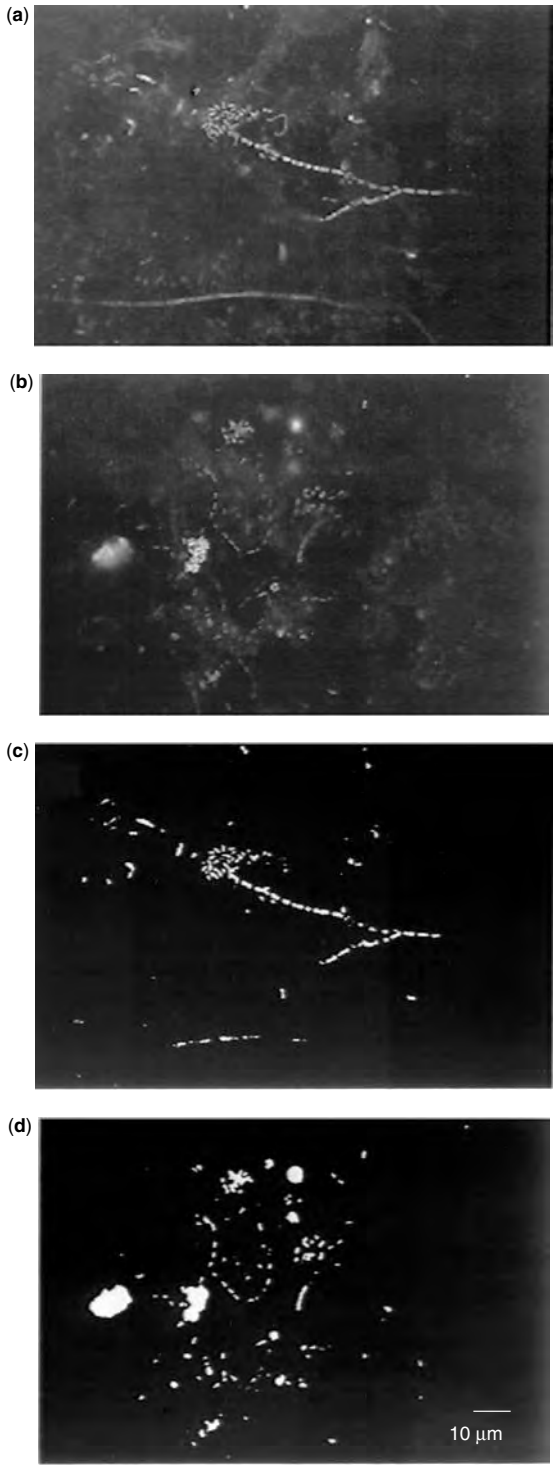

Figure 2. Two gray scale images of hybridized cells showing an "easy image" with minimal debris and nonspecific staining (**a**) and a "complex image" with noncellular debris and nonspecific fluorescence signals (**b**), the images in (**c**) and (**d**) are the respective binary images. In this instance, size selective cutoffs might reduce the error, or manual editing to remove nonobject material could be required. (Reprinted from Manz and associates, 1998).

that a reference or blank image has not been obtained. In this case, image-processing is used to remove the objects from the image leaving only the background to be used as a shading correction (6). Figure 3 illustrates the effect of applying a shading correction to improve image quality before analysis.

Mathematical Filtration

A number of mathematical filtration operations have been used to facilitate the analysis of microbiological systems, including smoothing, (Gaussian, median, lowpass), sharpening, (highpass, Laplacian, and Sobel), and so on.

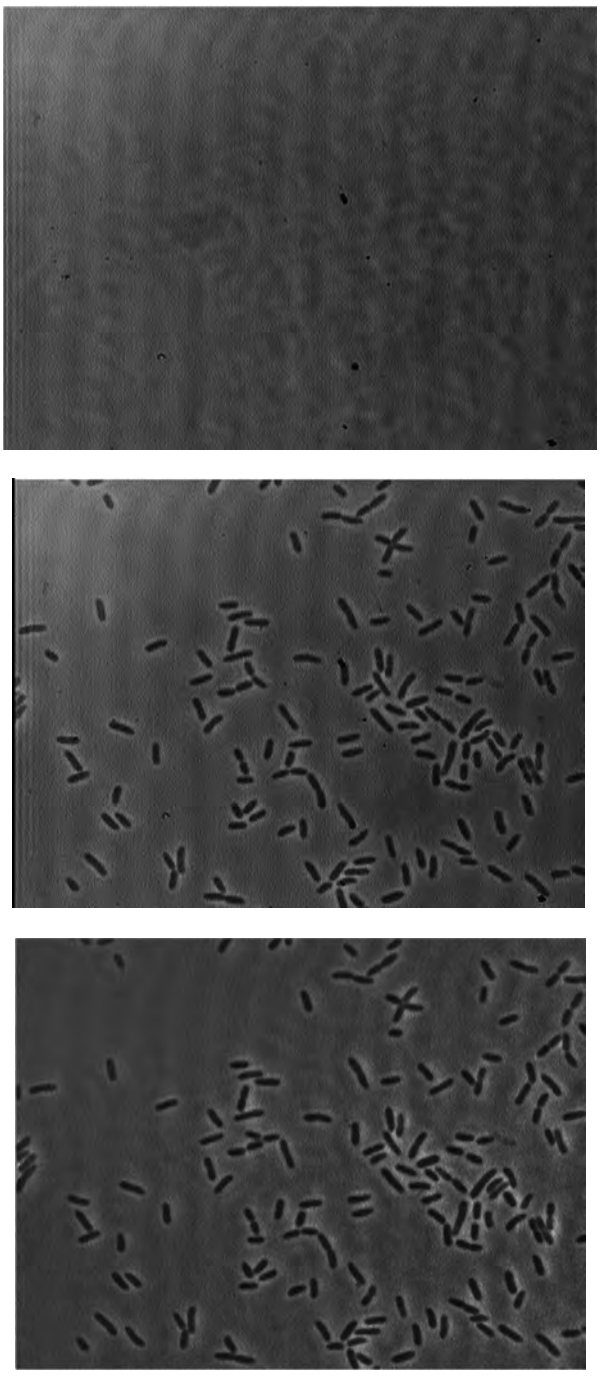

Figure 3. Effect of a shading correction (**a**) on an unevenly illuminated image (**b**) and the resultant image shown in (**c**).

Smoothing filters are commonly used to reduce image noise, and generally rely on the reassignment of the gray level value of a central pixel with the average value of itself and a matrix of surrounding pixels (may be referred to as a kernel operation). The size of the matrix is user-defined, and when applied, noise pixels are replaced with reasonable values resulting in an improved image. However, excessive application of smoothing filters can result in the loss of small objects, a loss of lateral resolution, and a decrease in the number of object pixels. Neighborhood-ranking filters such as the median filter may similarly be applied to remove noise, however, in this case a median pixel brightness value is assigned to the central pixel. An advantage of median filtration is that it does not shift boundaries as may occur in averaging or smoothing operations. There are many variations on the theme of image noise reduction (6). An example showing the impact of various strengths of median filter on noise, image quality, and object boundaries is shown in Figure 4.

High-pass filters are used to sharpen images, particularly the location of object edges. Laplacian filtration acts to increase image contrast at boundaries, thereby making edges more visible or sharper. Similar effects may be achieved using other common high pass filters such as the Roberts and the Sobel.

In some instances objects of interest may be clouded or obscured. Unsharp masking is a photographic process that may be performed digitally, where an out-of-focus image is used to mask bright regions allowing detail in these regions to be observed (see Figure 5).

Contrast Expansion and Histogram Equalization

Image analysis systems only detect object pixels having gray levels different from those of neighboring pixels. Ideally, the distribution of gray levels contained in an image will span the entire available range (i.e., 0–255 for 8-bit system; 0–4096 for 12-bit), however, this is seldom the case. Contrast expansion reassigns the image gray level values to encompass the full available range of gray levels but does not create any additional gray level information. So the image has a greater overall contrast (facilitating segmentation), but the same number of gray level values are missing. By averaging a number of contrast-expanded images that have been collected sequentially, a high-contrast image with a greater number of gray level values represented may be obtained. Histogram equalization is the selective spreading and compression of the displayed gray values so that the same number of pixels in the image show each of the possible brightness levels. Equalization may be used to bring out subtle detail in low contrast regions of an image.

Deconvolution

Deconvolution refers to the sharpening, or deblurring of a microscope image by removal of out-of-focus information, thereby mathematically producing an optical thin section. It may be used to improve both fluorescence and

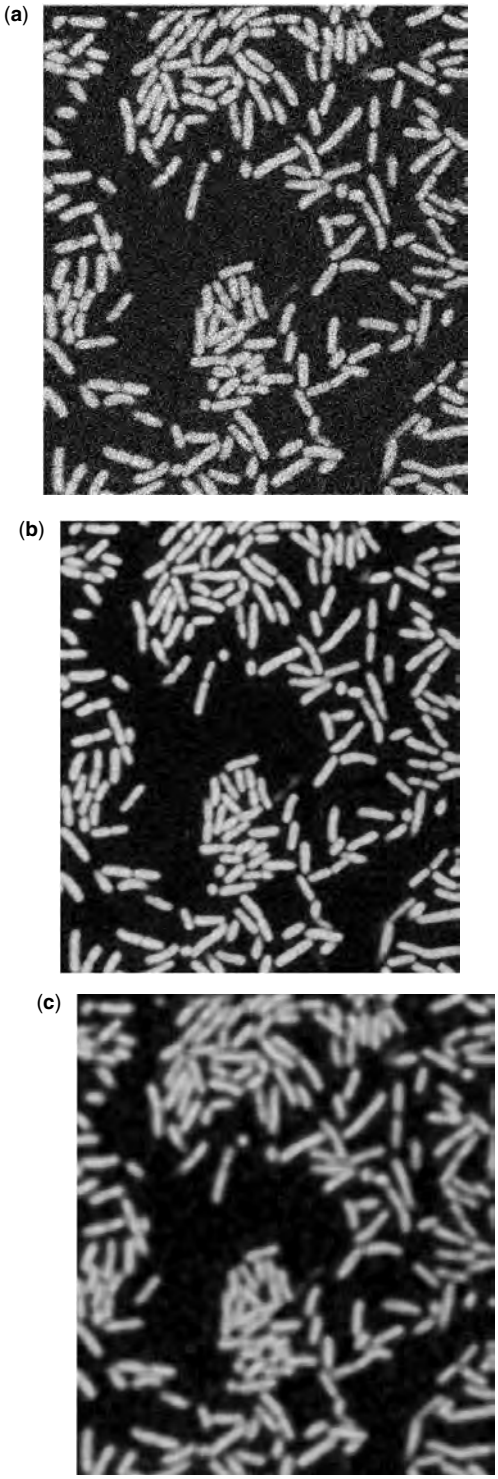

Figure 4. Presegmentation processing of a gray scale image of bacterial cells (**a**); to improve signal to noise ratio, and eliminate small debris through median filtration (**b**). The same image with a greater strength median filter showing degradation of cell edge features (**c**).

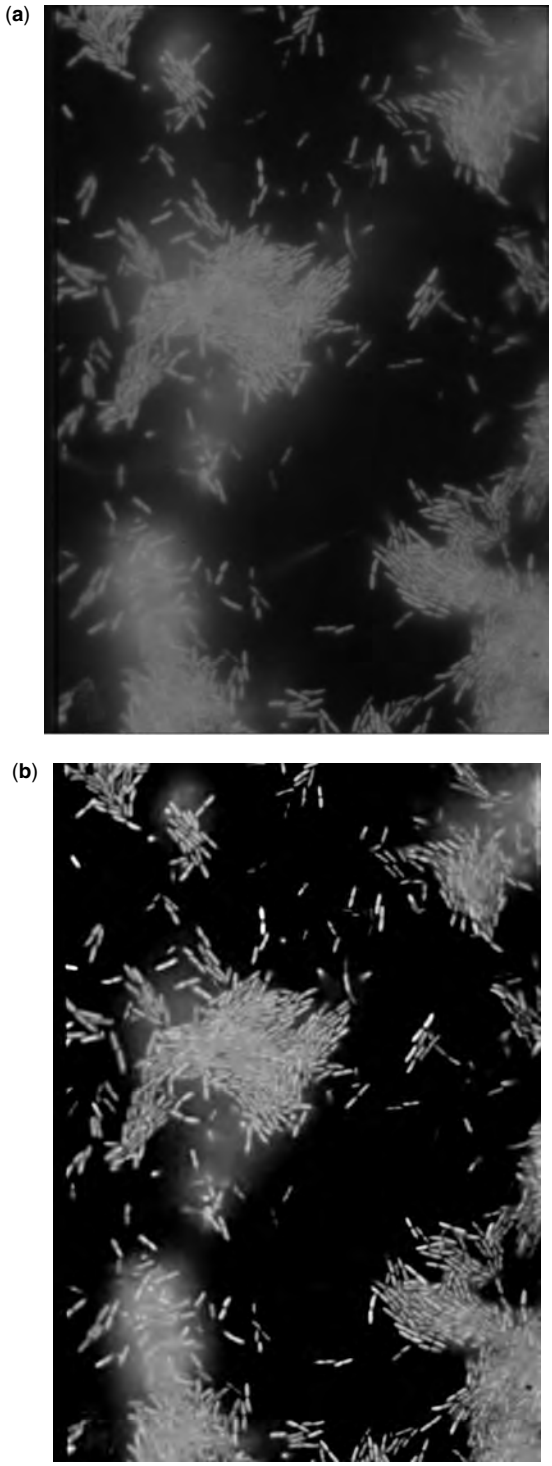

Figure 5. Application of an unsharp mask filter to an over-exposed or too bright image (**a**); to reduce haze and increase information content (**b**).

CLSM images. An ordered series or stack of high-quality primary images with perfect registration are required. A computer then calculates that information which results from objects located in other focal planes, and repositions these object pixels within the image stack. The most common algorithm is based on nearest-neighbor calculations; however, it is also the least accurate and the most artificial. Other options such as Blind Deconvolution, Iterative Maximum Likelihood

Estimation, and Iterative Constrained Tekhonov-Miller are included in certain software packages. Deconvolution methods that are based on the use of the point spread function are the most accurate for reconstruction, as it incorporates the distortion caused by the non-ideal optics of the microscope and out-of-focus pixels are placed back where they came from (photo reassignment processing) (3,46). These methods can be applied to images from the microscopy techniques described earlier, provided an image stack has been obtained.

Although mathematical approaches for deblurring microscopic images are less expensive than hardware-based optical-sectioning methods (CLSM, 2-PLSM), there are limitations to the number of depths that may be used during the calculations, and the complexity of the image. For example, a structurally simple, 3-slice image stack may be deconvolved rapidly and with excellent results. Manz and associates (3) were able to process 21-image stacks using a 200-MHz PC running under Microsoft Windows 95. Verveer and associates (47) applied various algorithms for the deconvolution of images obtained using fluorescence microscopy and CLSM. Both Agard (40) and Gorby (41) discuss the benefits of applying deconvolution. See also Squire and Bastiaens (48) for more information. Manz and associates (3) provide an excellent illustration of the application of deconvolution with EPR-deconvolution software (Scanalytics, Billerica, MA). They used a practical determination of the point spread functions using fluorescent beads (Fluospheres, Molecular Probes Inc., Eugene, OR) that had a broad excitation emission spectra. Deconvolution software such as Huygens (Scientific Volume Imaging, B.V., Hilversum, The Netherlands), AutoDeblur (Autoquant, Inc. Waterfliet, New York, U.S.A.), Micro-Tome^{TM}, HazeBuster (VayTek, Inc., Fairfield, IA) are available either through commercial sources or in the open literature. For examples of the application of deconvolution to serial epifluorescence images of hybridized bacteria including color illustrations, the readers are referred to the paper by Manz and associates (3).

SEGMENTATION/THRESHOLDING

Images must be segmented or thresholded to tell the computer which objects are to be measured during the analysis. Figure 6 shows a zoomed image of a bacterial cell illustrating the nature of the pixels forming the image and the boundary zone between what is cell (object) and background (nonobject pixels). The effect of selecting two different gray values for boundary values is shown. The resulting binary (black and white) image is then used to extract geometric data, on size, shape, number of objects, and so on. Most segmentation involves determining the boundary or the edge of the object to be measured, based on brightness or on textures. In the case of microorganisms, brightness or gray value is usually the basis for determining the object. In contrast, objects may be defined directly by grouping pixels that share certain properties and are connected, or only on their properties without regard to connectivity (43). There are also contrasting approaches concerning the degree of user interaction. Thresholding may be performed

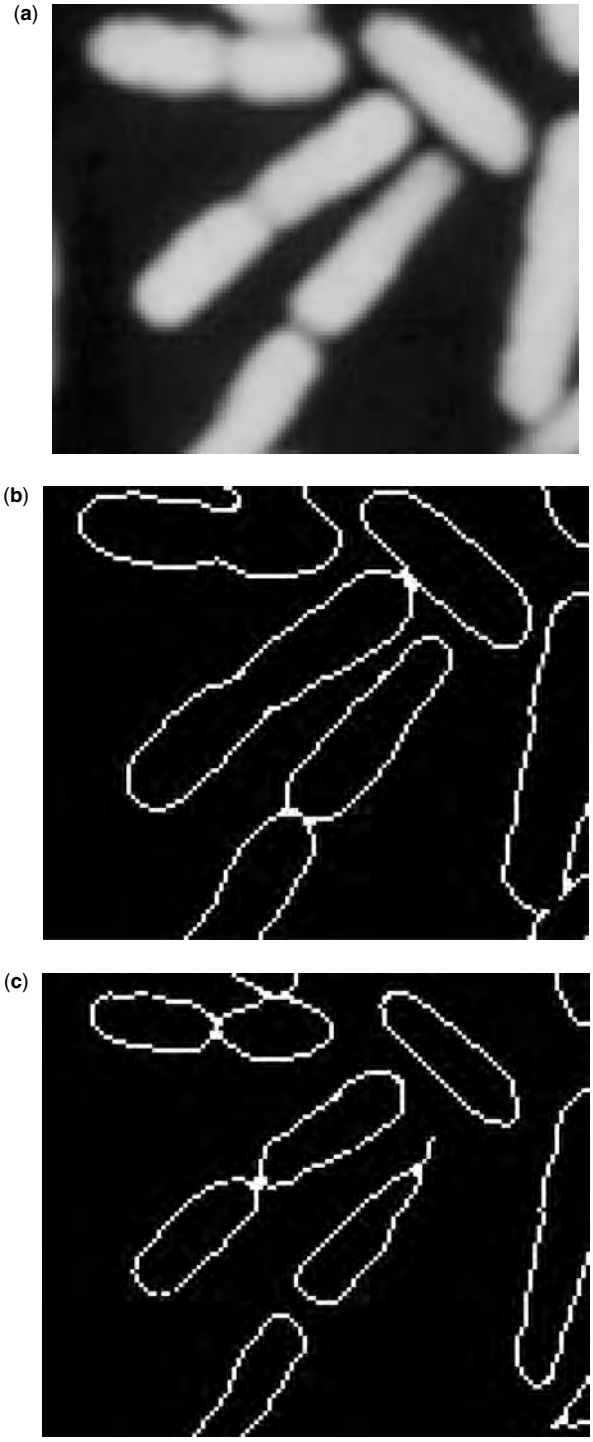

Figure 6. (**a**) Magnified boundary of the digitized image of a bacterial cell illustrating the pixelated nature of the image and how image processing software "sees" a bacterial cell. The challenge in segmentation is to correctly interpret which gray-level boundary represents the boundary of the cell for the purposes of defining and measuring the object. Once the decision is made, the software will reliably if not accurately place that boundary for all measurements. (**b**) Boundary is defined at a gray-level cutoff of 130 where black is 255 and white is 0. (**c**) Boundary of the cells is defined at a gray-level cutoff of 80. Note that cell area is reduced when the lower the gray level is used to define the object.

subjectively (with the user manually defining the gray-level cutoff value) or using automatic thresholding functions (e.g., using a probabilistic model) (49). During manual thresholding, pixels with a gray value below a user-set level (between 0–255) are considered background (gray value reset to 0), whereas pixels with gray values above this level are redefined as objects (gray level reset to 255), creating a binary (black and white) image. Manual methods are relatively easy to use, routinely available, and allow segmentation of any image that the user can interpret correctly. Liu and associates (14) used interactive discrimination to establish the cell boundary in phase contrast images, and also used a manual pencil tool technique to eliminate pixels and separate touching cells. Detection and placement of the cell boundary may be done with reasonable accuracy using phase contrast or bright-field illumination; however, accurate boundary or object detection in fluorescence images is confounded by a number of factors. These include the length of exposure to light (long times result in bleaching and an apparent reduction in object size), the "halo" effect (which makes the fluorescent object seem larger), and user subjectivity. Some authors have concluded, for example, that it may be impossible to find the true edge of fluorescently stained bacteria. In this instance, there may be a need or advantage to the use of automated methods. Additional considerations in manual versus automated segmentation include the need to exclude bias, the need to manually edit the image to remove nonobject material, and the number of images to be handled (the tedium factor). When there are large image sets to handle, it may be worthwhile to spend time developing algorithims for semiautomated or fullyautomated analysis. Automated segmentation functions should not be universally applied to all image analysis situations, as automatic settings do not necessarily agree with each other or with the manual settings of an experienced operator.

There are a wide variety of automated, edge-seeking algorithms. Sieracki and associates (50) evaluated nine different automatic thresholding methods, using fluorescent microspheres with known diameters as controls, to position the boundary of fluorescent objects. They also found that user threshold selection usually resulted in an overestimation of the object size. They reported that the gray-level histogram analysis of individual cells, present within images containing a number of cells could be used to construct a circular cell profile. This profile was then analyzed to determine the maximum in the second derivative, and used to calculate the "best" thresholding level for the entire image. Viles and Sieracki (51) subsequently found this approach, although suitable for nanoplankton analyses, did not function well with smaller picoplankton and so used a combination of edge detection and adaptive edge strengthening. Wilkinson (43) provides an excellent overview of the various methods used for determination of object boundaries in fluorescent images including Marr-Hildreth (a combination of a Gaussian smoothing function and a Laplace filter for edge amplification) and edge strength methods.

Møller and associates (38) used isointensity-thresholded images of fluorescently stained cells with the cell boundary positioned at a point equivalent to 20% of the smoothed, cell intensity maximum gray-level value. Blackburn and associates (39) found that applying Marr-Hildreth filtration in conjunction with thresholding to a constant value provided acceptable edge-detection results. Adiga and Chaudhuri (52) also deal with segmentation and counting of CLSM images of fluorescence in situ hybridization.

It should be noted that the approaches mentioned earlier should only be required where accurate details on the area of the cell or average gray value are required, and would not be necessary for simple object enumeration. The user can consider two schools of thought: (*1*) attempting to accurately size objects for determination of, for example, biomass, versus (*2*) simple counting or obtaining reproducible comparable data to assess treatment effects, and so on. The former may represent the "holy grail" of image analysis of bacteria, whereas the other represents the practical efficient application of the available technology.

Attempts to count single bacterial cells illustrates several additional problems associated with object recognition. Problems include distinguishing between specifically stained microbial cells and other fluorescent objects (e.g., soil particles), and whether the cell number is determined accurately despite the presence of microcolonies, clumps, and different cell morphologies. Simple solutions have been applied, such as the exclusion of cell clumps from the analysis (38) or dividing the number of objects by two in the case of analyzing a diplococci monoculture (53). Exclusion of circular objects allowed determination of hyphal length and biomass of fungi (37). Pattern recognition systems have allowed the extraction of single cells from small clumps in a mixed culture of methanogenic *Archaea* based on cell shape (36). These also represent situations where user intervention or manual editing may be required to achieve realistic analysis as is illustrated by Liu and associates (14) or Manz and associates (54) (Fig. 2).

Double- or multiple-thresholding may be applied when difficult to threshold objects are of interest. In this case, the user initially segments an object but finds that the objects are poorly represented. A second segmentation operation is then performed where more pixels are recognized as objects, showing all the object boundaries but including more image background noise. A Boolean feature-AND (6) then combines the two binary images, and a skeletonization step erodes the boundaries to a defined width resulting in accurately placed object boundaries.

ENHANCEMENT OF BINARY IMAGES

Following segmentation and formation of a binary image, the user may then choose to interactively edit the image to remove minor imperfections, or measure the desired parameters directly.

Erosion and dilation are commonly applied in combination to remove nonobject debris not in the same size class as objects of interest. Essentially, objects are eroded by a set number of iterations at a user-defined intensity, eliminating pixels from a binary image that should not have been present (e.g., resulted from noise). This erodes the

outer layer of pixels for image features by a user-defined amount. The image is then dilated by the same user-defined amount, returning all remaining objects to their original size. In Figure 7, an example of postsegmentation processing shows the application of an erode function to remove noise and noncell debris, and a dilate function to restore the cells to their original size and fill in missing pixels in the objects.

Close and open functions involve erosion and dilation operations but are in general used to connect or disconnect closely positioned features in binary images. Note that the open function acts as a combined erosion and dilation, where an erosion step removes edge-touching pixels (disconnecting closely positioned objects), and a dilation step restores the size of the objects while not reconnecting the object boundaries. The steps are reversed in closing, in which a dilation step is performed, connecting boundaries or joining fractures in the binary image, followed by an erosion to bring the object boundaries to their original size.

Binary images may also be eroded into skeletons that represent connected lines and indicate boundaries between objects. During the process of skeletonization, essentially all connected pixels are retained during erosion steps. This procedure may result in improved feature recognition, extraction, and measurement. This type of operation has proven useful in analysis of fungal hyphae (55). Furthermore, Boolean operators (AND, OR, NOT) may be exploited to improve images where pixels have improperly been classified as an object or background, or where the user wishes to selectively combine binary information. Korber and associates (56) used the Boolean operator OR to logically sum eight images of motile diatoms, allowing the construction of a motility track. This data was subsequently used to determine the chemotactic responses of *Amphora coffeaeformis* in mannose gradients (56).

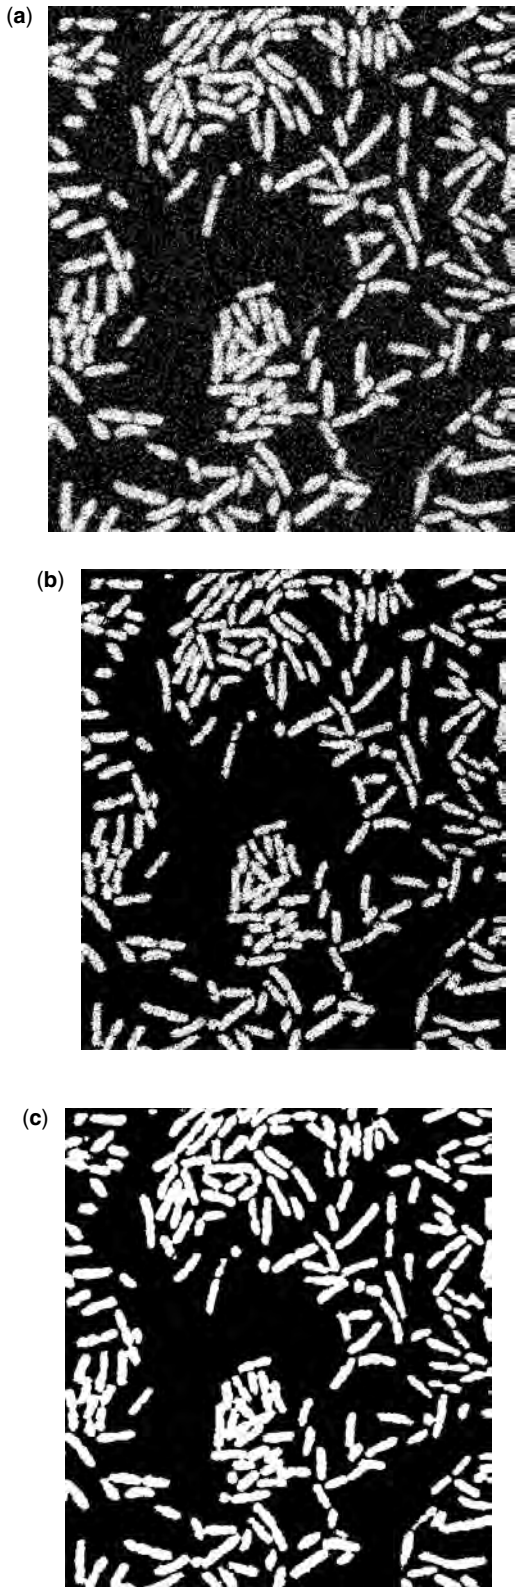

Figure 7. Postsegmentation processing showing the impact of erode and dilate operators on S/N in a binary image. The erode function was applied to eliminate the noise and small noncell objects, whereas dilate functions were applied to restore the bacterial cells to their original size, and connect pixels inside the objects.

DIFFERENCE IMAGERY

Difference imagery (the digitization of two sequential images and subtraction of their respective gray values) may be used to detect changes within the field of analysis over discrete time intervals, showing the difference between the two images as black objects on a gray background (44). During microbiological analyses, difference imagery may be used to detect the number of moving objects within the field of analysis, or may identify those cells or microcolonies that exhibit growth over a defined interval. Caldwell and Germida (57) used difference imagery to evaluate the growth kinetics of *Ensifer adherens* in agar slide culture, evaluating the potential for the separation of growth events from nonbiological debris. Difference imagery has also been used to enumerate the number of motile cells present within the hydrodynamic boundary layer of continuous-flow slide culture chambers during the recolonization phase of surface colonizing bacteria (42,58). Difference imagery may also be used to detect changes in images obtained from different focal planes within biological material. This may prove useful during the comparison of optical thin sections obtained from different regions of

biofilms using laser microscopy. An example of difference imagery showing change in location of cells with time is shown in Figure 8.

Alternately, image summation may also be performed. Lawrence and associates (59) used image summation and Helmert transformation (60) to digitally increase the depth of field. Phase micrographs were obtained from different focal planes, enhanced, aligned, and summed to create composite 2D images for discrimination and quantitative analysis of *Pedomicrobium* sp. growth and development. Using summed images, growth rates were determined for mother and daughter cells that were not developing within the same focal plane. Thus, this technique increased the effective resolution and operating depth of field of the light microscope.

FIELD AND OBJECT PARAMETERS

Parameters measured may be field-specific, meaning that all object pixels in the image are presented as a single value, or object-specific, meaning that each object in the image is identified and analyzed independently. Values obtained may be either direct (i.e., total number of objects in the field), or derived (calculated) (i.e., the percentage of the field occupied by objects).

Typical field and object-specific parameters include, field area, object area, or object number, whereas a derived parameter would be percentage field or object area. A program such as ImageTool can calculate 19 different object-specific attributes including object size, Feret diameter, major and minor axis, shape (roundness, elongation, compactness), orientation, gray scale density, integrated density, and so on and spatial position (x, y centriodes). Liu and associates (14) have developed plug-ins that expand these to include maximum curvature of the object, length, width, width/length, length/width, area bounding box area, eight Fourier descriptors, and aspect ratio. Addition of these features allows calculation of all the parameters required to use the CMEIAS Morphotype classifier facilitating identification and enumeration of 11 bacterial morphotypes. Other commercial systems may allow the user to derive as many as 250 parameters per object. Thus, the user must select the program and the parameters that are required to achieve quantitative image analysis and data required to test their hypotheses.

CALIBRATION

Image analysis is based on determination of the number of pixels that are associated with the defined objects, however, it is usually necessary to convert these to absolute values. This may be complex as in the case of fluorescence images or relatively straightforward as in phase contrast. Calibration may be achieved using a stage micrometer to check microscope objectives and magnification. Fluorescent or nonfluorescent beads (Molecular Probes Inc., Eugene, OR) are also useful, they may be purchased with specific sizes and volumes and applied to calibrate microscope images in terms of

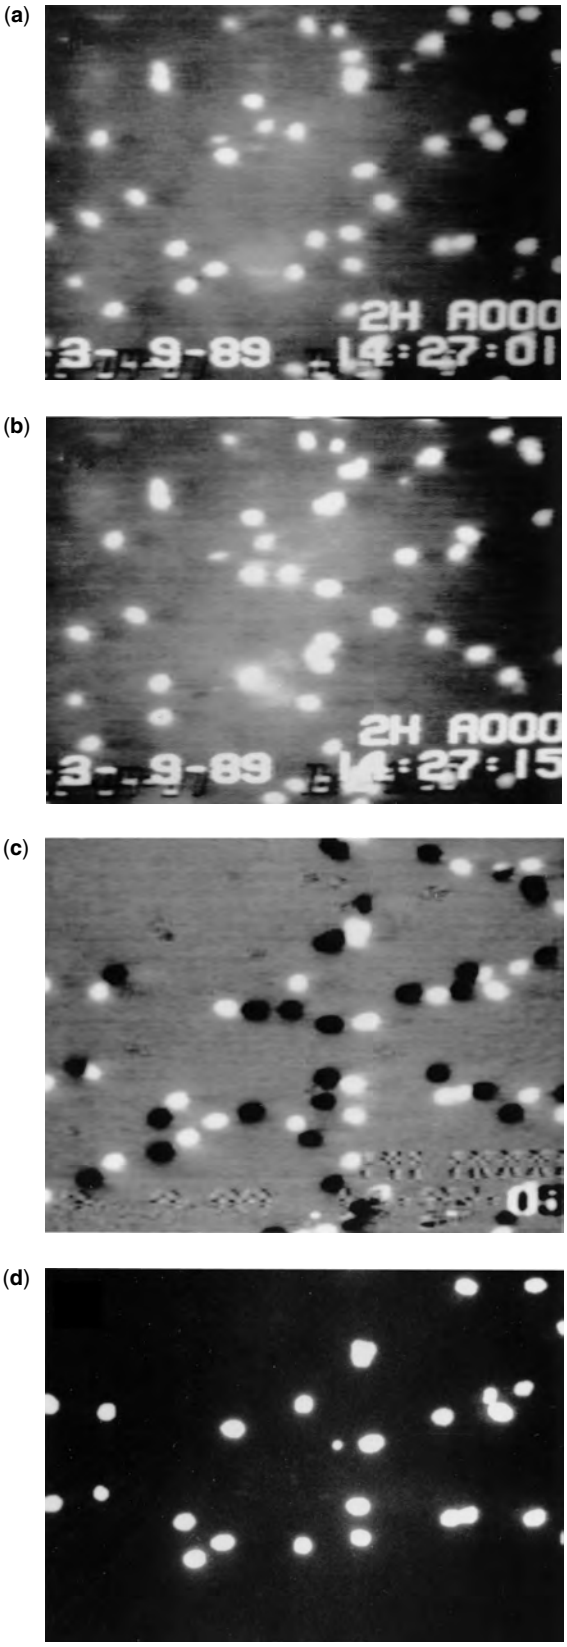

Figure 8. Images illustrating the result of application of difference imagery, (**a**) time 1, (**b**) time 2 (**c**) the resultant difference image showing movement of the diatoms, and (**d**) selection and segmentation of moving objects before enumeration.

magnification and point spread functions (3). Massana and associates (61) used Polysciences Fluoresbrite latex beads that were 0.51, 0.71 and 2.44 microns in diameter. They reported that they found 3–8% over estimation of bead area and under estimation of bead volumes by 4–13%. Similar values have been reported by other authors (35).

REPLICATION AND SAMPLING INTENSITY

The application of image analysis in microbiology is relatively new and efforts have focused on improved observation and analysis of the microbes growing in a variety of habitats. An aspect that has not received enough consideration in many studies is statistical representation. Similar to other areas of scientific research, image analysis of microbes requires representative and statistically reproducible sampling. Usually this can be achieved only if the sample size or number of replicates is large enough. Factors that may have an effect on the representative value of data were discussed by Kuehn and associates (62). These include the species under investigation, the absence or presence of growth inhibitors or stimulators, microbial behavioral factors, and experimental design. Furthermore, the distribution and type of extracellular polymeric substances, the presence of large cells such as algae and protozoa in the case of mixed species biofilms or debris may also have a significant effect.

Although image analysis offers the potential for analysis of extensive numbers of images with greater facility, the level of effort involved is still an important consideration. A number of studies have addressed the question of sample size and reproducibility. In general, the more cells, samples or area examined, the better the estimate. However, beyond a specific point, increasing effort results in only minimal improvement in the estimate. Massana and associates (61) considered the number of cells and images to be examined to obtain accurate estimates of bacterial volume. They concluded that 200 to 250 cells in 4 to 6 images resulted in a good estimate with minimal variation for the least effort. Korber and associates (63) used a computer-controlled microscope stage and CLSM to construct montages of contiguous biofilms and analyzed elements of these montages to define the area required for representative analysis. Using this approach, Korber and associates (63) demonstrated that biofilms formed by a nonmotile *Pseudomonas fluorescens* were more variable than the motile variant of this species and therefore required a larger area of analysis for statistically valid comparisons. Moller and associates (64) used CLSM and examined contiguous biofilm areas in the same size order ($>2.8 \times 10^5 \mu m^2$) during a study of the architecture of biofilms formed by a degradative microbial community. Dandurand and associates (65) also applied geostatistical analysis using covariance to compare colonization patterns of the rhizoplane, whereas Gibbs and Bishop (66) applied these approaches to the analysis of microbial biofilm surface roughness. Fractal analysis has also proven useful for the analysis of biofilm structures (67).

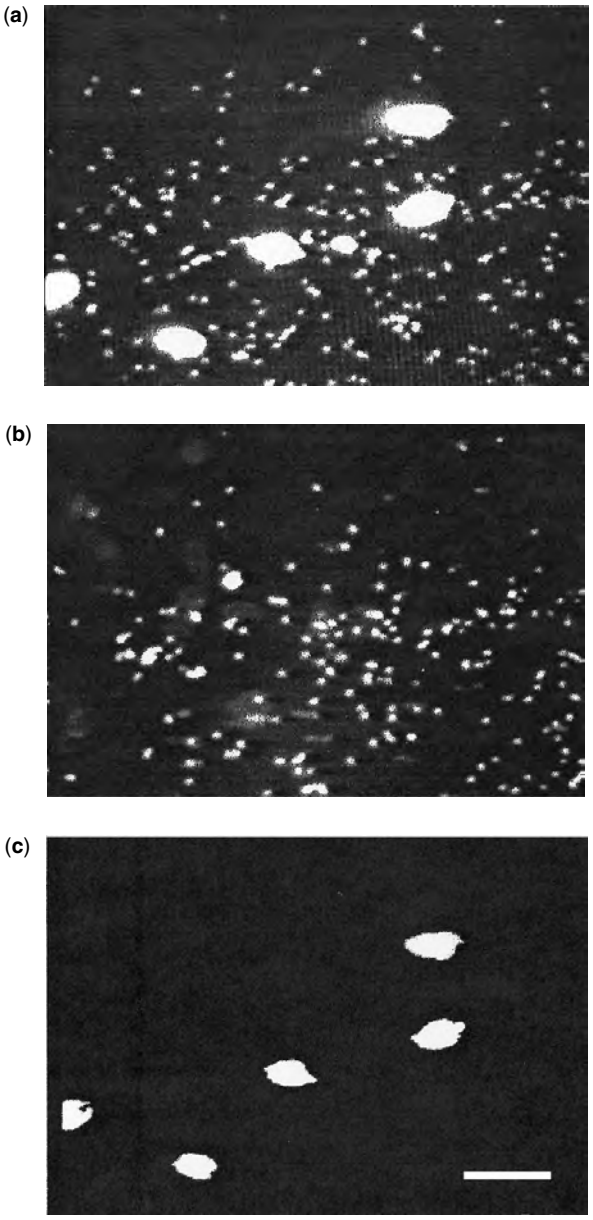

Figure 9. Digitized images showing the presence of both ciliates (*Euplotes* sp.) and bacteria (**a**), an averaged image showing the ghosting of the moving ciliates and their elimination from the image (**b**), and application of size-selection based on maximum dimension to a segmented image to eliminate the bacteria and enumerate the ciliates (**c**) (the reverse procedure allows enumeration of the bacteria). From Lawrence and Snyder (1998).

APPLICATIONS OF IMAGE PROCESSING AND ANALYSES

The use of digital image analysis is becoming increasingly widespread in environmental microbiology. The number of published studies and range of applications is extensive. The following publications all show good examples of multiple step image analysis applied to studies in environmental microbiology (3,8,24–27,35,38,39,42,50,56,59,63,68,69).

Image analyses have been used for quantification of microbial cell numbers and/or biovolume, in aquatic samples (51,61) on surfaces (38,53) or in soil samples (35). Manz and associates (54) used rRNA probes and image analyses to determine population dynamics of bacterial groups in river biofilms. Species specific counts of *Methanosaeta* and *Methanosarcina* in anaerobic granules have been made using fluor conjugated rRNA probes and digital image analysis (70). An example of determining the change in bacterial cell area with time and as impacted by protozoan grazing is shown in Figure 9. In this case, attached cells were imaged using phase contrast microscopy, images digitized, individual cells segmented, binarized, and cell area measured. Combining various input modes with size selective cutoffs and segmentation can be used to determine the rate of change in the number of bacteria and ciliates within an observation area (17,42). Figure 10 shows typical results of applying this type of processing and analysis scheme.

Increasingly, more sophisticated use of object-derived parameters to determine shape of objects are being applied to differentiate and enumerate morphological types (14) and to study filamentous organisms such as fungi (55,71).

In addition to the analysis of binary images, gray scale images may be used to determine dynamic processes associated with bacterial metabolism and activity. A number of papers describe the quantification of signal intensity after hybridization of bacteria with rRNA-targeted probes to determine the ribosome content and thus estimate the actual metabolic activity or growth rate in pure cultures or biofilms (38,72–75). Laser microscopy and digital image analysis were used to follow the influx of

ethidium bromide into individual Bacillus spores during germination (76).

Lawrence and associates (77) used analysis of the rate of change in gray level to determine the rate of diffusion of various fluorescent size fractionated probes and subsequently calculate diffusion coefficients for mixed species biofilms. De Beer and associates (78) used a similar approach to determine diffusion rates of molecules in biofilm matrices. Figure 11 shows a time series of CLSM images showing the diffusion of size-fractionated fluor labeled dextrans in a microbial biofilm. The results of image analysis of a number of these time series following the diffusion of a range of fluorescent probes are shown in Figure 12. A more extensive discussion and presentation of this approach is presented in Lawrence and associates (77).

CONCLUSION

Digital image processing and analysis are powerful tools that can be and are being applied in environmental microbiology. This combined with the evolution of fluorescent probe technologies, for example, those specific for phylogeny, gene expression, activity, and environmental chemistry, permits truly comprehensive ecological studies of events occurring at the microscale. For example, using phylogenetic probes one can enumerate specific groups while autofluorescence may be used to detect phototrophs, general nucleic acid stains to enumerate bacteria, and lectins to detect and quantify exopolymers. Furthermore, the existence of relatively inexpensive and user friendly hardware and software opens the application of these approaches to any researcher.

INFECTIOUS AIRBORNE BACTERIA

Jon Rosenberg
Janet M. Macher
California Department of Health Services
Berkeley, California

Infectious airborne environmental bacteria consist of those bacteria naturally present in the environment that cause human disease as a result of transmission through the air. Airborne transmission occurs by dissemination of either dust particles containing the infectious agent or airborne droplet nuclei from evaporated droplets of water containing microorganisms. Infectious bacteria are those that cause disease through the multiplication of organisms within the body, thus excluding those diseases caused by hypersensitivity or the direct inhalation of toxins. Despite their abundance in soil and water, few environmental bacteria are responsible for airborne diseases. Bacteria that thrive in soil are generally saprophytes (ones that live and feed on dead organic matter) of low pathogenicity to humans. Although outdoor and indoor air contains many bacteria and particles containing bacteria for people to inhale, few of these bacteria ever colonize or infect the respiratory tract, the principal effects of airborne exposure. Fewer bacterial species multiply in water rather than soil, and aerosolization of water is usually associated with artificial sources that use water treated to eliminate most pathogens, which reduces the risk of disease transmission. The principal pathogen in water aerosols, *Legionella* species (spp.), is reviewed in Legionellae, this Encyclopedia.

For many of the agents discussed here, the role of the bacteria that are airborne relative to other routes of exposure is uncertain, even for pulmonary infections. Ingestion and inoculation followed by hematogenous spread to the lungs or ingestion followed by aspiration are considered alternative, if not more important, routes of exposure for *Mycobacterium avium* complex (MAC) and *Burkholderia pseudomallei*. Cystic fibrosis patients colonized with *B. cepacia* can transmit the agent to noncolonized fellow patients in health care and social settings (person-to-person airborne transmission), but infection also may be acquired by inhalation of dust from soil that contains the organism. The relative importance of these two exposure routes for these patients is uncertain. Some organisms that are present in outdoor air, originating from soil and water, (e.g., species of the aerobic gram-negative bacilli *Pseudomonas, Klebsiella*, and *Enterobacter*) also are found in hospital environments in discharges from colonized patients. These bacteria are primarily nosocomial pathogens (ones that affect persons in hospitals and other health care settings), but an agent may have been acquired from the environment and have colonized the respiratory and gastrointestinal tracts of a patient before the manifestation of the disease in that person while hospitalized. Characteristics that favor survival and growth in the external environment would confer these same advantages to bacteria in hospitals and other health care settings.

Airborne bacterial pathogens for which the principal reservoir is humans, [e.g., *Mycobacterium tuberculosis* (tuberculosis)] and those for which the principal reservoir is animals [including *Bacillus anthracis* (anthrax), *Brucella* spp. (brucellosis), *Coxiella burnetii* (Q fever), and *Chlamydia psittaci* (psittacosis)] exist in the environment to little or no extent or have limited impact on human health as a result of their environmental presence. Although *B. anthracis* spores are commonly found in the soil where infected animals died, few if any cases of human illness have been reported as a result. Bacterial pathogens that affect humans in agricultural and outdoor settings are

discussed in Bioaerosols in Agricultural/Outdoor Settings, this Encyclopedia. Airborne endotoxin is an important cause of human disease in occupational settings, but this cell wall component of gram-negative bacteria does not cause infection and is covered separately in Endotoxins, this Encyclopedia. The environmental bacteria that do infect humans as a result of airborne transmission, although few in number and of low pathogenicity, are of increasing importance because of the rising population of immunosuppressed and otherwise compromised people. The human immunodeficiency virus (HIV) epidemic, in particular, has transformed previously obscure pathogens such as MAC into major worldwide causes of morbidity and mortality. The global movements of humans, animals, soil, and water can increase the geographic distribution of these agents. The widespread distribution of bacteria in soil and water makes control of environmental exposure extremely difficult, if not infeasible. Thus, the impact of environmental airborne bacteria on human health and our appreciation and understanding of resulting infectious diseases will continue to increase for the foreseeable future.

ENVIRONMENTAL RESERVOIRS AND SOURCES

Bacteria are found in a wide range of ecological sites in the environment, primarily natural water, groundwater, wastewater, soils, and in association with plants. However, bacteria often go unrecognized because of their small size and frequent absence of warning properties (such as odor or taste) to alert people of their presence. The bacterial agents discussed in this article are saprobes (saprophytes) because they use nonliving organic material (e.g., dead or decaying plant or animal debris) as nutrient sources. Along with fungi and protozoa, saprobic bacteria are responsible for the decay of organic materials and the recycling of nutrients.

A reservoir of a bacterial agent is any person, animal, arthropod, plant, soil, substance, or combination of these in which the bacterium normally lives and multiplies, on which it depends for survival, and where it reproduces and from where it can be transmitted to a susceptible host. A person or other living animal is a host to a bacterial agent if the human or animal provides subsistence to the bacterium under natural conditions. A person, animal, object, or substance becomes a source of a bacterial agent when it is the immediate location from where the bacterium passes to a host. For instance, an outbreak of melioidosis occurred when the source, a potable water supply, became contaminated and people drank, bathed in, and inhaled aerosols of the water. However, the reservoir for the etiologic agent, *B. pseudomallei*, was the soil surrounding the water-treatment facility where the contamination occurred. Identifying the reservoirs of infectious agents (not just their immediate sources) often is important for understanding their transmission and achieving long-term prevention (1).

AIRBORNE TRANSMISSION

Transmission describes the physical means by which an agent spreads from a source or reservoir to a susceptible host. Infectious agents are transmitted by five routes, namely, contact, droplets, air (droplet nuclei, dust, and spores), common vehicles, and vectors (invertebrate animals such as ticks and mosquitoes). Before people understood the causes of infectious diseases, diseases were called *contagious* if they were known to be transmitted through contact. However, this term has lost much of its significance and these diseases now are considered *communicable* diseases. Diseases referred to as communicable are transmitted from an infected person, animal, or inanimate reservoir to a susceptible host. This transmission may be direct or indirect, the latter involving an intermediate plant or animal host, a vector, or the inanimate environment. Airborne transmission is generally thought to be directly from a source to a host, although infectious material may be resuspended from surfaces.

Some of the bacteria in this article have multiple transmission routes, which may result in the same or distinct diseases. For example, pathogenic actinomycetes such as *Nocardia* spp. cause pulmonary disease when inhaled and cutaneous or ocular infections when directly inoculated. Some of the nontuberculous mycobacteria (NTM), notably MAC, and *B. pseudomallei* may cause pulmonary disease when inhaled but are believed to do so primarily as the result of septicemia following ingestion or direct contact.

True airborne transmission results from the inhalation of bacterial spores, dust particles carrying bacteria, or droplet nuclei containing bacterial cells. Droplet nuclei are the solid residues of dried droplets, usually less than or equal to 5 μm. The diameter of infectious particles containing vegetative bacterial cells or spores is determined not only by the physical size of a single organism or cluster of cells, but also by the presence of salts, proteins, and debris in varying states of hydration that accompany airborne bacteria (2).

Small particles can remain suspended in air for minutes to hours. Thus, people very close to a source of a bacterial aerosol readily are exposed, but people at some distance also may become infected if sufficient numbers of bacteria were generated and enough survived until they reached a susceptible host. Inhaled particles with diameters larger than 3 μm most often deposit in the upper respiratory tract (the nose, pharynx, and larynx). Deposition in the lower respiratory tract (the trachea, bronchi, and pulmonary or alveolar regions of the lungs) is greatest for particles with diameters in the 2 to 5 μm-range. Only infectious agents to which the upper respiratory tract is relatively resistant but the alveoli are vulnerable are considered truly airborne because few particles greater than 5-μm reach the alveolar region in appreciable numbers.

INFECTIOUS DOSE

Successful transmission of a bacterial disease requires not only that the agent reach a host but also that the bacterium arrives in sufficient numbers to resist defense mechanisms and multiply. Outdoor air typically contains 10 to 10,000 live bacteria per cubic meter of air and activities such as turning dry compost or

working with soil can expose people to even higher concentrations. Indoor air may be cleaner or contain more bacteria depending on the location. Efforts are made to keep the number of airborne microorganisms very low in hospitals and microbiology laboratories, but the air in animal confinement buildings and indoor waste-processing facilities may have several million airborne microorganisms per cubic meter. Thus, at a typical breathing rate of 1 cubic meter per hour, an adult inhales 24 cubic meters of air per day. Along with this air, we inhale hundreds to billions of living microorganisms, of which we capture a variable percentage somewhere in our respiratory tracts.

The infectious dose of a pathogen is the number of cells or amount of toxin required to produce infection or disease. Epidemiologists and researchers often express infectious dose as ID_{50} (the dose that produces infection in half of exposed hosts). The infectious dose is not known for most human infections and probably varies greatly depending on agent virulence, host resistance, and other factors. The ID_{50} has been determined for few airborne bacterial infections. While animal experiments suggest that deposition of a single cell of *M. tuberculosis* in a susceptible lung may lead to tuberculosis (3), the relevance of this information for human risk is uncertain.

AIRBORNE BACTERIAL PATHOGENS

Nontuberculous Mycobacteria

Introduction. The NTM are the *Mycobacterium* spp. other than the *M. tuberculosis* complex (which includes *M. tuberculosis*, *Mycobacterium bovis*, *Mycobacterium microti*, and *Mycobacterium africanum*). They are bacilli that are considered gram-positive and are acid-fast. First isolated in 1885, three years after Koch's discovery of *M. tuberculosis*, they were not recognized as important human pathogens until the discovery of *Mycobacterium ulcerans* in 1948. Between 1949 and 1954, cases of infection were reported caused by *Mycobacterium kansasii*, *M. avium*, *Mycobacterium marinum*, *Mycobacterium chelonae*, and *Mycobacterium intracellulare* (4). Before 1979, these organisms were referred to as *atypical mycobacteria*, but since then they have been treated as separate disease entities (5). The acquired immunodeficiency syndrome (AIDS) epidemic dramatically changed the epidemiology of nontuberculous mycobacterial disease. Before the epidemic, nontuberculous mycobacterial disease was predominately pulmonary (caused throughout the world by *M. kansasii*, *M. avium*, and *M. intracellulare*) in elderly males with underlying lung disease or heavy occupational exposure to dust, such as in farming (5). Exposure to NTM was presumed to be from environmental aerosols. *Mycobacterium malmoense*, identified in 1977, presented a similar picture but was confined primarily to northern Europe and Great Britain. Additionally, *M. marinum* caused skin infections following cuts and abrasions and exposure to water. The epidemiology of *M. ulcerans* infection, which results in skin ulcers, has remained unchanged since its first description in 1948. Today, as a consequence of AIDS, nontuberculous mycobacterial disease is most commonly caused by MAC; 20 to 40% of AIDS patients (depending on the stage of disease) in the United States and Europe have disseminated infections of MAC. There has been a concomitant increase in both pulmonary and disseminated infections caused by the other NTM that cause pulmonary disease in immunocompetent patients, that is, *M. kansasii*, *Mycobacterium xenopi*, and *Mycobacterium simiae*. While isolation of *M. malmoense* has been increasing, in contrast to the preceding NTM, it is only occasionally isolated from AIDS patients (6).

The NTM are generally considered opportunistic pathogens, primarily causing disease in individuals with immunodeficiency, underlying disease, or following trauma or surgery. However, their presence in the environment provides them an opportunity to enter and colonize the human respiratory tract and also to contaminate clinical specimens. It is often difficult, particularly in immunodeficient patients, to distinguish among infection, colonization, and specimen-contamination. Recently discovered NTM that occasionally cause pulmonary disease in immunocompetent individuals with underlying pulmonary disease or disseminated disease in immunosuppressed patients include *Mycobacterium celatum*, *Mycobacterium genevense, Mycobacterium conspicuum*, *Mycobacterium lentiflavum*, *Mycobacterium haemophilum*, *Mycobacterium heidelbergense*, and *Mycobacterium szulgai* (4). *Mycobacterium gordonae* is ubiquitous in the environment and is commonly isolated from water and soil (4). Because it is found in hospital water, it can contaminate clinical and bronchoscopy specimens during collection and processing, often resulting in pseudooutbreaks. *Mycobacterium gordonae* occasionally causes pulmonary and disseminated infections similar to those caused by the other pathogenic NTM (4). The following NTM species have been isolated from human or environmental sources but have not yet been associated with any disease: *Mycobacterium alvei*, *Mycobacterium bohemicum*, *Mycobacterium brumae*, *Mycobacterium cookii*, *Mycobacterium gadium*, *Mycobacterium gastri*, *Mycobacterium hibernae*, *Mycobacterium confluentis*, *Mycobacterium hasiacum*, *Mycobacterium valientiale*, *Mycobacterium madagascarence*, *Mycobacterium mageritense*, *Mycobacterium murale*, *Mycobacterium novastrense*, and *Mycobacterium triplex* (4).

All of the aforementioned organisms grow slowly on standard mycobacterial media. The rapidly growing mycobacteria, *Mycobacterium fortuitum*, *M. chelonae*, and *Mycobacterium abscessus*, most often cause skin and soft tissue (including wound) infections and disseminated disease, associated with direct contact with contaminated potable water. They also have been reported to cause pulmonary tract colonization and occasionally pulmonary disease, presumably as a result of inhalation of water aerosols.

Mycobacterium spp. in water-based metalworking fluids also may cause hypersensitivity pneumonitis in machine workers. Outbreaks of hypersensitivity pneumonitis in association with NTM in metalworking fluids have been reported in which the NTM identified

in one case was *M. chelonae* (7) and in another was a newly described *Mycobacterium* sp. (proposed name being *Mycobacterium immunogen*) (8).

Natural Occurrence. Mycobacteria may be obligate parasites, saprophytes, or opportunistic pathogens. Most of the latter two groups are free-living and are isolated readily from water, soil, plants, house dust, and other environmental sources (9). Clinically important NTM have been linked with potable water systems as sources. A number of species (*M. kansasii*, *M. xenopi*, and *M. simiae*) that are isolated only rarely from natural waters or soils have been isolated from tap water near people with clinical disease or frequently positive specimens (9). *Mycobacterium malmoense* has been isolated from water and soil mainly in northern Europe and Great Britain, the same regions where infections have been identified. The MAC consists of serovars of two distinct species, *M. avium* and *M. intracellulare*. Isolates have been cultured from natural water (fresh, brackish, and ocean), public drinking water systems, soil, and food. The physiologic characteristics of MAC organisms together with their relative chlorine resistance favor their presence in municipal drinking-water systems and their concentration in hot water distribution systems in hospitals (5). In San Francisco, sampling of the home environment of 290 HIV-infected people revealed that MAC was isolated more often from potted plant soil (55%) than from water (0.76%) (10). Although MAC can be found in water in diverse areas of the world, culture of 91 water samples found higher isolation rates in the United States and Finland (18 of 52, 35%) than in Zaire and Kenya (4 of 39, 10%) (11). MAC was isolated from hospital water in the United States and Finland, but not in Zaire or Kenya. The rapidly growing mycobacteria have been found in numerous natural water sources, potable water systems, and hospital water sources, and soil.

Routes of Exposure. There is no evidence of person-to-person transmission for any of the NTM, although *M. simiae* can be transmitted among monkeys (5). For those organisms causing primarily pulmonary disease in immunocompetent individuals (*M. kansasii*, MAC, *M. xenopi*, *M. simiae*, and *M. malmoense*), exposure is thought to be by inhalation of soil dust or water aerosols. Exposure to MAC is presumed to be from the lungs by inhalation of water aerosols, from the gastrointestinal tract by ingestion, or by ingestion and aspiration; whether one or more of these exposure routes are predominant is uncertain (12). One study was able to specifically link MAC isolates in potable water in hospitals to those in patients, but exposure could have been by inhalation or ingestion (13).

Incidence. Approximately 25 to 50% of patients with AIDS in the United States and Europe are infected with NTM, mostly MAC. Disseminated MAC infection has an annual incidence of 20 to 35% after the occurrence of a first event defining the presence of AIDS, reaching 40% of patients with advanced AIDS (CD4 counts <10 cells per cubic millimeter) in the United States (14). The population incidence in the United States is unknown because MAC infection (along with other nontuberculous mycobacterial diseases) is not a reportable condition. In the Houston and Atlanta metropolitan areas, where CDC conducts active surveillance, the incidence is approximately 1 per 100,000 per year (15). This is consistent with studies in the United States, Japan, and Switzerland, showing incidences of 1.3, 1.3, and 0.9 cases per 100,000 per year, respectively (7). Incidence is decreasing among HIV-infected patients as a result of new treatment modalities, for example, combination therapy with nucleoside reverse transcriptase inhibitors and protease inhibitors, and antimycobacterial prophylaxis. However, antimicrobial resistance may be increasing.

Nontuberculous mycobacterial disease is much more common in the developed rather than the developing world, despite the high incidence of AIDS in the latter. The reason for the low incidence of disseminated MAC in AIDS patients in Africa ($<1\%$) is unclear. Decreased exposure (e.g., lower likelihood of MAC in water), disease-related factors (such as death of AIDS patients from other causes before CD4 cell counts become extremely low), and protection by prior exposure to *M. tuberculosis* have been suggested as possible explanations (14).

The most common nontuberculous mycobacterial disease in immunocompetent individuals is either *M. kansasii* or MAC, depending on geographic location (5). Surveillance for NTM is not conducted by any country, and so incidence data are unavailable. The rate of isolation of *M. malmoense* has been increasing in the United Kingdom, Scotland, and Scandinavia (5), but this may be due in part to improved laboratory methods and increased awareness of mycobacteria as potential pathogens (6).

Disease in Humans. Pulmonary disease caused by the NTM is similar to tuberculosis. Patients may have localized infiltrates, cavitation, or solitary or multiple pulmonary nodules (14). Fever is usually present, whereas weight loss depends on the duration of the untreated disease. The causative agent usually can be found in sputum by culture if not by smear. Among people with MAC pulmonary disease, isolates of the *M. avium* group are similar in number to those of the *M. intracellulare* group (14). MAC have been identified in the sputum of up to 14% of the patients with cystic fibrosis, a high percentage of whom have skin tests that are positive to *M. avium* sensitin, indicating infection and a possible role of MAC in the pathogenesis of this disease (16).

MAC, *M. kansasii*, and *M. malmoense* are known to cause lymphadenitis, primarily in the cervical lymph nodes in children less than five years of age. Infected children are immunocompetent and have no identifiable risk factors. Ingestion of milk may be the route of transmission for these infections, at least for MAC, which frequently is cultured from milk (14).

MAC is by far the most common cause of disseminated disease, almost entirely in AIDS patients. Infection usually begins in either the respiratory or gastrointestinal tract, suggesting acquisition through either route (14). Disease rapidly becomes systemic, involving fever, night sweats, anemia, weight loss, and hepatosplenomegaly.

Diagnosis is made by blood culture. *Mycobacterium kansasii* is the second most common NTM causing disseminated disease in HIV-infected patients (17). However, disease in these patients often resembles that from *M. tuberculosis*, more often causing pulmonary rather than disseminated disease. In one series of 49 HIV-infected patients with *M. kansasii* infections, 32 (65%) had pulmonary isolates only, whereas 17 (35%) had disseminated disease documented (17). Coinfection with another NTM, usually MAC, was present in about one-third of the patients. This behavior of *M. kansasii* may be the result of it being antigenically the NTM most closely related to *M. tuberculosis* (17). Disseminated disease in AIDS patients occurs less frequently from *M. xenopi*, *M. simiae*, *M. malmoense*, and *M. haemophilum* (5).

Actinomycetes

The term *aerobic actinomycetes* is an informal designation for bacteria belonging to the order *Actinomycetales* (18). Most stain as gram-positive, branched, filamentous rods with various degrees of acid-fastness. Their branched filaments often are incorrectly referred to as *hyphae*. Actinomycetes have many microbiological characteristics in common with the genera *Corynebacterium* and *Mycobacterium*. *Mycobacterium* spp. are considered to belong to the order *Actinomycetales* but, because of their clinical significance and inclusion of *M. tuberculosis* (whose principal reservoir is humans and not the environment), the mycobacteria usually are discussed separately, as they are here. The remainder of the order has been adopted into descriptive groups rather than formal taxonomic families (18).

Aerobic actinomycetes are ubiquitous in the environment, found worldwide in soil and organic matter. *Nocardia* spp. and related bacteria are considered saprophytic soil organisms, primarily responsible for the decomposition of organic plant material (18). They also have been found in fresh and marine water and in wastewater. Although nocardia are encountered in clinical practice infrequently, they can be important causes of human infections. The clinical manifestations, severity of disease, and prognosis vary with the route of infection and state of the host's immune function. Species from two genera, *Nocardia* and *Rhodococcus*, cause pulmonary disease in humans, primarily immunocompromised individuals, as a result of airborne exposure. Species from the genus *Gordona* (removed from *Rhodococcus* in 1988) occasionally are recognized as causing pulmonary infection, catheter-associated sepsis, or nosocomial wound infections (18). The pathogenic actinomycetes, most notably *Nocardia* spp., also cause cutaneous and ocular infections as a result of local, usually traumatic, inoculation. Members of the genus *Actinomadura*, notably *Actinomadura madurae*, cause infections of the skin, usually of the lower extremity ("madura foot"), as a result of soil contamination of a penetrating wound. *Dermatophilus congolensis* causes dermatitis in animals and humans, usually as a result of contact with infected animals or contaminated animal products (18). Thermophilic actinomycetes cause pulmonary disease that is immunologically mediated, and not infectious.

Nocardia

Introduction. *Nocardia* is a genus of the family Nocardiaceae. The misperception of their filaments as hyphae led to their being misclassified as fungi for many years. Nocardia can cause pulmonary disease as a result of airborne exposure, cutaneous, subcutaneous, and lymphocutaneous disease as a result of percutaneous introduction, and systemic and extrapulmonary disease either from the pulmonary or percutaneous exposure. Infections most often are caused by *Nocardia asteroides* and less frequently by *Nocardia brasiliensis*, *Nocardia farcina*, *Nocardia nova*, *Nocardia otitidiscaviarum*, and *Nocardia transvalensis*. *Nocardia asteroides* is a heterogeneous taxon from which *N. farcina* and *N. nova* now have been separated (18).

Natural Occurrence. Pathogenic species of *Nocardia* have been found in soil, house dust, beach sand, tap water, and swimming pools (18). In an outbreak in a renal transplant unit, the same strain isolated from patients was cultured from dust and air in the unit (19). There is limited information available on the geographic distribution of *Nocardia* spp. *Nocardia asteroides* appears to be widespread. *Nocardia brasiliensis* (the second most frequently isolated aerobic actinomycete in the clinical laboratory) is responsible for mycetoma in Mexico and South America and is most often identified in the United States in the southeast and southwest (especially Texas, North Carolina, California, Oklahoma, and Florida) (18). *Nocardia farcina* infections have been reported from Asia, Europe, and North America, emerging as the predominant nocardial pathogen in Germany (19).

Routes of Exposure. Pulmonary infection occurs as the result of inhalation of bacteria or bacteria-containing dust, which becomes airborne from soil, water, or vegetable matter. Rarely, pulmonary infection occurs from other nonairborne routes such as ingestion of contaminated food or following dental procedures (19).

Incidence. Nocardiosis is not a reportable condition, and so population estimates are unavailable. Infection occurs in people of all ages and in men three times more than in women. It is chiefly an opportunistic disease, with estimates of the percentage of cases in otherwise healthy individuals ranging from 10 to 40% (19). There are many conditions that increase the risk of infection. Among these are lymphoreticular and other neoplasms, systemic immunosuppression [particularly transplantation (accounting for approximately 4% of infections in renal transplant patients) and also steroid therapy, HIV infection, alcoholism, diabetes, intravenous drug use, and collagen, vascular, and immune dysfunction diseases], and preexisting pulmonary disease (19).

Disease in Humans. Pulmonary nocardiosis can be an acute, subacute, or chronic infection (19). Immunocompromised patients often suffer from a brief acute pneumonia. Cavitation may be present, with or without pneumonia. Remissions and exacerbations often occur. Anorexia and weight loss commonly are present along with pulmonary symptoms. In immunocompromised patients, soft tissue

swellings, abscesses, or central nervous system manifestations may occur in conjunction with evidence of pulmonary involvement. The presence of lesions in two or more organs indicates dissemination. Common sites include the brain, skin, subcutaneous tissue, eyes, kidneys, joints, bones, and heart. The initial pulmonary infection may have cleared spontaneously before the diagnosis is established. *Nocardia farcina* may be more pathogenic than other species, with more than 50% of patients having disseminated disease (19). Treatment of pulmonary infections caused by strains susceptible to first-line antibiotics is usually successful, particularly if therapy is prolonged.

Rhodococcus

Introduction. The genus *Rhodococcus* is part of the phylogenetic group nocardioform actinomycetes, which includes the genera *Mycobacterium* and *Nocardia*. *Rhodococcus* spp. are aerobic, gram-positive, and partially acid-fast. The principal human pathogen, *R. equi*, previously was assigned to the *Corynebacterium* and *Mycobacterium* genera. *Rhodococcus equi* originally was isolated from pulmonary lesions of foals in 1923 and has since become a well-recognized veterinary pathogen, particularly in foals (18,20). Since the first reports of disease from *R. equi* in a patient receiving corticosteroid therapy in 1967 and in an HIV-infected patient in 1986, it has been identified with increasing frequency as a cause of pneumonia in immunocompromised patients (18,20).

Natural Occurrence. *Rhodococcus* spp. are widely distributed in the environment, particularly in soil. *Rhodococcus equi* is found in soil and herbivorous dung and multiplies in greatest numbers in the presence of herbivorous manure (18).

Routes of Exposure. Exposure is assumed to occur as a result of inhalation of contaminated dust. Although *R. equi*–infected patients often are reported to have a history of contact with farm animals, soil, or both (18), in HIV-infected patients, such exposure history frequently is lacking (21).

Incidence. Population estimates are unavailable, but infection with rhodococci is uncommon and primarily occurs in HIV-infected patients; it also is often misdiagnosed or undiagnosed. In addition to HIV-infected people, pulmonary and disseminated disease have been reported in patients receiving chemotherapy for hematologic and other malignancies, renal transplant recipients, patients receiving corticosteroids, and chronic alcoholics (18).

Disease in Humans. Infection with *R. equi* in HIV-infected patients usually is manifest as pneumonia, with fever, cough, dyspnea, and chest pain (20). Pulmonary abscess formation and cavitation frequently occur. The case mortality rate is 25 to 50% despite administration of antibiotics and surgical intervention (21). Delay in diagnosis, which often requires biopsy, contributes to the severity of the illness. *Rhodococcus equi* may be misidentified or undetected because the organisms often appear as nonspecific coccoid forms in macrophages. Cavitary lesions, detection of acid-fast bacilli in sputum, and an interim response to antituberculous drugs may result in a misdiagnosis of mycobacterial infection (18). Infection in immunocompetent patients has been reported in only 19 cases (22). In contrast to HIV-infected patients, in immunocompetent patients, localized infections are more common than pulmonary and the mortality rate is 11% (22).

Aerobic Gram-Negative Bacteria

Aerobic gram-negative bacteria include numerous pathogenic species that are widely distributed in soil and water and on plants. Many of these same species (but not necessarily the same strains) also can colonize human and animal intestinal, respiratory, and urinary tracts and can cause infections in those sites, including pneumonia. However, even if the strains that cause human disease were to occur in the environment, there is little evidence linking airborne or any other environmental exposure to human disease. The major exception is *B. pseudomallei*, the etiologic agent of melioidosis, which is discussed separately later. There also is evidence that airborne transmission of *Acinetobacter* spp. has a role in nosocomial transmission, as discussed later. However, it is possible that sporadic cases of pneumonia are caused by airborne aerobic gram-negative bacteria but, because of their sporadic nature, cannot be linked to an exposure. It is only in the context of outbreaks or endemic nosocomial occurrence that environmental exposures are likely to be suspected or sought.

Some pathogenic aerobic gram-negative bacilli (including *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *S. marcescens*, and *Enterobacter* and *Citrobacter* spp.) are common causes of nosocomial infections. In the hospital setting, the pathogenic reservoirs are the gastrointestinal tract and hands of health care personnel. Aqueous reservoirs (including medications, irrigation fluids, disinfectants, soaps, and dialysis fluids) have been responsible for point-source outbreaks, presumably as the result of contamination by human, not environmental, sources, and through direct inoculation, rather than airborne transmission. Contamination of nebulizers and other respiratory therapy equipment is a mechanism for entry of bacteria into the respiratory tract. These organisms may be found in any equipment using water (including sinks, aerators, shower heads, and whirlpool and hydrotherapy baths) but may have been deposited by patients or health care workers rather than an environmental source of exposure.

Burkholderia cepacia, *S. maltophila*, *Ralstonia pickettii*, and *Acinetobacter* spp. also may be present in the environment and increasingly are recognized as opportunistic nosocomial pathogens. *Burkholderia cepacia* is an important cause of respiratory tract colonization and disease in patients with cystic fibrosis and chronic granulomatous disease; the manner in which it is acquired, possibly from environmental sources, is uncertain. Evidence of person-to-person transmission of *B. cepacia* has led to the institution of surveillance programs and separation of colonized from noncolonized patients. Continued acquisition of the organism despite these precautions has

led to the speculation that the environment may be an important source. An environmental survey of 55 sites in a botanical complex yielded only 12 *B. cepacia* isolates, none of which displayed the phenotypic properties of a multiresistant epidemic strain associated with pulmonary colonization in patients with cystic fibrosis (23). In another study, 916 samples from homes of patients with cystic fibrosis, control homes, salad bars, and food markets were analyzed for *B. cepacia* (24). The agent was isolated from 5 (18%) out of 27 homes, and from 20 (4%) out of 509 cultures collected outside homes. These studies suggest that the environment is a relatively low-risk source of *B. cepacia* for these patients. However, the organism has been developed as a biological pesticide for protecting crops from fungal diseases and has potential as a bioremediation agent for breaking down recalcitrant herbicides and pesticides. This has lead to concern about increased human exposure through environmental contamination, and the possibility of acquisition of increased virulence through horizontal gene transfer between the strains applied and existing soil organisms, particularly *B. pseudomallei* (25).

Acinetobacter spp., primarily *Acinetobacter baumannii*, have been recognized as a nosocomial pathogen of increasing importance (26). *Acinetobacter* spp. can be found in soil and water and grow well in water (27). Compared with other genera of gram-negative bacilli, they survive better on dry environmental surfaces, probably contributing to their propensity to cause prolonged outbreaks of nosocomial infection (26,28,29). However, there is no evidence that outbreak strains have enhanced environmental survival capacity compared with nonoutbreak strains (28,29). *Acinetobacter* spp. have been isolated from the air of hospitals, vents of nursery air conditioners, and aerosols in association with nosocomial infections (30). Although transmission may have occurred through airborne contamination of equipment, medication, or skin in some cases (in particular, in outbreaks of bloodstream infections), direct transmission to the respiratory tracts of patients is evident in others. Nosocomial *Acinetobacter* spp. infections in the United States have been observed to demonstrate seasonal variation, with significantly higher rates during July to October than during November to June (30). This may be mediated through changes in moisture within the hospital environment as a result of changes in outdoor humidity or increased use of air conditioners that emit contaminated aerosols.

Acinetobacter spp. rarely cause community-acquired infections, even in the presence of underlying disease. However, an outbreak of acinetobacter pneumonia in foundry workers has been reported (31). Foundry and other metal workers are at increased risk of pneumonia because of chronic exposure to metal particles; an *Acinetobacter* sp. was found in the air in the foundry where the outbreak occurred, but a source was not identified. Nontuberculous mycobacteria and Legionellae have been cultured from water-based metalworking fluids and have been associated with hypersensitivity pneumonitis, as described earlier, or Pontiac fever.

Most pathogenic aerobic gram-negative bacteria have intrinsic resistance to multiple antibiotics and have demonstrated increasing acquired-antibiotic resistance, particularly as a result of acquisition of extended-spectrum β-lactamases (32). Thus, selective antibiotic pressure in hospitals (particularly in settings such as intensive care and transplant units, where use of antibiotics and invasive devices is particularly common) contributes to the increasing incidence of nosocomial infections from aerobic gram-negative bacteria.

Burkholderia pseudomallei (Melioidosis)

Introduction. Melioidosis is a disease with a wide and variable spectrum of clinical manifestations, including acute, localized suppurative infection, acute pulmonary infection, acute septicemic infections, and chronic suppurative infection. It is recognized primarily in the tropics, particularly in Southeast Asia and northern Australia, but has occurred throughout the world between 20 degrees north and south latitudes (33). The etiologic agent, *B. pseudomallei*, is a gram-negative aerobic bacillus that, with *B. cepacia*, recently was moved from *Pseudomonas* to its own genus on the basis of RNA homology. The bacterium first was isolated in 1911 from a patient with pneumonia, and the disease was named in 1921. The term is derived from the Greek "melis" meaning "a distemper of asses." Another common name for infection with *B. pseudomallei* is pseudoglanders because the disease resembles glanders, which is predominantly a pulmonary disease in asses caused by *Pseudomonas mallei* (33).

Natural Occurrence. Melioidosis initially was thought to be a zoonotic disease with a reservoir in rodents. However, *B. pseudomallei* now is known to be a widely distributed environmental saprophyte that can be isolated from soil, surface water (stagnant streams, ponds, and rice paddies), and market produce in endemic areas (34). The disease is endemic in Southeast Asia, with the greatest concentration of cases in Thailand, Malaysia, Cambodia, Myanmar (Burma), Laos, and northern Australia (35). Indigenously acquired cases also have been reported in Indonesia, southern China, the Philippines, Guam, Sri Lanka, the Indian subcontinent, Africa (Kenya and Central West Africa), Borneo, Iran, Turkey, and Central and South America. In Thailand, the percentage of positive soil and rice paddy water cultures and disease incidence are highest in the northeast section of the country (36). *Burkholderia pseudomallei* is able to survive in water for prolonged periods without any form of nutrient and is tolerant to a range of adverse environmental conditions such as low pH. However, little is known about the climatic, physical, chemical, and biological factors that control the proliferation and survival of *Burkholderia* spp. in the environment, although epidemiological studies show space-time clustering of melioidosis (34).

Routes of Exposure. It is assumed that most human and animal melioidosis arises from exposure to contaminated soil or muddy water, although only 6% of human cases have a clear history of inoculation and a further 0.5% of cases follow near-drowning (34). Occupational or recreational exposure to soil or muddy water is thought to increase the risk of infection. Laboratory animals have

been infected by inhalation, but evidence of infection acquired naturally by this route remains anecdotal. Infection of American helicopter personnel in the Vietnam War has been viewed as evidence of airborne exposure. Sporadic cases have resulted from laboratory accidents and person-to-person or animal-to-person spread. An outbreak in western Australia was linked to contamination of the potable water supply, but the route of exposure could not be determined (37).

Incidence. Melioidosis is reportable only in Thailand, Hong Kong, and Singapore. Clinically apparent disease is common in Thailand but rare elsewhere. The infection rate in patients attending government hospitals in 1997 in northeastern Thailand (137.9 per 100,000 inpatients) was significantly higher than that in the northern (18 per 100,000 inpatients), central (13.4 per 100,000 inpatients), and southern (14.4 per 100,000 inpatients) regions and accounted for 19% of the admissions in that region (36). Serological surveys indicate that clinically inapparent infection is common in other endemic areas. Most of the clinical cases in the United States have occurred in people who have traveled or lived in endemic areas, with only one or two cases of unequivocal transmission from native soil to a patient.

Disease in Humans. Infection ranges from rapidly fatal septicemia, with or without pneumonia, to more chronic soft tissue involvement of almost any part of the body. The most common form of melioidosis is pulmonary, which may be a primary pneumonitis or hematogenous pneumonitis as a result of septicemia. Illness can be acute, subacute, or chronic. A notable feature of melioidosis is recurrence months or even years after the initial acute infection, due to the ability of *B. pseudomallei* to survive inside phagocytic cells. Cases have been reported in which acute infection occurred after a disease-free interval of decades following presumed environmental exposure. The severity of disease is higher in people with diabetes or chronic renal failure.

Infection is diagnosed by culture of *B. pseudomallei* from blood, sputum, or other focal site (as indicated by the clinical presentation), or by rising antibody titer. A rapid immunodiagnostic test is available. Confirming the identity of a suspected *B. pseudomallei* culture isolate can be difficult. Some commercial culture identification systems are prone to misidentify *B. pseudomallei* as other genera or species such as *Chromobacter violaceum*, *B. cepacia*, or *P. aeruginosa*.

PREVENTION AND CONTROL MEASURES

Elimination or Reduction of Reservoirs and Sources

All the airborne bacterial infections discussed in this article are transmitted in the workplace and other settings. Occupational exposures often can be anticipated, on the basis of locations and activities of the workers. Consequently, practices that potentially put workers at risk of exposure to bacterial agents can be identified and modified. However, given the ubiquitous nature of most of these organisms in the environment and their diffuse distribution when they are present, elimination or reduction of reservoirs generally is not feasible. When bacterial presence in a health care facility poses a risk of nosocomial infection to patients, modification of the identified environmental reservoir may be considered. The possibility of control of MAC in hospital potable water, through methods similar to those used for *Legionella*, has been proposed (12). Identification and elimination of gram-negative bacilli in environmental reservoirs often is necessary to control nosocomial outbreaks. A comprehensive set of recommendations for environmental management in health care settings is under preparation by The Centers for Disease Control and Prevention and will be available in 2001.

CONCLUSION

Many species of bacteria are present in soil and water and hence become airborne, often in particles that can be inhaled. Yet, only a small proportion of these bacteria cause infectious diseases in humans, because many environmental bacteria are opportunistic pathogens, primarily affecting people with immune dysfunction or other underlying diseases. Currently, adverse health effects related to airborne bacteria account for a relatively small burden of human disease, often of limited geographic distribution. However, that burden is increasing and their geographic range is expanding; as the global population of immunocompromised individuals increases, the movement of humans, animals, equipment, and soil expands, and travel for business and pleasure increases. Thus, infectious airborne bacteria are expected to be of increasing importance in the future, as the population at risk increases and new pathogens and diseases are recognized.

INORGANIC NUTRIENT USE BY MARINE MICROORGANISMS

DAVID L. KIRCHMAN
University of Delaware
Lewes, Delaware

Microbes participate in reactions involving virtually every element found in the periodic chart, but of the 90 natural elements only those with atomic numbers less than 53 are considered biogenic (1), and only a few of these are essential for microbial growth. Some of the biogenic elements occur in compounds used as electron acceptors or donors in redox reactions mediated by bacteria (e.g., the reduction of SO_4^{2-} and SeO_4^{2-} by sulfate-reducing bacteria) and are not assimilated into biomass; that is, they are not nutrients. Compounds containing the most abundant biogenic elements, C, H, and O, are also usually not considered nutrients, although they make up nearly all of microbial biomass. This article focuses on the remaining elements (Table 1) found in nutrients that supply either major biogenic (e.g., N, P, and S) or trace (e.g., Zn and Fe) elements, all of which are necessary for microbial life. All marine microbes are considered, but heterotrophic bacteria are emphasized.

A fundamental problem in examining the ecophysiology of marine microbes is that few can be isolated and studied in pure culture. This problem is especially acute for heterotrophic bacteria. It has been known since ZoBell (2) that less than 0.1% of the bacteria observed by direct microscopy can be grown and isolated on agar plates. One consequence of this inability to culture most marine bacteria is that it is necessary to infer the physiology of uncultured microbes from field studies of mixed assemblages and from the physiology of nonmarine bacteria and those marine microbes that can be cultured. Molecular approaches are beginning to provide some insights into nutrient uptake by uncultured marine microbial assemblages (3). In addition, inorganic nutrient use by cultured bacteria appears to represent what marine bacteria do in the oceans, with some notable exceptions.

It is difficult, however, for laboratory experiments to reproduce the biogeochemical environment that marine microbes must contend with. Foremost, concentrations of all nutrients are usually very low in marine systems compared with standard laboratory cultures and other

Table 1. Summary of Elements Found in Inorganic Nutrients Used by Marine Microbes

Element	Form in Seawater[a]	Location or Use in Cells
Major Biogenic Elements		
N	N_2, NO_3^-	Protein, nucleic acids
P	PO_4^{3-}	Nucleic acids, phospholipids
S	SO_4^{2-}	Protein
Si	SiO_4^{4-}	Diatom frustrales
Trace Biogenic Elements		
V	$H_2VO_4^-$	Nitrogenases
Mn	Mn^{2+}	Superoxide dismutase
Fe	Fe^{3+} organic	Electron transfer system (see Table 3 for others)
Co	Co^{2+} organic	Vitamin B_{12}
Ni	Ni^{2+} organic	Urease; hydrogenase
Cu	Cu^{2+} organic	Electron transfer system, superoxide dismutase
Zn	Zn^{2+} organic	Carbonic anhydrase, protease
Se	SeO_4^{2-}	Formate dehydrogenase
Mo	MoO_4^{2-}	N_2 fixation
Cd	Cd^{2+} organic	Carbonic anhydrase
I	IO_3^-	Electron acceptor (anaerobic respiration)[b]
W	WO_4^{2-}	Hyperthermophilic enzymes

[a] (Taken from W. Stumm and J. J. Morgan, *Aquatic Chemistry*, John Wiley & Sons, New York, 1981). Those metals with "organic" occur mainly in organic complexes.
[b] See reference (118), for example. The text cites references for the other metals or also see reference (119).

environments. Little is known about the consequences of these extremely low concentrations on the physiology of marine microbes because few studies have examined the physiological processes of bacteria growing on low concentrations of both organic and inorganic compounds (4). In addition, marine microbes live in a complex chemical milieu consisting of many inorganic and organic compounds, a concoction that is difficult to reproduce in a laboratory experiment. Because of the differences between the ocean and the laboratory and between uncultured and cultured bacteria, it is important to consider field studies to help us understand inorganic nutrient use by marine bacteria.

THE MAJOR NUTRIENTS

Nitrogen

Basic Pathways and Enzymes. Nitrogen is found mainly in protein, which makes up about 60% of the microbial cell (Table 1). Heterotrophic marine bacteria obtain much of their nitrogen from dissolved organic nitrogen, mostly in the form of amino acids, but two inorganic forms, ammonium (NH_4^+) and nitrate (NO_3^-), are also major nitrogen sources for heterotrophic and autotrophic marine bacteria and autotrophic eukaryotic algae. Nitrite (NO_2^-) can be ignored in considering assimilatory nitrogen uptake as nitrite concentrations are usually negligible in marine environments. Nitrite is produced and consumed during nitrification and denitrification, but the nitrogen compounds involved in these redox processes are not considered as nutrients.

Figure 1 summarizes the uptake mechanisms for nitrogen acquisition by marine heterotrophic bacteria. A schematic diagram for autotrophic microbes would be similar, but would not have pathways for use of free and combined amino acids, although some phytoplankton may have cell-associated amino acid oxidases (5). Much of Figure 1 is based on work on nonmarine bacteria, because few of these pathways have been examined explicitly in marine microbes. Fortunately, the basic mechanisms are likely to be the same in all microbes. The kinetic parameters and regulation of nitrogen acquisition may differ.

Three important enzymes mediating assimilation of inorganic nitrogen have been found in marine bacteria and in natural assemblages of bacterioplankton. Nitrate assimilation depends on assimilatory nitrate reductase, which catalyzes the reduction of nitrate to nitrite. Genes for this enzyme have been found in coastal waters (3). The two other enzymes are glutamine synthetase (GS) and glutamate dehydrogenase (GDH), which are involved in ammonium assimilation. As observed in nonmarine bacteria, GS is found in the marine bacterium *Vibrio harveyi* growing on low ammonium concentrations (<1 mM, which is actually quite high for natural environments), whereas GDH mediates ammonium assimilation at high ammonium concentrations (Fig. 2) (6).

Glutamate is the end-product of both pathways, but the energetic costs differ. The low affinity GDH system expends only one nicotinamide adenine dinucleotide

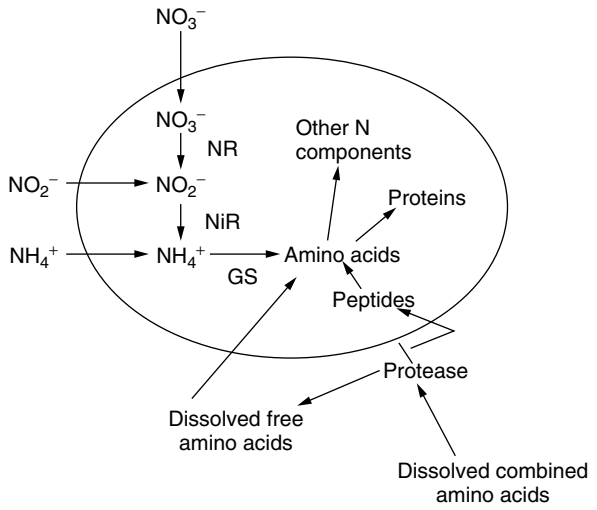

Figure 1. Summary of nitrogen acquisition by heterotrophic bacteria. GS = glutamine synthetase; NR = nitrate reductase; Nir = nitrite reductase. "Dissolved combined amino acids" is the term used by organic geochemists to refer to the amino acids released by acid hydrolysis from proteins, other polymers, complexes or adsorbed to other material. (Taken from D. L. Kirchman, in D. L. Kirchman, ed., *Microbial Ecology of the Oceans*, Wiley-Liss, New York, 2000, pp. 261–288).

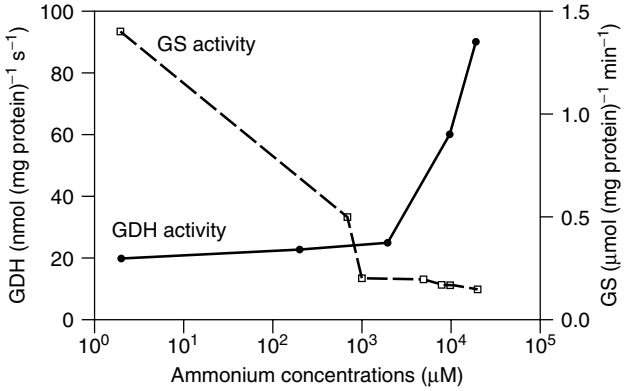

Figure 2. Activity of glutamate dehydrogenase (GDH) and glutamine synthetase (GS) in the marine bacterium *Vibrio harveyi* as a function of ammonium concentrations. (Data taken from M. P. Hoch, M. L. Fogel, and D. L. Kirchman, *Limnol. Oceanogr.* **37**, 1,447–1,459 (1992)).

(phosphate) (NAD(P)) in assimilating ammonium in a reaction catalyzed by a single enzyme, GDH:

$$NH_3 + \alpha\text{-keto-glutarate} + NADH = \text{glutamate} + NAD^+ \quad (1)$$

whereas the high affinity system requires two enzymes and expands one adenosine 5′-triphosphate (ATP) in addition to the one NAD(P)H. First, ammonium is assimilated to form glutamine, a reaction catalyzed by GS:

$$NH_3 + \text{glutamate} + ATP = \text{glutamine} + ADP + Pi \quad (2)$$

To regenerate glutamate, GS must be accompanied by glutamine α-ketoglutarate aminotransferase (GOGAT), which catalyzes the following transamination reaction:

$$\text{glutamine} + \alpha\text{-keto-gluturate} + \text{NADH} = 2\ \text{glutamates} + \text{NAD}^+ \quad (3)$$

Glutamate produced by the GDH and GS-GOGAT systems is a nitrogen donor in transamination reactions with appropriate α-ketoacids to form the other amino acids and nitrogenous compounds needed by microbial cells for growth.

Ammonium concentrations are never high enough in marine waters for the GDH system to be effective and thus ammonium must be assimilated by the GS-GOGAT system. However, concentrations may be sufficiently high in sediments for GDH to be active. Highest concentrations excepted (6), ammonium transport across the cell membrane is probably an active, ATP-requiring process, because the charged species, ammonium (not ammonia) predominates at seawater pH (ca. 8.2); the ammonium/ammonia reaction has a pK_a of 9.5.

Regulation of Inorganic Nitrogen Uptake. Extensive work with nonmarine bacteria has shown that ammonium transport and assimilation are inhibited, and genes synthesizing enzymes mediating these processes are repressed, by glutamate and glutamine. Analogous studies with natural marine bacterioplankton suggest that similar mechanisms may be operating with uncultured bacteria in the ocean (7,8). Presumably, use of amino acids avoids the energetic costs associated with transporting and assimilating ammonium. These feedback mechanisms, however, do not appear to prevent use of ammonium in the presence of amino acids when the organic carbon supply is adequate, as demonstrated in both lab (9) and field experiments (10).

The energetics of nitrogen use lead to the prediction that growth rates of marine bacteria using amino acids will be higher than growth rates of bacteria using ammonium and a carbon source. Indeed, there is some evidence for this hypothesis (11), but other studies have failed to find any difference in growth rates (12). It has been argued that the transport costs of using amino acids cancel the energetic advantage of avoiding ammonium assimilation (12,13), thus explaining the similarity in growth on amino acids and ammonium. The impact of concentrations on energetic costs has not been examined.

The energetic cost of using nitrate seems clearer, although no study has examined this issue specifically for marine bacteria. In probably all microbes, reduction of nitrate eventually to ammonium requires at least five NADH, four more than ammonium assimilation using GDH (14). For this reason, it was not surprising to learn that nitrate is the least preferred nitrogen source for marine bacteria (15) and eukaryotic phytoplankton (16), although concentrations of nitrate are much higher than other nitrogenous compounds, except dissolved organic nitrogen. Energetic considerations may be particularly relevant in understanding growth of marine bacteria in seawater with very low concentrations of organic compounds. Often the growth rate of natural bacterioplankton is limited by organic carbon (17,18), which supplies both the carbon and energy needed by heterotrophic bacteria.

Ecological and Biogeochemical Considerations. Ammonium and nitrate are the two largest nitrogen sources supporting growth of marine primary producers (cyanobacteria and eukaryotic phytoplankton), but these compounds also supply much nitrogen for heterotrophic growth. Heterotrophic bacteria can account for as much as 50% of the total uptake of both ammonium and nitrate in the oceans (15). In addition to helping us understand biological production in marine systems, the uptake of ammonium and nitrate by heterotrophic bacteria has several important ecological and biogeochemical implications.

First, uptake of these nitrogen sources by bacteria and other small microbes helps to shape the size structure of the phytoplankton community in the oceans. The large surface area to volume ratio of bacteria and other microbes gives them a competitive advantage in using low concentrations of dissolved compounds. This competitive advantage explains the abundance of small cells in oligotrophic oceans and their success in using ammonium (19), forcing large phytoplankton to use an energetically less favorable nitrogen source, nitrate. Heterotrophic bacteria cannot truly compete with phytoplankton for inorganic nitrogen because phytoplankton provides the organic carbon needed by these heterotrophs. Because low availability of nitrogen often limits primary production and phytoplankton growth in many oceanic regimes, a superior heterotrophic competitor would eventually lead to a decrease in primary production and ultimately less organic carbon. The decrease in organic carbon would inhibit growth of the heterotrophic bacterium and lower its use of inorganic nitrogen.

Nitrate and ammonium fluxes are used in carbon and nitrogen budgets and for examining fluxes of both elements out of the upper layer of oceanic regimes. Uptake of nitrate is used to examine the influx of new nitrogen and the export of both carbon and nitrogen from the surface oceans (20), as illustrated in Figure 3. Nitrate uptake is used to estimate "new production" (21) because, if other external nitrogen sources (e.g., N_2 fixation and terrestrial runoff) are ignored, nitrate is the only nitrogen compound imported into the upper oceanic layer and thus is "new." Because ammonium, on the other hand, comes only from grazing activity and bacterial mineralization, uptake of it represents "regenerated production," if nitrification in the euphotic zone is negligible. Uptake of either nitrate or ammonium by heterotrophic bacteria may not necessarily change estimates of new or regenerated production, but it certainly complicates these concepts (15).

Phosphorus

Nitrogen is generally thought to be the limiting element in the oceans, but there are now several reports of phosphorus limitation, and the North Pacific gyre may be switching from nitrogen to phosphorus limitation (22). Because evidence of phosphorus limitation in the oceans is quite new, phosphate uptake has not been examined

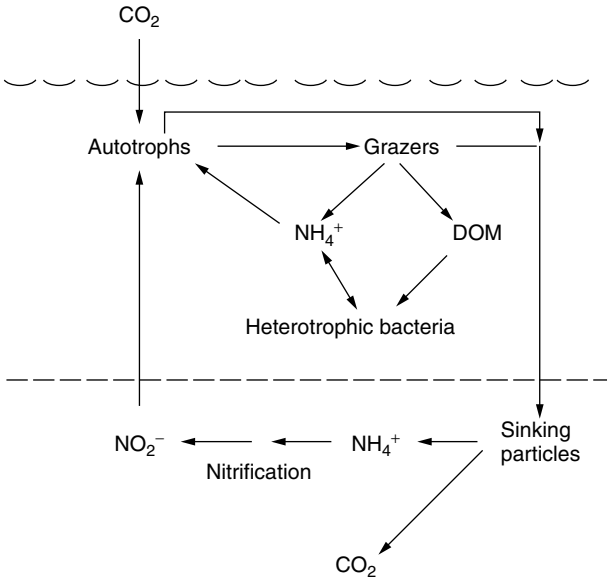

Figure 3. A schematic diagram to illustrate "new production" (nitrate uptake) and its link to carbon dioxide drawn down from the atmosphere and export of carbon below the euphotic zone (represented here by the dashed line, about 100 m deep).

by marine microbial ecologists as extensively as pathways of the nitrogen cycle. Furthermore, most of the work on phosphorus use by bacteria has focused on the uptake of organic phosphorus compounds, although orthophosphate uptake may account for much of the phosphorus needs of heterotrophic bacteria in the oceans (23). One indication of the importance of phosphate uptake by heterotrophic bacteria is that these microbes appear to account for over 50% of total phosphate uptake, on average, in marine systems (24). Phosphate undoubtedly supplies much phosphorus for both heterotrophic and autotrophic bacteria in the oceans.

The impact of phosphate on organic phosphorus use may be unusual in marine bacteria. Alkaline phosphatase, which releases phosphate from organic phosphorus compounds, is usually inhibited by the presence of phosphate in bacterial cultures and in freshwater. Natural marine bacterioplankton apparently have another phosphatase, a 5′-nucleotidase that is not inhibited by phosphate (25). With this enzyme, bacteria could continue to use organic phosphate even in the presence of orthophosphate. This potentially novel regulation may be an adaptation to low phosphorus concentrations of the marine environments. Even if phosphorus does not limit biological activity in the oceans, concentrations of orthophosphate and labile organic phosphorus compounds are very low, often undetectable in surface waters. There may be no need for regulation of phosphatases by phosphate if concentrations are never high.

Phosphorus Content of Marine Bacteria. In addition to the high uptake of phosphate by bacteria, another ecologically-relevant observation is that cellular phosphorus is higher in bacteria than in eukaryotic phytoplankton larger than 1 μm. The measure of phosphorus content commonly used by freshwater ecologists and oceanographers is the C : P ratio. This ratio for phytoplankton is classically set at the Redfield ratio; that is, C : P is equal to 106. In contrast, bacteria have much more phosphorus and consequently, the C : P ratio is much lower, as low as 50 (15). Cell size explains the difference in C : P ratios.

The diameter of an average heterotrophic bacterium in the oceans is about 0.5 μm, significantly smaller than phytoplankton, including cyanobacteria, which are usually 0.8 μm or bigger. Consequently, the surface area to volume ratio is much larger and thus the amount of membrane per cytoplasmic material is higher for heterotrophic bacteria than for phytoplankton. Membranes are phosphorus-rich because of phospholipids, whereas proteins with little phosphorus dominate the cytoplasm; some enzymes are regulated by phosphorylation. The net result is a higher P : C ratio for heterotrophic bacteria than for phytoplankton.

It is also important to note that the C : P ratio for bacteria varies greatly, by as much as 60-fold, compared with a fourfold variation in C : N ratios (9,15). This difference is probably due to changes in the biochemical composition of bacteria as a function of growth rates (15) as illustrated in Table 2. The amount of phosphorus-rich ribosomal ribonucleic acid (RNA) increases with growth rate in both marine and nonmarine bacteria (26). Growth rates also affect cell size and thus the relative amounts of phosphorus-rich membranes. Likewise, the amount of DNA per cellular carbon varies with growth-related changes in cell size, even if genome size (DNA per cell) is constant (Table 2). The net result is large changes in the phosphorus content of bacteria with different growth conditions. In contrast, the carbon and nitrogen content of bacterial cells is largely set by the largest cellular constituent, protein, which is an approximately constant 60% of bacterial dry weight, regardless of growth rate.

Bacteria are often said to be more nitrogen-rich than phytoplankton, but the difference is relatively small compared with the large difference in C : P ratios. The Redfield ratio for phytoplankton is 6.6, whereas the most recent estimates of C : N ratios for natural marine bacterioplankton average 6.8 ± 1.2 and 5.8 ± 1.1 for coastal and oceanic samples, respectively (27). Lab studies have found similar ratios (28), although a C : N ratio as low as 4.5 for a bacterial culture has been reported (12). Recently, Goldman and Dennett (9) found C : N ratios as high as 13 for slowly growing marine bacteria in nitrogen-limited continuous cultures. If these laboratory experiments can be applied to marine bacterial assemblages, field studies showing that bacteria have C : N ratios of Redfield or lower argue against nitrogen limitation and are consistent with the hypothesis that growth of these microbes is carbon-limited.

Sulfur

The high concentrations of sulfate in seawater ensure that sulfur never limits the growth of bacteria or phytoplankton in marine systems, with the potential exception of anoxic habitats where sulfate reduction can deplete sulfate to low levels. Even when sulfate concentrations are high, the energetic cost of assimilatory sulfate reduction presumably exacerbates the difficulties of heterotrophic

Table 2. Biochemical Composition of a Bacterium Growing Fast (Generation Times of One Hour or Less) and Slow (Day Timescale)

	% of Dry Weight		Source of Data for
	Fast[a]	Slow	Slow-Growing Cells
Protein	55.0	55	Simon and Azam (120)
RNA	20.0	13.7	Calculated by difference[b]
Lipids	9.0	12.0	Same lipid/SA ratio[c]
Lipopolysaccharides (LPS)	3.4	3.3	Watson and coworkers (121)
Cell wall (peptidoglycan)	2.5	4.1	Same PG/LPS ratio
C Storage (glycogen)	2.5	0.0	Assume C limitation
DNA	3.0	10.0	Fuhrman and Azam (23)
Monomers	4.0	2.1	Set arbitrarily

[a] Cell composition for a bacterium growing rapidly in the lab (122).
[b] Amount of RNA was calculated by subtracting the sum of all other amounts from the total estimated dry weight for a slow-growing natural bacterium.
[c] I assumed that the ratio of lipid or peptidoglycan (PG) per surface area (SA) measured for fast-growing bacteria in the lab can be applied to slow-growing natural bacteria. We do not know lipid or peptidoglycan amounts of natural bacteria.
Note: The dry weight of a slow-growing cell was estimated from the carbon content (12 Fgc/Cell) measured by Fukuda and coworkers (27) and assuming that carbon is 50% of dry weight.
Source: Taken from D. L. Kirchman, in D. L. Kirchman, ed., *Microbial Ecology of the Oceans*, Wiley-Liss, New York, 2000, pp. 261–288.

bacteria living on low concentrations of organic compounds in seawater. Indeed, marine bacteria prefer to use sulfur amino acids rather than sulfate, because sulfur amino acids inhibit sulfate uptake (29,30). Recently, Kiene and coworkers (31) suggested that marine heterotrophic bacteria obtained much of their sulfur from two nonamino acid sulfur compounds, dimethylsulfoniopropionate (DMSP) and methanethiol. DMSP may be particularly important in providing sulfur and some carbon for heterotrophic bacterial growth (32), which has consequences beyond understanding marine bacterial ecology, because dimethylsulfide (DMS) is released during DMSP utilization (33). Oceanic DMS is a major source of reduced sulfur in the atmosphere and acts as cloud nucleation sites (34).

Silicon

Silicon occurs as silicate (SiO_4^{4-}) in the oceans and is considered a major nutrient because fairly high concentrations of it are required for growth by selected eukaryotic phytoplankton and protozoa. Diatoms, which are algae and the most abundant and ecologically important silicon-containing organisms, require approximately equal amounts of silicon and nitrogen on a mole basis. Low silicon concentrations can limit diatom growth, especially following spring plankton blooms, which diatoms often dominate. A few rarer eukaryotes (e.g., the protozoa Radiolarians and silicoflagellates) in the plankton require silicate, but it is not required by other phytoplankton, nor by any prokaryotic group, including cyanobacteria. Heterotrophic bacteria are involved in mineralization of silicate during degradation of diatoms (35).

TRACE ELEMENTS AS ENZYME COFACTORS

Several key enzymes in microbial metabolism require metallic cofactors. None of these trace metals are needed in high concentrations, and it is common to grow marine bacteria in simple media without the addition of these metals because they are present as contaminants in other media constituents. Although high amounts are not needed, dissolved concentrations of these trace metals are very low in the oceans, low enough to affect (if not limit) the metabolism of all marine microbes. Marine microbiologists and oceanographers have examined the impact of Fe the most. Growth of autotrophic cyanobacteria (*Synechococcus* and *Prochlorococcus*) and eukaryotic phytoplankton can be limited by iron, but heterotrophic bacteria are generally not thought to be limited directly by these elements, as discussed in the following paragraphs.

Iron

Marine bacteria live in some of the most iron-poor environments in the biosphere, the open oceans in which iron concentrations in the surface layer are often below detection limits, that is, less than 50 pM (10^{-12} M). In general, bacteria do not require high amounts of iron, and in fact, a few nonmarine bacteria appear not to have any nutritional need for iron; examples include the soil bacterium *Lactobacillus plantarum* (36) and the Lyme disease pathogen *Borrelia burgdorferi* (37). However, iron has been shown to be essential for the growth of all marine bacteria isolated so far into pure culture. In fact, lab and field data indicate that marine cyanobacteria and heterotrophic bacteria contain as much iron, if not more, as other microbes (38,39).

Cellular Requirements for Iron. Table 3 summarizes the dominant iron-containing enzymes found in heterotrophic bacteria. Most of the iron in marine bacteria and other microbes is found in the electron transfer chains of photophosphorylation (phototrophic

Table 3. Common Microbial Enzymes with Iron

Pathway	Enzyme	Fe per Cell (10^{-20} mol)	% of Total Cellular Fe
Electron transfer chain	NADH dehydrogenase	89.4	57.8
	Cytochrome b_1	5.2	3.4
	Cytochrome oxidase	3.8	2.5
Kreb's cycle	Aconitase	1.1	0.7
	Succinate dehydrogenase	46.7	30.2
	Total[a]	155	100
		Fe per enzyme	
Others	Superoxide dismutase	1	5.3
	Catalase	1	0.1
	Nitrogenase[b]	30	
	Nitrate reductase[c]	4	
	Nitrite reductase[c]	1	
	Hydrogenases[d]	2 or 6	

[a]Includes superoxide dismutase and catalase with 8.2 and 0.2×10^{-20} mol iron per cell, respectively.
[b]Component I of nitrogenase in *Azotobacter vinelandi* (71). Component II has only four iron.
[c]Assimilatory nitrate and nitrite reductases (123).
[d]Catalytic sites of iron-only hydrogenases have six iron, whereas NiFe-hydrogenases have a binuclear NiFe center. See papers cited in reference (124).
Note: The percentages were forced to add to 100% and the data cannot rule out the presence of other iron-containing components.

cyanobacteria and eukaryotic algae) and oxidative phosphorylation (heterotrophic bacteria) (40). Other iron-containing enzymes include assimilatory nitrate reductase and nitrogenase. Low iron is one reason that nitrate builds up in some oceanic regimes (discussed in the following sections). Heterotrophic bacteria probably use nitrate only as a last resort because they are limited by organic carbon, not iron, but nitrate use by phytoplankton is thought to be limited by iron because of the requirement of nitrate reductase for iron.

Low iron concentrations in marine habitats may select microbes that can decrease their requirement for iron by switching to enzymes that do not require iron. Examples include the switch from ferrodoxin to flavodoxin in phototrophs, which has been demonstrated in both lab and field experiments (41). Ferrodoxin is an iron-sulfur protein in the electron transfer chain of photophosphorylation. An example from heterotrophic bacteria is superoxide dismutase, a ubiquitous enzyme in oxic environments. The nonmarine bacterium, *Streptococcus sui*, has managed to replace iron in superoxide dismutase with manganese (42).

Iron concentrations are probably too low, even in waters where production is not limited by iron, to enable marine bacteria to store iron (43); but iron storage by marine microbes has not been examined.

Iron Acquisition by Marine Bacteria. Iron is present mainly as Fe (III) in most natural environments, including seawater. Although inorganic Fe (III) is quite insoluble, the oceans do contain very low concentrations of dissolved iron (the iron passes a 0.2 μm-pore-size filter) that is complexed with soluble organic chelators (44,45). How bacteria in the oceans acquire this complexed iron is not completely understood. Extensive work on nonmarine bacteria has demonstrated that bacteria can acquire iron by excreting siderophores, which are low molecular weight organic compounds (often peptides) that bind to Fe (III) with a high affinity. Eukaryotic algae do not synthesize siderophores, although they can acquire iron complexed to siderophores (46). Siderophores may be excreted and reacquired by attached bacteria because bacterial densities can be high on organic detritus and other surfaces, and the distance between sibling cells is likely to be small. Under these conditions, excreting siderophores probably benefits, if not the original cell that synthesized the siderophore, a daughter cell or another cell of the same species. But attached bacteria are not representative of all marine bacteria. Unattached bacteria, which usually dominate marine waters, live in a very different environment and may use a different mechanism for acquiring iron.

Microbial ecologists are faced with a dilemma in trying to understand iron acquisition by free-living bacteria. On the one hand, several pieces of evidence indicate that marine bacteria do acquire iron by excreting siderophores. On the other hand, this strategy does not make ecological sense. Unlike detritus-associated bacteria, unattached bacteria live in a nutritionally dilute, but species-rich environment. The number of different bacterial "species" in the oceans is not known, but may be as high as 1,000, each separated by about 60 μm, if the abundance of free-living bacteria is about 10^6 mL^{-1}. In this dilute but diverse world, a siderophore (or an extracellular enzyme) released by a bacterium is likely to be encountered and used by another microbe from a different phylogenetic group rather than the original bacterium or its siblings. Not surprisingly, marine bacteria are able to use iron complexed to siderophores produced by other species (47). In addition to iron piracy, siderophores may be used as

carbon and nitrogen sources by other microbes. Thus, excretion of siderophore by free-living microbes seems futile.

But siderophore-like compounds have been found in the dissolved organic matter pool in seawater (48), as if these compounds had been excreted by bacteria. In addition to structural similarities, dissolved iron organic ligands in seawater have stability constants similar to bona fide siderophores (49). Further, both cultured bacteria and natural microbial assemblages rapidly use siderophore-complexed iron (50,51); the existence of an adaptation to use this complexed iron is one argument for the existence of excreted siderophores. At least for those microbes cultured and studied in the laboratory, excretion of siderophores is the only iron acquisition mechanism known for marine bacteria (51–55). Finally, our ecological intuition about the futility of siderophore excretion may be faulty. Völker and Wolf-Gladrow (56) used a theoretical model to argue that the benefits of siderophore excretion can outweigh the costs under some conditions. These data and model results indicate that free-living bacteria do acquire iron by excreting siderophores.

There are counterarguments, however. First, the current model of Völker and Wolf-Gladrow (56) may not be totally applicable to real microbial assemblages. One problem is that heterotrophic bacteria were not examined explicitly by Völker and Wolf-Gladrow. The diversity, size, and abundance levels of various bacterial groups differ from that of the phytoplankton considered by Völker and Wolf-Gladrow. Also, the cost of siderophore excretion is probably higher for heterotrophic bacteria, because these microbes are often limited by organic carbon, whereas cyanobacteria are not. In their analysis of a problem analogous to siderophore excretion, Vetter and coworkers (57) pointed out that excretion of enzymes to hydrolyze biopolymers was energetically favorable only for attached bacteria.

Questions on the applicability of laboratory experiments to real oceans can also be raised. Perhaps the iron acquisition system used by cultured bacteria is not representative of bacteria found in the oceans. It is well known that cultured heterotrophic bacteria are quite different from those found in the oceans by culture-independent approaches (58). Several of the dominant cyanobacteria of the oceans have been brought into culture, so it is difficult to dismiss laboratory studies demonstrating siderophore excretion by these microbes (59). Incidently, siderophore production has not been found for a few marine bacteria (51), leaving open the possibility of alternative iron-acquisition systems for even cultured bacteria.

Cell-associated siderophores would seem more effective for free-living bacteria than excretion of siderophores, again analogous to cell-associated enzymes. Siderophores could become "dissolved" by viral lysis or by grazers egesting partially-digested bacteria, similar to the pathway for many other components of the dissolved organic pool (60). To date, a cell-associated siderophore-like complex has not been demonstrated for any bacterium, but one siderophore from a marine bacterium has some properties that are likely to be found in a cell-associated iron chelator. Martinez and coworkers (61) presented the structure of two classes of siderophores produced by two isolated marine bacteria, *Halomonas aquamarina* and *Marinobacter* sp., both members of the gamma subdivision of proteobacteria. What makes these siderophores interesting is their fatty acid moieties (Fig. 4), which potentially could anchor the siderophore into a cell membrane. The siderophores found by Martinez and coworkers, however, are excreted. The few siderophores from the other marine bacteria examined so far (54,55) are not like marinobactin and aquachelin (61).

Oceanographic and Ecological Importance of Iron. Several oceanic regimes have relatively high concentrations of the major nutrients (nitrate, phosphate, and silicate), yet algal biomass is low as measured by chlorophyll concentrations. These high nutrient, low chlorophyll (HNLC) oceans include the subarctic Pacific, the equatorial Pacific and the Southern Ocean. The Southern Ocean is especially important in global change models and in attempts to understand climate in the geologic past. John Martin (62) originally hypothesized that increases in iron fluxes to the Southern Ocean led to higher primary production and lower atmospheric CO_2 during the last glacial maximum. This hypothesis has generally been supported by other data, but a recent study questions it (63). Upwelling regions, such as off the coast of California, are also iron-limited at times (64).

Bottle and in situ fertilization experiments have shown that growth and standing stocks of large phytoplankton, most notably diatoms, are greatly enhanced by the addition of iron (65). Growth rates of autotrophic cyanobacteria

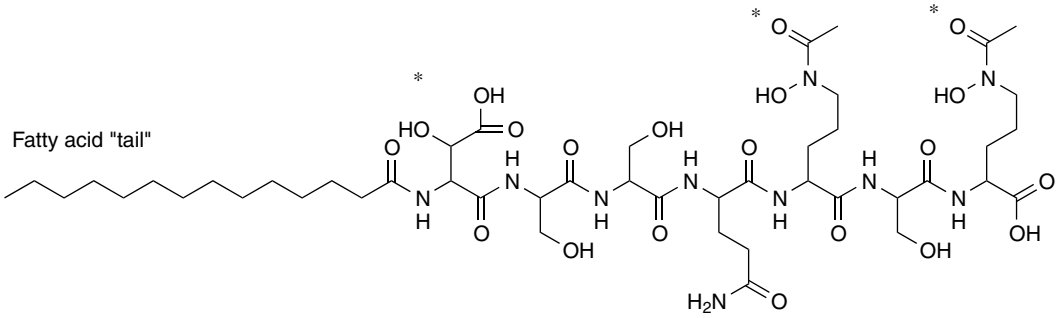

Figure 4. Structure of aquachelin D, a siderophore from the marine bacterium, Halomonas aquamarina. The asterisk indicates the probable iron-binding sites. (Taken from J. S. Martinez et al., *Science* **287**, 1,245–1,247 (2000)).

(*Synechococcus* and *Prochlorococcus*) are also limited by iron (66) but biomass levels do not change greatly following iron additions (67,68), unlike the large phytoplankton response (65). The lack of change in cyanobacteria and other picoplankton is because grazing rates by protist grazers and zooplankton increase and thus prevent large changes in biomass levels of their prey.

Nitrogen fixation, a process carried out exclusively by prokaryotes, specifically cyanobacteria in the oceans (69), is another process that may be limited by iron (70). Component I of nitrogenase, the key enzyme in dinitrogen fixation, alone requires 30 moles of iron (71). Raven (72) suggested that nitrogen-fixing cyanobacteria require orders of magnitude more iron for photosynthesis than phytoplankton, relying on ammonium. However, Sanudo-Wilhelmy and coworkers (73) found a mathematical error in those calculations. Their recalculations suggest much lower iron requirements for nitrogen-fixing cyanobacteria than originally reported by Raven, although the theoretical iron efficiency of photosynthesis based on nitrogen fixation is still 2.5- to 5-fold lower than ammonium-based photosynthesis. More importantly, the experimental evidence of Sanudo-Wilhelmy and coworkers (73) indicates that nitrogen fixation in the Sargasso Sea is limited by low concentrations of phosphate, not iron. Regardless, rates of oceanic nitrogen fixation are currently being revised and may be higher than previously believed.

In contrast to the impact of iron on phytoplankton growth, marine heterotrophic bacteria do not appear limited by iron (17,74), although this may not always be the case (75). In the HNLC oceans and in the California upwelling, growth rates of heterotrophic bacteria are limited by organic carbon (17,74,76). Perhaps heterotrophic bacteria are iron-stressed (Fig. 5), because addition of organic carbon along with iron occasionally stimulated growth more than just organic carbon additions alone (17,74). Heterotrophic bacteria appear to compete successfully for iron and can account for a large fraction of iron uptake (38,77). In contrast to the numerous studies on phytoplankton, few studies have examined iron-heterotroph interactions.

Other Trace Elements

Many trace elements in addition to iron have "nutrient-like" depth profiles in the oceans (Fig. 6), consisting of relatively high concentrations below the euphotic zone and low concentrations in the euphotic zone, where biological activity is highest because of light-driven primary production. Also, similar to iron, the concentrations of these other trace elements in surface waters are extremely low (Table 4), and many of these elements are found in organic complexes that impact their availability to the biota (Table 1). Microbes and other marine organisms may still require an element not having a nutrient-like depth profile. One example is manganese (discussed later).

Molybdenum

Although the regulation of nitrogen fixation may differ among organisms, the nitrogen fixation apparatus itself

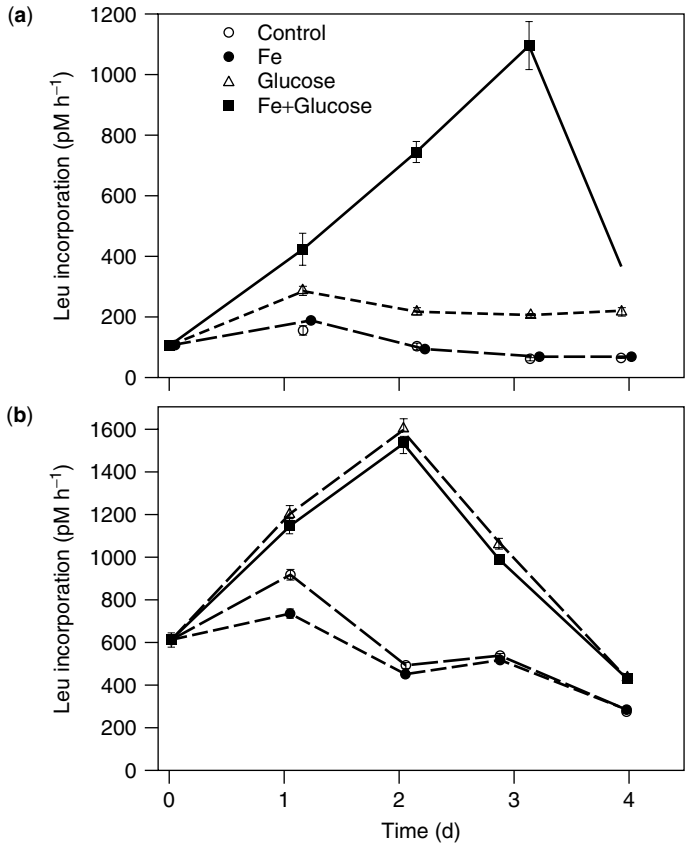

Figure 5. Examples of the effect of organic carbon and iron on bacterial growth as measured by leucine incorporation. Experiment conducted at a station with high dissolved iron concentrations (**a**); experiment conducted at a station with low dissolved iron concentrations (**b**). (Data taken from D. L. Kirchman et al., *Limnol. Oceanogr.* **45**, 1,681–1,688 (2000)).

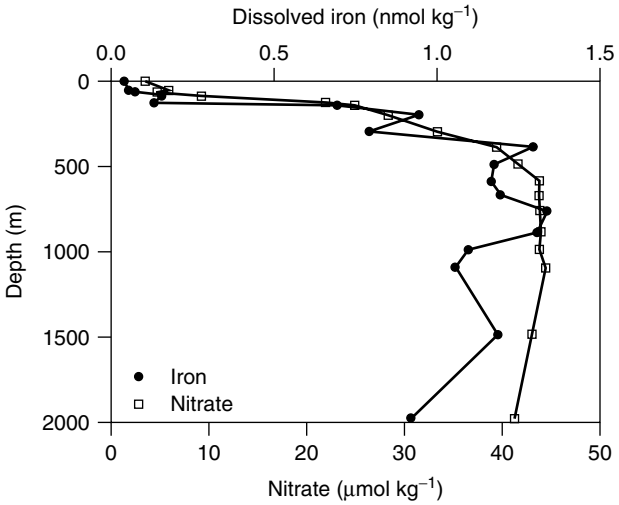

Figure 6. Depth profile of iron and nitrate in the northeast Pacific. The concentration units of μmoles and nmoles per kg are approximately equivalent to μM and nM, respectively. (Data taken from J. H. Martin and R. M. Gordon, *Deep-Sea Res. I* **35**, 177–196 (1988)).

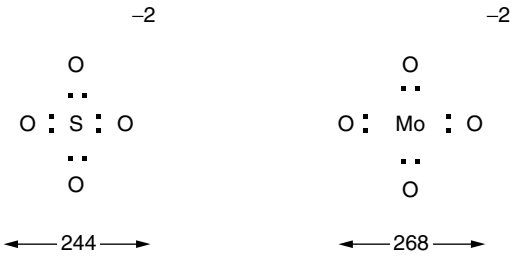

Figure 7. Lewis dot diagram illustrating the similarity of SO_4^{2-} and MoO_4^{2-}. The other six outer shell electrons for the oxygens were omitted for clarity. The units for the molecular dimensions are 10^{-12} m (George Luther, unpublished data).

is quite similar among all nitrogen fixers, ranging from *Trichodesmium* spp. in oligotrophic oceans to the symbiotic bacterium, *Rhizobium* sp., in organic-rich soils. However, marine nitrogen fixers face the unique problem of obtaining molybdenum, which component I of nitrogenase requires, in the presence of high sulfate concentrations. Molybdenum occurs as molybdate (MoO_4^{2-}) in surface oceanic waters, which is quite similar in charge and size to sulfate (Fig. 7).

Howarth and coworkers (78) first suggested that high sulfate concentrations sterically hinder molybdenum uptake and cause molybdenum limitation of dinitrogen fixation, although cyanobacteria require only low levels of molybdenum. Subsequent work demonstrated that Molybdenum transport was indeed inhibited by sulfate (79) and that statistical models for explaining cyanobacterial abundance in saline lakes were improved by including data on molybdenum concentrations (80). But additional experiments have failed to show any evidence of molybdenum limitation in the oceans (81,82). One reason for marine nitrogen fixation not being limited by molybdenum is the prevalence of "alternative nitrogenases" that have vanadium (V) instead of molybdenum (83,69).

Zinc

Depth profiles of zinc in the oceans are similar to the major nutrients because zinc is used as a cofactor by several enzymes in planktonic organisms. Of the many enzymes that use zinc, two are especially relevant for a review of marine microbes.

Morel and colleagues have been examining the impact of zinc and other metals on carbonic anhydrase in marine phytoplankton (84–86). Carbonic anhydrase is a widespread enzyme that catalyzes the reaction

$$H^+ + HCO_3^- = CO_2 + H_2O \qquad (4)$$

This reaction does occur spontaneously but at rates too slow for many cellular functions. The role of carbonic anhydrase in carbon fixation by terrestrial C4 plants is well known, but it is also important in marine phytoplankton. Because the dominant form of inorganic carbon is bicarbonate (HCO_3^-) at the pH of seawater, phytoplankton have evolved transport

Table 4. Concentrations of Some Trace Metals in Surface and Deep Waters of the Subtropical Oceanic Gyres (Units, nM)

Element	North Atlantic Gyre		North Pacific Gyre	
	Surface Water	Deep Water	Surface Water	Deep Water
"Nutrient-like"				
Cd	0.0020	0.29	0.0015	0.87
Cu	1–1.5	2.0	0.5	4.0
Ni	2.3	6.0	2.1	10
Zn	0.06	1.7	0.07	8.5
Conservative				
Pb	0.17	0.025	0.075	0.005
Mn	2.4	0.6	1.0	0.2

Note: See figure 6 for an example of "nutrient-like" depth profiles of elements in the oceans. Conservative elements are those with concentrations that covary with NaCl and are not appreciable used by microbes.

Source: Data from R. Chester, *Marine Geochemistry*, Unwin Hyman, London, U.K., 1990.

mechanisms of bicarbonate (HCO_3^-) (87), necessitating intracellular conversion of it by carbonic anhydrase to carbon dioxide, the substrate for the carbon dioxide fixing enzyme, ribulose bisphosphate carboxylase. Low zinc concentrations may lead to changes in carbonic anhydrase activity and thus carbon dioxide fixation patterns that impact fractionation of ^{12}C versus ^{13}C (84) and perhaps even the success of various phytoplankton groups (88). Data on $^{12}C/^{13}C$ ratios are useful in food web studies, oceanography, and paleoceanography.

Recently, Lane and Morel (86) showed that when grown under zinc limitation and low carbon dioxide partial pressure, the marine diatom *Thalassiosira weissflogii* produces another form of carbonic anhydrase that does not have zinc, but requires cadmium instead. Previously, it was thought that cadmium did not have any biological roles, although it was known that cadmium concentrations follow a nutrient-like depth profile.

It is not as well known that carbonic anhydrase is also found in heterotrophic bacteria (89). In *Escherichia coli*, carbonic anhydrase is part of the cyn operon that encodes the enzyme cyanase and catalyzes the following reaction (90):

$$NCO^- + 3H^+ + HCO_3^- = 2CO_2 + NH_4^+ \qquad (5)$$

Carbonic anhydrase facilitates degradation of cyanate (NCO^-) by maintaining high intracellular concentrations of HCO_3^- via the reverse of Reaction 4 given in the preceding section. Carbonic anhydrase also appears to have a role in regulating intracellular pH in a heterotrophic marine bacterium in which the enzyme is induced by high carbon dioxide partial pressure (91). The impact of low zinc concentrations on carbonic anhydrase in heterotrophic bacteria has not been examined.

The other zinc enzyme of interest to marine microbiologists is the ectoenzyme leucine aminopeptidase. Fukuda and coworkers (92) compared the activity of leucine aminopeptidase with the activity of another ectoenzyme, β-glucosidase, which does not require zinc. They found that the activity of leucine aminopeptidase, relative to β-glucosidase, correlated with zinc concentrations in depth profiles and along an east-west gradient in the North Pacific Ocean (92). Although overall growth of heterotrophic bacteria may not be controlled by zinc or other trace elements (see section on iron), the study of Fukuda and coworkers raises the possibility that degradation of organic matter may be impacted by trace elements such as zinc.

Nickel

Five microbial enzymes are known to require nickel (93): urease, hydrogenase, methyl coenzyme M reductase, carbon monoxide dehydrogenase, and one class of superoxide dismutase. Of these, urease is perhaps best known and most important to marine microbes in the surface ocean. Urea is commonly excreted by zooplankton and sometimes bacteria (94,95), and it can be an important nitrogen source for phytoplankton growth (96,97). In laboratory cultures, nickel limitation prevents urea from being used by phytoplankton as a nitrogen source (98). Palenik and coworkers (99) showed that use of another nitrogen source (hypoxanthine) by eukaryotic phytoplankton was also affected by nickel limitation, suggesting a role for urease in degrading this nitrogenous compound, although perhaps some other unknown enzyme required for hypoxanthine degradation has a nickel cofactor.

Copper

Copper is a necessary metal for several enzymes found in microbes but it can also be toxic in high concentrations. The bacterial enzymes known to require copper include superoxide dismutase (100), methane monooxygenase (101) that participates in methane oxidation, dissimilatory nitrite reductase (102), and amine oxidases (103). A more common use of copper, however, is in the oxidative phosphorylation electron transport chain of heterotrophic bacteria and other cells. The requirement for copper by these enzymes has not been examined in marine microbes, except for a superoxide dismutase in a marine yeast (104).

More work has been done on copper toxicity of both heterotrophic (105) and autotrophic microbes (106). Moffett and coworkers (107) suggested that the relatively high copper concentrations characteristic of estuarine and coastal water explain why the marine cyanobacterium *Synechococcus* is more abundant in open oceanic regimes.

Tungsten and Other Metals in Marine Hyperthermophiles

Some of the most unique environments in the biosphere are hydrothermal vents that are found at tectonic spreading zones in the ocean floor. Hydrothermal vents release many reduced metallic and other inorganic compounds, including sulfides used by chemolithotrophic bacteria, the primary producers in these environments. Chemolithotrophic production supports diverse communities of bacteria, archaea, and eukaryae in and near hydrothermal vents. Some of the most interesting organisms are the hyperthermophiles, those bacteria and archaea able to live in exceptionally high temperatures (>60 °C). These organisms are interesting for several reasons, one being their role in understanding the evolution of early life.

A hyperthermophile may have been among the first life-forms on the planet. Some of the oldest microbial fossils are from a Precambrian submarine thermal spring system (108), and thermophilic bacteria and archaea are the most deeply branched groups in 16S rRNA phylogenetic trees (109), implying an ancient origin. The metals found in selected enzymes from these microbes are unusual, and the enzymes as well as the bacteria provide several interesting test cases about the evolution of early life.

Adams and colleagues have been examining tungsten (W)-containing enzymes in marine hyperthermophilic archaea (*Pyrococcus furiosus*) originally isolated from hydrothermal vents (110,111). Some examples of enzymes with tungsten include formate dehydrogenase, formyl methanofuran dehydrogenase, and acetylene hydratase (112). These tungsten-dependent enzymes may model ancestral forms of the now more common molybdate-containing enzymes. Tungsten and molybdenum share several chemical properties because both

are in the chromium group (Group 6) of transition elements. Tungsten is also used by moderate thermophiles; but when grown without tungsten, these organisms produce analogous molybdoenzymes (113). Tungsten may be more readily stabilized than molybdenum because of the higher first ionization energy of tungsten (114). This stability is necessary for enzymes operating in the high temperatures of hydrothermal vents (113). As life moved away from hydrothermal vents and ready sources of tungsten, molybdenum may have taken its place during evolution in low temperature environments.

SODIUM, CHLORINE, POTASSIUM, AND CALCIUM: OSMOTIC BALANCE AND SALT BRIDGES

In concluding this review, it is appropriate to comment on some of the most common elements required by marine microbes, although they are not nutrients in the same sense as the compounds discussed earlier. The following elements include the most abundant ones in seawater: Na^+, Cl^-, K^+ and the divalent cations, Ca^{+2} and Mg^{+2}. These are not trace elements, of course, as the concentration of NaCl, for example, is 0.6 M in seawater. They are neither used as enzyme cofactors, nor in the synthesis of macromolecules. Magnesium (Mg^{2+}) is needed for the proper function of several enzymes (e.g., DNA polymerases) and Ca^{+2} helps to stabilize polymers, but these roles are important in all organisms. Calcium is used, however, in a unique way that is restricted to one group of marine microbes. A group of eukaryotic marine phytoplankton, coccolithophorids, uses Ca^{+2} and CO_3^{-2} to build unusual cell wall structures (coccoliths). Formation and subsequent sinking of these coccoliths contribute to the biological pump and the export of carbon from the upper layer to the deep oceans, one mechanism by which the oceans influence atmospheric carbon dioxide concentrations and climate change. Once preserved in sediments, coccoliths become a marker for deciphering primary production in the geologic past. Other than coccolithophorids, however, marine and nonmarine microbes have very similar uses for the common ions found in seawater.

But a defining feature of marine microbes is their capacity to grow in saltwater. Although bacteria had been isolated from seawater since before Zobell (1946), their great similarity to nonmarine strains raised doubts of whether there were any bacteria unique to oceanic environments (115). The growth of a microbe in seawater, per se, is insufficient evidence to conclude that it is truly marine; even *E. coli* grows in otherwise sterile seawater (116). Unlike other microbes, however, marine bacteria lyse when salt concentrations are dropped below seawater concentrations, although some strains can adapt and grow slowly in as low as one-tenth oceanic concentrations (115). In some strains, NaCl is required and cannot be replaced by Li^+ or Br^+ (115). In any case, the requirement for these salts was used to demonstrate that truly "marine" bacteria existed and that bacteria found in the oceans had not just washed in from land or freshwater.

CONCLUSION

The similarities in the inorganic nutrient needs of marine and nonmarine microbes are more striking than the differences. Both groups of microbes require and are composed of the same elements. On the basis of the few studies with relevant data, the mechanisms of uptake are similar for all microbes. What may differ are the kinetic parameters and regulation of the acquisition mechanisms. Unlike laboratory cultures and many nonmarine environments, concentrations of nearly all inorganic nutrients and organic compounds are very low in the oceans. Even the most productive regions have pico- to micromolar concentrations of key inorganic nutrients and organic substrates. These low concentrations and the complexity of the oceanic chemical environment may select for suites of regulatory mechanisms that differ from those observed to date in laboratory-reared microbes. More studies of marine bacteria growing on the vanishing low concentrations found in the open oceans may reveal new uptake mechanisms and regulatory pathways not seen in microbes from other environments.

Marine microbes may also teach us more about the evolution, biochemistry, and physiology of trace elements in biological systems. The extremely low concentrations of elements such as iron and molybdenum probably select microbes with enzymes that replace scarce metals with more abundant ones, for example, manganese for iron in the case of superoxide dismutase. The biochemical role of various metals in enzymatic reactions is also illuminated by comparing tungsten and molybdenum-containing enzymes, for example. Nature has already conducted the experiments to examine the impact of these switches, but now more work is needed to decipher the results.

The study of marine microbes provides more than just new models of regulation pathways or novel insights into biochemical reactions. The various inorganic nutrients discussed here are essential for microbial growth in the oceans. Understanding the acquisition and fate of these nutrients will also help us understand the ecology and biogeochemistry of the basis of oceanic life, the microbes.

Acknowledgments

I thank George Luther for providing information about trace metal chemistry and Charles Trick and especially David Hutchins for their comments and input. Preparation of this article was supported by NSF grants.

Richardson
Dallas, Texas

Simply defined, microbial insecticides consist of a single microorganism or several microorganisms or metabolic end product(s) as the active ingredient. Microbial insecticides control a variety of insect pests, although each separate microorganism or by-product is relatively specific for its target pest(s). They may be used to control insects by inducing diseases in target insects, or to suppress the population of insects directly or in combination with chemical insecticides. All types

of microorganisms are represented among the potential microbial control agents.

There are more than 2,000 naturally occurring microorganisms or their products, which hold promise for the control of major insect pests. Microorganisms that affect insects are termed *entomopathogens*. More than 100 species of bacteria and more than 1,000 viruses have been isolated from arthropods and more are being discovered every year. All classes of fungi are represented among the 750 known entomopathogenic fungi. Protozoa are also likely candidates as microbial control agents, because many insects not attacked by other entomopathogens are susceptible to at least one of the 300 known species of entomophilic protozoa.

Among the known microbial species with insecticidal action, the most widely used and appreciated microorganism is the ubiquitous soil bacterium *B. thuringiensis*. In fact, use of microorganisms as biological pest control began with the recognition of *B. thuringiensis* as an entomopathogen (1). *Bacillus thuringiensis* has been used for more than 40 years as a microbial insecticide to control numerous pests and vector insects, which have importance in agriculture, forestry, and medicine, and it is proven to be one of the most effective, safe, and intensely used biological pesticides. There are more than 30 species of microorganisms registered by the U.S. Environmental Protection Agency (EPA) and most of them are subspecies of *B. thuringiensis* carrying different Cry toxin genes. Extensive information regarding the scientific, economic, and regulatory issues relating to *B. thuringiensis* and its toxins is available. There are reviews emphasizing the development of *B. thuringiensis*–based biopesticides and the utility of *B. thuringiensis* toxins in transgenic plants for field crop protection against pest insects (see Additional Reading).

The aim of the this article is to summarize (*1*) the importance of microbes and their toxins as insecticides, with particular emphasis on Cry toxins of *B. thuringiensis* as insecticides, (*2*) recent and emerging insights into understanding Cry toxin receptors and insect responses to toxins, (*3*) mechanisms and effects of resistance to Cry toxins, and (*4*) future trends.

PRODUCTION TECHNOLOGY

Entomopathogens are produced in living insects, in cell/tissue cultures and by fermentation methods. Fermentation technology is used for some bacteria and fungi, whereas, living insects are used for the production of obligatory parasitic viruses and protozoa. Both processes have been successfully used to produce commercial entomopathogenic products. Submerged fermentation, generally, is used for the commercial production of *B. thuringiensis* and *B. sphaericus* and the fungi *Beauveria bassiana* and *Entomophthora virulenta*. Surface fermentation is employed to produce pathogenic fungi such as *Nomuraea rileyi* and *Metarrhizium anisopiliae*, and a combination of both surface and submerged techniques can be used for *B. bassiana* and *Hirsutella thompsonii*. Living insects are used almost exclusively as substrates for the production of the respective nucleopolyhedrosis viruses of *Heliothis zea*, *Porthetria dispar*, and *Hemerocampa pseudosugata*. Recent developments in cell and tissue culture methods have made their use more practicable and efficient for mass production of a number of entomogenous viruses. A book on the formulation of microbial pesticides has been written (2).

SAFETY AND SPECIFICITY

Entomopathogens are infectious, replicating living organisms that are a natural part of our environment. Evidence that microbial insecticides pose little human or environmental hazard has been demonstrated by laboratory animal testing data developed to support federal pesticide registration. Nevertheless, safety cannot be absolutely guaranteed for all entomopathogens in every living system, and it is important that potential hazards for new entomopathogens be known before their use. The EPA has listed several advantages of microbial insecticides that include the following: (*1*) usually, inherently less harmful than conventional pesticides, (*2*) generally, affect only the target pest and closely related organisms, in contrast to broad spectrum, conventional pesticides that may affect organisms as different as birds and mammals, (*3*) often, are effective in very small quantities and often decompose quickly, thereby resulting in lower exposures and largely avoiding the pollution problems caused by conventional pesticides, and (*4*) when used as a component of Integrated Pest Management programs, they can greatly decrease the use of conventional pesticides, whereas crop yields remain high.

No deleterious effects at normal field-use rates have been reported in tests with a number of bacteria such as the gram-positive sporeformers *B. thuringiensis*, *B. sphaericus*, *Bacillus subtilis*, *Bacillus popilliae* and *Bacillus lentimorbus*, and the gram-negative nonsporeformers *Agrobacterium radiobacter*, *Streptomyces griseoviridis*, and several species of *Pseudomonas*. Baculoviruses do not appear to replicate in vertebrate embryos or in cell lines derived from birds, fishes, amphibians, and mammals. Although allergens are encountered among the fungi, including *Beauveria*, *Entomophthora*, *Hirsutella*, *Metarrhizium*, and *Nomeraea* species, these fungi are not toxic or infectious to vertebrates. Entomopathogenic protozoa infectious to grasshoppers, for example, *Nosema locustae*, to mosquitoes, for example, *Nosema algera*, and to beetles, for example, *Mattesia trogodermae*, are not infectious to nontarget organisms, including vertebrates.

EFFICACY

Entomopathogens are effective variably against a number of diverse insects including mites, ticks, mosquitoes, black flies, sand flies, grasshoppers, beetles, and moths, among others. Microbial insecticides, like chemical insecticides, usually are sprayed or dusted on agricultural crops, stored products, forest trees, ornamental trees, and shrubs, and in aquatic habitats for mosquito control. Entomopathogens may also be successfully introduced and established in an ecosystem by other application methods to provide

long-term control of pest populations. Examples are (*1*) insects themselves that can be used to disseminate the entomopathogens, (*2*) transgenic insect-resistant plants, and (*3*) microbial materials harboring genes that encode toxic end products, such as the insecticidal proteins of *B. thuringiensis*.

Virus or fungus epizootics might be induced in an insect population before crop-damaging proliferation takes place. It is possible in some instances to manipulate the environment to create conditions in which naturally occurring pathogens exert their greatest effect. Some of the approaches may provide levels of control equal to or better than those currently obtained with chemical insecticides.

The development and use of entomopathogens or their by-products as microbial control agents are rapidly increasing in popularity worldwide among environmentalists, industrialists, scientists, users and consumers, and government policy makers. Unfortunately, their commercial development and use is underexploited.

VIRUSES

More than 1,000 viruses have been isolated from insects. Most of these viruses (>85%) have been isolated from moth and butterfly larvae, which represent some of the most serious economic pests. Insect viruses are grouped into five major categories: (*1*) nucleopolyhedrosis viruses (NPV), (*2*) cytoplasmic polyhedrosis viruses (CPV), (*3*) granulosis viruses (GV), (*4*) entomopox viruses (EPV), and (*5*) noninclusion viruses (NIV). The most promising candidates are the NPV and GV because of their specificity, safety, virulence, and stability. No representative of the CPV, EPV, and NIV have been registered for commercial use by the EPA.

Insect viruses are strict parasites and must be mass-produced in living hosts or cell/tissue cultures. The standard protocol entails rearing the host insect and producing the virus by artificial infection, harvesting the virus, and formulating an effective insecticidal preparation. Obviously, such a process is labor-intensive and costly. However, some recent advances in tissue/cell culture and recombinant DNA technology may allow for the efficient in vitro production of insect viruses, thus reducing the manufacturing costs normally associated with in vivo production.

FUNGI

As is true for the viruses, there are more than 1,000 fungal species, representing at least 100 genera, which have been reported to infect insects. Nearly all major fungal groups are represented, as is virtually every kind of insect. The EPA for commercial use has authorized approximately 15 species. The production of fungi varies from growing them in laboratory media to harvesting the organisms from their natural substrates. In short, fungi can be produced in virtually any locale with technology geared to available facilities and personnel. Because fungi are slow acting, requiring up to 10 days to kill their hosts, attention has been directed toward identifying and purifying metabolites and by-products, which have insecticidal activity. Often, these compounds are quick acting and can be formulated in much the same way as chemical insecticides. Safety considerations, however, are of the utmost concern because many fungal metabolites are carcinogenic and allergenic.

PROTOZOA

Although the majority of protozoa are free-living, many are intimately associated with insects, in relationships ranging from compatible to harmful. Most of the approximately 300 described species of entomophilic protozoa are included in the orders Microsporidia (Subphylum Cnidospora) and Neogregarinida (Subphylum Sporozoa). Microsporidia, particularly common in insects, generally possess the greatest potential for use as control agents. Among the microsporidia, the genus *Nosema* contains most of the promising entomopathogens. Some species are pathogenic to grasshoppers, crickets, mosquitoes, and various caterpillars.

The biggest obstacle to using protozoa as insecticides is that they must be produced in living hosts. The primary hosts are generally used to produce spores, although alternate hosts sometimes can be used. Most protozoa are relatively host-specific, although some have a fairly expansive host range. For example, more than 60 species of grasshoppers and crickets are susceptible to *N. locustae*. Plants, human beings, and animals seem to be resistant to infection by insect protozoa.

Few field studies of protozoa as insecticides have been conducted. Most protozoa are considered more suitable for long-term suppression programs. The slower, debilitative effects of chronic infections, such as reduced fertility and shortened life span, generally preclude their widespread use as quick-acting agents. A comprehensive review of entomogenous protozoa and fungi has been written (3).

BACTERIA

Many bacteria are associated with insects, most of which belong to the families Pseudomonadaceae, Enterobacteriaceae, Lactobacillaceae, Micrococcaceae, and Bacillaceae. Members of these families may be obligate or opportunistic entomopathogens, depending on their host association in nature. Obligate entomopathogens, generally, are fastidious and are restricted to growth in a living host insect. The occasional or opportunistic pathogens are free-living in nature, although they commonly may be found associated with one or more hosts. About 200 bacteria have been reported as entomopathogens, but only a few, including *B. thuringiensis*, *B. popilliae*, *B. lentimorbus*, and *B. sphaericus*, have been closely examined as insect-control agents. These species are sporeformers, the first two produce, in addition to the spore, discrete parasporal crystalline inclusions within the sporulating cell, the last two do not.

Fermentation processes are employed in the production of *B. thuringiensis* and *B. sphaericus* spores, whereas *B. popilliae* and *B. lentimorbus* are produced exclusively in living insects. Two types of fermentation methods are used

for the production of *B. thuringiensis* and *B. sphaericus*, namely, surface or semisolid and submerged. For the in vivo production of *B. popilliae* and *B. lentimorbus*, third instar Japanese beetle (*Popillia japonica*) larvae are infected with spores and incubated in soil seeded with rye to feed the larvae. The infected larvae are harvested 1,621 days after infection. Living insects must be used to propagate these bacteria because artificial culture methods, which will support cost-effective, large-scale sporulation of *B. popilliae* and *B. lentimorbus*, have not yet been developed.

Bacillus thuringiensis, *B. popilliae*, *B. lentimorbus*, and *B. sphaericus* have been subjected to many safety tests, which had no harmful effects on animals or human beings. Furthermore, commercial applications of various formulations of these four bacillus species have been used for insect control worldwide for the past 15 to 30 years without any documented report of adverse effect on humans and animals, nontarget organisms, or the environment. In other words, these particular microbial insecticides have withstood the tests of time and utility.

BACILLUS THURINGIENSIS

Bacillus thuringiensis is a ubiquitous bacterium and has been isolated from a variety of ecological niches including soil, stored grain, insect cadavers, and plant surfaces. It is a spore-forming bacterium characterized by the production of parasporal protein crystals along with the spore. It is likely that production of the crystal proteins during sporulation provides a means for the bacterium to replace water during spore formation and afford a survival advantage by exerting lethal action on target insects that, in turn, can provide sufficient nutrients to allow germination of the dormant spores and their return to vegetative growth. The toxic crystalline proteins are referred to as "Cry toxins" (4) and are of great agronomic importance and scientific interest. Mixtures of *B. thuringiensis* spores and parasporal crystal are used in a variety of formulations as biological insecticides. Furthermore, Cry toxin genes have been expressed in transgenic plants to render crops resistant to insect pests. Transgenic maize, cotton, and potato carrying certain *cry* genes have been introduced for large-scale cultivation, and, since 1996, both the U.S. and the worldwide market shares of these and other transgenic crops has increased.

CRY TOXINS

To date, 89 different genes encoding crystal proteins have been cloned from *B. thuringiensis* and two other species. A given strain may produce single or multiple Cry toxins in various crystal formations. For example, a new subspecies of *B. thuringiensis* (Fig. 1) has been isolated in Egypt, which contains at least 15 *cry* genes. The genes for Cry toxins can be found both on plasmids and on chromosomal DNA. Individual Cry toxins have highly specific insecticidal activity, usually restricted to a few species within one particular order of insects. To date, toxins for insect species in the orders Lepidoptera (butterflies and moths), Diptera (flies and mosquitoes), Coleoptera (beetles and weevils), and Hymenoptera (wasps and bees) have been identified. A few toxins have an activity spectrum that spans two or three insect orders. The most recent Cry toxin nomenclature (5) is based on comparative amino acid sequence identity, molecular mass, and toxicity.

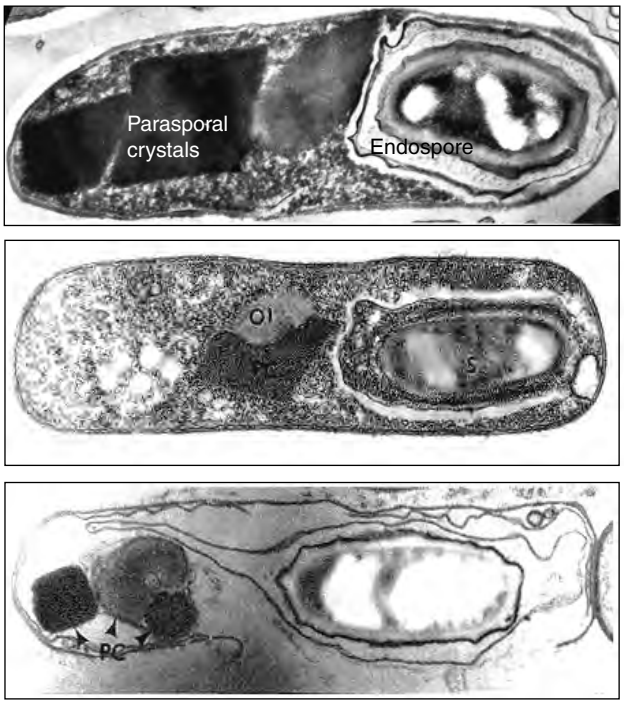

Figure 1. *Bacillus thuringiensis* spores and parasporal crystals. The bacterium has a life cycle, which includes vegetative growth and sporulation. The spore is the dormant stage of the organism and can withstand adverse environmental conditions, including extreme heat and low humidity. The transmission electron micrographs of sporulating *B. thuringiensis* subspecies (from top): *aegypti*, *berliner*, and *israelensis* reveal parasporal crystals (PC) lying adjacent to the endospore (S) of all three subspecies. The crystals vary in size, shape, and number and are composed of protoxin proteins that are expressed by *cry* genes. The outer coat of the spores also contains protoxin protein, which is insecticidal. Subspecies *aegypti* harbors 15 different *cry* genes, rendering entomopathogenic activity against three different orders of insects, Diptera, Coleoptera, and Lepidoptera. Subspecies *berliner* and *israelensis* produce cry toxins effective against moths and beetles, respectively.

The parasporal crystals of the different subspecies of *B. thuringiensis* all contain protoxins (ca. 70,140 kDa) that are single repeating subunits, which are converted, on activation, to lower molecular weight (ca. 6,067 kDa) toxins. Parasporal crystals associated with endospores of three different species of *B. thuringiensis* with different host insect range specificities are provided in Figure 1. For *B. thuringiensis* subsp. *tenebrionus*, the protoxin is a 72-kDa protein, which is converted to a 67-kDa toxin, whereas the protoxin of *B. thuringensis* subsp. *berliner* is a 130-kDa protein that, on activation, produces two molecules of about 65 kDa. One of these conversion products is protease-resistant and is toxic, whereas the other protein

is protease-sensitive and is not toxic (Fig. 3). The tertiary structures of Cry 3A, Cry1Aa, Cry2Aa, and Cry3Bb1 toxins have been elucidated (6–9). The Cry3A toxin of subspecies *tenebrionis*, the Cry3Bb1 toxin of subspecies *tolworthi*, and the Cry1Aa and Cry2Aa toxins of subspecies *kurstaki* bind to specific receptors located in the epithelial cells that line the midgut of a number of susceptible insects, including beetles by Cry3A and Cry3Bb1, moths by Cry1Aa, and both moths and mosquitoes by Cry2Aa.

CRY TOXIN RECEPTORS

Although most of the Cry toxins described in the literature exert highly specific activity toward insects in the orders Lepidoptera, Diptera, and Coleoptera, there also are reports of other isolates of *B. thuringiensis* active against other insect orders, including Hymenoptera, Homoptera, Orthoptera, and Mallophaga, and against nematodes, mites, and protozoa. Apparently, they are not effective against other nontarget organisms, including humans and animals. The toxicity and specificity of *B. thuringiensis* Cry toxins correlates directly with the binding of toxins to the epithelial cells that line the midgut of susceptible insects. The interaction of toxins with the midgut surface brings about distortion, enlargement, and detachment of the epithelial cells (Fig. 2), leading to devastation of the midgut tissue (Fig. 3) and death of the insect (Fig. 4).

Specific high-affinity receptor molecules that line the midgut epithelium of susceptible insect larvae mediate the lethal action of the *B. thuringiensis* Cry toxins. For example, the tobacco hornworm *M. sexta* contains a high-affinity receptor, BT-R_1, for the Cry1A toxins of *B. thuringiensis* (10). Both the cloned and natural BT-R_1 have high affinity ($\sim$ 1 nM) and specificity for the Cry1A family of toxins, all of which are extremely toxic to the tobacco hornworm. Expression of BT-R_1 is tissue-specific and only the epithelial cells of *M. sexta* midgut tissue harbor BT-R_1 mRNA and its translated protein. On the basis of the deduced amino acid sequence and predicted molecular structure, BT-R_1 is a 210-kDa membrane glycoprotein (Fig. 5) composed of four domains, ectodomain (EC), membrane-proximal extracellular domain (MPED), transmembrane domain (TM), and cytoplasmic domain (CYTO). The ectodomain consists of 12 cadherin repeats composed of β-sheets that are structured as ectodomain modules (EC1 through EC12).

The expression profile and structural features, along with the protein-domain architecture of BT-R_1, indicate that the protein is important in specific cell-to-cell adhesion events in the insect midgut. Most probably, the molecule has heterophilic interaction with other cell adhesion molecules. Toxin binding involves protein-to-protein interactions and appears to concern multiple structural determinants on both toxin and receptor, possibly intervening with the function of the receptor and disrupting cell-to-cell attachment and structural integrity of insect midgut epithelium. Indeed, the histpathological changes associated with *M. sexta* midgut epithelial cells exposed to Cry1Ab toxin support the notion that the pathological symptoms of Cry toxin exposure involves adverse effects brought about by dysfunctional cell adhesion (Fig. 2). Recruitment of cadherin receptors by *B. thuringiensis*

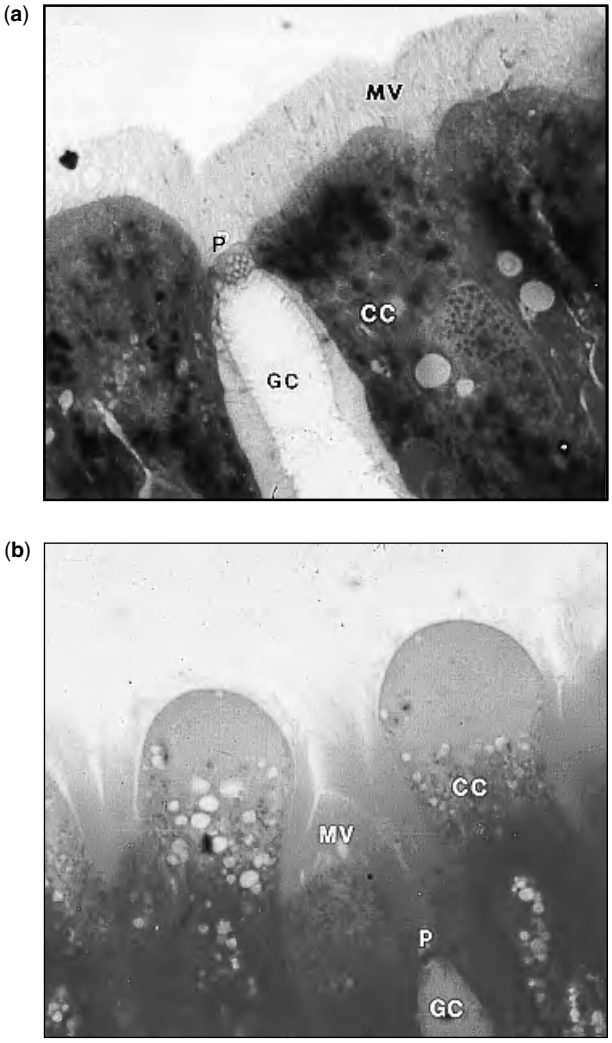

Figure 2. Effects of Cry1Ab toxin on *Manduca sexta* midgut epithelium. The midgut of insect larvae is a tube lined with columnar epithelial cells (CC). The apical ends of the midgut epithelial cells contain microvilli (MV) and this surface appearance is referred to as a *brush border*. Another type of cell that is present in the midgut is the goblet cell (GC). Goblet cells are intercalated with the columnar epithelial cells. Goblet cells contain a pore (P) at their apical ends through which enzymes and ions are secreted into the midgut. All cells that are facing the inner cavity of the midgut are attached to a basal membrane, which surrounds the tissue. The normal morphological features of the midgut epithelium change dramatically in about 1,530 minutes when a susceptible insect ingests Cry toxin. Micrographs of longitudinal sections of healthy (Panel A) and intoxicated (Panel B) midgut tissue from fourth instar *M. sexta* larvae show the morphological changes in the epithelial cells. On exposure to Cry1Ab toxin, the columnar cells swell and lose their microvillar structure, whereas the goblet cells do not appear to be affected, suggesting that toxin receptors are specifically expressed on the epithelial cells. Apical cell membrane distortion and total cell disruption occurs within one hour of intoxication, leading to devastation of the midgut tissue and death of the insect. See color insert.

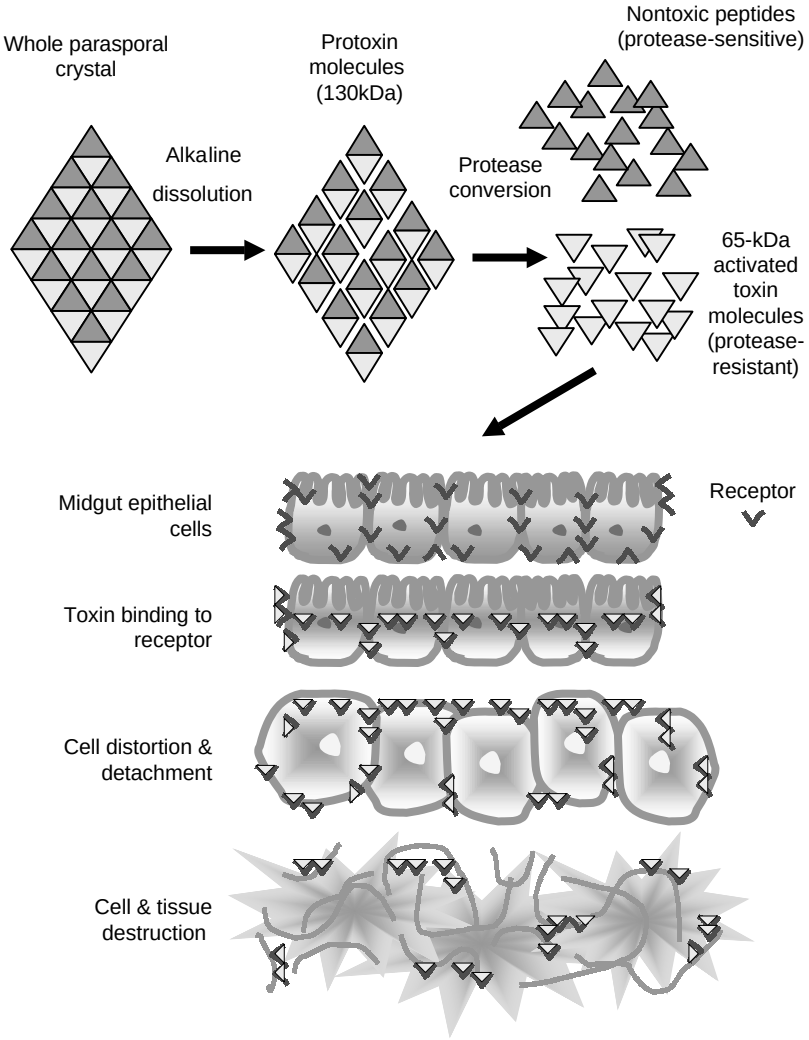

Figure 3. Activation of parasporal crystals and receptor mediated toxicity of Cry proteins. The entomopathogenic activity of *B. thuringiensis* mainly resides in the parasporal crystals that are composed of protoxin protein molecules. Following ingestion by a target insect, the protoxin is solubilized and converted to active toxin that binds to specific receptors on the surface of midgut epithelial cells. Both the specific physiological environment and the activity of proteolytic enzymes in the midgut of susceptible insects are involved in protoxin activation. Protoxin activation generates two polypeptide fragments, one that is hydrolyzed by midgut proteases and one (activated toxin) that is quite resistant to proteolytic attack in the target insect. Toxin binding to specific receptors on the epithelial cells brings about distortion, enlargement, and detachment of the cells, leading to devastation of the midgut tissue and death of the insect. Specific receptor-toxin interactions also determine the range of insect species killed by individual subspecies of *B. thuringiensis*. See color insert.

Cry toxins appears to be similar to that observed for certain other bacteria, such as *Clostridium perfringens* and *Listeria monocytogenes*, in which these pathogens target cell-to-cell and cell–matrix interactions of their host cells. It is intriguing that the Cry1A toxins of *B. thuringiensis* recruit a molecule related to cell adhesion, which is essential for a diverse range of functional properties including differentiation, growth, cell migration, and development. Certainly, *B. thuringiensis* Cry toxin receptors are pivotal to understanding insect responses to the entomopathogen and to developing new biorational insecticides.

BT-R_1 of the tobacco hornworm *M. sexta* is the first receptor cloned and characterized for the Cry1A toxins of *B. thuringiensis* (11). Since then, homologous cadherin receptors have been identified and studied in other insects. In addition to cadherin receptors for Cry toxins, several 120-kDa Cry toxin-binding proteins also have been identified in some lepidopteran insects. These proteins, in fact, exist as multiple forms of a ubiquitous gut protease, aminopeptidase N (APN). Although APN interacts with Cry toxins and is an important component of the insect midgut surface, APN's do not serve as functional receptors to mediate toxicity of Cry proteins. On the other hand, BT-R_1 and related homologous cadherin receptors for the Cry proteins are linked directly to toxicity exerted by the Cry toxins. Indeed, heterologous expression of BT-R_1 on the surface of both insect and mammalian cells mediates the toxicity of the Cry proteins, providing strong support to the idea that cadherin receptors are involved in cytotoxicity and insecticidal action of Cry toxins.

INSECT RESISTANCE TO MICROBIAL INSECTICIDES

One of the most desired goals for the utilization of *B. thuringiensis*–based insecticides is to replace most chemical pesticides. Because the binding of *B. thuringiensis* toxins to high-affinity receptors in insect midgut is critical to insecticidal activity of the toxins, the means for developing new and improved *B. thuringiensis*–based insect-control agents relies on understanding the mode of action of the toxins and how insect receptor molecules for the toxins mediate toxicity. Therefore, identification of Cry toxin receptors and understanding the mechanism of cytotoxicity will facilitate the design of novel

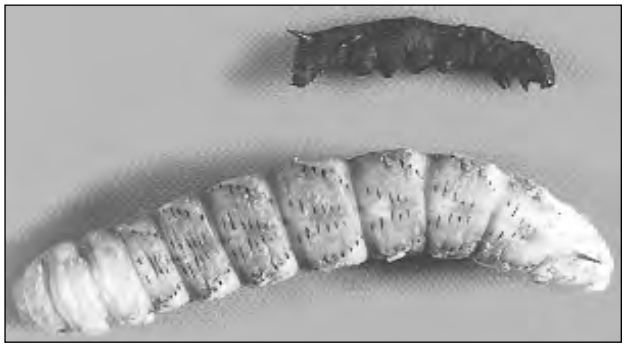

Figure 4. Effect of Cry1Ab toxin of *B. thuringiensis* on *M. sexta* larva. *Bacillus thuringiensis*–based insecticides are applied much like synthetic insecticides. Such insecticides are inactivated within a few days in most outdoor situations compared with the long-lasting presence of many chemical insecticides. Soon after ingesting whole cells of *B. thuringiensis* or activated toxin, susceptible insect larvae are poisoned and they stop feeding. If the appropriate amount of material is applied at the right time, the immediate and highly selective effect of *B. thuringiensis* is realized. *Manduca sexta* larvae feeding on a normal diet are large and green in color. Larvae that have consumed Cry1Ab toxin turn black and usually die immediately or within a couple of days after sepsis. Vegetative cells of *B. thuringiensis* may multiply in the infected host, however, without producing abundant spores or parasporal crystals. The end result is that no infective units are released into the environment when a poisoned insect dies. Until the early 1980s, commercial *B. thuringiensis* products were effective only against caterpillars. However, strains that kill not only caterpillars but also several other types of pests have been identified and developed for commercial use. New isolates of *B. thuringiensis* with new Cry toxin variants will increase the spectrum of pests that can be controlled. See color insert.

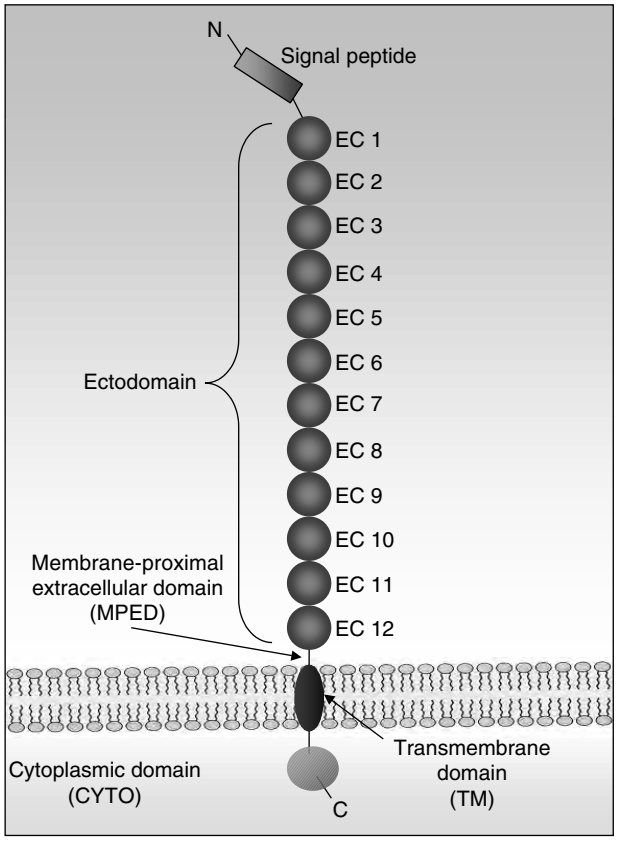

Figure 5. BT-R_1, the cadherin receptor of *M. sexta* for Cry1A toxins. On the basis of the predicted amino acid sequence, the BT-R_1 receptor (210 kDa) is composed of four domains: (*1*) ectodomain (EC), (*2*) membrane-proximal extracellular domain (MPED), (*3*) transmembrane domain (TM), and (*4*) cytoplasmic domain (CYTO). Downstream of a membrane signal sequence, the ectodomain consists of 12 cadherin repeats composed of β-sheets that are structured as ectodomain modules (EC1 through EC12). The ectodomain harbors putative molecular adhesion sequences. The structural features along with the protein-domain architecture indicate that BT-R_1 is a new type of heterophilic cadherin with a close relationship to protocadherins in the cadherin superfamily. The Cry1A toxins of *B. thuringiensis* bind to BT-R_1 with high affinity and specificity. Most probably, toxin binding adversely affects the structure and function of BT-R_1, consequently, compromising the integrity of the midgut epithelial cells that express the receptor molecule. See color insert.

insecticidal agents with higher affinity to receptor(s) and with the desired specificity against targeted insects. Furthermore, insects exhibiting resistance to particular Cry toxins have reduced or no binding capacity for the toxins, underscoring the importance of identifying additional toxin receptors and advancing our knowledge of toxin-receptor interactions. Such knowledge most assuredly will aid our understanding of why insects become resistant to *B. thuringiensis* and how this problem can be circumvented for the continued usage of this entomopathogen as an effective and safe biological control agent. Unfortunately, the widespread and intensive use of Cry toxins commercially to control agriculturally and industrially important insects have increased the possibility of the development of insect resistance to *B. thuringiensis*. In fact, there is a growing list of field-selected and laboratory-selected insect species, including the diamondback moth, the Indianmeal moth, the Colorado potato beetle, the cotton leafworm, the beet armyworm, the tobacco budworm, and the European corn borer, all of which exhibit varying degrees of decreased susceptibility to the Cry toxins.

One contributing mechanism of resistance to Cry toxins is the decrease in the receptor binding to toxin in the insect midgut. Epithelial cells in the midgut tissue of resistant insect strains retain their structural integrity on exposure to Cry toxin action, whereas the toxin devastates the midgut tissue of susceptible insects. Also, changes in physiological and proteolytic activities in the midgut of susceptible species are implicated in resistance to Cry toxins. Overall decreased receptor binding and alterations in the composition and activity of midgut proteases are correlated with the resistant state in the midgut epithelial tissue, implicating the involvement of adaptive responses in the resistance phenomenon.

Microorganisms share common strategies to overcome their hosts during pathogenesis. One common strategy is to make effector molecules that interact with specific receptor molecules in the respective host to mimic, suppress, or modulate host pathways and to enhance pathogenicity, thus rendering survival advantage to the

pathogen. However, the interactions of pathogens trigger innate defense reactions in the host cells. These innate cellular defenses consist of nonspecific responses and are found in organisms ranging from plants to humans. In particular, insects, which do not produce antibodies and T cells to combat microbial challenges, rely mostly on innate cellular responses to defend themselves against invading microbes and their toxins. Constant interaction with microorganisms and molecules has necessitated the evolution of innate defense mechanisms to guard the insect against invasion by pathogens while tolerating normal microbial flora and a plethora of potential antigens present in food. In fact, the interactions with pathogenic microorganisms generate evolutionary forces aiming to destroy an endless race among species to find new ways to become refractory to microbial challenges (Fig. 6). In this race, innate responses are significant, because they not only determine the outcome of microbial challenges at the first site of pathogen contact or attack, but they also are involved in information relays inherent in adaptive immunity as well. The innate defenses against unwelcome microbes and antigens include rapid-acting responses such as secretion of small antimicrobial peptides and adaptive changes that modulate cell surface and activity. The innate responses triggered on the surface of midgut epithelial cells, in turn, promote special physiological adaptations on the cell surface that somehow protect the cell against foreign invaders. Most often, these reactions sustain cellular adaptation on prolonged exposure to microbial activity or other stress conditions and, eventually, lead to resistance, or, in some instances, cell death.

There appears to be two levels of adaptive responses in insects that bring protection against the lethal action of Cry toxins. The first level involves changes in the profile of midgut proteases that physiologically position the tissue for response to toxin stress. The second level involves adaptive responses that can be genetically transmitted to progeny insects for future survival advantage. The innate responses and adaptive changes in the insect midgut epithelium and their functional involvement in rendering immunity to *B. thuringiensis* toxins is fundamentally important in explaining resistance. Indeed, elucidating the mechanism(s) of how midgut epithelium cells in resistant insects avoid toxin binding is critical in understanding insect resistance.

To date, the control of pest insects by microbial insecticides represents the most successful biological control strategy. However, the emergence of insect populations resistant to biological insecticides raises significant concerns. Like global warming, the resistance phenomenon may be part of the reason for the recent increase in insect infestations worldwide. These factors necessitate a fundamental understanding of insect responses to microorganisms. Certainly, the continued and improved use of microbial insecticides depends on progress in several areas, including identification of insect receptors of microbial toxins, elucidating their mode of action in mediating toxicity, and understanding how microorganisms design entomopathogenic actions. Diverse, natural microbial products and genetically engineered materials should

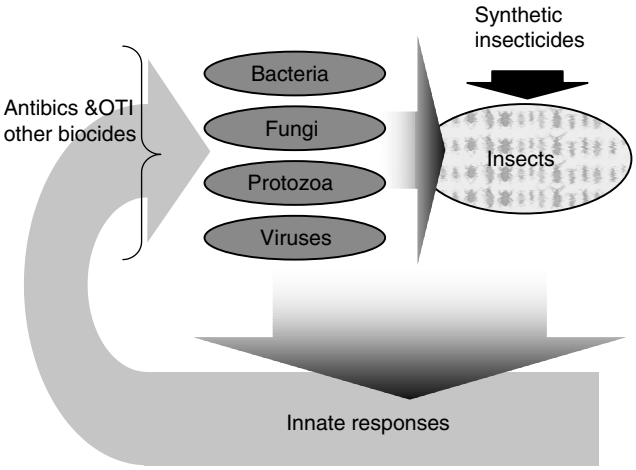

Figure 6. The relationship between innate responses and resistance to microbial insecticides. Innate cellular defense involves nonspecific responses found in organisms ranging from plants to humans. Invertebrates, including insects, do not produce antibodies and T cells to combat microbial challenges, as do vertebrate animals and humans. Instead, they rely primarily on innate responses to defend themselves against biological challenges. Constant contact of epithelial cells in the mucosal linings of animals harboring various microbes, and a large number of diverse antigens, has brought about the evolution of innate defense mechanisms. Innate responses are first-line cellular defenses and are pivotal to protecting an organism from potential invasion by various pathogens, while tolerating an indigenous microbial flora and a plethora of antigens commonly present in different food sources. Furthermore, information relays between innate defense reactions and adaptive protective devices now are appreciated as ancient evolutionary conserved immune responses. In fact, since the discovery of antimicrobial activities in the cabbage looper *Hyalophora cecropia*, studies of the fruit fly *Drosophila melanogaster* and mosquitoes have revealed notable conservation of innate defense mechanisms in both insects and mammals, especially in mucosal epithelia. Some innate defense mechanisms that guard against unwelcome microbes and antigens respond rapidly and promote adaptive functional changes, including the expression of those molecules that modulate various cell surface activities. The responses are triggered on the surface of epithelial cells on recognition of particular molecular motifs by certain surface receptors. Communication with signaling pathways promotes special physiological adaptations to the cell surface that somehow protect the cell against foreign invaders. Most often, these reactions sustain cellular adaptation on prolonged exposure to microbial activity or other stress conditions and eventually lead to resistance. However, the quick evolution of microbial pathogens is a potential for overcoming such resistance, generating natural competition involving continual challenges and responses that lead to resistance development among species. For instance, widespread commercial use of *B. thuringiensis* Cry toxins to control pest insects has produced insects that are resistant to this entomopathogen. Moreover, chemical insecticides stress insect populations forcing many individuals to acquire an enhanced detoxification capacity and increased state of resistance, raising the potential for insects to become refractory to multiple insect-control agents. Therefore, it is crucial to implicate integrated pest management strategies with microbial insecticides and chemical-based pesticides to gain the greatest possible benefits. See color insert.

provide sufficient biological resources to safely and effectively control pest insects now and in the future. However, new discoveries and development efforts are needed to meet the complex challenges in agriculture, medicine, and industry because insects have the uncanny ability to cope with newly designed insecticides regardless of their origin or creation.

SUSTAINABLE AGRICULTURE, HEALTH, AND ENVIRONMENT

Agriculture is fundamental to human society and it significantly contributes to the advancement of other industrial technologies. Sustainable agriculture refers to the means used to maintain yields and quality of crops while reducing potential threats to public health and the environment. One overriding concern related to sustainable agriculture is the use of chemical pesticides. The comprehensive knowledge gained by the research of soil, water, genetics, biochemistry, and population dynamics indicates that synthetic chemicals pose a major threat to both human health and the environment. Obviously, reducing our dependence on chemicals by introducing new, improved biological control agents and strategies is critical to sustain agriculture.

Microorganisms are essential for the makeup of the earth's ecosystems. Microbes can be pathogenic, parasitic, mutualistic, or existent in a variety of other symbiotic relationships. A number of microorganisms and their ecological relationships have been studied and the knowledge gained from studying these associations have contributed to our understanding of the importance of beneficial microorganisms in agriculture and medicine. Applications of this knowledge include disease and pest control, proper recycling of nutrients, and environmental remediation. For example, biological agents derived from certain microorganisms for the control of pests, pathogens, and weeds to reduce dependence on chemical treatments are important for human health, management of biological diversity, and habitat conservation. There is an arsenal of disease-and pest-resistant genes and useful microbes, which can be used for agricultural, biomedical, and industrial purposes. Thus, it is critical to understand and intelligently manage the diversity and complexity of microbes involved in helping maintain all sustainable systems. More reliance on natural systems and less on synthetic products for pest and disease control, to sustain suitable crop yields, is the watchword for the future health and well-being of human kind. Certainly, biotechnological advances hold promise in delivering appropriate, rational solutions to manage sustainable ecosystems. The technological scenario includes microorganisms for the creation of new products and processes, which are safe to users, consumers, and the environment.

Continued expansion of the use of *B. thuringiensis* and other microbial-based pesticides depends on progress made in a variety of research and development activities. In the case of *B. thuringiensis*, the search for new toxins continues to progress, and, so far, the discoveries have provided sufficient diversity to meet the challenge of field resistance. However, new scientific discoveries are equally important in developing new and improved insecticidal products. Also, insights into the basis of insect resistance to Cry toxins are essential as well. All in all, the continued use of microorganisms such as *B. thuringiensis* will require a combination of the discovery of new strains and new toxins, identification of target receptor molecules, and a fundamental understanding of the structural and functional relationships between toxins and their receptor molecules.

Bloemendaal, The Netherlands

"Just a glass of water! You see a glass in front of you, filled with pure water from a water supply. It is without taste and odor; it is clear; there is nothing remarkable in sight. Nonetheless, this glass contains a world of wonders (...). Although your eye presumably sees nothing but pure water, it is the residence of a large number of animals that are invisible to the naked eye, to which the glass is a large pool, a vast lake, a sea (...). However, drink it without concern: the little creatures are completely harmless and will, taken in by your body, soon have lost their lives."

These translated parts of a chapter of the *Reading Book for Primary Schools*, published in 1899 in The Netherlands (1), present a view on the significance of free-living invertebrates and protozoans in drinking water on health, that most likely is still valid for drinking water in developed countries in temperate zones. It, however, also emphasizes the unease that was and still is stirred in most drinking water consumers when confronted with the knowledge that "animals," although microscopically small, are emerging from their taps. When invertebrates emerge in a clearly visible form, it is not surprising that these animals usually evoke downright disgust. Man has learned to associate the presence of worms, insect larvae, and crustaceans in food and water with a diminished wholesomeness and, since the discovery of microorganisms as possible origins of diseases, with diminished hygiene. In many domestic situations, this association is justified and the presence of protozoans and invertebrates in drinking water in developing countries may be far from harmless.

The presence of invertebrates, being present in all natural freshwater habitats, is to be expected in most, if not all drinking water distribution systems in the world. Drinking water and the distribution systems by which it is supplied are not sterile, nor should they be. Adequate source water treatment and hygiene during operations will prevent contamination with pathogens and will limit multiplication of (micro)organisms in distribution systems. Free-living invertebrates should however be considered a natural part of the biocoenosis (i.e., an association of organisms forming a community) in drinking water supply systems. This contribution will discuss the significance of the presence of invertebrates and, briefly, free-living protozoans in drinking water and water supply systems, preceded by a summary of the significance of their parasitic relatives. The fact that monitoring of invertebrates is apparently not required by law anywhere is the probable cause of the relative scarcity of knowledge available on the subject. An overview of the most important taxa is presented, followed by an evaluation of ecological processes (immigration, survival, feeding, growth, and reproduction) and an impression of the abundance of invertebrates found in drinking water and mains. Finally, control strategies and benchmark values are presented.

SIGNIFICANCE

Parasitic Invertebrates and Protozoans

The WHO (2) assumes that pathogenic invertebrates only may be present in drinking water in Asia, Africa, and South America and only when contaminated surface water or groundwater is not treated prior to (distribution and) consumption. *Dracunculus medinensis* (Nematoda) and *Schistosoma* spp. (Platyhelminthes) are mentioned as the most important pathogens; other worms are considered of lesser or very little importance for drinking water. An infection by the guineaworm *D. medinensis* is considered the only disease transmitted exclusively by drinking water. The larvae reach the stomach of many millions of people via their intermediate hosts, some cyclopoid Copepoda [mostly *Mesocyclops* spp. (3)], and 5 to 10 million people are taken ill each year. The infection usually is not lethal, but the adult female can reach lengths of more than 50 cm in limbs (mostly the legs) and causes painful ulcers (from within). Cercaria (i.e., one of the larval forms) of *Schistosoma* spp. in most cases enter the human body via the skin during bathing or washing of clothes in contaminated water, snails being the intermediate hosts. Although infections may occur by the distribution of untreated surface water, most infections occur in wells and ponds. An estimated 200 million people are infected yearly by schistosomiasis and some die from this intestinal or kidney infection (2,4). In temperate zones as well, invertebrate parasites are known to be (possibly) waterborne, such as *Ascaris lumbricoides* (Nematoda) and nonhuman parasitic Schistosomatidae (Platyhelminthes). Outbreaks via drinking water have not been reported (5). However, the presence of parasitic Nematoda and other invertebrates in drinking water from surface water supplies may be a transmission route for plant diseases (6).

As for parasitic protozoans, the possibility of contamination of finished water with pathogenic protozoans such as *Entamoeba histolytica* has long been acknowledged, as well as the multiplication in drinking water distribution systems of free-living protozoans such as *Naegleria fowleri* and *Acanthamoeba* spp. that may be pathogenic under certain conditions (5,7). For a large part of the twentieth century, water supply utilities in most developed countries relied on the capacity of disinfectants — in most cases

chlorine, chlorine derivatives, or ozone — to inactivate pathogens in surface water treatment. The importance of multibarrier treatment to remove chlorine-resistant (oö)cysts of the pathogenic protozoans *Cryptosporidium* spp. and *Giardia* spp. from surface water and their high resistance to disinfectants became painfully clear in both small and large epidemics caused by their presence in drinking water at the end of the twentieth century in the United States and the United Kingdom (5,8–11). Other pathogenic protozoans (*Toxoplasma*, *Cyclospora*, *Microsporidium*) are possibly important for drinking water hygiene as well and are presently under scrutiny (5,11).

Invertebrate and Protozoan Hosts for Pathogens

As invertebrates may harbor pathogenic viruses, bacteria, and protozoans in and on their body, mostly in their digestive tracks, invertebrates resistant to disinfection may take these pathogens with them while penetrating drinking water distribution systems through treatment plants. Nematoda, in particular, have been under scrutiny and are still suspect, although their role in pathogen entry into drinking water has never been fully established. It has been suggested that small crustaceans and fly larvae could also affect microbiological safety by harboring pathogenic microorganisms in or on their body (12). No pathogenic bacteria or fecal coliforms could however be found associated with individuals isolated from drinking water (13), although midge fly larvae (Tipulidae) have recently been associated with the number of total coliforms in finished water of a groundwater treatment plant in Germany (14). Some protozoans have been shown to protect pathogenic bacteria from chlorination (15). *Legionella* bacteria may multiply in free-living amebae in distribution systems and also be protect by them from chlorination (16,17); *Acanthamoeba* spp. have been known to harbor *Mycobacterium* spp. and viruses, accentuating the public health importance of these organisms (5).

The significance of intermediate hosts in distribution systems as possible vectors for invertebrate parasites in temperate zones also has been suggested (18). Theoretically, the penetration of parasitic worms or their intermediate hosts into the distribution system cannot be excluded, for example, in the case of mains bursts and other situations in which the integrity of the system is impaired. The intermediate hosts may be infected with parasites and may survive in the distribution system. A small percentage of surface water Asellidae (Crustacea, Isopoda), for example, can be infected with the larvae of Acanthocephala, a group of parasitic worms that infect the digestive tract of vertebrates (19,20). Freshwater snails can be intermediate hosts of blood flukes (Schistosomatidae, Platyhelminthes) causing "swimmer's itch," and Copepoda may be intermediate hosts of parasites such as *Gnathostoma spinigerum* (Nematoda) and *Spirometra mansonoides* (Platyhelminthes) (5). Although finished water of treatment plants is microbiologically safe, chances that an infected intermediate host (*1*) penetrates into the distribution systems, (*2*) survives, (*3*) emerges from a consumer tap, and (*4*) can pass on the parasite to a human will have to be considered negligible.

Aesthetic Significance and Consumer Complaints

An anonymous pamphlet distributed in London in 1827 pointed out the presence of a large variety and quantity of invertebrates, protozoans, and algae in the Thames river water distributed for domestic use. The pamphlet drew public attention to the inlet being situated within three yards of one of the largest city sewer outlets (21). After the start of slow sand filtration in London in 1829 (21), an introduction of this technique throughout Europe followed, although many cities (partly) continued to be supplied with untreated surface water long after. The quality of the water in distribution systems subsequently improved greatly in Europe and the rest of the industrialized world in the nineteenth and twentieth century, causing a distinct reduction of drinking water-related outbreaks of microbiological diseases. Simultaneously, major changes took place in the invertebrate communities in distribution systems. However, at the same time, consumer expectations regarding water quality rose. The sudden infestations of invertebrates emerging from taps and the resulting consumer complaints have driven water utilities to despair. Presently, consumer complaints concerning invertebrates under normal conditions probably are not abundant in most distribution systems in developed countries, but there is little or no literature to corroborate this assumption. In The Netherlands (population 16 million), consumer complaints regarding invertebrates currently are estimated to be limited to an average of 10 each year, although there is no comprehensive overview available. In Antwerp, Belgium, complaints about Asellidae and Gastropoda emerging from taps were approximately 25 to 30 each year before major air-scouring mains started in 1975, reducing complaints to maximally one per year since 1985 (22). During a symposium on consumer complaints in 1965, the London Metropolitan Water Board disclosed that 160 (3%) of the complaints in the period between 1957 and 1964 concerned "crustaceans, worms, insects and so forth" (23). The literature shows that most problems elsewhere are also caused by these three groups of invertebrates.

Invertebrate taxa that also have caused complaints are Gastropoda (snails) (22,24–27), Cladocera (water fleas) (27), Copepoda (copepods) (26,27), Hirudinea (leeches) (27,28) and Gammaridae (freshwater shrimps) (27,29,30). Not just invertebrates but their fecal pellets (31), body parts, and degradation products as well can lead to consumer complaints. The death of large numbers of invertebrates used to cause taste and odor problems in the early days of water supply, especially when oxygen concentrations dropped. Large numbers of invertebrates present in distribution systems normally are noticed because individuals are likely to emerge from taps, but sessile invertebrates such as Bivalvia (mussels) (28), Ectoprocta (bryozoans) (32) and Porifera (sponges) (32,33) were only detected when they caused taste and odor problems or clogged pipes. Their presence is usually limited to untreated surface water because these sessile filter feeders depend on relatively high densities of POM (particulate organic matter) in the water. Mussel larvae (Bivalvia), for

instance, may penetrate surface water treatments, but levels of POM in drinking water are usually too low to sustain mussel growth in present-day distribution systems (34).

The other effects of large numbers of invertebrates can be the clogging of service lines and water meters. Clogging by Asellidae has been reported in The Netherlands. Furthermore, freshwater snails and mussels will easily cause clogging owing to their hard shells (22,24–26,35). Especially in the early years of distribution systems, when water treatment was absent or rudimentary, mains constrictions and clogging were more common, for example, by Bivalvia (36), Ectoprocta (32), and Porifera (33).

Invertebrates not originating from the distribution system can be a nuisance for water utilities as well: spiders and adult insects seeking refuge in the neck of taps will emerge when water is used. Particles may also be mistaken for invertebrates. Convincing consumers of the excellent hygienic quality of their drinking water in these cases usually has been proven difficult.

Microbiological Deterioration of Water Quality

A detectable transmission of pathogenic microorganisms into drinking water by invertebrates has never been reported. However, protozoans and bacteria may multiply on the remains of invertebrates [e.g., ciliates (37,38).] and in or on their fecal pellets [*Aeromonas* bacteria in pellets of midge fly larvae (39)]. These substrates presumably contribute to heterotrophic plate counts in sediments [as high as 6.10^8/g DW (40) and 5.10^9/g DW (41)] and plate counts of *Aeromonas* spp. (30 °C) in sediments [as high as 5.10^9/g DW (41)]. Many heterotrophic bacteria will grow on easily assimilable low-molecular compounds from the water, forming a biofilm on the sediment particles, much in the same way as it is formed on all water-exposed surfaces in distribution systems. *Aeromonas* bacteria however are also able to use high-molecular substrates present in dead (micro)organisms such as proteins, fats, and complex carbohydrates (42), for example, chitin from the exoskeletons of insects (unpublished personal observations by D. van der Kooij). As the bacteria were hardly found in the fresh biofilms (43), it is likely that multiplication of *Aeromonas* in distribution systems in The Netherlands predominantly occurs in sediments, using dead microorganisms and invertebrates as part of their food supply. Total coliforms have been found in sediments from distribution systems as well, with averages ranging from 10 to 1.10^5/g DW. Samples were collected via hydrants and were not handled aseptically and therefore contamination of the samples could not be ruled out (41). In conclusion, it is likely that invertebrates lower the overall density of bacteria and protozoans in distribution systems by feeding on them, therefore increasing the conversion rate of organic carbon to carbon dioxide and hence limiting the total food supply for microorganisms. Invertebrates however also change the composition of the microorganism community in distribution systems by their presence (stimulating symbiotic microorganisms) and by converting their food into fecal pellets and eventually in molting cuticles and dead bodies, changing the substrates available for microorganisms. It is likely that these changes benefit coliforms and (opportunistic) pathogens.

DRINKING WATER FAUNA

Figure 1 shows pictures of a protozoan and invertebrate taxa commonly found in drinking water distribution systems, giving an impression of their morphology. Protozoans, Rotifera, and Tardigrada are very small and are not known to have caused consumer complaints or specific problems for water utilities. Hydrachnellae have been encountered in distribution systems in Japan, probably contributing to the colonization of swimming pools (44), but have not been known to be a nuisance. Ostracoda normally are not ubiquitous and have a high density owing to their hard shell and will not be flushed out easily via consumer taps, probably explaining the lack of consumer complaints about these organisms. Collembola (springtails, 0.5 to 5 mm, not shown in the figure) are insects sometimes found in samples of sediment flushed out of mains via hydrants. Although these organisms most likely originate from the dry part of hydrants, contaminating the samples during sampling, they are sometimes quantified in samples as possible members of drinking water fauna.

Protozoans

A wide variety of free-living protozoans are present in surface water and groundwater. It is very likely that many species that are able to feed on bacteria from biofilms also multiply in water supply systems. Many species have been found in treatment works (47), finished water (reservoirs) (48,49) and drinking water distribution systems (37,45,46). In finished water reservoirs and distribution systems they have been found to multiply on the cadavers of invertebrates (37,38). Free-living species of the Mastigophora (flagellates) (37,49), Sarcodina (amebae) (37,49), and Ciliophora (ciliates) (37,38,47) have been reported.

Nematoda

Nematoda (nematodes or roundworms) are eel-like worms (Fig. 1) that usually range in length from 0.5 to 2.5 mm. Although able to swim, nematoda usually glide through biofilms. Free-living species prey on microorganisms and small invertebrates, generally reproducing sexually via eggs. Upon investigating tap water for the presence of amebae in Ohio (U.S.A.) in 1955, Chang and coworkers (50) detected the nematoda (*Diplogaster nudicapitatus*[1]) in their samples. A few years earlier, the presence of the nematoda (*Trilobus gracilis*) was also established in finished water and tap water in Norwich (U.K.) (51), and even long before that, nematoda were reported to be common in drinking water (52). Although the abundance of the organisms in Norwich led to investigations on control methods, the (free-living) organisms were not considered a possible health threat (51). Chang and collaborators however suggested the possibility of drinking water contamination by pathogenic bacteria, ingested by

[1] It should be noted that in many cases the names of species and genera of organisms referred to in literature have been changed since publication. In this contribution, the names originally used have been presented.

Figure 1. nematoda and thus protected against chlorination during surface water treatment. They found many species during a survey of nematoda in the water supplies in United States (53). Pathogens (*Shigella*, *Salmonella*, and Coxsackie virus) were found to be able to survive several days in some chlorine-resistant species (*Cheilobus quadrilabiatus* and *D. nudicapitatus*) (54). The latter results were later corroborated by research on *Salmonella* survival in *Pristionchus lheritieri* (55). Chang and collaborators however could not prove the infectiveness of nematoda on mice (56) and concluded that under normal conditions the chances of pathogens actually being transmitted into drinking water distribution systems by nematoda must be considered very remote (57). This conclusion however did not lessen interest and ever since, investigations on nematoda removal in treatment plants and presence in drinking water have been reported predominantly in the United States (58,59,60), but also in Canada (61,62), Germany (63), India (64), Italy (65), and Poland (66). In Italy, no pathogenic bacteria could be isolated from nematoda collected in both raw and finished water of a surface water treatment plant (67). In the Netherlands, many water utilities monitor finished water of surface water treatment plants for nematoda, among other invertebrates (68). Numbers of more than 1,000 per m^3 are considered very high for finished water of surface water treatment plants. For groundwater treatment plants, numbers of 100 per m^3 or more are very high (45).

Oligochaeta (Annelida)

Oligochaeta (oligochaete worms) form a group of segmented freshwater worms (see Fig. 1) and terrestrial worms (e.g., the earthworm), also known as the common worms, generally feeding by ingesting detritus and sediments, digesting the organic matter. Although some species may grow to be much longer, the length of Oligochaeta usually ranges from 1 to 100 mm. They reproduce by dividing or budding, but the organisms are hermaphrodite and can reproduce sexually as well, provided they are sexually mature and densities are high enough to find a mate. The organisms usually burrow through these sediments; many species however are able to swim as well. Common genera such as *Nais*, *Tubifex* (Aristotle already noticed worms resembling *Tubifex* in large quantities in polluted water wells (21)), *Aeolosoma*, *Chaetogaster* or *Stylaria* probably are part of the biocoenosis in all drinking water treatment plants and distribution systems. Generally, Oligochaeta may be abundant in rapid sand filters and GAC filters (69–72). A freshwater family of Oligochaeta that may infest filter beds, namely, the Lumbriculidae, resemble earthworms and provide a less attractive sight during backwashing or when the filter beds are at rest (personal observation). Removal of Oligochaeta from filter beds is possible by backwashing with 5% NaCl (70) or with 0.01 M NaOH. The presence of biofilm as food supply will however provide for the reproduction of the few remaining Oligochaeta, their eggs or new immigrants. The numbers may also be high in the distribution system, even when numbers in the filter beds are low. It is likely that the organic matter in treatment plant filter beds and the sediments in distribution systems provide the food to sustain the Oligochaeta populations in water supplies. In the Netherlands, major Oligochaeta infestations have occurred in water supplies in 1939 (73) and 1964 (74), causing many complaints and much negative publicity. Little is known about the causes and control of the first infestation, other than that it instigated the installation of the Biological Research Commission, leading to many decades of (micro)biological research since. Limiting detritus in distribution systems to cut food supply was considered the most effective long-term control measure. The second Oligochaeta infestation was the result of overloading the 90-year old river water treatment plant in Rotterdam, which was only relieved when in 1966 the new plant increased the city's water supply capacity. Meanwhile, chlorine concentrations were increased by dosing chloramine, starting at 2 mg/L Cl_2, causing disintegration of the worms. After the infestation in the distribution system subsided, numbers were controlled with chloramine doses of 1 mg/L Cl_2. Similar problems and solutions have been reported by utilities in the United Kingdom and the United States (52,75). Maintaining concentrations of 0.2 mg/L free chlorine is considered a long-term control measure for Oligochaeta (27). Short-term control measures include high chlorine concentrations and mechanical cleaning methods, for example, flushing. The long-term effects of periodic control methods are limited (76) because of reproduction of worms that survive in dead ends (e.g., mains couplings) or those that cling to mains surfaces (e.g., *Aeolosoma* and *Nais* for this purpose use their mouthsuckers and their tails respectively).

Asellidae (Crustacea, Isopoda)

Asellidae, commonly known as water lice or aquatic sow bugs, are crustaceans that feed on dead organic matter in surface water (in Europe e.g., *Asellus aquaticus* (see Fig. 1), *Proasellus meridianus* and *P. coxalis*) and groundwater (in Europe e.g., *P. hermallensis* and *P. cavaticus)*.

Figure 2 shows the mouth parts of *A. aquaticus*, enabling the organism to scrape the surface of (organic) matter, preferably in decaying condition. Reproduction is sexual, limiting chances to establish a population from low initial densities. Locomotion is limited to walking on surfaces. Their well-developed ability to cling to these surfaces enables them to migrate upstream and to pass vertical obstacles. The Asellidae which, on a regular basis, emerged from taps in Rotterdam, the Netherlands, at the end of the 19th century were thought to be reproducing in abandoned uncovered slow sand filters in the river water treatment plant and were thought to enter the finished water through cracks in the finished water canals (29). Some 30 years later in Amsterdam it was assumed that the organisms, causing complaints in this city as well, were reproducing in the distribution system itself, using biofilm as a food source (77,78). A recent survey in the Netherlands showed that Asellidae were found in 35 of 36 investigated distribution systems (45,76,87). Most consumer complaints about invertebrates in the Netherlands presently concern Asellidae and the clogging of water meters by these organisms has been reported. The number of complaints in the United Kingdom are higher in the summer because many adults die after reproduction and are swept more easily from the mains (27).

Since 1930, dozens of publications and notes described attempts to remove Asellidae from water supplies in Germany (28,79–81), the United Kingdom (30,82–86), Belgium (22), the Netherlands (78), and France (79). The most effective method to remove the organisms, albeit temporarily, proved to be flushing of the distribution system after treatment with the botanical insecticide

Figure 2. Scanning electron micrograph of the ventral view of the head showing the mouthparts of *Asellus aquaticus* (Crustacea: Isopoda), scale line = 1 mm; from (45).

pyrethrum (78,80,82) or the synthetic variant, permethrin (pyrethroids). This latter method is still applied in the United Kingdom (27) although under strict conditions to prevent consumer exposure to the risk of poisoning for kidney patients that apply extracorporeal dialysis at home and also commercial and domestic fish collections. The use of chlorine or other disinfectants to control Asellidae is very difficult (27) because the organisms are very resistant and it is difficult to maintain a high disinfectant residual in all parts of the distribution systems. In Antwerp (Belgium) and Hamburg (Germany), periodical air scouring of the distribution system proved to be very effective (22,81). Air scouring is advised in the United Kingdom as well (as is swabbing), especially because sediments and other invertebrates are removed better than during flushing with permethrin, preventing an increase of other species numbers that frequently follows a pyrethroids dosing exercise (18,27). Experiences in the Netherlands indicate that flushing the distribution system may be more cost effective than intensive methods such as swabbing and air scouring (76,88). Limiting biofilm formation and sediment accumulation in mains is thought to be the most effective long-term control measure.

Chironomidae (Insecta, Diptera)

Of the insects, the larvae of the nonbiting Chironomidae midge flies (Fig. 1) are most commonly found in distribution systems. Midge fly larvae usually range in length between 4 and 30 mm. Most likely, the species that live in drinking water distribution systems feed on organic material in sediments, which is also used by some species to build a case glued to surfaces. Outside this sediment case, they can swim in an undulating manner, much like the nonburrowing members of the same family. Especially in the first part of the twentieth century and also more recently (89,90), utilities in the United States and elsewhere were confronted with the infiltration of distribution systems by midge fly larvae via uncovered finished water reservoirs or poorly screened air inlets in treatment plants and reservoirs. In some cases, these infestations led to larvae emerging from consumer taps (6,89,91,92). The covering of reservoirs and the screening of ventilation ducts in most cases proved an effective remedy, but other control methods were used as well, including the method of adding DDT into the reservoir that is currently strongly discouraged (93). Because most insects can only reproduce sexually and adults depend on the presence of air for their oxygen supply, preventing immigration usually is effective to control the presence of insect larvae in distribution systems.

Some midge fly larvae however may procreate in the distribution system itself. This was discovered in 1937 in Germany (94) and in 1973 in Essex (England) (95). The water supplies were not able to control the organisms by closing all entrances for adult midge flies. The organisms eventually were identified as *Paratanytarsus* sp., a parthenogenetic genus that can reproduce eggs asexually in the so-called pharate adult stage before the adult stage (Fig. 3). Flushing after treatment with the insecticides pyrethrin or permethrin has proven to be an effective method (27,94,96), as it is for controlling

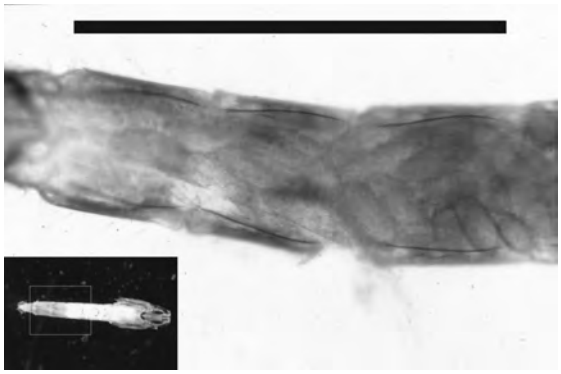

Figure 3. Pupal cuticle, containing discharged eggs, at the abdominal end of a pharate adult female of an unidentified parthenogenetic midge fly (Diptera: Chironomidae) collected from a drinking water mains in the Netherlands. Insert shows the habitus of the female, scale line = 1 mm; from J. H. M. van Lieverloo, et al., *J. — Am. Water Works Assoc.* (submitted).

Asellidae. Recently, a food-grade coagulant has been found effective in controlling the parthenogenetic species *Paratanytarsus grimmii* (97) as was shock chloramination for normal midge fly larvae (90).

Vertebrates

Eels and sticklebacks were common in early distribution systems supplying untreated surface water (98,99). Still, however, incidents of vertebrates such as a small eel clogging a water meter (in 1983) and a frog clogging a mainscock (early 1990s) have been reported in the Netherlands. These organisms must have entered the mains at one point, possibly after a mains break. Although it is not likely that these organisms survive in the mains for a long period, owing to the scarcity of food, a whole colony of eels has recently been pigged out of a potable water mains in the United States (100). Evidently, public reports on these incidents are rare.

ECOLOGY

Immigration from Groundwater

Although less conspicuous than in surface water, groundwater biocoenoses may harbor an abundance of invertebrates that are visible to the naked eye. The composition of the biocoenosis highly depends on soil structure and hydrology, because evidently the biocoenosis is interstitial (i.e., between the grains). Coarse sediments and cracks in rocky bottoms will facilitate the passage of surface water into groundwater supplies, especially via shallow wells. Soils with finer grains and coarse deep layers that are covered by fine-grained layers only harbor invertebrate species that are confined to groundwater and caves. Large sand formations usually are relatively poor in organic matter, resulting in the presence of oxygen. Even at concentrations of 0.2 mg/O_2L, invertebrates may be ubiquitously present, although it is not known whether the organisms are concentrated in pockets with higher

oxygen concentrations (101). Straining sometimes is necessary to remove relatively large groundwater species such as *Niphargus* sp. (Crustacea, Amphipoda) and *Proasellus* sp. (Crustacea, Asellidae) from groundwater obtained from coarse sediment layers (unpublished observations in groundwater from horizontal wells at 18-m depth, by the author and J. Notenboom). Finer sediments operate as giant slow sand filters and therefore allow only low numbers of small invertebrates such as Copepoda, Hydrachnellae, and Nematoda to pass into the water supply. Marshes, peats, and other formations rich in organic matter result in quick oxygen depletion, and therefore few or no invertebrates are present (101).

Immigration from Surface Water

Earlier, the abundance and diversity of the organisms in distribution systems carrying untreated surface water depended largely on the biocoenosis in the source system. Many species however cannot survive in distribution systems because of physical conditions, such as the lack of light and air, and the colonization of the system is limited by biological conditions, such as predation or unsuitable food. The constant supply of invertebrates from the source however will result in the presence of a large variety of surface water species, as was the case in many large cities in the nineteenth century and the start of the twentieth century, for example, in Breslau, Poland (102), London, United Kingdom (103); Boston, United States (33); Hamburg, Germany (98,99); and Paris, France (36). The microbiological quality of the water, although underestimated for a long time, was however of more concern than the zoological quality. Regrettably, this is still the case in large parts of developing countries. From the start of central water supply in the Netherlands (e.g., in 1853 in Amsterdam and in 1873 in Rotterdam), slow sand filters were used for surface water treatment (104). Presently, in most surface water treatment plants, protozoan and invertebrate removal is part of algae removal and is usually considered of minor importance. Microstrainers probably form the only treatment process applied specifically to remove invertebrates, especially those straining the filtrates of rapid gravity filters and GAC-filters. However, small motile invertebrates such as nematoda (59,60,62,64,65) and Rotifera (38,105) are hardly removed by some surface water treatment plants using coagulation and sedimentation followed by rapid gravity filtration, with or without chlorination. Nematoda are known to be resistant to high chlorine concentrations (106), but chlorination or ozonation before rapid gravity filtration improves the removal of invertebrates (27,38,107). Planktonic species however are better removed in treatment than benthic species (107). Furthermore, slow sand filters are known to remove invertebrates better than rapid gravity filters (27,107,108), and the backwash rate of rapid gravity filters controls invertebrate removal (109). In a survey of 17 finished water reservoirs in Germany, sediments in reservoirs of surface water supplies were found to harbor high numbers and a wide variety of planktonic species next to some benthic species, whereas the sediments in reservoirs of groundwater supplies contained only low numbers of Rotifera and nematoda. Furthermore, the numbers of Rotifera and larvae of Copepoda in one of the supplies dramatically decreased with distance from the treatment plant (110,111), probably owing to diminished food supply. Similar results were obtained in Switzerland (112). All these results indicate that penetration of invertebrates through surface water treatment plants is rather common. In finished water of at least 64% of 55 surface water treatment plants in the United States, invertebrates (predominantly nematoda) and free-living protozoans were found. Not all of these however were also found in the influent, indicating that part of the organisms may have originated from multiplication in the treatment plant itself (48).

Multiplication in Treatment Plants and Finished Water Reservoirs

Protozoans (47,49) and invertebrates may enter distribution systems by elution from water treatment systems and finished water reservoirs in which they multiply. Before slow sand filters and finished water reservoirs were covered, contamination of these systems led to infestation of the distribution systems supplied. Unscreened or poorly screened ventilation ducts still can be important immigration routes, especially for flying insects such as midge flies and for crawling invertebrates. Contamination may also occur via cracks in walls and roofs, although coliform counts will rise as a result of contaminated water seeping through, instigating inspection of structural integrity. For Asellidae, even backwash water outlets are possible routes to enter treatment plants from backwash water reservoirs or surface waters (79). Nowadays, in most cases, penetration into a treatment plant predominantly occurs from the water source, and the filter biocoenosis would seem most likely to resemble the benthic interstitial biocoenosis in (oxygenous) surface water sediments or groundwater systems. In surface water treatment plants, filter beds are expected to be harboring surface water species (21). The biocoenosis of the slow sand filters in Bremen (Germany), predominantly harboring groundwater species, resembles that of the banks of the supplying river (113). In Zürich (Switzerland), the surface water species *Canthocamptus* sp. (Copepoda, Harpacticoida) dominates the slow sand filters and the finished water reservoirs. Although the organism is not regularly found in the raw water, it is present in the sediments of the source water lake (114). However, in some plants in Germany, a limited variety of taxa have been found in the slow sand filters, predominantly consisting of groundwater species of Nematoda, Oligochaeta, and harpacticoid Copepoda, although Turbellaria, cyclopoid Copepoda, Cladocera, Asellidae, and Gammaridae have been found as well. For the slow sand filters in the water supplies using water from the river Ruhr (Germany), a colonization with groundwater species from below is likely because the filters are used to supplement the groundwater that is collected for drinking water production (115–117). GAC-filters have also been found harboring invertebrates (63,71,72,118). Filter grain size and backwashing procedures prove to be very crucial for filter colonization and invertebrate numbers in

filtrates. Removal of invertebrates from filtrates by straining with, for example, 30-μm mesh microstrainers is often necessary (68).

Immigration by Intrusion into Distribution Systems

When distribution system integrity fails (e.g., during mains breaks), organisms may inadvertently enter the mains, even when the water is still running (e.g., Asellidae). Rough surfaces, dead ends, and blind spaces in mains junctions prevent the invertebrates from being flushed out after repair. Holland (83) ascribed the presence of Asellidae in the Coventry (United Kingdom) distribution system, first detected in a water meter in 1942, to contamination of the system after many mains were broken during heavy bombardments in 1940 and 1941. Other possible immigration routes are as follows:

- Back-siphonage of wastewater or surface water via unprotected connections;
- Cross connections (18);
- Contamination during mains construction and repair (18).
- Locking-in of soil and dirt by unprofessional use of underground hydrants (i.e., opening the hydrant valve before opening the top-piece).

Chances of colonization due to (temporarily) diminished integrity of the distribution systems probably are much lower than the chances of immigration via surface water and groundwater treatment plants, but research data to corroborate this assumption are not available.

Survival and Settlement

Survival and settlement of invertebrates that penetrated into a distribution system depends on physical, chemical, and biological factors. Although air pockets may remain in mains after air scouring, normally air is absent and adult insects are bereft of oxygen (their larvae breathe through their skin or use gills). Most planktonic organisms will not withstand the current in distribution systems, although velocities are usually very low, and will be flushed out via consumer connections. Most Monogononta (Rotifera), for instance, are planktonic surface water species and their presence in distribution systems will depend entirely on their ability to pass surface water treatment. As far as chemical composition is concerned, normal concentrations of chlorine and chloramine in water leaving treatment plants are not very effective against most invertebrates found in distribution systems (27), but do limit the survival of some invertebrates. For instance, 1 to 2 mg/L of free chlorine will limit settlement of freely swimming mussel larvae (Bivalvia) (27). Considering drinking water standards in most countries, toxicity of other compounds will probably not be a determinative factor. Salinity, acidity, or alkalinity may however be too low to support some freshwater organisms. Facultative parasites, pathogenic microorganisms, and especially predators may have a large impact on chances for colonization of the distribution system by an invertebrate species. Competition for food however is most likely to determine long-term chances of successful colonization.

Feeding, Growth, and Reproduction

Availability of sufficient and suitable food is most likely to determine the abundance of invertebrates in distribution systems. Planktonic species (most Rotifera, Cladocera, and Copepoda) and sessile filter feeders [Porifera (sponges), Coelenterata (polyps), Bivalvia (mussels), and Ectoprocta (bryozoans)] depend on relatively high densities of algae or POM (particulate organic matter) in the water. Removal from surface water by coagulation and sedimentation, especially if followed by filtration, usually suffices to limit growth of these taxa in distribution systems. A study of invertebrates in sediments in finished water reservoirs in Germany revealed a significant decrease of Rotifera and larvae of Copepoda during distribution. The numbers of two planktonic surface water species of Rotifera (*Notholca caudata* and *Triarthra longiseta*) clearly decreased, whereas the numbers of benthic Rotifera slightly increased (111).

In most distribution systems, concentrations of dissolved compounds present in finished water from treatment plants are most likely to determine the abundance of bacteria, protozoans, and invertebrates. On all water-exposed surfaces in the distribution systems, benthic bacteria form the basis of a biofilm, a slime layer colored yellow, brown, or black by suspended particles that attach to it. Probably most of the bacteria are heterotrophic, using organic matter both as an energy source and as a source of base materials. Additionally, incomplete removal of ammonium, nitrite, and methane in treatment plants using anoxygenous groundwater will lead to growth of nitrifying bacteria and methane-oxidizing bacteria in distribution system biofilms as well. In these biofilms, the bacteria form the living food for protozoans and invertebrates (Nematoda, benthic Rotifera, Gastrotricha, Tardigrada, Turbellaria, Gastropoda, Ostracoda, benthic Copepoda, benthic Cladocera, juvenile Hydrachnellae, and Chironomidae larvae) that graze on these bacteria and protozoans. Large invertebrate species will mainly be found feeding on the biofilms at the bottom of mains and the biofilm-covered sediment particles accumulating there. These sediments are formed by (*1*) precipitation of particles suspended in finished water, (*2*) insoluble compounds formed in mixed water types, (*3*) parts of mains materials, and (*4*) sloughed-off biofilms, increasing the surface area available for bacteria and protozoans to grow on. Oligochaeta burrowing in these sediments ingest whole sediment particles and Asellidae scrape off biofilm from surfaces, meanwhile ingesting rust, bitumen, and asbestos fibers, as shown by the composition of fecal pellets of Asellidae ubiquitously found in sediments collected from mains (41). Small invertebrates such as Rotifera and small nematoda are attached to the biofilm while feeding and are likely to be ingested by biofilm grazers and sediment feeders. Planktonic Copepoda are found whirling up particles to feed on while skimming the sediment surface. Predators of many taxa may thrive on other invertebrates, provided the abundance of prey is sufficient and predators are not visually orientated. Figure 4 schematically summarizes the hypothesis

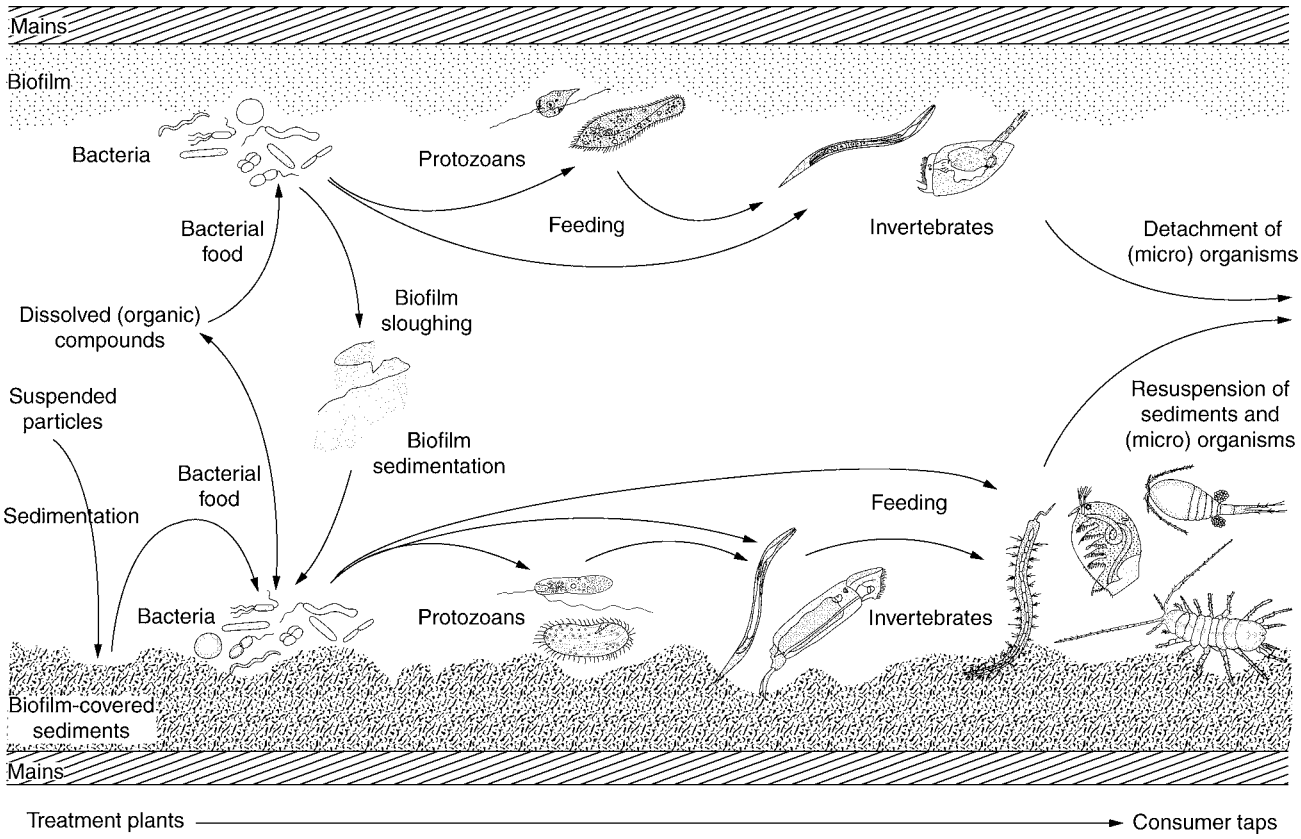

Figure 4. Schematic depiction of the hypothesis on food supply and feeding in drinking water distribution system biocoenoses; from J. H. M. van Lieverloo et al., *J.—Am. Water Works Assoc.* (submitted).

of food supply and feeding processes in the distribution systems (45).

Those species that are successfully competing for food in distribution systems will also depend on reproduction for establishing and maintaining a population. Although protozoans and most drinking water invertebrates can reproduce asexually, some taxa, for example, Copepoda and Asellidae, can only reproduce sexually, causing their chances of colonizing a distribution systems to depend on the initial population density, that is, the chances of mating. The abundance of relatively large benthic invertebrates in distribution systems such as Asellidae and Oligochaeta, compared with the low abundance of most of these organisms in finished water from treatment plants, could be seen as an indication that reproduction in the distribution system is largely determining abundance for these taxa. It is however very difficult to quantify immigration of benthic invertebrates walking and sliding into distribution systems, considering the size of trunk mains carrying the finished water of treatment plants.

ABUNDANCE

Methods to Assess Invertebrate Abundance

Freshwater zooplankton is usually collected by filtering water through plankton nets. Benthic invertebrates usually are scooped from the bottom or are filtered from sediment samples. Owing to the closed character of distribution systems, filtering of water emerging from the system is the most practical and cost-effective sampling technique. Planktonic invertebrates and suspended benthic invertebrates are collected by filtering finished water from treatment plants and by filtering drinking water from consumer taps, using plankton nets or filters, usually ranging between 10- and 45-μm mesh. In the Netherlands, 10-μm mesh filters are most commonly used, for it is known that large percentages, especially of protozoans, Nematoda, and Rotifera will pass even these filters. Benthos is collected by flushing or air scouring the mains via hydrants and filtering the flushing water with plankton nets, usually ranging between 30- and 500-μm mesh. Figure 5 shows a special sampling top-piece that was developed in the Netherlands over a period of 50 years for collecting invertebrates from mains. Of most taxa, an average of 50% or more is flushed from the mains; Oligochaeta and Chironomidae are flushed out less effectively however. On an average, only of Nematoda, Turbellaria, and larvae of Copepoda, less than 50% of the individuals is retained in the 100-μm mesh filters. Presently, extra 30-μm mesh filters are used to improve sampling efficacy (119). The invertebrates in the samples are identified and enumerated using an inverted microscope (drinking water samples) or a stereomicroscope (flushing-water samples).

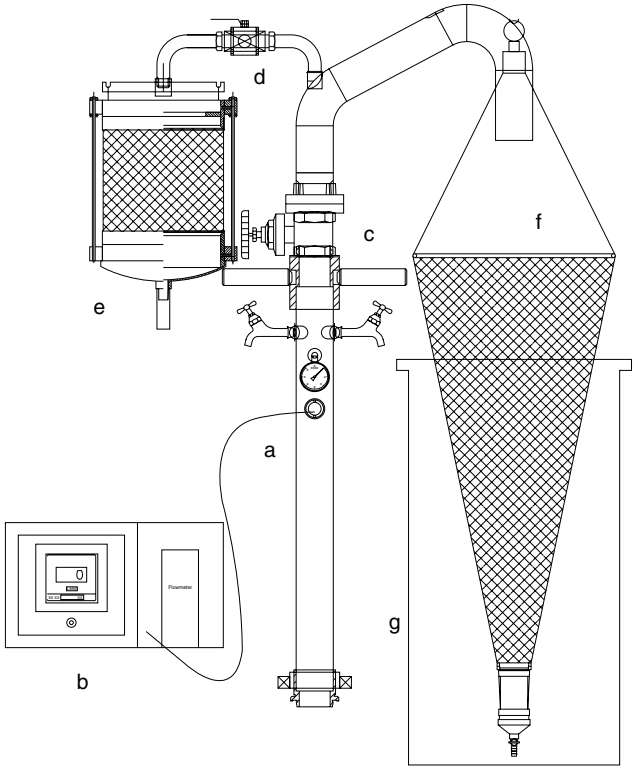

Figure 5. Drawing of the device for sampling flushing water, consisting of a top-piece for underground hydrants and filters a = Georg Fischer MK515 paddle wheel flow sensor in an aluminum plug; *b* = Georg Fischer F86 flow and volume indicator; *c* = slide valve; *d* = ball valve; *e* = 100-μm mesh plankton gauze filter containing a removable 500 μm mesh plankton gauze filter; *f* = 500-μm mesh plankton net; *g* = filtrate vessel with overflow. Not shown is the 30-μm mesh plankton gauze filter presently used to filter the filtrate of the 100-μm mesh filter. (From J. H. M. van Lieverloo et al., *Water Res.* (submitted).

Invertebrate and Protozoan Abundance in Drinking Water

Although water utilities may be aware of the presence of invertebrates in their distribution systems, not many periodically assess the size and composition of the community, most likely because it is not obligatory. If they do so, this information usually is not published (120). Results of some surveys, mostly targeting Nematoda, have been published (53,61,111,121,122) along with results of periodical monitoring by water utilities (22,58,68,114,116,123). In Figure 6, mean numbers of invertebrate taxa in finished water from treatment plants, drinking water from consumer taps and flushing water from mains are presented. The figure shows that data from literature (period 1948–1996), data from six utilities in the Netherlands using surface water (period 1964–1995), and those from a recent survey of 36 distribution systems in the Netherlands (period 1993–1995) (45,76,124) match surprisingly well for most of the invertebrate taxa.

Cladocera and Copepoda dominate the mains biocoenosis in numbers, mean numbers mounting to several hundreds per cubic meter of flushing water, whereas these and other visible invertebrates are hardly found in finished water from treatment plants and in drinking water from consumer taps. Most organisms under normal flow conditions apparently are not easily whirled up from the bottom of the mains. Owing to their size, Asellidae and Oligochaeta dominate the mains biocoenosis in biomass, forming approximately 86% and 12% respectively of total invertebrate biomass in the Netherlands (based on estimated biomass per individual organism) (45). Numbers in finished water from treatment plants and drinking water from consumer taps are dominated by protozoans, Rotifera, Nematoda, and Copepoda. Numbers of protozoans, Rotifera and Nematoda probably also are very abundant in the mains, but on account of their limited size, their numbers usually are not accurately (Nematoda) determined in water flushed from mains.

CONTROL

In 1964, the Biological Research Commission in the Netherlands, consisting of biologists and operators of research institutes and water utilities, formulated the following recommendations for invertebrate control: (*1*) limit assimilable organic matter in drinking water by intensive water treatment, (*2*) prevent mains contamination during mains construction and repair (and caused by cross connections) and (*3*) systematically flush distribution systems (18). In 1982, this view was still endorsed by the industry, adding the obvious necessity to adequately remove invertebrates in treatment plants (68). The balance of the intensity of all these control measures should depend on cost-benefit evaluations that include benefits for other variables (e.g., microbiology, color), environmental costs (e.g., wasting flushing water), and inconvenience to communities (e.g., pressure drops and colored water during flushing).

Limitation of Immigration

When finished water is microbiologically safe, immigration of invertebrates is not likely to play a major role in the abundance of invertebrates in distribution systems and drinking water. The increased awareness of possible contamination of finished water with the very small (oo)cysts of *Giardia* spp. and *Cryptosporidium* spp. will enhance the quality of many treatment plants throughout the world, probably diminishing the possibilities of a contamination by invertebrates even further. Furthermore, awareness of the risks of intrusion of microorganisms into distribution systems is growing (127), which could lead to the limitation of intrusion of invertebrates as well.

Periodical Removal from Distribution Systems

Flushing of distribution systems, either only with water or by injecting air (air scouring) or by introducing plastic swabs (swabbing), is only effective temporarily because the organisms that were not removed will be able to reestablish the population, using sediments and biofilms as food. If distribution systems are flushed periodically, abundance and species diversity will diminish and some species will be flushed out entirely. Many benthic species such as Asellidae however are used to periodic increases of water flows (128) and will be able to withstand high water

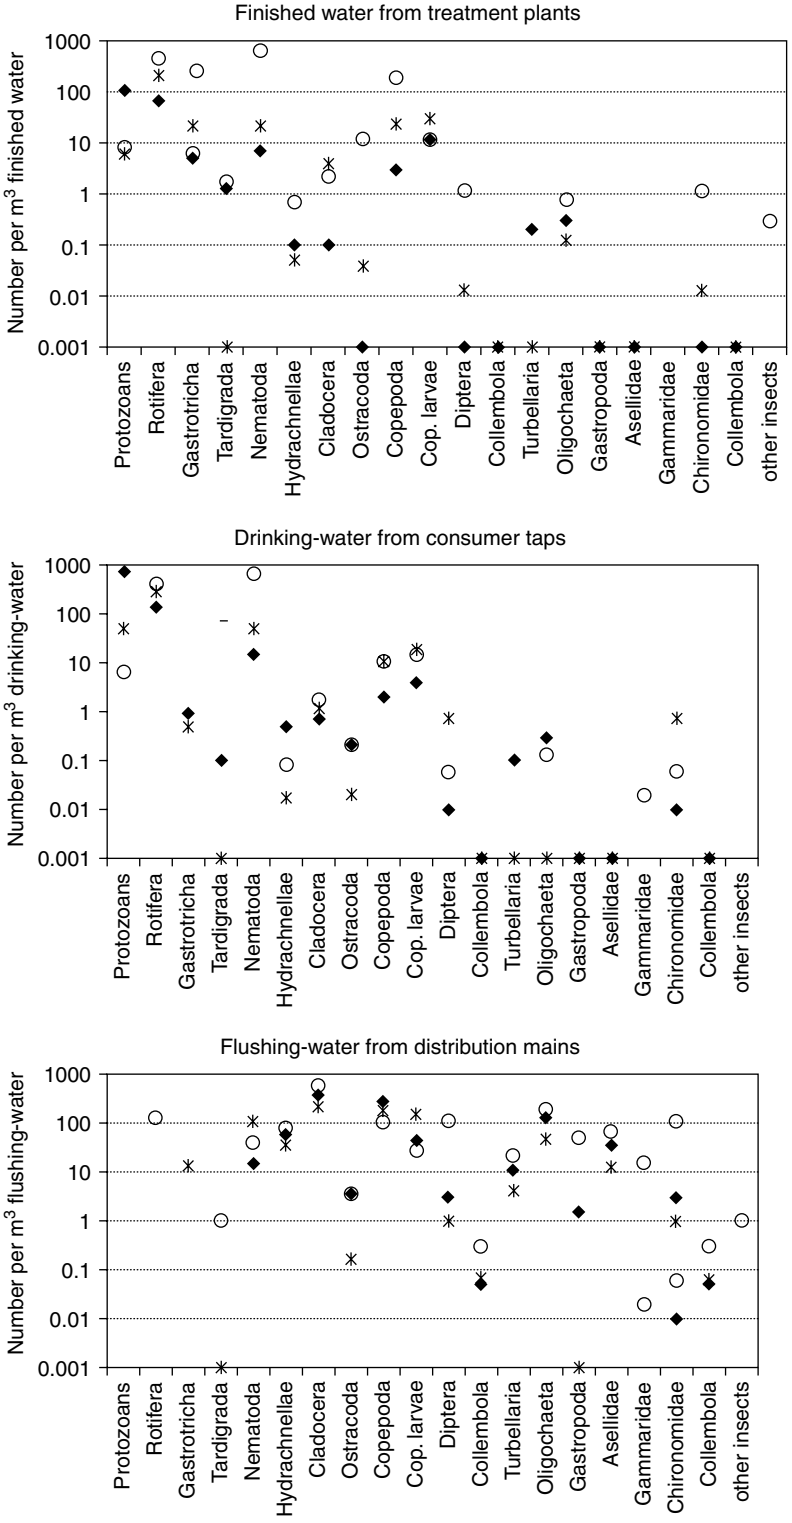

Figure 6. Abundance of protozoans and invertebrates in water supplies. ○ Literature data: arithmetic mean of means provided, calculated, or estimated per reference (1948–1996) (22,50,58,59,61,65, 68,78,95,105,107,111,114,116,121–123,125,126). ∗ Data from six utilities in the Netherlands predominantly using surface water, one report per utility (1964–1995): mean of means provided per report. ♦ Averages from a survey in distribution systems of 36 treatment plants in the Netherlands (1993–1995) (45,76,124). Means of invertebrates taxa that were looked for, but were not found, are presented as 0.001 per 1,000 L.

velocities (83). In seven experiments studying sampling accuracy in the Netherlands, only 42% (SD 15%) of living Asellidae and 83% (SD 29%) of dead Asellidae were sampled from mains at 1,0 m/s (119). Another study in the Netherlands showed that levels of invertebrates (predominantly Asellidae and Oligochaeta), sediments, and bacteria in flushing water from hydrants were back to previous levels within nine months after systematically cleaning parts of distribution systems. Only fine sediment volumes (retained in 30- to 100-μm mesh filters) remained significantly lower for more than 15 months. Although the immediate effects of intensive techniques such as air scouring or pigging were larger than the effects of flushing, there were no long-term differences, probably

because of reaccumulation of sediments from trunk mains (not cleaned) and from the treatment plants (76,88,124). In Antwerp, Belgium, good results were reported in removing Asellidae and Gastropoda only after five years of annually air scouring all mains generally distributing water at low flows, that is, dead ends, mains with drastically changing diameters and shuttle zones. Consumer complaints about invertebrates dropped from 25 per year (1975) to below 1 per year (since 1985) (22). In Hamburg, Germany, and in the United Kingdom, air scouring is used successfully as well (27,81). The cleaning frequency required is likely to depend on the rate of sediment accumulation and biofilm formation in the distribution system. If only mechanical methods are used, multiplication of invertebrates is usually only limited by cleaning very frequently. Although the organisms under these conditions may not get very large, the reproduction rate of species such as Asellidae and Oligochaeta probably is enough to keep the population stable albeit small. Low-frequency application of mechanical cleaning methods is less effective because important parts of distribution systems cannot be reached by mechanical methods, that is, dead ends, mains couplings, and, in case of corroding cast iron mains, encrustations. Chemical methods are more effective in killing these invertebrates, when used in combination with systematic flushing, although diffusion rates into dead spaces do limit the efficacy of these methods as well. Asellidae, Gammaridae, and Insecta are very sensitive to pyrethrins or permethrin, pesticides that are used in the United Kingdom for controlling these organisms under strict conditions (27). Oligochaeta can be controlled by maintaining 0.5 to 1.0 mg/L free chlorine residuals for weeks in combination with systematic cleaning of the mains (27).

Prevention of Multiplication of Invertebrates and Microorganisms

Multiplication of invertebrates in distribution systems probably depends on the presence of food sources, namely, biofilms and (biofilm-covered) sediments. Biofilm formation may be limited by maintaining a disinfectant residual in the distribution system and it may have a limiting effect on some invertebrates as well. An infestation with Oligochaeta can be prevented with residual concentrations of 0.2 mg/L free chlorine (27). Normal residuals of chlorine and chloramine in water leaving treatment works however are not very effective against most of the invertebrates found in distribution systems (27). Secondly, it is difficult to maintain a disinfectant residual throughout the distribution system. In the Netherlands, 65% of drinking water is produced from groundwater supplies, treated and distributed without a disinfectant, while surface water is treated in multiple barrier plants including chemical disinfection. Only 22% of all drinking water is chlorinated after treatment and in only 10% of all drinking water, a disinfectant residual is detectable, most of it barely (0.05 mg/L). Multiplication of microorganisms and invertebrates in distribution systems is limited by a far-reaching removal of biodegradable compounds in water treatment, aiming at achieving water with a high degree of biological stability. Biological stability of water can be assessed by measuring concentrations of easily assimilable organic carbon (AOC) (129,130), concentrations of biodegradable dissolved organic carbon (BDOC) (131,132), or by assessing the biofilm formation rate (BFR) (133).

Furthermore, maintaining biological stability in distribution systems also implies the use of biostable materials, for example, plastic materials that do not release biodegradable compounds into the water (134).

Benchmark Values

Guideline values for invertebrate numbers in distribution systems should be the result of balancing costs for invertebrate control and consumer perception of water quality. A quantitative relation between invertebrate numbers in distribution systems and consumer perception however is not yet available, partly because of the low number of consumer complaints. Benchmark values, based on percentiles of numbers found in distribution systems, can be used by water utilities for comparing their chances of consumer complaints.

If monitoring shows high numbers compared with benchmark values, chances of consumer complaints are higher as well, increasing the incentive for control. In the Netherlands, national benchmark values have been collectively set in 1993 for surface water supplies (136), which recently have been extended and amended to apply for all water supplies (Table 1). Finished water from surface water treatment plants is sampled monthly, independent of abundance. Other sampling frequencies depend on invertebrate numbers in previous samples. Samples are collected every five years if numbers previously found were low to normal, every three years when numbers were elevated, every year when numbers were high, and every six months when numbers were very high. One sample per series is collected from finished water of a (groundwater) treatment plant, and for each 5.10^9 L/yr drinking water distributed, one flushing-water sample is collected in the distribution system (but at least three flushing-water samples are collected for each treatment plant) (45,135). Benchmark values proposed in East-Flanders (a province of Belgium) for individual samples are less discriminating: 0.4/1000 L (elevated), >= 2/1000 L (high), and >= 20/1000 L (very high) for all large invertebrates (generally the same taxa as in the Netherlands, benchmarks valid per taxon, values per square meter converted to values per 1000 L, assuming an inner mains diameter of 100 mm). Values for small invertebrates are 1,000 times higher, values for very small organisms are approximately 2,000 times higher than values for large invertebrates (137). In the city of Antwerp, Belgium, guideline values for Asellidae and Gastropoda (snails) are below 10 per 100 m^2, that is, 4/1000 L (assuming 100 mm inner diameter) based on a relationship between complaints and abundance (22). The benchmark value for median numbers of Asellidae in the Netherlands is strikingly higher ($\geq 30/m^3$ is considered high), considering the limited numbers of complaints reported by the water utilities in the Netherlands (estimated 10 per year) (45).

Table 1. Benchmark Values in the Netherlands for Protozoans and Invertebrate Taxa in Finished Water from Treatment Plants and Water Flushed from Mains (Numbers/1000 L) [From J. H. M. Van Lieverloo, *J. Am. Water Works Assoc.*, (submitted) (45).]

	Finished Water From Treatment Plants[a]							Water Flushed from Distribution Mains[b] (both surface water and groundwater)			
	Elevated numbers[c]		High numbers		Very high numbers						
	Surface water	Groundwater	Surface water	Groundwater	Surface water		Ground water	Elevated	High	Very high numbers	
Numbers/1000 L	Median ≥	Sample ≥	Median ≥	Sample ≥	Median ≥	Sample ≥	Sample ≥	Median ≥	Median ≥	Median ≥	Sample ≥
Very small (<0.5 mm)											
Protozoa	10	30	30	100	500	3,000	1,000	Not determined			
— Ciliophora	5	nd[d]	10	nd	500	1,000	nd	These very small organisms are not collected quantitatively by filtering through 30-μm mesh plankton filters. Furthermore, these organisms are difficult to identify and quantify between the sediment particles in samples.			
— Gymnamoeba	5	nd	5	nd	5	100	nd				
— Testacea	5	nd	10	nd	30	500	nd				
Rotifera	300	30	1,000	100	5,000	10,000	500				
Gastrotricha	5	5	5	10	300	1,000	50				
Tardigrada	5	5	5	5	10	30	30				
Small (0.5–2 mm)											
Nematoda	30	5	80	10	100	1,000	100	50	300	1,000	10,000
Hydrachnellae	5	5	5	5	5	5	5	10	50	100	1,000
Cladocera	5	5	5	5	5	30	10	50	300	1,000	10,000
Ostracoda	5	5	5	5	5	5	5	10	10	10	100
Copepoda	5	5	80	10	100	1,000	50	30	300	1,000	5,000

Oligochaeta	5	5	5	5	5	30	10	30	100	300	10,000
Gastropoda	5	5	5	5	5	5	5	1	1	5	50
Asellidae	5	5	5	5	5	5	5	1	30	100	100
Chironomidae	5	5	5	5	5	5	5	1	1	3	50

[a] 200 L from a finished water tap is filtered through a 10-μm mesh filter.

[b] 1,000 L is flushed out of mains via a hydrant at a flow increase (in mains) of 1.0 m/s and filtered through 500-μm mesh plankton filters. Simultaneously, approximately 100 L of the volume is also filtered through a 30-μm mesh filter (119).

[c] Median numbers per system (treatment plant, distribution system) or numbers in individual samples are classified 'low to normal numbers' when lower than the benchmark value for 'elevated numbers'. Numbers are 'elevated' when higher than or equal to the benchmark value for 'elevated numbers' but lower than the benchmark value for 'high numbers' etc. Benchmark values can be equal for different classifications due to detection limits. Detection limits are 5/1000 L for finished water from treatment plants and 10/1000 L for water flushed from mains.

[d] nd: not distinguished. Protozoan taxa are not distinguished separately in groundwater supplies.

CONCLUSION

The presence of invertebrates in drinking water can be a nuisance to consumers and therefore to water utilities, causing complaints about visible organisms, their body parts, or fecal pellets emerging from taps. The blocking of water supply, especially in water meters, and effects on taste, odor, and microbiological quality are known to occur as well. According to the World Health Organization, the presence of invertebrates in finished water from surface water supplies however is no health risk in developed countries (2). This view is not generally endorsed because of risks attributed to surface water invertebrates protecting pathogenic microorganisms from disinfectants in treatment plants (13,138). Protozoans are known to protect (micro-)organisms from disinfectants, and in some species *Legionella* bacteria may multiply. Therefore, protozoans and invertebrates, especially nematoda, are still under scrutiny from a health point of view (5,139,140).

Invertebrates and protozoans present in source water may immigrate into distribution systems by passing treatment systems, others may intrude via openings in the structure of treatment plants, finished water reservoirs, and distribution systems. In these systems, the organisms may multiply, provided they can adapt to the conditions and they can find enough and suitable food. Adult insects, for instance, are not able to survive in distribution systems because of the absence of air. Planktonic species and filter feeders will perish in most systems owing to a lack of suspended food particles. Benthic grazers, scrapers, and sediment feeders are most likely to flourish, especially when biofilm formation rate on water-exposed surfaces, including sediments, is high. Normal disinfectant residuals will only partly limit biofilm formation, invertebrate survival, and invertebrate multiplication, whereas periodical removal with pesticides, high disinfectant concentrations, or mechanical methods will only temporarily control invertebrate numbers. Because invertebrate populations are able to reestablish quickly, using biofilm and newly accumulated sediments, water utilities will be forced either to frequently repeat reactive control measures or to proactively limit biofilm formation rates and sediment accumulation rates. Considerations about increasing disinfectant residuals to control invertebrates would have to include a balance between consumers opinion about rarely detecting visible invertebrates and a continuous presence of a taste of disinfectants. The limitation of consumer complaints and microbiological deterioration of drinking water during distribution is likely to be attained most efficiently by limiting the availability of food sources for bacteria, protozoans, and invertebrates in distribution systems. An integral cost-benefit evaluation, including the costs of flushing and the use of bottled water as well as the benefits on other quality aspects such as microbiology, toxicology, and discoloration, is however necessary to substantiate further investments in treatment plants.

Acknowledgments

The authors thank Dr. J. Notenboom (RIVM, the Netherlands) and Dr. G. J. Medema (Kiwa, the Netherlands) for their contributions to the paragraphs on groundwater invertebrates and parasitic protozoans, respectively. The authors are much indebted to many colleagues from almost all water utilities in the Netherlands and from Kiwa for collecting and analyzing samples, supplying information on water quality and operations, as well as co-organizing the research within the scope of the Joint Research Program carried out by Kiwa Water Research for these utilities.

ISOSPORA

DAVID S. LINDSAY
Virginia Tech
Blacksburg, Virginia

Isospora species are coccidial parasites of man and domestic animals. The intestinal disease caused by infection by these intracellular parasites is called *coccidiosis*. Human cases of *Isospora belli* coccidiosis are often found in underdeveloped countries of the world where sanitation is poor. Detection of the parasite in feces is the best way to confirm infection.

CLASSIFICATION

Isospora species are in the Kingdom Protista, Phylum Apicomplexa, Class Sporozoasida, Subclass Coccidiasina, Order Euccocidiorida, Suborder Eimeriorina, Family Sarcocystiidae, Genus *Isospora* (1,2). They are in the group of organisms referred to as *coccidia*. They are a group of parasites that must live inside the cell of a host animal. Only their resistant cyst stage (the oocyst) can survive outside of a host cell in the environment (Fig. 1). Coccidia are economically important pathogens of poultry, domestic farm animals, and humans. Coccidia have extremely complex life cycles. Members of the genus *Isospora* can complete their entire life cycle in a single host. However, several have evolved the ability to use paratenic hosts (transport hosts) in their developmental cycles. *I. belli* is the only member of the genus *Isospora* that infects humans, whereas other *Isospora* species are parasites of cats, dogs, pigs, and monkeys. The present discussion primarily considers *Isospora belli*.

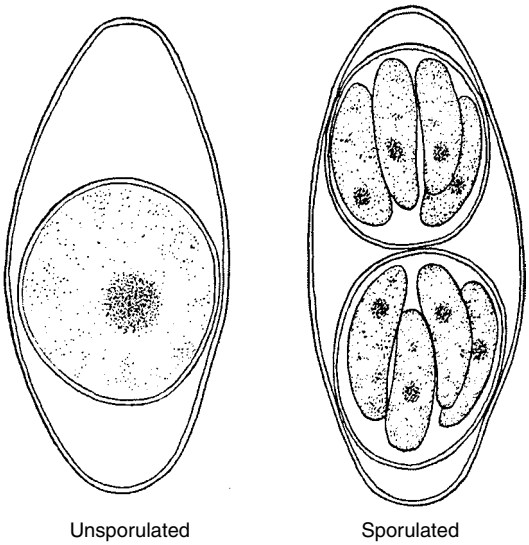

Figure 1. Line drawings of unsporulated and sporulated oocysts of *Isospora belli* from humans.

STRUCTURE AND DEVELOPMENT

Isospora species are eukaryotic protozoan parasites. Their developmental stages are inside of a host cell within a host cell membrane–derived vacuole. Only the environmentally resistant oocyst stage can live outside of a host cell. The Isospora life cycles are complex (Fig. 2). The structure of a specific stage varies with its place in the developmental cycle. The asexual stages are structurally different from each other and anisogametes are produced. Different organelles are present in asexual and sexual stages, but the cell membrane, nucleus, ribosomes, endoplasmic reticulum, golgi bodies, and mitochondria are present in all Isospora developmental stages. The motile asexual stages possess an additional compilation of organelles that form the apical complex of the parasite. The coccidian apical complex is composed of polar rings, conoid, rhoptries, micronemes, and subpellicular microtubules (3). The apical complex is probably involved in host cell penetration. The body of the sporozoite or merozoite is enclosed by a trimembranous pellicle.

The infective Isospora oocyst consists of an oocyst wall that surrounds two sporocysts. Each sporocyst consists of a sporocyst wall that encloses four sporozoites. The wall may contain a pluglike Stieda body in some species or the sporocyst wall may be composed of four plates in other species. The size and shape of an oocyst and sporocyst are characteristic of a particular *Isospora* species.

Genetics

Little is known about the genetics of the *Isospora* species. Phylogenetic analysis of small subunit ribosomal RNA gene sequences from the two major types of *Isospora* species — those with a Stieda body in their sporocysts and those without a Stieda body in their sporocyst (i.e., *I. belli*)–indicates that the two belong to different families (2,4). Based on genetic analysis there is agreement that members of the genus *Isospora* that lack Stieda bodies in their sporocysts should be removed from the family Eimeriidae (2,4,5) and placed into the family Sarcocystidae within the suborder Eimeriina (4).

Life cycle

Coccidial life cycles are complex (Fig. 2). Exogenous (outside the host) and endogenous (inside the host) cycles are present. Paratenic (transport) hosts may also be present.

Exogenous cycle. Sporogony occurs outside the host and is the exogenous phase of the coccidial life cycle. Sporogony (sporulation) is the developmental process that leads to production of infective sporozoites within sporocysts inside the oocyst. Sporogony is dependent on moisture, temperature, and adequate oxygen. Temperatures greater than 40 °C or less than 20 °C inhibit sporulation of Isospora oocysts. Rapid sporulation (<16–24 hours) of

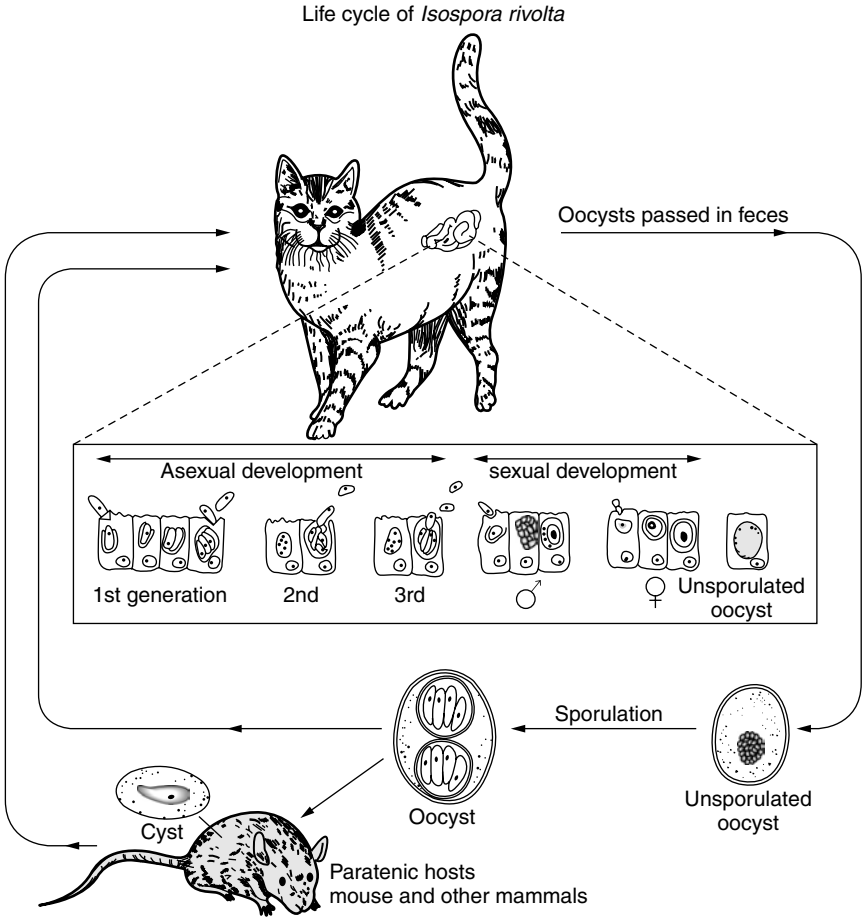

Figure 2. Life cycle of *Isospora rivolta.*

oocysts occurs at 30 or 37 °C. Structural events that occur during sporogony are similar in all *Isospora* species of mammals. Oocysts are excreted in the feces and they usually have a contracted sporont. A few oocysts that are in the sporoblast stage (two-celled stage) are excreted. As the nucleus of the sporont divides, a clear nuclear streak is formed; nuclear division occurs and the sporont divides to form two uninucleate sporoblasts. Nuclear division occurs again and the nuclei are visible as clear areas at the poles of the sporoblast. Nuclear pyramids may be seen at the poles of the sporoblasts. The sporoblasts become elongated and form the sporocyst stage. Nuclear division occurs again and the outline of developing sporozoites soon becomes visible. When the sporozoites are fully visible the oocyst is considered sporulated.

Excystation. Excystation is the process by which sporozoites are released from the sporocysts and oocysts. The process is basically the same for all *Isospora* species of mammals (6). Sporozoites become motile within the sporocysts and tumble or glide around one another. This movement is not continuous, but is interrupted by periods of inactivity. Eventually, the sporocyst wall opens along four platelike junctions and the sporozoites exit through the openings that are formed. Sporozoites excyst from oocysts through indentations or fractures that form in one or both ends of the oocyst wall.

Endogenous Development. Sporozoites enter cells in the intestine but usually do not form rounded uninucleate trophozoites. Some sporozoites and/or merozoites leave the intestine and form dormant cyst stages in extraintestinal tissues. Intestinal sporozoites may retain their elongate sporozoite shape, become binucleate, and divide by endodyogeny to form two daughter merozoites. These daughter merozoites divide by endodyogeny an indefinite number of times. For this reason, the number of sequential asexual merogenous cycles cannot be determined and developmental stages are referred to as structural types instead of generations (6). Eventually, multinucleate meronts are formed. These meronts are elongate and retain their merozoite shape. Several meronts may occur in the same host cell. Eventually, sexual stages are formed. Macrogamonts are uninucleate and are the female gamete, whereas microgamonts are multinucleate and produce biflagellated microgametes (sperm). Microgamonts and macrogamonts may occur in the same host cell. After fertilization, a resistant oocyst wall is laid down around the zygote. The endogenous life cycles in animals that ingest oocysts and in those that ingest paratenic hosts are similar (7). The prepatent period may be shortened in these infections.

Extraintestinal Stages. Extraintestinal stages occur in the tissues of the definitive host in canine and feline *Isospora* species (7–9) and *I. belli* of humans (10). Instead

of undergoing the normal developmental cycle in the intestinal tract some sporozoites or merozoites leave and invade extraintestinal sites in the host. Mesenteric lymph nodes are most often infected; other tissues such as the liver, spleen, and tracheobronchial and mediastinal lymph nodes can also be infected. Infected host cells are probably macrophages.

Mice, rats, hamsters, dogs, cats, cattle, sheep, and camels have been shown to be paratenic hosts for several *Isospora* species. Sporozoites exit from oocysts and invade extraintestinal tissues. Mesenteric lymph nodes are most often infected; other tissues such as spleen, liver, and skeletal muscles are sometimes parasitized. Parasites are most often found as single organisms: division has not been confirmed. For this reason it is more accurate to refer to the host as a paratenic, rather than an intermediate host.

CLINICAL DISEASE AND EPIDEMIOLOGY

Clinical Symptoms

Isospora belli causes serious and sometimes fatal disease in immunocompetent humans. As in all coccidial infections, infants and young children suffer more serious diseases than do adults. Symptoms of *I. belli* infection include diarrhea, steatorrhea (fatty diarrhea), headache, fever, malaise, abdominal pain, vomiting, dehydration, and weight loss (11,12). The cause of the headache is not known. Blood is not usually present in the feces, helping to differentiate *I. belli* diarrhea from other intestinal protozoa (i.e. *Entamoeba histolytic* and *Balantidium coli*). The disease is often chronic, and parasites are present in the feces or small intestinal biopsies from several months to several years. Recurrences are common because of extraintestinal stages in lymph nodes (10).

Isospora belli infection produces diarrhea in AIDS patients. The diarrhea is often very fluid and secretory like, and leads to dehydration necessitating hospitalization. Fever and weight losses are also common findings. Other opportunistic pathogens are also common copathogens in these patients. *I. belli* induces intestinal lesions and responses to chemotherapy are usually similar to those observed in immunocompetent patients.

Isospora belli infections are essentially cosmopolitan in distribution but are more common in tropical and subtropical regions, especially Haiti, Mexico, Brazil, El Salvador, tropical Africa, Middle East, and Southeast Asia. Poor sanitation is a major contributor to *I. belli* transmission.

Modes of Transmission

The only known mode of transmission of *I. belli* is by ingestion of sporulated oocysts in contaminated food or water. Transmission studies indicate that humans are the only true definitive hosts following administration of *I. belli* oocysts. The use of human feces as fertilizer can lead to the contamination of food that is eaten uncooked. Transport hosts such as flies and cockroaches may mechanically carry *I. belli* oocysts on or in their bodies and spread the oocysts from one location to another.

Reservoirs

It is not known if animals may serve as paratenic hosts for *I. belli*. The role of paratenic hosts in the transmission of *I. belli* needs to be investigated to establish if a possible mode of transmission other than by ingestion of oocysts into contaminated food or water exists.

Persistence in the Environment

Coccidial oocysts differ in their ability to survive in the environment, depending on their being sporulated or unsporulated. Unsporulated oocysts are more sensitive to environmental conditions than are sporulated oocysts because sporogony is an active aerobic process. Environmental temperature and availability of oxygen and moisture influence sporogony and oocyst survivability. High temperatures ($>35\,^{\circ}C$) and low temperatures ($<10\,^{\circ}C$) adversely affect the sporulation of coccidial oocysts. Unsporulated oocysts may survive freezing to $-7\,^{\circ}C$ for nearly two months but are usually inactivated within 24 hours at $40\,^{\circ}C$. They do not survive desiccation.

High environmental temperatures are more detrimental to the survival of sporulated oocysts than are low temperatures. Sporulated oocysts are unlikely to survive freezing for more than a few days, or temperatures of $>60\,^{\circ}C$ for more than a few hours. Sporulated oocysts will probably survive for a year or more in the environment under appropriate conditions. Sporulated oocysts cannot survive desiccation.

Methods of Detection

Isospora belli oocysts are 23–36 μm in length and 12–17 μm in width, making them the largest of the coccidial species present in human feces (13) and readily visible unstained with light microscopy. Many methods have been used to detect *I. belli* in human feces. Stained fecal smears made from concentrated samples may aid in the detection of *I. belli* oocysts (13). The modified acid-fast stain produces pink-staining oocysts that contain bright red sporonts or sporoblasts. Additionally, oocysts stained with carbol-fuchsin fluoresce bright red under green light (546 nm). Oocysts stained with the auramine–rhodamine procedure fluoresce bright yellow. When the Giemsa stain is used both oocysts and sporoblasts stain pale blue. The heated safranin-methylene blue technique produces oocysts that are orange red. The trichrome stain, routinely used for other intestinal protozoa, is of little diagnostic value.

Sheather's sugar (specific gravity 1.33) flotation method is an excellent concentration method for recovering oocysts of *I. belli* in fecal samples (14). Oocysts will be in a slightly higher plane of focus than other parasite cysts or ova. Flotation methods are superior to direct fecal smears for recovering *I. belli* oocysts in fecal samples. Other flotation media such as zinc sulfate (specific gravity 1.18) can also be used to concentrate oocysts for recovery from fecal samples.

No work has been published on methods for recovering or concentrating *I. belli* oocysts from environmental samples. Methods used to recover and concentrate

Cryptosporidium parvum oocysts from environmental samples should be effective for *I. belli* oocysts.

K

KINETICS (MICROBIAL): THEORY AND APPLICATIONS

D. K. Button
University of Alaska
Fairbanks, Alaska

Growth kinetics define the dynamics of microbial processes such as the rates of nutrient exchange with the environment and the rates of population change. In natural aquatic environments growth constitutes the synthetic portion of a quasi steady state process in which the organisms produced are consumed by others, resources are used, and waste products are liberated. The uses of growth kinetics include (*1*) estimating the ambient rates of microbial growth, productivity, and metabolic product input such as recyclable minerals; (*2*) measuring the efficiency of nutrient capture for growth and energy as compared to those nutrients that are bioconverted, leaked, or lost, (*3*) evaluating the rate of nutrient acquisition by whole cells as they may be affected by environmental parameters such as alternative nutrients, temperature, and, in particular, the concentration of nutrients, (*4*) determining how the ambient levels of nutrients in the environment are set through kinetic control of in situ microflora, (*5*) assessing the significance of toxins and allelopathic chemicals to the ability of particular species to compete for substrates, (*6*) explaining how particular microbial species in a multinutrient environment may successfully compete with other species, and (*7*) evaluating aspects of cytoarchitecture such as how permeases are distributed on the surface of the cell for maximal capture efficiency with minimal investment in permease and cytoplasmic protein investment.

BASIC CONCEPTS

In kinetic terms microbial growth is an autocatalytic process in which the increase in microbial mass X (Table 1) depends on the amount of mass present and a pseudo first-order rate constant defined by Monod (1) as the specific growth rate μ

$$\frac{dX}{dt} = \mu X \tag{1}$$

The rate constant is actually second-order; both biomass and substrate concentration S control the rate of growth when S is small, as described later. The population attained after a period of growth depends on the initial population and the duration of growth to give a geometric increase in population over time t

$$X = X_0 e^{\mu t} \tag{2}$$

In excess substrate the growth rate constant μ assumes a maximal value μ_{max} that is characteristic of the organism and conditions. In predominantly pelagic systems such as the oceans, μ is typically much smaller than for commonly grown cultures such as *Escherichia coli* due to the evolutionary pressure of limited substrate availability and the energy necessary to transform this substrate into macromoleacules. Then the rate of growth depends on the rate (historically velocity v) of substrate acquisition and the efficiency or yield Y of cells produced from substrate acquired

$$\mu = vY \tag{3}$$

This conversions of substrate S to cell material is at rate μ and observed doubling time of $t_d = \ln 2/\mu$, so that the rate of growth depends principally on the rate of substrate acquisition and yield.

Steady State

The kinetics of growth are often taken from the kinetics of enzyme reaction in vitro. One distinction is the idea of steady state. In enzyme kinetics, steady state means that there is equilibrium between the rates of formation and the rates of release of product from the enzyme surface, with little change in the amounts of enzyme-substrate present as compared to the large changes in the concentrations of free substrate and product over the course of the reaction. Microbial kinetics differ from those used to describe catalysis by isolated enzymes. As used in the laboratory when producing cells or in the fermentation industry, where organisms or their products such as ethanol are a short-term objective, there is also depletion of substrate and an increase in the concentration product over time. But nutrient flux on a per organism basis remains constant and maximal. Often a growth curve with three phases is observed. These are (*1*) lag phase in which adjustment to the new environment occurs — there may be some nutrient uptake with an increase in cell size without formation of new cells, (*2*) exponential growth in which there is a geometric change in population and the exponent in Equation 2 is constant, (*3*) a stationary phase in which growth is terminated due to exhaustion of nutrient or some other reason. Quorum sensors (2) that control populations before exhaustion of nutrient may be involved. Otherwise, the logarithmic phase breaks sharply into the stationary phase as limiting nutrient is exhausted. The transition between exponential and stationary phases is rapid at usual concentrations of limiting nutrients, particularly for aquatic organisms because affinity constants are very small; on the order of 10^{-8} M for organics. When substrate limitation is the prevailing force, such a culture inoculated at 10^{-2} M substrate would grow at its maximal growth rate over nearly its first millionfold reduction in concentration, and (*4*) a decline phase in which the population count decreases due to factors such as starvation, apoptosis, and phage attack.

The steady state for aquatic organisms is somewhat more complete than that for isolated enzymes or for batch

Table 1. Symbols and Units

Term	Definition	Dimensions
a°_S	specific affinity for substrate S; base or unsaturated value	l mg-cells^{-1} h^{-1}
a°_{max}	specific affinity of a perfectly absorbing sphere	l mg-cells^{-1} h^{-1}
a_s	specific affinity for substrate S as reduced by saturation	l mg-cells^{-1} h^{-1}
c	collection constant	5 D M r_S^2 (2 r_X^4)$^{-1}$ l cell (g-cells site h)$^{-1}$
D	molecular diffusion constant	cm^2 s^{-1}
k_{cat}	catalytic constant	moles substrate transformed mole-protein^{-1} s^{-1}
K	substrate concentration at half maximum membrane potential	g l^{-1} or molar
K_a	affinity constant, S at $a^\circ_S/2$	g liter^{-1}
K_μ	Monod, S at $\mu_{max}/2$	g liter^{-1}
K_p	Per particle rate constant	liter particle^{-1} time^{-1}
K_m	Michaelis-Menten constant: concentration of S at $V_m/2$	g liter^{-1}
L	translation coefficient	h^{-1}
M	molecular weight	Daltons
N	number of molecules of a particular permease	molecules cell^{-1}
ψ	membrane potential	volts
R_X	radius of a spherical cell	cm
r_S	effective radius of a permease site	cm
R	ratio of cytoplasm to total organism mass	dimensionless
S	intracellular concentration of substrate; S_i, inside substrate concentration; S_n natural substrate, S_a, added substrate.	g l^{-1} or molar
t_d	time for population to double	time^{-1}
μ	specific rate of growth, μ_{max}, maximal rate	time^{-1}
V	rate of substrate uptake by a cell (v_X) or population of cells	g S l^{-1} h^{-1}, g S cell^{-1} h^{-1}, or g S g-cells h^{-1}
V	maximal rate of substrate moved through a particular enzyme at a given enzyme concentration, V_m, maximal rate	g-substrate accumulated g-cells^{-1} h^{-1}
X	Biomass	g-cells (wet weight) l^{-1}
Y	cell yield	g-cells produced g-substrate-consumed^{-1}

cultures undergoing exponential population increase. Where both organisms and their substrate have a supply and a sink, changes over time are smaller. Over short periods, such as hours, they can be taken as constant. Such systems are at steady state in a different sense. For example, phytoplankton blooms may release amino acids through leakage and sloppy feeding by predators. These nutrients are accumulated in aquatic bacteria largely by active transport in order to attain sufficient cytoplasmic concentrations for efficient distribution to the many enzymes that harvest energy and produce macromolecules. The bacteria reproduce and would also grow in number but are also removed by bacterivores and viral attack. All processes are regulated by negative feedback. If the bacterial removal terms are small, the bacterial population increases, their nutrient consumption rate increases, the concentration of nutrients decreases, and their rate of growth then slows due to nutrient depravation. This is similar to the process in continuous culture in which the rate of growth is controlled by the rate of dilution with fresh medium and the biomass is separately controlled by the amount of limiting nutrient in the fresh medium. The continuous culture steady state process was formulated and elegantly discussed by Herbert and coworkers (3). The amount of limiting nutrient around the cell is controlled by the organism's ability to sequester it, a characteristic of the cytoarchitecture of the species involved. In a well-behaved continuous culture, the concentration of the limiting nutrient can remain constant for days to months, and until upset by an external force. This steady state is formulated as

$$X = Y(S_0 - S) \tag{4}$$

where X is biomass, Y is cell yield, S_0 is substrate concentration in the influent medium, and S is the concentration of substrate surrounding the cells. Under any particular set of conditions, all parameters are constant. However, a change in any parameter such as the flow rate of influent medium, changes all parameters. An increase in the rate of fresh medium supply would lead to a larger S, and therefore a faster rate of growth. The faster rate of growth leads to induction of more enzymes, a change in the distribution of chromosome numbers as given by cell cycle theory (4), larger cells, and

a change in the yield constant Y (5). The yield may either increase due to a decrease in endogenous requirements for enzyme repair and the maintenance of membrane potential relative to consumption by growth processes or decrease due to decreased efficiency and increased loss of metabolic products. The biomass would increase with the added substrate as modulated by changes in yield Y. So at each set of conditions there is a different steady state comprising organisms of different composition and with different properties. Formulations of the kinetics of microbial growth seek to relate rates to nutrient concentration. But these relationships, unlike those for enzymes, span a set of organisms that, even of common species, have different biochemical properties such as DNA content (chromosome number), cell size, and enzyme content as described.

Kinetic Constants as a Measure of S

Growth-rate limiting concentrations of S are too small to easily measure and there have been many attempts to evaluate them by use of kinetics. Droop (6) formulated the rate of growth as a function of the concentration of limiting nutrient by relating changes in cell yield to both μ and S. This was done with a factor called the cell quota Q. The cell quota is the amount of limiting nutrient per cell rather than the amount of cell material produced per limiting nutrient consumed. The difference depends on the amount of limiting nutrient leaked or discarded after harvesting some of its free energy and discarding the waste products in the case of microheterotrophs. For autotrophs the amount of limiting nutrient per cell represents the accumulation of reserves. Q was seen as varying between a minimum value at low rates of growth to a large one when growth rate was maximal. Steady states at different conditions involve organisms of different composition, a change that should be taken into account in kinetic expressions because the nature of the catalyst (the organisms) has changed. But there was too much difference in the way various nutrients were allocated to cell material and the system was too species-dependent to be of general use.

Another technique was to evaluate the change in the rate of change of incorporation of added radiolabeled substrate. The concentration intercept of a Woolf plot, S/v versus S, is the negative of the ambient substrate concentration plus the Michaelis constant, and the ambient concentration of substrate alone when K_m is small (7). But as shown in Figure 1, isotope dilution gives hyperbolic-looking Monod plots (Fig. 1b) even when the kinetics are zero-order (Fig. 1a). Hyperbolic kinetics, like linear kinetics, give linear Woolf plots (Fig. 1c), which in this case, extrapolate to the ambient concentration of substrate since K_m is zero. When the kinetics are mixed as may occur in single-species systems, and certainly in mixed cultures, the S intercept reflects the kinetics of the system with the smaller K_m. In all cases of K_m and S_n the ambient concentration of substrate is ambiguous. Values obtained for carbon sources such as glucose tend to be near analytical values but not for phosphate. This agreement between ambient substrate concentrations and Michaelis constants may simply

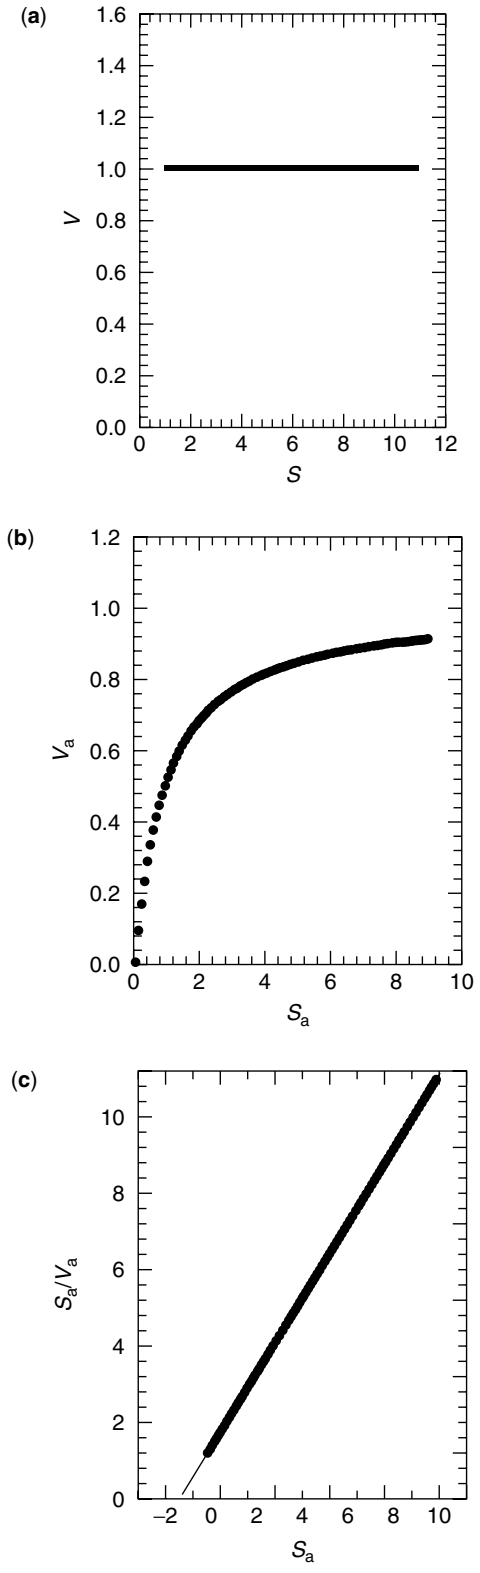

Figure 1. Isotope dilution. (**a**) Michaelis Menten plot of zero-order kinetics with no change in rate with concentration. (**b**) Michaelis Menten plot of apparent kinetics due to dilution of the added isotope S_a with natural substrate S_n calculated from the equation $v_a = va\, S_a/(S_a + S_n)$. (**c**) Woolf plot of the apparent rates showing the same linear transformation as obtained from truly hyperbolic kinetics.

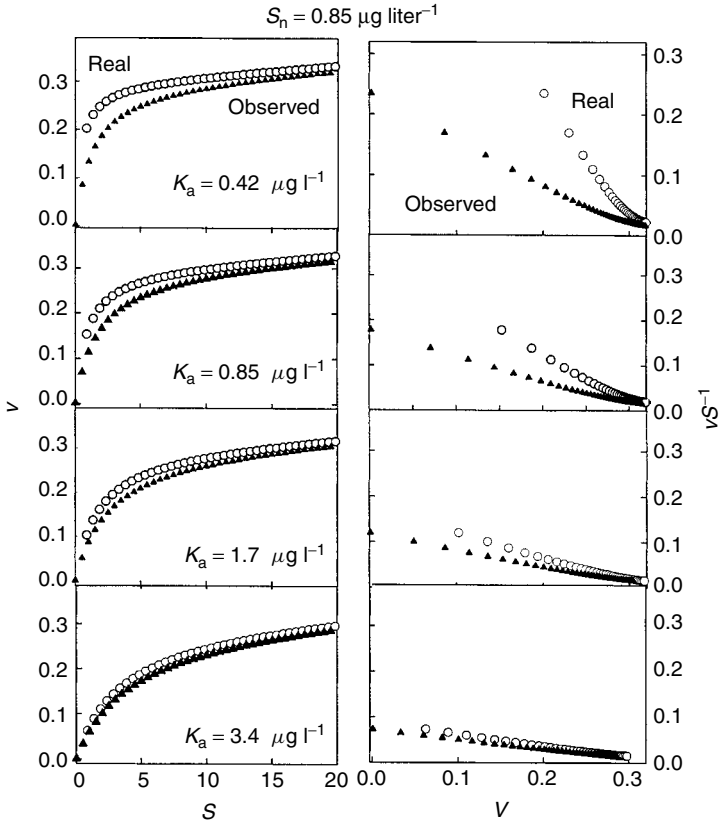

Figure 2. Effect of background substrate S_n on real and observed kinetics on a system having a constant affinity constant K_a. Left, Michaelis Menten plots; right, affinity plots.

reflect the competitive advantage of building only enough cytoplasmic enzymes to use transported substrate at the rate it is supplied from ambient concentrations by the permeases. Truncation of the maximal velocity V_m, for example, by a limited quantity of cytoplasmic enzymes consistent with unneeded rapid rates in low-substrate systems, leads to a proportionate reduction in K_m. This appears to be the main reason that ambient substrate concentrations are reflected by the Michaelis constants of the indigenous microflora.

The effect of background substrate on simulated kinetics from *Marinobacter arcticus* leucine-uptake kinetics is shown in Figure 2. The rate constant that specifies uptake when multiplied by the concentration S is called the affinity a_s (see Equation 18). As background increases, data at small concentrations are eliminated and real specific affinities (ordinate intercepts) of the Scatchard or affinity plots on the right increase. Note that apparent specific affinities decrease with the concentration of naturally occurring substrate. One may calculate the apparent affinity constant by determining v_a/S_a at the half-maximal value, $0.088/0.155 = 0.57$ μg leucine l^{-1}. The real value may be calculated the same way if S_n is known. The effect of the affinity constant on the real and observed kinetics are shown in Figure 3. Notice that the effect of background substrate on kinetics is minimized with increasing K_a. Also, the vertical positioning of the data in the affinity plots remains constant, values are only shifted with respect to rate. This means that the specific affinity of a culture or population a_S may be determined irrespective of the concentration of background substrate. The rate will be that at ambient substrate concentration and calculated from measures of S_b. Even when unknown, values are an accurate comparative determination of the activity of the population toward the added substrate that may be reported in the absolute units of specific affinity.

KINETIC FORMULATIONS FROM COLLISION FREQUENCY

A General Rate Constant

Other factors being constant, the rate of substrate acquisition depends on the concentration of the substrate. For the special case of a single substrate such as phosphate or glucose limiting the rate of substrate collection by a reasonably large cell ($r_x \approx\geq 0.5$ μm), uptake rate depends on the frequency of successful collisions of substrate with the cell (8). For a perfectly absorbing particle the rate is defined by the second-order rate constant k_p. considering a single cell, the population term is unity and

$$v_p = k_p S \tag{5}$$

The rate constant k_p is a composite constant that may be influenced by (*1*) the diffusive-resistance of the medium, (*2*) the abundance, kinetic characteristics, and energization of the permeases, (*3*) the disposition of transported substrate among resources for cytoarchitectural and maintenance requirements, and (*4*) potential downpathway limitations to the flow of material such as few cytoplasmic enzymes. It has been the implicit subject of several reviews (5,9,10). The simplest and most popular

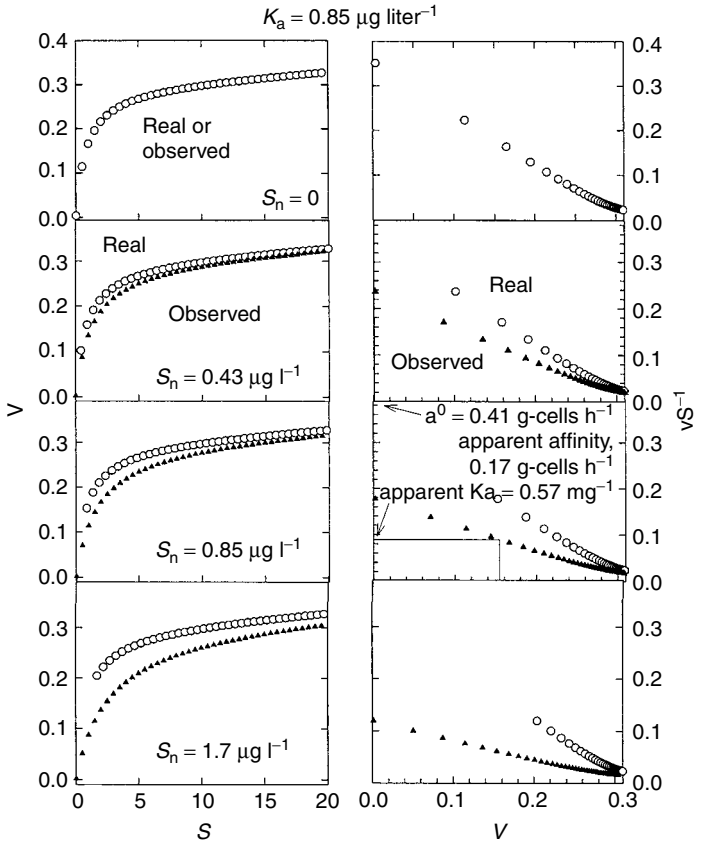

Figure 3. Same as Figure 2, showing the effect of the affinity constant K_a on system kinetics when background substrate S_n is constant.

formulation derives from the hyperbolic Michaelis Menten relationship for an enzymatic reaction (11).

$$v = \frac{V_m S}{K_m + S} \tag{6}$$

It is written for the rate of transport by a whole cell by taking V_m as the maximal rate of substrate transport by the cell. The basis of the formulation is that V_m is a characteristic of the organism set by the rate of substrate release from the substrate-permease complex or related rate-limiting step. At low concentrations of substrate, saturation is alleviated and the rate constant will increase due to a larger portion of the substrate-permease collisions being amenable for collection. When the substrate concentration is lowered sufficiently to reduce the transport rate by half, the Michaelis constant K_m is defined by that concentration. K_m is affected both by the decrease in transport due to the smaller concentration of substrate and by the increase in the rate constant for transport because the effects of saturation are less significant. It is commonly taken as a property of the permease that reflects increasing affinity with decreasing values. However, increasing numbers of permeases increase the ability of the cell to accumulate substrate without directly affecting K_m due to a corresponding increase in V_m. K_m can therefore be eliminated from Equation 6 by dividing through by V_m/K_m. When V_m/K_m is defined as the maximal value of the rate constant for uptake called the specific affinity a°_S is V_m/K_M (12). It obtains from the rate constant portion of Equation 6, $V_m/(K_m + S)$ at $S = 0$, and

$$v = \frac{V_m a^\circ_S S}{V_m + a^\circ_S S} \tag{7}$$

Specific Affinity

Specific affinity can be taken as a measure of the ability of cells to accumulate substrate. Values maximize at decreasing concentrations of substrate so long as nutrition is sufficient to maintain activation of the permeases. The associated Michaelis constant is taken as the concentration at which transport rate is reduced by saturation to half the unsaturated value in cells that have abundant cytoplasmic enzymes sufficient to process the product, intracellular substrate, as it is pumped in. This may apply to many easily cultivated large bacteria such as *E. coli*. For abundant but difficult-to-isolate aquatic bacteria it might better be taken as a measure of the ratio of cytoplasmic enzymes to permeases. These organisms require abundant permeases to collect substrate but few cytoplasmic enzymes to process them because substrate concentrations are always low. Then as substrate concentrations increase this capacity is overloaded, saturation appears, and K_m decreases. In either case the specific affinity should remain unchanged in its ability to reflect the capacity of the cells to accumulate substrate at concentrations that are small. It may be determined in the presence of background substrate if the background is small with respect to K_m,

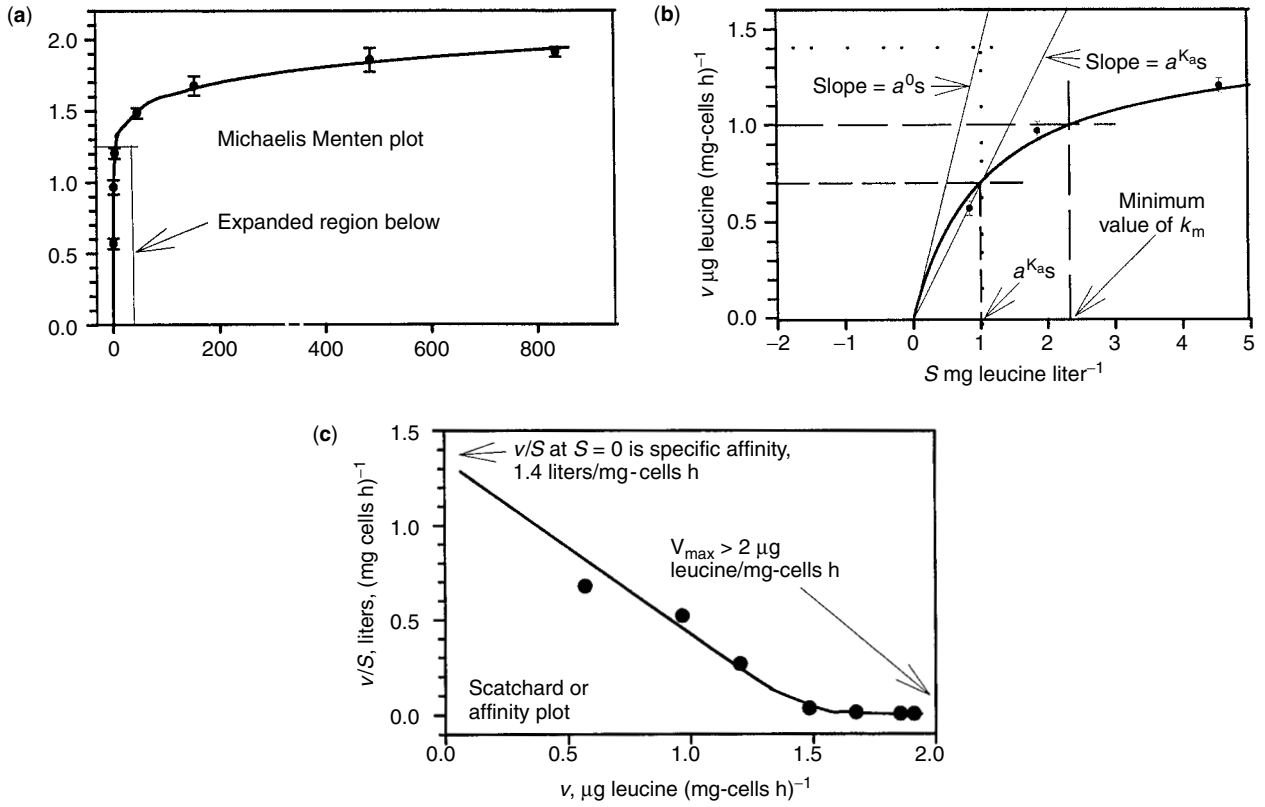

Figure 4. (**a**) Michaelis Menten plot of radiolabeled leucine uptake by toluene grown *M. arcticus* over time. (**b**) Expanded low-concentration data. (**c**) Scatchard or affinity plot of all data. Ordinate intercept gives the specific affinity and abscissa intercept gives the maximal velocity, which in this case is indeterminant. Kinetic constants are identified in (**b**) showing the specific affinity as the initial slope of the kinetic curve, the affinity constant as the concentration when the specific affinity is reduced by half, and the Michaelis constant as the substrate concentration when the maximal velocity is reduced by half.

or more accurately K_a, because a°_S is a measure of the second-order rate constant and both the uptake rate and concentration of radiolabeled substrate are diluted with background substrate by equal amounts. The various kinetic constants are represented diagrammatically in Figure 4. The specific affinity is a rate constant that measures affinity while K_a is a capacity term that measures how large S must be before saturation becomes significant. The other capacity term V_m is a measure of maximal capacity. When on a biomass basis it is like the specific affinity, and unlike K_a and K_m, which depend on V_m, in that it can be independently specified.

Monod Growth Kinetics

The common derivative of the Michaelis Menten equation for substrate transport is the Monod equation for growth (1) that is obtained from Equation (6) by replacing V_m with the maximum rate of growth μ_{max}, and K_m with K_μ the substrate concentration at $\mu_{max}/2$ so that $\mu = vY$ (Equation 1) and

$$\mu = \mu_{max}\frac{S}{K_\mu + S} \tag{8}$$

Limiting concentrations of substrate are generally below those which may be accurately analyzed so departures of experimental data from the theory are generally insufficient to distinguish among various models (10) and the Monod formulation, like its parent Michaelis Menten relationship from enzyme kinetics, and substrate transport discussed above remains a popular way of expressing the relationship between nutrient concentrations and growth. In aquatic systems additional factors such as endogenous metabolism and membrane potential attain dominant significance as affectors reducing μ when S is small. In this case it is useful to consider the underlying theory.

Molecular Collision Frequency and Nutrient Accumulation

The theoretical upper limit for the rate of substrate transport at concentration S depends on the radius of the cell, r_X, and the molecular diffusion constant D of the substrate (13).

$$v = \left(\frac{4\pi r_X D}{1,000}\right)S \tag{9}$$

This rate, written in terms of the second-order biomass-based rate constant for uptake or specific affinity gives

the theoretical maximal rate constant $a^\circ_{\max}$ and assumes complete coverage of the cell surface with permease. The real value a°_S is smaller according to the area (radius) of the active site r_S of each *active* permease, their number N, and the radius of the organism to give the base (unsaturated) value of the specific affinity a°_S

$$a^\circ_S = a^\circ_{\max}\left(\frac{N\pi r_S^2}{4\pi r_X^2}\right) \tag{10}$$

At substrate molecular weight M, the number of permease molecules per organism, as specified by the specific affinity according to the active surface area based on the diffusivity of the substrate D is

$$N = \frac{2a^\circ_S r_X^4}{5DMr_S^2} \tag{11}$$

For the case of hyperbolic saturation, usual in nonsteady state systems in which the organism composition is constant, incubation times are short, and all permeases are active, then $a^\circ_S = V_m/K_m$ and uptake rate in terms of the specific affinity, maximal rate, and substrate concentration is approximated by Equation 7. V_m defines the reduction in rate of substrate import due to saturation because it specifies the time τ that the relevant protein is occupied by substrate according to $\tau = NV_m^{-1}$ in the case of limitation by permease alone. If the activity of a particular enzyme is taken as reflective of maximal rate through the pathway, then the maximal rate V_m is $k_{cat}N$ where k_{cat} is the catalytic constant for that representative protein. The concentration-dependent specific affinity a_S becomes

$$a_S = a^\circ_S - \frac{va^\circ_S}{k_{cat}N} \tag{12}$$

or in terms of residence time in the permease

$$a_S = a^\circ_S - \frac{va^\circ_S\tau}{N} \tag{13}$$

If $5\ D\ Mr_S^2/2r_X^4$, which has the units liters cell (g-cells site h)$^{-1}$, is set equal to a constant c, the maximal value of the specific affinity $a^\circ_S = Nc$. Since rate is related to substrate concentration by the saturation dependent affinity a_S and $v = a_S S$, Equation 14 becomes a more compact formulation of the specific affinity

$$a_S = \frac{Nc}{1 + Sc\tau} \tag{14}$$

which gives the permease-dependent rate constant for substrate uptake in molecular terms.

Janusian Kinetics

Oligobacterial cytoarchitecture is thought to favor high permease content over large amounts of cytoplasmic enzyme to facilitate nutrient collection without the overhead of a large or densely packed cytoplasm (14). Flux control may then shift from transport to metabolism. Conventional treatments of coupled enzyme reactions are generally designed to explicitly treat a changing concentration of substrate and become complex. However, the kinetics can also be treated with Janusian kinetics, so named because the central rates respond or "look" in both directions, forward and back like the Roman god Janus (15).

We may formulate transport as a series of steady state processes with rates and rate constants that differ at each concentration. Solution is obtained by writing a material balance around the concentration of the cytoplasmic substrate (Fig. 5) to arrive at a different concentration of transported substrate at each rate of transport, where R is the ratio of cytoplasm to total organism mass.

Change in cytoplasmic concentration of S_C = Transport of S into cytoplasm − output of S_C from cytoplasm

$$R\frac{dS_C}{dt} = \frac{NcS}{1 + Sc\tau} - \frac{VS_C}{K_m + S_C}$$

The relationship between the concentration of substrate in the cytoplasm and the rate of transport of substrate to the cytoplasm can be specified by a translation coefficient L. Based on experimental evidence for the transport of phosphate (16) this relationship was taken as linear and first-order in substrate. When rate is translated into concentration with L, the overall rate of transport $v = LXRS_C$, where X is biomass and R is the ratio of cytoplasm mass to cell mass. At steady state $dS_c/dt = 0$, and the second two terms are equal. Solving for S_C and substituting into Equation 7 gives the rate of transport in molecular terms

$$v = \frac{VNcS}{K_mRL(1 + S_c\tau) + NcS} \tag{16}$$

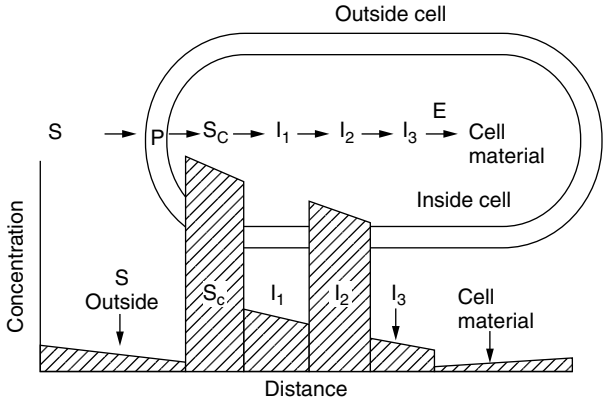

Figure 5. Model for solving Janusian kinetics in which the system flux is taken as flow to and from an intracellular pool S_C. These are in equilibrium with a series of intermediates I at various concentrations (histogram) depending on their relative amounts and kinetic characteristics. One enzyme labeled E catalyzes a particular difficult step that controls rate when S is large. Otherwise that rate is controlled by the number of permeases P and the concentration of S. Due to changes in S_C and the various intermediates, some control of rate is shared by all steps.

Specific affinity is the initial slope of Equation 15, that is, the rate constant for uptake at any external concentration of substrate when all the permeases are activated but concentrations are sufficiently low to avoid significant saturation by substrate. Differentiating as described (15) we obtain the rate of transport in terms of kinetic constants as

$$a^{\circ}_{S} = \frac{NVc}{KRL} \tag{17}$$

SOME PROBLEMS THAT MAY BE SOLVED BY USING MICROBIAL KINETICS

Theoretical Analysis of Cytoarchitectural Requirements

Equation 18 shows the value of increasing both number of permeases and cytoplasmic enzymes for an increased specific affinity. However, an increased cytoplasmic enzyme content at constant cell volume to mass ratio leads to larger cells, which decreases the collection constant c. So specific affinity and permease content are directly related, counter to the common paradigm taken from enzyme kinetics (17) in which affinity is a property of the quality of an enzyme or microbial species. Cytoplasmic enzyme concentration, when modeled as an increase in V_m, increases the ability of cells to collect substrate at concentrations that are small due to S_c removal, but the effect on rate at large substrate concentrations is greater. However, maximal velocity may not be constant over a change in the steady state concentration of substrate and the rate is likely to be a complex function of S. For example, when substrate concentration is low for extended periods, the membrane potential $\Delta\Psi$ may collapse and the effective number of permeases is decreased until sufficient substrate concentrations are experienced to empower them. In this case N should be replaced with the number of energized or active permease molecules N_a where $N_a = f\ (N,\ \Delta\psi)$. Thus, kinetics may be used to resolve the physiological composition of microbial populations.

Nutrient Acquisition Ability

For purposes of producing many cells or much product, μ_{max} is the most appropriate measure. Organisms require many cytoplasmic enzymes and much RNA for this purpose. For growing in dilute environments specific affinity is the best measure. From it the rate of growth can be calculated from the ambient concentration of nutrients. If a particular nutrient is used by an independent pathway, the specific affinity of that pathway adds to that of others to give a net effective value. If different nutrients are transported through the same permease and the permease is limiting, then inhibition transport of one nutrient competes with another. If limiting is by independent cytoplasmic enzymes with specificity for particular nutrients, then inhibition is absent.

Rates of Growth

Most direct measures of growth rate are imprecise, but values can be calculated from specific affinities and ambient concentrations of nutrients. These concentrations are difficult to measure as well, but precision is possibly greater than the uncertainty in the rates of growth. Kinetic constants for a number of systems are shown in Table 2. Taking a large springtime value for the uptake of leucine by the heterotrophic bacteria in Resurrection Bay as 830 liters/mg-cells h, and the concentration of leucine as 1 μg/liter the rate of growth from leucine may be calculated. Using the per particle rate constant from Equation 5 as the specific affinity before saturation becomes significant,

$$v = a^{\circ}_{A}A \tag{18}$$

where A is the single substrate leucine from a mixture. Marine bacteria are thought to be very dilute, that is, low in cytoplasmic enzyme content, to maximize surface to mass ratios and give ample room for their genomes, below 20% in dry mass (14). Taking the yield constant as unity for wet mass produced from substrate consumed

$$\mu = vY \tag{19}$$

Combining Equations 2 and 19

$$\mu = \left(\frac{830\ \text{liter}}{\text{g - cells h}}\right)\left(\frac{1\times10^{-6}\ \text{g leucine}}{\text{liter}}\right)\left(\frac{1\ \text{g cells}}{\text{g leucine}}\right) = \frac{8\times10^{-4}}{\text{h}} \tag{20}$$

The calculated doubling time is $\ln 2/\mu = 860$ h, a large value for an active system. Assumptions are that all the bacteria used to measure the specific affinity are alive and able to use leucine. Other substrates could contribute to the substrate flux and shorten the doubling time accordingly.

The ambient value for growth rate may also be determined by diluting out natural populations with filtered raw fresh or seawater. Since predation is a second-order process, their effects are minimized and the rate of growth is approximated by Equation 2 and the apparent rate should approach the true rate as X approaches 0 (40). These dilution-culture based measurements of growth rate are complicated by nutrients released from larger organisms during filtration and the fact that dilution inhibits growth and metabolism for reasons unknown. Again values should agree with values computed from nutrient flux or other methods.

Leakage Rates

Unidirectional fluxes and associated rate constants may be computed from a pulse of radiolabeled substrate. The best experimental platform for conducting these relaxation experiments is a continuous culture system in which the radioactivity of nutrient feed can be controlled and the system remains at a chemical steady state. Easily derived, the equations are somewhat bulky and the reader is referred to detailed treatments (16,41).

Ambient Concentrations of Nutrients

These can be accurately determined in continuous culture by extrapolation of Equation 4 to zero-added substrate concentration while changing the rate of growth by altering the rate of dilution. As the chemical composition

of the feed is known, it can be isotopically labeled, the intercellular radioactivity can be separated into substrate and products if any, and concentrations and kinetics can be determined. If the organisms used are typical of the system, the ambient concentration can be inferred.

For natural systems one can follow indirect measures of growth such as the ratio of two to one chromosome cells, membrane potential, RNA content, and others. The first two (unpublished, this laboratory) and possibly the third (42) can be done by flow cytometry. Nutrient combinations are then added until a positive response is attained and the ambient concentrations are inferred from the additions required to elaborate the response. If the organisms are also labeled with species-specific probes, the response can be related to particular species. One problem is to isolate changes in the concentration of the probed parameter from interspecies differences in permeability to the probe. Another is toxicity of the probes. These methods remain to be developed.

CONCLUSION

Microbial kinetics, the quantitative description of how nutrient concentrations control microbial dynamics, are an integral component aquatic system behavior. Formerly based on chemical catalysis by isolated enzymes,

formulations may now be based on first principles that specify aspects of organism cytoarchitecture. Continued advances depend in part on improved quantitative analyses of both the molecular biological components of microorganisms such as the molecule count of particular enzymes and the concentration of identified nutrients in aquatic systems. Key kinetic constants are the specific affinities of the organisms because they give the rate of nutrient uptake from the ambient concentrations of nutrients and also give an absolute comparative basis of the ability of species or populations to sequester nutrients, and maximal velocity, which gives the rate of nutrient uptake when nutrient concentrations are large and a measure of the nutrient uptake capacity of the system. These completely define the kinetics when the kinetics are Michaelian. When maximal velocities increase with substrate, saturation can also be specified with an affinity constant that identifies half-saturation concentrations by comparison with the maximum value of the specific affinity. These kinetic constants define a quasi-steady state that largely sets the total biomass in the oceans and the rate that both the microflora and the concentrations of nutrients turn over because populations have maximized when nutrients become too dilute to support growth. The nutrient concentration just sufficient to support growth is set by the nutrient sequestering ability or specific affinity of the organisms. That is, in turn, a biochemical property of the organisms that is set by organism cytoarchitecture. So organism kinetics set the nutrient concentration of the oceans as well. Specific affinities can be obtained by measuring the rate of acquisition of added radiolabeled nutrients together with organism biomass present but the nutrient concentrations that they act upon are best determined by chemical analysis.

KINETICS OF MICROBIAL PROCESSES AND POPULATION GROWTH IN SOIL

DAVID A. LIPSON

STEVEN K. SCHMIDT
University of Colorado
Boulder, Colorado

The kinetics of microbial growth and substrate utilization in liquid culture have been worked out in great detail (1,2). However, it has become acknowledged that kinetics in soil are greatly affected by the complex physical environment of soils. Much progress has been made towards incorporating soil physical effects into the current understanding of the kinetics of microbial processes in soils. It is also becoming recognized that significant microbiological activity occurs in soils under extreme environmental conditions. For example, recent work shows significant microbial activity in frozen soils. Further integration of soil physics and microbiology is needed to address this issue. This review synthesizes new and classic work on the physical and biological factors that affect kinetics in soil. Physical properties of soils that affect movement and availability of chemicals, properties of soil microbial populations and communities that affect growth and uptake kinetics, and environmental factors that modulate the activities of soil microbes will be discussed.

SOIL PHYSICAL FACTORS

Important factors that can limit the rate of microbial processes in soil are properties of the soil that limit the movement of chemicals to microbes. The effect of abiotic processes on the bioavailability of organic molecules has received much recent attention by ecotoxicologists and soil microbiologists (3). In addition, many empirical studies have demonstrated the rapid decrease in availability of chemicals after addition to soil (e.g., 4,5). One study (4) showed that cinnamic acid (0.1 mg/g) could not be extracted from sterile soil after only two days of incubation. This decreased bioavailability of chemicals in soil can be because of several factors including: (*1*) slow rates of chemical diffusion in soil, (*2*) sorption of chemicals to soil particles, (*3*) processes such as sequestration into soil organic matter or micropores, and (*4*) interactions between microbial enzymes and the soil matrix. More details of how each of these physical factors affects the kinetics of microbial processes are given in the following sections.

Diffusion of Solutes Through Soil

Slowed diffusion of chemicals in soil relative to aquatic environments can be explained in terms of the complexity and tortuosity that chemicals must transcend as they move through the soil matrix (Fig. 1). In order for a compound to get from point A to point B, it not only has to diffuse through the soil solution but it also has to diffuse around and through the labyrinth that is the three-dimensional structure of soil. This tortuosity greatly slows the movement of chemicals from their point of release to organisms capable of transforming the chemical. The size, structure, charge, and polarity of the chemical can also affect this rate of chemical movement in soil. Another consequence of the tortuosity of soil is that chemicals interact with many surfaces and micropores as they move through soil. This increases the chances of the chemical being sorbed or sequestered as it moves through the soil.

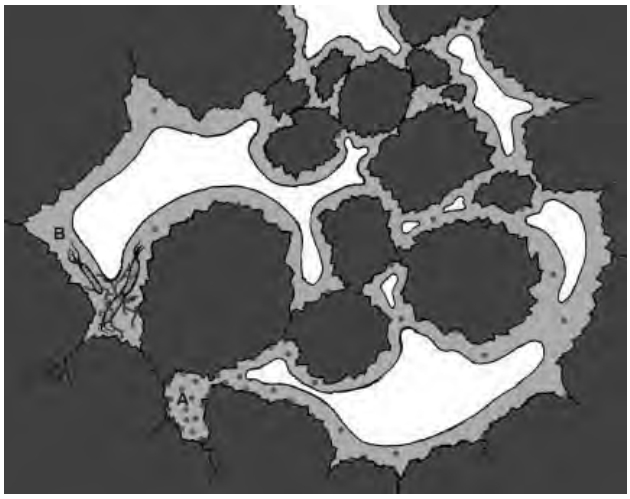

Figure 1. Diagram showing substrate molecules (red dots) diffusing down a concentration gradient from micropore A to bacterial colony B. The solid phase is shown in brown, the liquid phase in blue, and the gas phase in white. Note the relatively long distance that molecules must travel despite the short linear distance between A and B, because of the tortuosity of the water films. The substrate molecules are also shown adsorbing to soil surfaces, further slowing their movement. See color insert.

The diffusion rate of molecules down a concentration gradient through soil is directly proportional to the Nye diffusivity parameter, D_e (units of $m^2\ s^{-1}$), which is defined by the equation:

$$D_e = \frac{\theta f D_L}{\beta_e} \tag{1}$$

where θ is the volumetric soil water content (mL H_2O cm^{-3} soil, unitless), f is the impedance or tortuosity factor (unitless), D_L is the diffusion coefficient in liquid ($m^2\ s^{-1}$), and β_e is the buffering capacity of the soil (unitless). The characteristics of the soil affect most of these parameters. The volumetric soil water content is, of course, subject to the water holding capacity of the soil, which is determined by texture and organic matter content. The impedance factor is a function of water content, bulk density, and texture. For silt loams and lighter-textured soils, workers (6) found that:

$$f = 1.6\theta - 0.172 \tag{2}$$

In a different study (7), it was found that f was the highest in silt loams at a bulk density of 1.3, and decreased above or below that value. Values of f are much lower (i.e., higher tortuosity) for finer-textured soils.

The liquid diffusion coefficient is described by the Stokes-Einstein equation:

$$D_L = \frac{K_B T}{6\pi r_i \eta} \tag{3}$$

in which K_B is the Boltzmann constant (1.3807×10^{-23} J/K), T is the absolute temperature (K), r_i is the ionic radius (m), and η is the viscosity of the liquid (kg m^{-1} s^{-1}). Because of the temperature term in the equation, and because the viscosity of water decreases with increasing temperature, the diffusion rate is sensitive to temperature.

The buffering capacity, β_e, describes the tendency for a specific compound to bind to soil surfaces. The general effect of a high β_e on kinetics is to lower the effective concentration of the substrate in the soil solution. This results in higher apparent half-saturation constants (K_s) of microbes in soil compared to liquid culture (8,9). For example, one study (9) found that the amount of dinitrophenol needed to induce the half-maximal growth rate (μ_{max}) was 20 to 130 times higher in soil than in liquid culture for two different microbial populations. The buffering capacity is defined as:

$$\beta_e = \frac{\delta C_S}{\delta C_L} \tag{4}$$

where C_S is the bulk soil concentration of the compound and C_L is the soil solution concentration (both in units of kg m^{-3}). This parameter is related to the slope of the adsorption isotherm (10). The adsorption isotherm shows equilibrium values of partitioning between the solid and liquid phases for different initial concentrations. In most cases, the isotherm asymptotically approaches a maximum as the solid phase becomes saturated at high concentrations. This curved type of adsorption isotherm is known as the "L (Langmuir) type." Unless the adsorption isotherm is of the linear type, or the soil concentration is sufficiently low as to lie on the quasilinear part of the curve, β_e varies with substrate concentration. The buffering capacity is also affected by soil pH and the presence of high salt concentrations. Nonlinear adsorption can complicate kinetics; one study (11) found that biodegradation of glutamate diffusing out of artificial aggregates did not always fit a model that included constant diffusion and sorption terms.

The buffering capacity (β_e) is a measure of solutions at equilibrium with the solid phase. The use of β_e in Equation (1) therefore assumes that equilibration of the diffusing molecules is rapid relative to their motion through the soil. This is not necessarily the case. One researcher (12) pointed out that experimentally derived adsorption isotherms rely on artificially high solution:soil ratios, which could affect substrate-soil interactions, and presented a method for calculating D_e from a measured diffusion profile in a soil. Some studies have used two-compartment kinetic models to describe release of substrates from fast- and slow-desorbing soil fractions (13,14). In the latter study, the slow-desorbing fraction was interpreted as constituting a limited number of binding sites with high affinity for the substrate. In the former study, the slow-desorbing fraction was interpreted as soil aggregates or organic matter particles, from which diffusion was slow. The presence of aggregates can affect degradation rates in soils by controlling diffusion of oxygen and substrates. Researchers (15) combined two models to simulate degradation of contaminants within aggregates and in macropores between aggregates. It was found that biodegradation rates were lower in soil with large aggregates (>1 cm) compared to homogenized soil. Experiments and model simulations of biodegradation in artificial aggregates showed that biodegradation was slower in soil with larger aggregates, and that the effects of diffusion and sorption were required to model this process (11,16).

Diffusion of Gases Through Soil

Unlike the positive relationship between soil moisture content and the diffusion of solutes through soil solution discussed in the preceding section, soil moisture content strongly limits the rate of gas diffusion in soil because gas diffuses much more slowly through water-filled pore spaces than through air-filled pore spaces (17). This fact is illustrated by the one-dimensional equation for diffusion of gas through soil derived from Fick's law:

$$F = \tau \theta_A D \left[\frac{\delta C}{\delta z}\right] \tag{5}$$

where F is the flux rate (mol m^{-2} s^{-1}), τ is the tortuosity of the air-filled pore space (unitless), θ_A is the fraction of pore space filled with air (unitless), D is the diffusion constant for the gas in free air (m^2 s^{-1}), and $\delta C/\delta z$ is the concentration gradient (mol m^{-4}). This tortuosity factor (τ) (not to be confused with f mentioned earlier in terms of water films) has been modeled (18) as:

$$\tau = \theta_A^{(1/3)} \tag{6}$$

$\tau = 1$ in free air. Both, the tortuosity and the pore space decrease with increasing water content, in turn slowing the diffusion of the gas through soil.

The availability of oxygen (O_2) can be the limiting factor for aerobic microbial activity, and can determine the extent of anaerobic activities such as denitrification or methane production. Therefore, CH_4 and N_2O production are frequently related to soil water content (19–23). However, Sierra and Renault (23) found that immediately after heavy rainfall events, O_2 can be trapped in soil pore water and that an equilibrium between soil water and atmosphere is not reached for 12 to 24 hours in these cases.

Sorption

The kinetics of microbial processes in soil is greatly complicated by the mineral and organic matter fractions of soil. These solid phases bind substrate both reversibly and irreversibly. Reversible sorption leads to slowed

rates of movement and lower substrate concentrations in the soil solution, whereas irreversible sorption leads to overall decreases in the quantity of substrate available to microbes. Soils with high levels of organic matter or high clay contents generally retain compounds more than sandy soils (4,24). The types of clay and aluminum and iron hydroxides in soil can influence the ability of soil to adsorb molecules (25). Because many phenolic acids have a relatively low pK_a (<5), they are ionized at the pH values of all but the most acidic soils (4) and as such are more likely to interact with positively charged sites on clay minerals.

Sorption usually involves reversible interactions with exchange sites on soil surfaces, but irreversible complexation of chemicals can also occur. Although the exact mechanisms of these reactions are not completely understood, they do seem to be of importance in certain soils. In general, such reactions lead to strong (probably covalent) linkages with the humic fraction of soil rendering the chemical unavailable to microorganisms (3,26). Humus can fix ammonium and amino acids to a state where these compounds become resistant to acid hydrolysis (27), and a wide variety of organic compounds are associated with mineral fractions of soils (28). In one study, binding of surfactants to humics prior to incubation in soil slowed biodegradation of the surfactants, whereas preincubation with illite or montmorillonite reduced the overall extent of biodegradation (29). In another study, the addition of moderate amounts of clay minerals to protein slowed degradation by bacteria without affecting the overall yield, whereas higher clay to protein ratios protected some of the protein from hydrolysis, thus lowering the yield (30). Clearly, the extent of irreversible sorption depends on many factors, including the concentration and type of substrate and the types of organic and mineral soil colloids present.

Extracellular Enzymes

Another novel aspect of soils that affects the kinetics of microbial processes is the widespread presence of extracellular enzymes in soil. These enzymes are especially important in the degradation of large and complex molecules, such as protein, cellulose, and lignin. Extracellular enzyme activity is generally correlated with microbial biomass levels (31–33), however certain enzymes can persist in soils long after the death of the microbes that released them. Stable enzyme-clay and enzyme-humic complexes have been shown to function in soils (34,35). Interactions between enzymes and soil components have a variety of effects on enzyme activity, affinity and stability. For example, urease forms a stable complex with hydroxyapatite in alkaline soils. Relative to the free enzyme, the complexed form shows an increased pH optimum and stability to storage and proteolysis, whereas the half-saturation constant (K_s) is unchanged and the maximum velocity (V_{max}) decreases only slightly (36). The adsorption of enzymes onto clays frequently increases their pH optima, probably because of conformational changes in the enzyme owing to charge interactions with the clay surfaces (37). Clay and humus colloids can increase enzyme resistance to thermal stresses, such as heating and freeze-thaw cycles (38). In the case of acid phosphatase, enzyme-clay complexes have higher K_s values and lower stability to storage and proteolytic attack relative to the free enzyme (39). Whereas montmorillonite binds and inhibits acid phosphatase, it was found that the addition of aluminum hydrous oxide to the enzyme-clay mixture increased both the binding of the enzyme and its residual activity (40). Manganese oxides aid in the formation of phenolic-enzyme complexes, which may occur in the formation of humus (41).

Microbial enzymes can act in concert with soil abiotic factors in immobilizing chemicals. Soil microorganisms can transform chemicals into more recalcitrant and less toxic forms, which contribute to the humic fraction of soils. A number of microorganisms have been shown to polymerize phenolic compounds using enzymes, such as polyphenoloxidases and laccases (42,43). Polymers produced by these fungi are usually dark colored and can appear rapidly in response to additions to soil of suitable substrates such as ferulic acid (44).

Catalytic Properties of Abiotic Soil Components

Some abiotic components of soils are capable of catalyzing reactions in soils. For example, clays can catalyze the polymerization of amino acids to form peptides (45). Amino acids can polymerize or be mineralized by reactions with phenolics in soil (41). Manganese oxides, such as birnessite can enhance the abiotic mineralization of carbon and nitrogen from amino acids (46). The coenzyme, pyridoxal-5′-phosphate, can deaminate amino acids in the absence of enzyme using metal salts and clays as catalytic surfaces (47).

BIOLOGICAL FACTORS

Many processes in soil are microbially mediated, and so the properties of the microbial populations present in soil have fundamental importance for the kinetics of these processes. The most obvious controlling factor is the size of the functional group or population that can carry out a specific process. However, the growth and uptake kinetics of these organisms are equally important, as is their requirements for limiting nutrients and electron acceptors. Each of these factors will be discussed in turn.

Population Size

In many cases, the zero-order rate of a process is directly related to the size of the functional group responsible for carrying it out. This relationship is so obvious that the rate of a given process is often used as a way to estimate the size of the functional group carrying out the process. For example, substrate induced respiration (SIR) (48), the substrate-induced growth response (SIGR) method (49–51), and arginine ammonification (52) all correlate with various other more direct measures of microbial biomass. In one study on the rate of amino acid degradation in soil, differences in rates of glycine and glutamate degradation were related to the size of the group of microbes able to metabolize each substrate (53). In the extreme case, a process will not occur at all unless there

Table 1. Differential Forms of Equations for Substrate Disappearance and the Conditions Under Which They Theoretically Appear (S is the Substrate Concentration, X is the Biomass, K_s is the Half Saturation Constant, and μ_{max} Is the Exponential Maximum Growth Rate)

	Growth ($S_0 \gg X_0$)	Nongrowth ($S_0 \ll X_0$)
$S_0 \ll K_s$	Logistic $-dS/dt = dS(S_0 + X_0 - S)$	First order $dS/dt = \mu_{max}(X_0/K_s)S$
$S_0 > K_s$	Monod $-dS/dt = \mu_{max}S(S_0 + X_0 - S)/(K_s + S)$	Michaelis-Menten $-dS/dt = \mu_{max}X_0S/(K_s + S)$
$S_0 \gg K_s$	Logarithmic $-dS/dt = \mu_{max}(S_0 + X_0 - S)$	Zero order $-dS/dt = \mu_{max}X_0$

is a population capable of carrying out the process, as in many bioremediation studies in which specially selected organisms are added to contaminated soil (e.g., 54).

The organisms that are collectively responsible for carrying out a specific observable process are referred to as a functional group. The size of a functional group affects not only the overall rate, but also the type of kinetics observed. If a group of organisms is utilizing an organic substrate, the size of the functional group relative to the substrate concentration determines whether growth or nongrowth kinetics will result (see Table 1, and discussion in the section titled The Use of Respiration Data in Studies of Kinetics in Soils). For example, workers attempting to model mineralization kinetics for low concentrations of pesticides in surface and subsurface soil found that growth models best fit the subsurface soil, whereas nongrowth models best fit the surface soil (55). This is easily explained by assuming a smaller microbial population in the subsurface soil that was stimulated by low pesticide inputs that were insufficient to support growth of the larger surface population. On the other extreme, if a small population is confronted with excessive amounts of substrate, long lags can occur before measurable degradation occurs, or degradation of the substrate can halt altogether. In a study of the degradation of various concentrations of mecoprop in surface and subsurface soil, the maximum concentration that allowed growth was lower in the subsurface soil, again indicating a smaller subsurface microbial population (56).

Growth and Uptake Parameters of Soil Microbial Populations

The ability of microbial populations to absorb and assimilate a particular substrate directly affects its fate in soil. The kinetics of microbial population dynamics in soil can be described by a number of mathematical models, most of which were conceived for microbes growing in liquid media, for example, Michaelis-Menten or Monod kinetics (1,50). As one example, the Monod equation describes the essential properties of a microbial population with respect to the disappearance of a growth-limiting substrate:

$$-dS/dt = \mu_{max}\frac{S(S_0 + X_0 - S)}{(K_s + S)} \quad (7)$$

where S is the substrate concentration at time t ($mol\,m^{-3}$), S_0 is the initial substrate concentration ($mol\,m^{-3}$), X_0 is the initial biomass ($g\,m^{-3}$), μ_{max} is the maximum specific growth rate (s^{-1}), and K_s is the half-saturation constant ($mol\,m^{-3}$). Because biomass appears in this equation in units of substrate required to create the biomass, the growth yield is another parameter that is implicitly contained in this equation. Put more simply, the rate determining factors for a given population size using a growth-limiting substrate are the growth rate, the affinity for the substrate, and the efficiency with which the substrate is assimilated into biomass. The Monod equation is a good heuristic tool for understanding the relationships between population characteristics and the utilization of substrate, but it seldom accurately describes microbial processes in soil. The reasons for this include soil physical factors that limit the movement of chemicals to microbial cells (see preceding section titled Diffusion of Solutes Through Soil), and nutrient limitation and other biological factors, discussed in the following sections.

Limiting Factors and the Effect of Second Substrates

Often the substrate of interest is not the growth-limiting factor. In these cases, other characteristics of the microbes become important, such as requirements for a limiting nutrient (e.g. 57) or terminal electron acceptors (58,59). Nutrient limitation completely changes the kinetics of biodegradation (60,61). Degradation under such conditions is determined by the supply rate of the limiting nutrient, which can cause logistic or linear growth curves (62,63). Nutrient limitation can also enhance degradation; some nitrogen- or phosphorous-containing organic compounds will only be utilized if the microbial community is nutrient limited (64). Another important characteristic of a given functional group is the range of substrates it can utilize. In one study (65), workers induced growth kinetics in the degradation of low levels of *para*-nitrophenol by adding larger levels of phenol to the soil. Thus, the rate of transformation of a compound in soil is affected by the presence of similar compounds that the microbial population can utilize.

Effects of Microbial Community Composition

Soil microbial communities are complex, containing thousands of bacterial types (66). A study of the kinetics of DNA reassociation showed soil microbial communities to be orders of magnitude more complex than aquatic microbial communities (67). The composition of the microbial

community can cause deviations from standard growth models and has a profound influence on kinetics in soil. Filamentous microbes, such as fungi and actinomycetes, grow linearly over time on agar, and in liquid culture the cube root of the mass increases linearly over time (68). The predominance of filamentous microbes in a community could lead to nonexponential growth rates in soil. There is evidence that first-order kinetics does not always apply to fungal cultures in soil under conditions in which first-order kinetics would be expected with bacterial populations (63). The fungal-to-bacterial ratio in soil can also affect the apparent growth yield of functional groups in soil (69). Changes in growth yield by microbial biomass have been observed in response to fertilization (70,71). In both studies, microbial biomass was not affected by inputs of mineral fertilizer, but rates of respiration were affected. Long-term inputs of nitrogen can also cause shifts in the relative sizes of functional groups. Nitrogen limitation during decomposition of wheat straw caused a reduction in fungi but bacteria were unaffected (72). Nitrogen-fertilized alpine soils showed significantly reduced phenol degradation but degradation of glutamate and glucose were relatively unchanged (Schmidt and Lipson, unpublished data). Community shifts can also occur in response to seasonal changes, causing shifts in substrate utilization (73), and temperature response (74). Competition experiments using bacteria with different temperature optima and substrate affinities show that different organisms would dominate in different seasons (75), and so kinetic properties of the community could change as well.

Microbial community composition can also affect the kinetics of microbial processes in cases in which multiple populations are utilizing the same substrate. For example, it has been observed (9,76) that the kinetics of 2,4-dinitrophenol mineralization in soil indicated that two physiologically distinct populations were responsible for the process. One population functioned at high dinitrophenol concentrations (high K_s population) whereas the other was dominantly active at much lower dinitrophenol concentrations (low K_s population). Such "multiphasic" kinetics has been observed in several other aquatic and soil studies (77,78).

RESPONSES OF MICROBIAL ACTIVITY TO ENVIRONMENTAL FACTORS

From what has been stated in the preceding text, it is clear that the rate of a microbially mediated process in soil at any given moment is affected by a large number of variables. The picture is further complicated by the ever-changing soil environment. Microbial processes are subject to nonlinear effects from the dynamics of temperature, soil moisture, and predation. These are discussed in the following section.

Temperature

The rate of most chemical reactions increase exponentially with higher temperature according to the Arrhenius equation:

$$k = A \exp\left(\frac{-E_a}{RT}\right) \tag{8}$$

where k is the first-order rate constant (s^{-1}), A is a constant called the frequency factor (s^{-1}), E_a is the activation energy ($J\,mol^{-1}$), R is the ideal gas constant (8.3145 $J\,mol^{-1}\,K^{-1}$), and T is the absolute temperature (K). However, the effect of temperature on biological processes is harder to predict. Biologically mediated reactions are usually the result of several processes working in concert, each with its own response to temperature. Furthermore, enzymes and membranes can only function within a certain temperature range and so biological processes peak at some optimum temperature close to normal environmental conditions. Near the freezing point of water, physiological and diffusional effects further complicate rates of biological processes. Despite these factors, a narrow range usually exists where process rates obey the expected exponential relationship with temperature. This is especially true for enzymatic activity measured in isolation from other biological activities. One study (79) found that several soil exoenzymes obeyed Arrhenius kinetics within the range of 2 to 30 °C. They reported Q_{10}s (defined as the proportional increase in rate with a 10 °C increase in temperature) ranging from 1.3 to 4.1, with most falling close to 2.0. Workers (80) reported Q_{10}s for proteolysis and microbial uptake of amino acids as 1.98 and 2.57, respectively. As an example of how temperature responses of complex biological reactions can lead to subtle results, it was noted in the previous study that the higher temperature sensitivity of amino acid uptake compared to production could lead to higher availability of amino acids at lower temperatures. In an experiment with laboratory-incubated forest soils, researchers (81) reported that net nitrogen mineralization increased with temperature over the range of 5 to 25 °C, but that respiration showed a relatively flat response to temperature and peaked at 10 °C. The authors reasoned that microbial respiration became substrate limited at higher temperatures. In one study (82) it was observed that more labeled carbon and nitrogen from added substrate was retained in microbial biomass at lower temperatures, indicating that microbial turnover increased with temperature. This illustrates that mineralization is a balance between uptake and microbial turnover and that these processes have different temperature responses. A wide variety of positive, neutral, or negative relationships between microbial biomass and temperature have been reported (83).

Temperature affects not only the growth rate of microorganisms, but their growth yield and substrate affinity, as well. Lower growth yields are associated with higher growth rates (84), and hence, with higher temperatures. On the other hand, very slow growth rates can lead to low growth yields as well, as the energy required for maintenance of cells becomes significant relative to the carbon being assimilated into biomass (60,85). Substrate affinity sometimes decreases near 0 °C (75), although it has also been reported to increase with decreasing temperature (86).

Microbial and enzymatic activity can occur below the freezing point of water, and biological activities in soils at subzero temperatures have been reported (51,87–89). Significant mass loss of litter during winter has been observed in several ecosystems, although physical effects

could also be involved (90,91). The limit to biological activity in cold soils is not temperature, itself, but the availability of liquid water. There is always some liquid water present in frozen soils, but the width of the liquid film decreases, more or less sharply depending on mineral type, as temperature drops from 0 to −5 °C; liquid films of 50 Å or wider exist at 0 °C, and of about 6 Å at −5 °C or below (92). This creates a tortuous and discontinuous distribution of water in frozen soils, just as in very dry soils, that limits diffusion of molecules to microorganisms. Thus, diffusion coefficients of ions decrease with temperature in the same way the liquid water film width does (93).

Another important effect of freezing on the kinetics of soil processes is the disruptive effect of freeze-thaw events on soil aggregates and microbial cells. Freeze-thaw events tend to stimulate microbial activity in the short term (94–96) by releasing nutrients occluded in soil aggregates (97) or from lysis of cells (98,99). Researchers (95) have argued that repeated freeze-thaw cycles can have a long-term inhibitory effect on microbial activity by reducing the microbial population size. The rate of freeze determines the severity of effect on the soil microbial biomass. In an alpine soil, microbial biomass was not affected by freeze-thaw events designed to simulate spring and fall conditions (74,100).

Soil Water Content

In addition to the direct effects of soil water content on diffusion mentioned above, kinetics in soils are also affected indirectly by physical effects of fluctuating water content and by biological effects of osmotic stress on microbes. In dry soils, microbial activity can be limited both by osmotic stress and by diffusional limitation (101). Dry-rewet cycles can physically disrupt soil aggregates and microbial biomass much like freeze-thaw cycles do, as mentioned in the preceding text. This effect can enhance microbial activity by freeing substrate occluded in aggregates and by releasing nutrients from microbial biomass (102,103), but can reduce activity by lowering population sizes (104).

As discussed for temperature in the preceding section, the effect of soil water content on a given process depends on a complex set of factors. For most processes there is an optimum moisture content that balances both O_2 and water availability. In a field study of several alpine communities, CH_4 oxidation rates were stimulated by rainfall in drier soils, whereas the oxidation rates were negatively correlated with soil moisture in more moist soils (105). The stimulation of CH_4 oxidation by rainfall in dry soil may not have been purely because of release from water limitation of the methanotroph population, but may have been caused indirectly by creating anaerobic microsites in which methanogenic activity provided substrate for the growth of the methanotroph population (22,106). This again illustrates the complex interdependency among processes and environmental factors in soil.

Soil Texture and Carrying Capacity of Soil

Microbial growth in soil frequently follows a logistic pattern in which growth approaches a finite limit because of some environmental factors, such as substrate limitation (63). The carrying capacity can be also determined by some extrinsic factor such as the number of ideal sites for an organism. The abundance of colonizable surfaces and pores depends on soil texture; finer textured soils have smaller pores and more surface area. Bacteria living in small pores would be protected from predation by protozoa, whereas those in larger pores could be readily eaten. Various modeling studies (e.g., 107,108) predicted the turnover of microbial biomass according to the clay and silt content of soil.

MODELS OF MICROBIAL GROWTH AND SUBSTRATE USE

Many approaches have been used to model kinetics in soils. These include empirical models and models based on biological and/or physical theory. The shape of substrate disappearance curves depends on all the factors mentioned herein: the soil physical factors that affect substrate movement and availability, the initial substrate and biomass levels, the kinetic properties of the microbial community, and the many potential environmental factors, such as temperature and the availability of nutrients and water. In the following section we briefly review models of microbial activity, and discuss the practical matter of how to analyze respiration data from soils. For thorough reviews of mathematical models of microbial growth and biodegradation, see references (63,109).

The Use of Respiration Data in Studies of Kinetics in Soils

Carbon dioxide evolution from soil is commonly used to monitor degradation of added substrates (e.g. 48,49,110). Special caution should be exercised when analyzing carbon dioxide evolution data from soil incubations. Several research groups (e.g. 49,110,111) have stressed that analyzing accumulated CO_2 data leads to a number of statistical problems including nonrandom residuals, autocorrelated parameters and residuals, and underestimation of experimental error (Fig. 2). It is therefore preferable to use nonaccumulated rate data and the differential form of kinetic models to analyze soil respiration data. Examples of this approach to analyzing soil respiration data can be found in the literature (49,78). Most commercially available statistics packages contain algorithms for performing nonlinear regression and several reviews of this approach are available (109,112,113).

Variations on the Monod Equation

In liquid culture growth of bacteria occurs when initial substrate concentration (S_0) is high compared to initial biomass (X_0). Exponential growth occurs if S_0 is much higher than the half-saturation constant for the microbial population ($S_0 \gg K_s$), Monod kinetics occurs when S_0 is slightly higher than K_s ($S_0 > K_s$) and logistic growth occurs

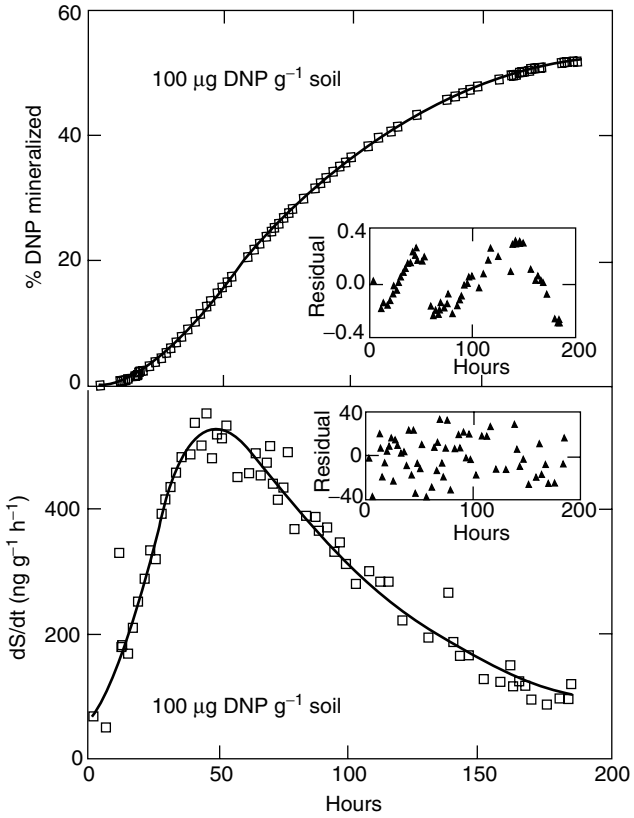

Figure 2. Respiration of ^{14}C-labeled dinitrophenol in soil graphed as cumulative CO_2 produced vs. time (A) and as CO_2 evolution rate vs. time (B). The residuals are shown in the inset of each panel, and show that fitting of accumulated data leads to nonrandom residuals. (Modified from Hess and Schmidt (110)).

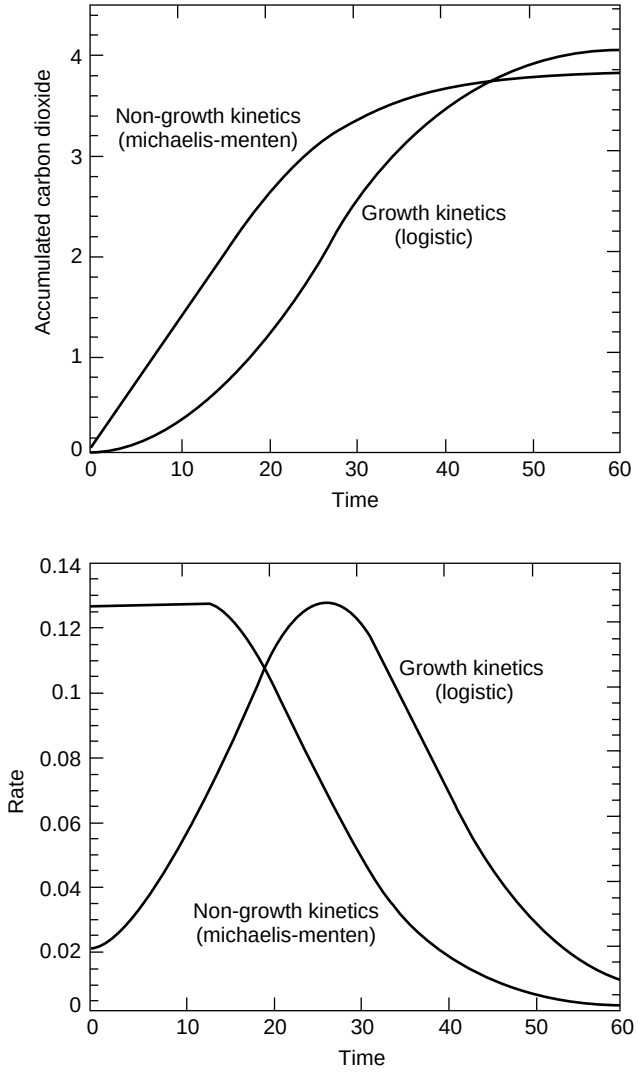

Figure 3. Shapes of typical growth (logistic) and nongrowth (Michaelis-Menten) kinetic curves: (A) graphed as accumulated product vs. time, and (B) as rate of product formation or substrate disappearance vs. time.

when $S_0 \ll K_s$. If S_0 is low relative to X_0, nongrowth kinetics occur, and conditions when $S_0 \gg K_s$, $S_0 > K_s$, and $S_0 \ll K_s$, result in zero-order, Michaelis-Menten, and first-order kinetics, respectively. The forms of these equations are all derived from the Monod equation, and are shown in Table 1. Examples of some of these types of curves are shown in Figure 3.

The Monod equation has been modified to include various biological effects (109). For example, several studies (e.g., 114) have modeled the biodegradation of inhibitory substrates using the variations of the Haldane equation:

$$\mu = \mu_{\max} \frac{S}{\left[(K_s + S)\left(1 + \frac{S}{K_i}\right)\right]} \tag{9}$$

where K_i is the inhibition constant, defined as the highest concentration of S at which $\mu = \mu_{\max}/2$. The Monod equation has also been modified to include the effect of metabolic maintenance requirements when microbial populations are subsisting on very low concentrations of substrate. The modified equation takes the form:

$$\mu = \mu_{\max} \frac{S}{(K_s + S) - a} \tag{10}$$

where a is the specific maintenance rate associated with nongrowth metabolic processes. This modification improved the modeling of degradation of low levels of pentachlorophenol and dinitrophenol in soils (85). The maintenance term, and other zero-order terms added to other models discussed in the following text, seem to be most important when very slow growth is occurring. This is when theory predicts growth yields would be low and maintenance requirements would be high (60).

Models of Microbial Activity in Soil

In soil, the effects of diffusion and sorption cause further deviations from the Monod model. Theoretically, observed kinetics in soils are best dealt with using two-compartment models that take into account the slow and fast release of substrate from soil aggregates and surfaces (e.g., 13–16). These models can be quite complex but represent a fairly realistic view of kinetics in soil. Data can also be modeled

effectively with an empirical approach, most commonly using 3/2 power kinetics (e.g., 29,56,62). The linear and exponential growth versions of the 3/2-order model are represented, respectively, as:

$$P = S_0 \left\{1 - \exp\left[-k_1 t - \frac{(k_2 t^2)}{2}\right]\right\} + k_0 t \quad (11)$$

$$P = S_0 \left\{1 - \exp\left[-k_1 t - \left(\frac{E_0}{\mu}\right)(\exp(\mu t) - 1)\right]\right\} + k_0 t \quad (12)$$

where P is product concentration, S_0 is the initial substrate concentration, and the k_n are rate constants. In Equation (11), k_2 is the linear growth rate, and in Equation (12), μ is the exponential growth rate. E_0 is related to the initial biomass by the relation, initial biomass $= E_0/a$, in which the constant, a, describes the dependence of the first-order substrate disappearance rate on biomass. It was found (62) that the linear model generally fit the data better except when microbial populations were first greatly reduced by gamma irradiation. The authors attributed this effect to the slow diffusion of substrates through thick layers of cells coating soil surfaces. The 3/2-order model is generally most effective under conditions in which little or no growth occurs, and has the advantage of fitting an initial acclimation phase and a late slow mineralization phase (62,63,115). Empirical models have the disadvantage of providing little heuristic information about the mechanisms affecting the observed kinetics. The parameters in the above 3/2 models are hard to interpret in a biologically or physically meaningful way. Some workers have interpreted the zero-order rate constant, k_0, to represent the "indigenous" slow, steady turnover of carbon in soil (62), others as the slow release of substrate from the soil matrix (29), and yet others as the metabolic energy expended by the microbes to maintain their biomass during long periods of slow growth (85).

Nutrient limitation or microbial community effects can cause growth to be linear or biphasic under conditions where exponential growth would otherwise be expected. The presence of stable soil colloid-extracellular enzyme complexes can further decouple kinetics from existing microbial populations. One study (29) found no correlation between the mineralization of contaminants and total microbial biomass or activity, but rather found major effects of the abiotic soil fractions present. In short, when observing microbial processes in soil, anything can happen. Fortunately, a variety of models have been developed, and existing models can be modified for most any given system.

CONCLUSION

Soil is a labyrinth of mineral and organic fractions with ever-changing microclimatic conditions and a diverse community of poorly understood microorganisms. To realistically include all potentially important factors in predicting a process rate would result in an excessively complicated and unworkable model. But despite the seemingly intractable complexity of the soil ecosystem, researchers have made great progress in understanding and predicting the kinetics of microbially mediated processes in soils. If one is flexible in one's model selection and allows for the myriad of possibilities that could arise, the situation is not hopeless. However, gaps in our knowledge still exist. More research is particularly needed to understand microbial community-level effects on processes in soil. Although we know almost nothing about the characteristics of most of the thousands of microbial species in soils, how they interact with each other, or their spatial and temporal distributions in soil microenvironments, this type of information is becoming increasingly available by way of powerful molecular techniques (116). It would be fruitful to integrate the current rapid advances in microbial ecology with the existing knowledge of microbial kinetics in soils.

LANDFILLING OF MUNICIPAL SOLID WASTES: MICROBIOLOGICAL PROCESSES AND ENVIRONMENTAL IMPACTS

I. A. WATSON-CRAIK
University of Strathclyde
Glasgow, United Kingdom

Waste treatment and disposal are increasingly assessed against the hierarchy of waste management (1), in which disposal is viewed as the ultimate option for those wastes whose management cannot be addressed by recovery (e.g., recycling, composting, and energy recovery), reuse, or minimization/reduction. With municipal solid waste (MSW), some waste minimization can be achieved through reduced packaging or by use of longer-lasting products. Materials recycling is well established but may not be appropriate in all cases, for example, in which the cost of reprocessing is greater than virgin production, in which there are abundant raw materials, or in which there is no market for the recycled product (1). In the United Kingdom, the landfill tax was introduced in 1996, as a nonregulatory instrument to encourage recycling and reduce the volumes of waste going to landfills. However, the effectiveness of this strategy in terms of MSW, in which disposal costs are passed on to local taxpayers, is not yet evident. What is clear is that landfilling is still the major route for MSW disposal (Fig. 1) and is likely to remain so for many years. Even in countries where geography, economics, and legislation have stimulated other management options (Fig. 1), landfill is still a major disposal route.

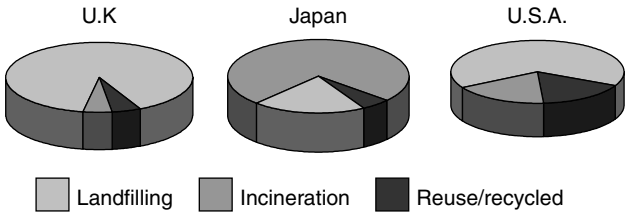

Figure 1. Waste disposal methods in the United Kingdom, Japan, and the United States.

MSW DECOMPOSITION AND STABILIZATION

The composition of MSW (1) shows clear geographic variations (Table 1), reflecting, for example, diet and the extent of domestic food preparation, solid fuel for domestic heating (ash content), and use of packaging materials (paper/card and plastics). Despite this variability, the decomposition and resultant stabilization of MSW follows a common pattern. Initial aerobic activity, whereby aerobic bacteria use soluble substrates such as sugars, as electron donors, is constrained by rapid depletion of oxygen (O_2). Within successive, layered, refuse depositions, conditions rapidly become anaerobic and a succession of chemical and microbial interactions mediates biodegradation of

organic polymers. The transient aerobic phase, similar to a composting process, is, nonetheless, important, because it is only the waste metabolic heat, which is retained within the site owing to the insulating properties of refuse layers, that permits long-term refuse temperatures greater than 30 °C.

Landfill sites may be considered as multimillion cubic meter anaerobic digesters, in which a heterogeneous, mainly carbohydrate, feedstock is digested under suboptimum environmental conditions, with minimal intervention, by a diverse microbial population (Fig. 2). MSW typically comprises 40 to 50% cellulose, 12% hemicellulose and 10 to 15% lignin on a dry weight basis (5), of which only cellulose and hemicellulose are potentially amenable to anaerobic biodegradation. Not only is lignin highly recalcitrant under anaerobic conditions, but its integration into cellulosic tissues may also limit access of hydrolytic enzymes to cellulose (6). The predominantly carbohydrate nature of MSW is reflected in the estimation that more than 90% of the methane potential of refuse can be attributed to the cellulose-hemicellulose fraction (5).

Microbial degradation of insoluble polymers requires extracellular, hydrolytic enzyme activity, and a range of studies has demonstrated the presence in MSW of proteolytic, cellulolytic, and amylolytic organisms (7,8). Reports either describe total numbers (7) or attempt species identification (8). For example, 10 mesophilic cellulolytic Clostridia isolated from an MSW anaerobic digester showed similarity to, but were distinct from, *Clostridium cellulolyticum* and other previously isolated mesophilic Clostridia (8). It is generally accepted that there is in landfill sites a diverse hydrolytic population, whose composition reflects specific site conditions, and that hydrolysis is not limited by the metabolic capabilities of the genetic pool but rather by mass-transfer and kinetic properties.

In close association, fermentative bacteria reduce these soluble products to volatile fatty acids (VFAs), alcohols, ammonia, and carbon dioxide (CO_2). The fermentation, in turn, of these VFAs and alcohols to acetate, CO_2, and hydrogen (H_2), by acetogenic bacteria (see BIOSOLIDS: ANAEROBIC DIGESTION OF, this Encyclopedia) requires low partial pressures of hydrogen. For example, the acetogenic fermentation of propionate is only energetically favorable ($\Delta G' = -5.3$ kJ) at pH_2 less than 10^{-4} atm (9). Despite transient H_2 concentrations less than or equal to 20% by volume that have been recorded in landfill gas (10), suitably low H_2 concentrations are common and presumed to be due to the hydrogenotrophic activities of methanogenic, sulfate-reducing (SRB), or homoacetogenic bacteria. The significance of homoacetogenesis in MSW has not been assessed, although it was suggested that methanogens would outcompete homoacetogens (11).

The low sulfate and sulfide concentrations in most landfills, as evident from leachate analyses (Table 2), suggest that sulfate reduction is not a significant hydrogen sink. Wang and coworkers (12) measured the biochemical methane potential (BMP) of refuse samples and calculated that even if all sulfate removal from the cultures was at the expense of methane production, the corrected BMP was still at least 96% of the uncorrected, theoretical value. Moreover, although it is generally accepted that SRB can theoretically outcompete methanogens, because of their enhanced substrate affinities for H_2 (13), it has been demonstrated

that under specific circumstances, for example, in which growth is predominantly attached, electron flow may be preferentially directed to methanogenesis (14). However, although of little significance in terms of overall electron flow, SRB may play an important role in the complex web of refuse-microbial interactions (Fig. 3). For example, as a reducing agent, sulfide may contribute to the low redox conditions (often <-300 mV) required for the growth of methanogens (15).

In actively methanogenic landfills, most electron flow is clearly directed toward methanogenesis. The transition of a site from the acetogenic to the methanogenic phase is signaled by concentration decreases in both H_2 and acetate. The initiation of significant methanogenesis may occur only after many months of acetogenesis, due presumably to a range of factors such as a requirement for redox potentials <-300 mV and low methanogenic growth rates. The significant decreases in soluble C subsequent to methanogenesis are commonly used to support the hypothesis that polymer hydrolysis and not syntrophic H_2 transfer ultimately limits methane release. The methanogenic phase may persist for several decades, depending on the quantities and characteristics of the landfilled refuse, environmental conditions, and site-management practices. Even under optimum conditions, complete degradation of the organic fraction of MSW

cannot be expected, owing to the biological recalcitrance of materials such as plastic, rubber, and leather, and the anaerobic persistence of lignin and lignocellulosic materials. Thus, landfills represent a net carbon (C) sink, whose significance in the global C-cycle was estimated (6) to be at least 119 million tonnes per year, or 5 to 10% of the 1–2 Gt C y^{-1} of "missing" C previously identified.

It is clear, however, that in situ C releases, as methane, from landfill sites fall far short of the theoretical yields. Variability in measurement techniques and waste type limits the usefulness of comparing yields. Theoretical yields have been reported to vary from 229–372 $m^3\,t^{-1}$ wet material (2) to 152 $m^3\,t^{-1}$ dry material (5), whereas estimated average yields vary from 100 to 240 $m^3\,t^{-1}$ wet material (2).

FACTORS INFLUENCING GAS YIELD AND COLLECTION

The factors that influence methane production in landfills have been extensively investigated and reviewed (4,22).

Moisture

There is general agreement that moisture in many sites is the single most influential modifier, although the optimum moisture levels reported have ranged from 60% to 80% (22), significantly in excess of fresh refuse values (15–45%). It is thus not surprising that leachate recycle has been shown to enhance the onset and rate of methanogenesis (23), given that this will increase moisture content and substrate availability, and provide a degree of mixing. A dry site cannot, therefore, be assumed to pose less of an environmental hazard, because future moisture infiltration could elicit a rapid microbiological response.

Temperature

In landfill sites, in which temperatures are defined by the length and activity of the aerobic phase and by site-management practices (for example, leachate recycle and refuse compaction), temperatures generally are mesophilic (22) and often below the optimum 35–40 °C. All methanogens so far identified are either mesophilic or thermophilic (15) (see BIOSOLIDS: ANAEROBIC DIGESTION OF), and although methanogenesis has been recorded environmentally at temperatures as low as 4 (24) and 6 °C (25), the laboratory samples in all cases exhibited optimum temperatures around 35 °C. Where methanogenesis has been recorded in sites at temperatures greater than 50 °C (26) it is not clear whether this reflects a truly thermophilic population.

Refuse pH

Significant methanogenesis can occur in refuse samples at pH 5.7 (27) and has been recorded in sites in which the pH ranged from 5.5 to 8.3 (28), although most methanogens are considered to have optima near neutrality (15). It is probable that this reflects refuse heterogeneity, by which the pH in refuse microniches may be greater than that in pore water. Nonetheless, a pH value less than or equal to 5.5 is still considered detrimental to the initiation of methanogenesis in situ (28). Whether the inhibition is due to general pH effects or to specific inhibition by individual VFAs was investigated by use of multistage continuous culture systems, in which the pH values were poised and which were supplemented with acetate, propionate, or butyrate (100 mmol l^{-1}) (29). Sulfate-reducing bacterial activity in a butyrate-catabolizing association was completely inhibited by acetate and propionate, although methanogenesis was stimulated, particularly by butyrate supplementation. It is more likely that elevated VFA concentrations in "young" leachate reflect the prolonged lag period before methanogenesis rather than inhibition of methanogens.

There are difficulties, often observed in laboratory cultures (27) and probably underreported, of consistently inducing methanogenesis in homogenized refuse samples, despite the ease with which temperature and moisture content can be controlled, and in which acidic leachate pH values can be neutralized. It is thus perhaps pertinent to ask whether the induction of methanogenesis in situ is in fact encouraged by the presence of suboptimum conditions. For example, reduced rates of acidogenesis may permit concurrent growth of the slower-growing methanogens, in the absence of acids accumulation and reduced pH values. Refuse heterogeneity and reduced fluid flow may provide protective niches for methanogens. The limited degree of intervention that is possible in situ will certainly not permit operators to achieve optimum rates of methanogenesis but may, paradoxically, allow the transition of sites from the acetogenic to the methanogenic phase.

BIODEGRADATION AND INHIBITION BY XENOBIOTIC CONSTITUENTS

Although most landfill sites are not licensed to accept hazardous or toxic wastes, it has been estimated that each household contributes greater than or equal to 4.5 liters of hazardous waste per annum to municipal refuse (30). These result in the presence, in leachate, of a wide range of organic xenobiotics (Table 3). The impacts of these organic compounds on refuse-microbial processes and their biodegradative potentials are poorly understood. Although, analyses indicate (Table 3) that most are present in leachate at low and presumably noninhibitory concentrations (<0.5 mg l^{-1}), the spectrum of compounds presents the possibilities of substrate interactions. For example, bacteria may use the aggregate of many compounds to gain electrons and energy, although the contribution of each specific compound is negligibly small (31). Where degradation requires enzyme induction, concentrations may be below the threshold value. However, the presence of a closely related molecule may induce the appropriate enzyme (31). Although, individually, concentrations are below the respective toxicity thresholds, aggregative effects may be significant, such that the total toxicity is either additive (the sum of the individual toxic values) (32) or synergistic (greater

Table 3. Selected Xenobiotic (Organic) Constituents of MSW Landfill Leachates

than the sum of the individual toxic values). Data are, however, lacking for toxic values of MSW.

Most studies on anaerobic biodegradability use digested sludge as inoculum, and relatively few have examined the potential for biodegradation in MSW samples. Both refuse-column (with and without leachate recycle) and batch-bottle studies were used (35–37) to investigate the anaerobic biodegradation of phenolics. With leachate recycle, 100% removal of phenol ($188\,mg\,l^{-1}$) was recorded with concomitant enhanced rates of methane release. The degradation of *o*-cresol was also reported (38), although its relative recalcitrance is emphasized by other MSW studies (39) in which no *o*-cresol mineralization was noted. Conversely, the degradation of *p*-cresol and m-cresol has been consistently identified in anaerobic MSW, although with a longer lag period than that recorded with phenol (39). Radiolabeling was used (39) to confirm the degradation of toluene in refuse-inoculated bottles, although other BTEX compounds (benzene, ethylbenzene, and xylene) were not degraded. Laboratory reactors have also been used, and the anaerobic degradation observed of chlorinated aliphatic compounds (1,1,1-trichloroethane, tetrachloromethane, and tetrachloroethylene) (40), trichlorofluoromethane, 1,1-dichloroethylene, and 2,4,6-trichlorophenol (41). In the latter study, no transformation of 3-chlorobenzoate, 2,4,6-trichlorobenzoate, or chlorotrifluoromethane was observed. The anaerobic biodegradation of other compounds such as ethylene glycol (42), 2-chlorophenol (43), 2,4,5-trichlorophenoxyacetic acid (44), and alkylbenzenes (45), albeit with sludge (42,43) as the inoculum or in groundwater samples (44,45), is also encouraging. It may be, however, that a combination of concentrations below enzyme-induction levels, poorly mixed conditions, low moisture and temperature levels, and limited in situ fluid flow prevent realization of the potential of landfill sites for xenobiotic treatment and removal.

INHIBITION BY INORGANIC MSW CONSTITUENTS AND GENERATED COMPOUNDS

The presence of potentially toxic or inhibitory metals in leachate (Table 4) has prompted speculation that these may inhibit initiation of methanogenesis (46,47). However, this seems unlikely at the concentrations typically recorded in leachate. In an MSW lysimeter amended with metal-plating sludge at a loading rate of $3{,}897\,mg\,Zn\,kg^{-1}$ MSW, leachate concentrations were not significantly different from the control. This was attributed to ligand formation and precipitation of the metal as its insoluble sulfide (48). On supplementation of anaerobic MSW leachate with zinc (Zn), lead (Pb), copper (Cu), and iron (Fe) at concentrations of 100, 10, 5, and $1{,}000\,mg\,l^{-1}$, respectively, inhibition was observed only with Zn (46). The importance of sulfide alleviation is supported by experiments in which Enterobacter and Aeromonas, isolated from landfilled refuse (47) but incubated aerobically, showed lower minimum inhibitory concentrations for Zn, Pb, and Cu, of 5,5, and $20\,mg\,l^{-1}$, respectively. In anaerobic digesters inoculated with sewage sludge the recorded toxicity scale was different, such that Cu > Zn > Pb (49). The importance of hydrogen sulfide on the alleviation of heavy metal inhibition (Fig. 3) was demonstrated (50) in a digester in which complete

inhibition was recorded with 20 mg Cu l^{-1} at a Cu^{2+}/VSS of 0.015. However, with sulfide addition, before spiking with Cu, recovery was rapid although the Cu^{2+}/VSS ranged from 0.054 to 0.058.

POPULATION STUDIES

Bacterial Populations: Conventional Techniques

Quantification and characterization of the microbial population of landfill sites was until recently performed by use of conventional enumeration techniques, based on culture on selective media and most probable number (MPN) counts. For example, the addition of ball-milled cellulose to mineral medium was used for the enumeration of cellulolytic bacteria (7), which were identified by clear zones around colonies. Similar clearing techniques were used for the identification of starch-degrading and proteolytic bacteria. By use of these techniques, from samples of refuse taken from depths greater than 3 meters, relatively high densities of both aerobic and anaerobic bacteria were recovered. Anaerobic counts ranged from 0.2 to 32.8×10^6 colony forming units (cfu) (g dry wt)$^{-1}$ at 22 °C; lowest numbers were found in the oldest refuse (24–27y). Interestingly, cellulolytic organisms were not recovered from any of the three site samples, although cellulolysis was recorded in other refuse samples (52), by use of similar techniques. As the refuse became methanogenic (Fig. 4), increases in cellulolytic, acetogenic, and methanogenic counts were recorded. Before this, total anaerobic counts increased, by 2 orders of magnitude, to exceed the methanogenic and acetogenic populations by a factor of 10^6. This increase, concomitant with accumulation of short-chain fatty acids, was presumed (52) to reflect population increases in fermentative bacteria.

Conventional techniques such as these have recognized limitations. The counts on solid media undoubtedly were conservative (7), because only some bacteria would be culturable on the medium provided. Moreover, isolation of viable organisms does not necessarily reflect in situ activity. Where fermentation is dependent on interspecies interactions, as in highly anaerobic environments, enumeration of fermentative bacteria will be underestimated if incubation conditions are not sufficiently rigorous to support the growth of hydrogen sink bacteria such as methanogens. Biomass measurements based on ATP or ester-linked phospholipid fatty acid concentrations have been applied to leachate-contaminated aquifers (53) but are likely to be of limited use in the heterogeneous refuse matrix. Direct examination of acridine orange-stained samples (7,53) may be an overestimation of viable bacteria.

Bacterial Populations: Molecular Methods

Increasingly, molecular methods are being applied to environmental samples (see ACTIVATED SLUDGE — MOLECULAR TECHNIQUES FOR DETERMINING COMMUNITY COMPOSITION) and are demonstrating the presence of as-yet uncharacterized and unidentified species. One of the earliest refuse studies (54) used conventional enrichment methods to isolate methanogenic bacteria from seven U.K. landfill sites before antigenic fingerprinting. Although two isolates were

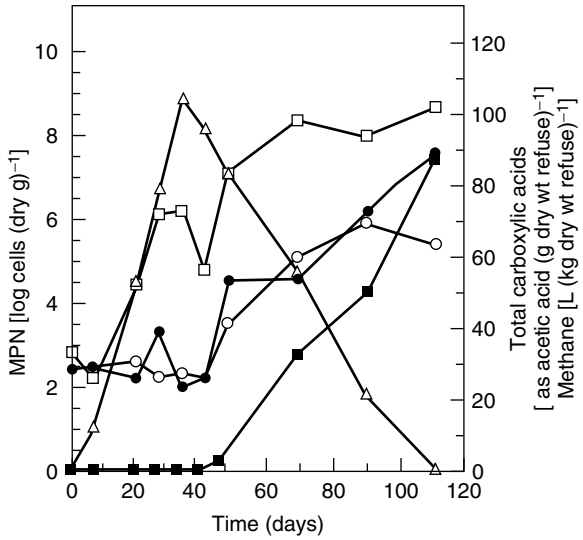

Figure 4. Changes in cellulolytic (○), acetogenic (●), and methanogenic (❑) populations, methane concentrations (■), and total carboxylic acid concentrations (△) in refuse samples [adapted from M. A. Barlaz et al., *Appl. Environ. Microbiol.* **55**, 55–65 (1989)].

closely related to *Methanobacterium formicicum* MF and *Methanosarcina barkeri* MS, a coccoid isolate was unrelated to any of the reference methanogens. Most research has, however, focused on the methanogenic subpopulations in other environments such as peat bogs (55), marine marshes (56), or anaerobic bioreactors (57). A polymerase chain reaction (PCR) method was used (58) to amplify 16s RNA sequences from digester contents, and 27 sequences were obtained that could be only partially matched with the sequences of bacteria in a general database. A major weakness of molecular methods so far is the requirement for characterized reference strains: a low correlation score may indicate either a generic match, or, conversely, a close match to a reference strain that has not been extensively characterized.

Similar techniques have been used to characterize other subpopulations such as syntrophic (57) and cellulolytic bacteria. In one study 10 cellulolytic mesophilic Clostridia were isolated from an MSW digester and differentiated by hybridization experiments with three cloned fragments carrying cellulase genes of *C. cellulolyticum* (8). From the results of these and other techniques (e.g., base composition of DNA, electrophoretic separation of soluble proteins, and CMCase activity) the authors concluded that all the strains were different from *C. cellulolyticum* and from other Clostridia described in the literature.

Both conventional microscopic or cultural examinations and amplification of nucleic acids have indicated that a huge diversity exists in a range of anaerobic environments. It is also clear that significant shifts in subpopulation development, in response to changes in environmental conditions, are characteristic of landfill sites (7,52). In such a temporally and spatially heterogeneous environment the high diversity represents a reservoir from which minority species may proliferate as conditions change.

Protozoa

Protozoa are widely distributed in anaerobic habitats, where they are the predominant and often the only consumers of other microorganisms (59). The presence of anaerobic protozoa in landfilled MSW was first reported in 1991, with the isolation of eight species (59), of which the most ubiquitous was the ciliate *Metopus palaeformis*. Each ciliate contained up to 500 methanogens, probably *Methanobacterium formicicum*, which were retained and transmitted in the cysts. It is likely that protozoa in landfills are commonly encysted (60), especially in drier (<40% water) sites, and the significance of protozoan activity in landfill sites is as yet not clear. In laboratory studies, methanogenesis was closely coupled to host metabolism and growth and although maximum methane-release rates of 0.35 pmol per ciliate per hour were recorded (61), it is difficult to extrapolate from this to likely rates in situ. There is, however, evidence that in anaerobic cultures, enhanced bacterial activity was positively correlated with the number of ciliates present (62). Ciliates with methanogens also produced methane under microaerophilic conditions, in which pO_2 was as high as 0.63 kPa (3% atm sat). In the rumen, another anaerobic environment characterized by the degradation of cellulosic substrate, anaerobic fungi as well as bacteria and protozoa are part of the autochthonous microflora. However, research has failed to enrich and isolate anaerobic fungi from landfilled MSW samples (63).

ENVIRONMENTAL IMPACTS OF MSW LANDFILLS

Health

Health and environmental concerns that arise from landfilling practices are diverse and include air quality and odors, leachate escape, and disease vectors, whether animal (seagulls, flies, rats, etc.), aquatic, or airborne. Studies on the health hazards associated with landfilling have included epidemiological studies (64,65), application of a public health assessment process (66), and direct examination of the microbiological identity of MSW (67), dust, and aerosols (68,69).

Epidemiological Studies. Epidemiological studies initially focused on sites that accepted hazardous wastes. For example, Paigen and coworkers (70) studied the health problems in children living near Love Canal, New York. Compared to the control sample, Love Canal children significantly were more likely to suffer from conditions such as seizures, hyperactivity, skin rashes, and incontinence. Intensity of exposure, measured in terms of either distance from the site or proximity to possible paths of chemical migration (i.e., wet homes) also demonstrated a dose response. Similar results were reported from a later study by Berry and Bove (64) who examined the effects on birth weight of residence near a hazardous waste site in which disposal ceased in 1971. Examination of birth-certificate information (1961–1985) indicated that proximity to the landfill had a significantly adverse effect on both average birth weight and proportion of low–birth weight babies, of a magnitude comparable to that associated with smoking in pregnancy. Although studies such as these may identify pathways for community exposure, such as inhalation of volatilized chemicals emitted from the landfill, the exposure of individuals to specific chemicals is almost impossible to measure. However, the presence of volatile chemicals such as benzene, toluene, methylene chloride, 1,2-dichloroethane, phenol, and formaldehyde was confirmed.

Potentially toxic volatile organic compounds (VOCs) have also been identified in the gas emitted from municipal waste–disposal sites not licensed to accept hazardous wastes. In a study on seven U.K. landfill sites, more than 140 VOCs were identified, of which chloroethene (>1–$87\ mg\,m^{-3}$) was the most abundant toxic component (71). At two of the sites studied, levels were in excess of the U.K. maximum occupational exposure limits ($18\ mg\,m^{-3}$) by factors of 5 and 3. In a comparable study on four Finnish landfills (72) the main chemical of concern was tetrachloromethane, which at concentrations from 1.7 to $34.3\ mg\,m^{-3}$ was occasionally present at levels above occupational air–quality norms ($14\ mg\,m^{-3}$). Although the dilution of vented gases in the atmosphere rapidly reduces VOC concentrations, there remain some concerns about possible effects on site employees. For example, at Fresh Kills landfill sites (N.Y.), which with a daily input of 14,000 tons of solid waste is one of the world's largest, there was a higher prevalence among site employees of a range of symptoms (dermatologic, neurologic, hearing, and respiratory) than among off-site employees (65). However, because of the exposure of employees to a number of potentially harmful substances and conditions including fungi, bacteria, diesel exhausts, dusts, medical wastes, heavy metals, noise, and temperature extremes, it was not possible to categorize employee exposure, and hence difficult to hypothesize specific health outcomes (65).

Microbial Pathogens. The actual health risks posed by the presence of microbial pathogens in landfilled refuse are also difficult to assess. Several studies have addressed the disposal of clinical wastes. Although most is incinerated, there is no doubt that some is still landfilled, legally or otherwise (67). In addition, the increasing tendency toward early hospital discharge and care at home generates clinical waste in a domestic setting (73); attendant disposal routes are dependent on local practices. Certain categories of clinical wastes such as incontinence pads, stoma bags, and urine containers can be landfilled, depending on site licences. Clinical wastes are not the only source of bloodstained or fecal materials, and large numbers of used disposable diapers and sanitary pads or tampons are discharged, with domestic refuse, to landfill sites. In the United Kingdom, the National Household Waste Analysis Project (74) reported that 4.3% of MSW comprised disposable diapers, of which approximately one-third may be soiled with feces (75). Other potential sources of pathogens include soiled cat litter and municipally collected dog feces. Undoubtedly, therefore, landfill represents a sink for pathogenic and

opportunistically pathogenic microorganisms. Collins and Kennedy (67) reviewed the pathogenic species found in both municipal and clinical waste (Table 5) but noted that in situ conditions at controlled landfill sites do not favor the growth or even survival of many pathogens.

Enteric viruses are common causes of juvenile gastroenteritis and thus likely to be deposited in landfills, in soiled disposable diapers. Although it was reported (76) that, in general, 10% of fresh soiled diapers were positive for poliovirus type 1 and echoviruses, few studies have addressed the persistence of enteric viruses in MSW. Of 110 soiled diapers recovered from landfill sites, and aged from 2 to 10 years, three were positive for poliovirus but negative for rotavirus and hepatitis A virus (77). This suggests that viruses were not viable after two years or more in the landfill environment. This conclusion is supported by earlier work on viral seeded lysimeters in which none were recovered after four months (78), due presumably to either inactivation at the temperatures generated in situ or their adsorption to MSW in the presence of high concentrations of dissolved salts. More than 90% inactivation of poliovirus type 1 was recorded within days at 37 °C, compared to 70% after 27 days at 4 °C (78).

Reports on the elution, in leachate, of enteric bacteria and fungi have focused largely on lysimeter and test-cell studies, in which MSW was artificially seeded. Reviewing the results, Gerba (76) attributed the variability of the results to variations in reactor configuration and operation, which render it difficult to assess accurately the risks posed by leaching of pathogenic species. The studies that have examined the microbial composition of leachate-contaminated aquifers (53) have not addressed possible pathogen transport.

Few studies have addressed the microbiological qualities of the air at landfill sites. In the working air of two large Finnish landfills, mesophilic bacteria and fungi exceeded 10^5 and 10^4 c.f.u. m^{-3}, respectively (68). In 67% of the samples, the concentrations of gram-negative bacteria exceeded 10^3 c.f.u. m^{-3}, although endotoxin levels were all below $0.1 \mu g\, m^{-3}$. The most commonly isolated bacteria were Pseudomonas, Enterobacter, and Bacillus spp., and could be considered opportunistic pathogens. Although inhalation of gram-negative bacteria may induce symptoms such as fever and chest tightness, and although such symptoms were shown to be associated with refuse handling (69), the effects of such exposure on health undoubtedly are difficult to evaluate, in the context of simultaneous exposure to other risk factors on site (65).

Table 5. Pathogens and Some Other Organisms in Both Municipal and Clinical Waste

Pathogens	Other Organisms

Serratia marcescens	Yeasts and microfungi
Staphylococcus aureus	
Streptococcus pyogenes	
Yersinia enterocolitica	

Gas Emissions

Concerns about future climate change rest to a significant degree on the increasing concentrations of a number of long-lived radiatively active gases, of which CO_2 and CH_4 are two. The present atmospheric CH_4 concentrations of 1,700 ppbv have increased from approximately 650 ppbv preindustrial levels, which links the increase to anthropogenic emissions (79). Estimates for total anthropogenic methane range from 277 to 477 $Tg\, y^{-1}$ (80). Methane, although responsible for only a small percentage of the direct greenhouse warming, has a great indirect influence, because any increase in temperature leads to increases in water vapor and clouds, which collectively are responsible for more than 90% of the natural greenhouse effect and keep the earth about 33 °C warmer than would otherwise be the case (81). From an actively methanogenic landfill site the gas released comprises, typically, 50–70% methane with the balance predominantly carbon dioxide. Trace constituents include H_2, hydrogen sulfide, and potentially toxic volatile compounds such as benzene, chloroethene, and toluene (71). Worldwide, estimates of the venting of landfill methane to atmosphere range from 10–20 $Tg\, y^{-1}$ (82) to 19–40 $Tg\, y^{-1}$ (80), although such data are difficult to equate with the suggested U.S. emission rates from landfill sites of 35 $Tg\, y^{-1}$ (83). The estimate of 2 $Tg\, y^{-1}$ (79) for U.K. landfills appears more realistic.

Passive venting of landfill gas may have more immediate effects, ranging from the relatively trivial (e.g., plant die-off) to the catastrophic. In 1986 a house in Derbyshire, United Kingdom was destroyed by a methane explosion, the cause of which was traced to uncontrolled subsurface migration of landfill gas from an adjacent closed site (84).

Alternatives for the management of landfill gas emissions include

1. encouraging the natural microbial process of methane oxidation in landfill-cover soils through which the gas is passively vented,
2. through a series of perforated pipes and sunk wells, directing the gas to flares, where it is converted to CO_2 and H_2O, or
3. recovering and exploiting the energy potential of the gas.

Methane Oxidation. Annually, soils consume about 40 $Tg\, CH_4\, y^{-1}$ from the atmosphere and contribute significantly to the atmospheric methane budget (85). In most soils, methane oxidation is constrained by the diffusive transport of methane in the aqueous phase, and thus rates of methanotrophy in soils from environments

as diverse as tundra, savannah, tropical forests, and prairie are comparable, typically falling into a range of 0.5–2 mg $CH_4\,m^{-2}\,d^{-1}$ (85). Landfill-cover soils present an environment in which subsurface biogenesis permits the diffusive transport of elevated methane concentrations in the gaseous phase, which was considered (83) to account for the high rates (45 g $CH_4\,m^{-2}\,d^{-1}$) recorded in 12-cm soil cores from a closed landfill site in California. Soil with an open structure is optimum for enhanced methanotrophy. Kightley and coworkers (86) considered that a 50-cm layer of porous coarse sand might prevent the emission of methane from up to 13-m depth of landfill. However, a coarse sandy soil will be particularly sensitive to moisture changes, and Whalen and coworkers (83) considered that oxidation rates were moisture- rather than methane-dependent. A relationship between methane oxidation and moisture content was reported in cores excavated from a German landfill site (87), where oxidation was recorded from depths of 55 cm, although rates were 18.4% of those recorded at 10-cm depth. In one of the few field studies, no net methane emissions were measured from a midlatitude landfill (Illinois, U.S.A.) (88), a warning not to predict emissions from estimated generation rates.

Energy Recovery from Landfill Gas. The European Commission's White Paper on Renewables proposed a target of doubling, by 2010, from 6 to 12%, the contribution of renewables to Europe's primary energy requirements (89). In the United Kingdom, where renewable energies already meet more than 2% of the electricity needs, energy recovery from landfill gas is an integral component of renewables technology. Under the NonFossil Fuels Obligation (NFFO) in England and Wales, and Scottish Renewables Orders (SRO) in Scotland, more than 288 projects had been contracted by November 1999 to provide 30.61 MW DNC (declared net capacity) (89).

The diminishing gap between costs and market unit price reflect the development of larger, highly engineered sites with purpose-built extraction systems. However, projections of the amount of gas generated throughout the lifetime of a site are highly variable, with estimates from 39 to 500 $m^3\,t^{-1}$ (1), at rates that typically range from 6 to 8 $m^3\,t^{-1}\,y^{-1}$. With these site variations it is clear that in most sites methane release may continue for many years, and that release rates may be significantly below optimum values. Much recent research has focused either on optimizing gas release [e.g., through manipulation of the moisture regime and microbial decomposition rates (23,90) or by improved understanding of fluid flow in landfills (91)] or on the development of more sophisticated and accurate models for prediction of the generation and release of methane (92,93).

Leachate Emissions

Leachate will be generated in any landfill site in which moisture content, as a result of inherent moisture content on emplacement and subsequent infiltration, exceeds field capacity. Leachate composition will thus reflect the climatic conditions, infiltration rate, and refuse constituents, density and absorbency. Infiltration rate is heavily influenced by preferential channeling, a movement mechanism not as yet well understood (94). The composition of leachate (Table 2) is also heavily influenced by site age; "young" leachates are characterized by low pH values, high biochemical oxygen demand (BOD) and chemical oxygen demand (COD) levels, and intermediate ammonia concentrations. In older leachates the higher pH values are associated with lower BOD values, and the BOD : COD and COD : TOC (total organic carbon) ratios have been used as indicators of leachate (and hence site) maturity (95). In a study on Hong Kong landfills, the COD : TOC ratios decreased from 4.1 in a young fill to 2.7 for an old fill (17). The BOD and ammonia concentrations of leachate represent an environmental hazard if leachate is allowed to discharge untreated to watercourses, whereas the other constituents, which include heavy metals and potentially toxic organic compounds (Tables 3,4), pose ecotoxicological challenges. Although temporal fluxes are commonly observed with leached BOD and COD, inorganic ions show less variation with time. However, as leachate pH rises, metal ions are less soluble and concentrations tend to decrease (1). The continuous elution of inorganic ions has proved useful as a tracer of groundwater contamination by leachate (96). Although leakage of leachate from older sites continues to present a threat, in particular to groundwater aquifers (53), the collection and extraction of leachates from lined landfills permit its treatment before discharge.

Landfill Leachate Toxicity. A range of bioassays has been used to evaluate the ecotoxicology of landfill leachates. For example, when the results of Daphnia acute-toxicity tests were compared with those of fish (sockeye salmon) bioassays (97), comparable $LC_{50;96-h}$ values were recorded for the two tests. Daphnia were, however, less sensitive to pH changes, and a pH decrease from 7.0 to 5.0 increased toxicity by only one order of magnitude, compared to 2 orders of magnitude with the salmon. Correlation of observed toxicity to leachate composition indicated that zinc was likely to be the most significant determinant. In one of the few studies of leachate genotoxicity (98), three standard bioassays (Tradescantia micronucleus, Tradescantia stamen hair mutations, and Allium root anaphase aberrations) were used, of which the Tradescantia micronucleus assay was the most sensitive. Micronucleus frequency increased by 258 (dry season) and 153% (wet season) on exposure to leachate, demonstrating the effects of leachate dilution on toxicity. The criteria used to evaluate toxicity vary: for example, duckweed (*Spirodela polyrhiza*) was used to derive leachate $EC_{50;96-h}$ values, that is, the concentration of leachate that inhibited growth by 50% compared to a control (99). The authors concluded that the toxicity probably was due to the un-ionized ammonia content (NH_4–N 1,300 $mg\,l^{-1}$; pH 8.3), although no evidence was presented. One of the few studies on anaerobic leachate toxicity (100) reported that in acetate–propionate supplemented cultures, the addition of less than or equal to 10% leachate had no adverse effect, as measured by methane release. The inhibitory effects at higher leachate concentrations were not attributed to specific physiological groups.

Ferrari and coworkers (101) drew attention to the range of reports that have described bioassays for the measurement of acute, chronic, or genotoxicity by use of diverse species (for example, *Vibrio fischeri*, *Salmonella typhimurium*, *Lemna minor*, *Daphnia magna*, and *Lactuca sativa*), and to the difficulties inherent in comparing these disparate studies. In an extensive program, vascular plants (oats, lettuce, and Chinese cabbage), bacteria (*V. fischeri*), algae (*Pseudokirchneriella subcapitata*), and microinvertebrates (*D. magna* and *Ceriodaphnia dubia*) were challenged by six different leachates. The results indicated that the alga was more sensitive than the vascular plants, in contrast to other studies that reported the vascular plant *Spirodela polyrhiza* was more sensitive than an alga (99), suggesting that algal tests cannot be used as a surrogate for vascular plant bioassays and vice versa. Bioassays, whichever are applied, ideally should form one thread of hazard evaluation (102) and be used in conjunction with physico-chemical analyses to develop strategies for treatment and discharge.

Leachate Treatment

"Dilute-and-Disperse" Sites. In older, so-called "dilute-and-disperse" sites, the absence of a site liner or containment matrix such as clay permits the emission of leachate. Although an array (103) of physicochemical mechanisms and biological activity in the subsurface may achieve a degree of leachate treatment, the degree of attenuation is often such that groundwaters or surface waters are polluted. The significance of specific attenuation mechanisms depends on the soil characteristics. For example, selective retention of K^+, Ca^{2+}, and Mg^{2+} over Na^+ was recorded in clay soils (16) and attributed to cation exchange, electrostatic adsorption, and chemisorption. The same study observed that Cl^- attenuation was relatively low; Cl^- is often used as an inorganic tracer or "pollution marker" to monitor leachate plume subsurface migration (96). It has been suggested that other elements may also be useful markers, either of landfill-influenced groundwaters [e.g., boron (B), bromine (Br), barium (Ba), nickel (Ni), Cu, cobalt (Co), titanium (Ti), and vanadium (V)] or of the presence of hazardous or industrial wastes in the refuse [e.g., arsenic (As), silver (Ag), cesium (Cs), mercury (Hg), and tungsten (W)] (96). A high dissolved organic carbon (DOC) content is also characteristic of groundwater contaminated with landfill leachate. Although there exists a limited understanding of the composition of the DOC, it largely comprises high-molecular-weight compounds, the fulvic acid component accounting for approximately 60% of the total DOC content (104). The humic and fulvic acid fractions may be important attenuating mechanisms (104) through their abilities to form complexes with heavy metals and to bind hydrophobic organic contaminants. However, as a result of doubts on the applicability of laboratory studies and the difficulties inherent in field studies (105), the extent of leachate attenuation in the subsurface is equivocal. For example, the persistence of *o*-cresol in an anaerobic leachate plume was observed (105), although the anaerobic degradation of *o*-cresol in refuse samples has been clearly demonstrated (38). Clearly, reliable and predictable treatment of leachates from dilute-and-disperse sites is not possible.

Containment Sites. Controlled methods for treating leachate have largely been drawn from the wastewater-treatment industry. Physico-chemical processes such as coagulation or precipitation, adsorption on to granular activated carbon, and reverse osmosis have been applied to the removal of specific leachate components such as heavy metals and oils (106). Such methods are most suitable for treating leachate before a biological process or as a final polishing stage. Although biological processes are widely implemented, the range of configurations or operational practices emphasizes that treatment solutions, because of the diversity of leachate composition, are largely site- and age-specific (107).

Perhaps because aerobic processes have the advantages of economy, simplicity, speed, and ease of control (106), they are more common than anaerobic processes. Aerobic lagoons, characterized by low maintenance and control measures, are popular, although because no intervention such as aeration or biomass retention is practiced, their size must be larger than activated processes. Aerobic-sequencing batch reactors are effective for the treatment of high-ammonia, methanogenic leachate, in terms of both COD removal and ammonia-N removal (17).

Anaerobic processes are suitable for "young" high-strength leachates, and have the added advantage of energy recovery, as methane (19). Configurations used have included anaerobic filters (108), two-phase anaerobic digesters (19), and anaerobic-sequencing batch reactors (20). Effective COD reductions can be achieved. For example, anaerobic-sequencing batch reactors achieved 64–85% COD removal at a volumetric loading rate of 0.4–9.4 $g\,COD\,l^{-1}\,d^{-1}$ from a high-strength leachate (16–20 $g\,COD\,l^{-1}$) (20). Similar values (92.6% COD removal and loading rate 0.51–3.4 $g\,COD\,l^{-1}\,d^{-1}$) were obtained with an anaerobic filter (19).

The additional heat required for the efficient operation of anaerobic digesters, at 35 °C (19,20,108), can be supplied by utilization of methane generated. Low-strength leachates (COD $\leq 1,000\ mg\,l^{-1}$) generate insufficient methane, and, hence, anaerobic digestion of low-strength leachates is only viable if it can be operated at ambient temperature. At these temperatures, reactor configurations that retain, and hence increase, biomass are required to reconcile the necessity for efficient COD removal at low hydraulic-retention times (HRTs) with the low anaerobic microbial growth rates. Laboratory-scale anaerobic-sequencing batch reactors, with an operating regimen of feed, react, settle, and decant, achieved 80–90% soluble COD (400–800 $mg\,l^{-1}$) removal, at temperatures and HRTs that ranged from 15 to 35 °C and from 12 to 48 h (109). Encouraging results were also reported from a pilot-scale upflow anaerobic sludge blanket (UASB) reactor (see WASTEWATER TREATMENT MICROBIOLOGY) treating leachate (COD 1.5–3.2 $g\,l^{-1}$) at temperatures from 13 to 23 °C (51). Despite changes in leachate quality, 65–75% COD removal was constantly achieved at temperatures down to 18 °C.

An alternative strategy for the treatment of leachate at temperatures higher than ambient, which eliminates the requirement for an external heat supply, is leachate recirculation through the refuse mass. Recirculation may serve other ends. One means of increasing the sustainability of landfilling is to promote rapid refuse stabilization, and because moisture content is generally considered to be the single most important parameter limiting refuse decomposition and methane production, leachate recycle may address this. In addition, moisture additions accelerate long-term site settlement, facilitating final site closure and after-use. It has been suggested (90) that the combination of enhanced biodegradation and settlement could shorten by 3–10 years the period required for the completion of stabilization. On a pragmatic basis, recirculation in temperate climates may be used as a management tool for the in situ storage of leachate, particularly in winter months when the capacities of treatment facilities are reduced.

Evidence of leachate treatment can be measured in terms of changes in the BOD : COD ratio. For example, the analysis of samples from both leachate drainage wells ("fresh" leachate) and sampling wells in the older waste through which the "fresh" leachate was recycled indicated that the BOD : COD ratio decreased from 0.53 to 0.1, whereas the pH increased from 6 to 8.3, reflecting the use of VFAs (18). Interestingly, population studies have failed to account for this apparent enhancement. In one study on actively methanogenic refuse samples the total anaerobic population and subpopulations of cellulolytic, acetogenic, and methanogenic bacteria were the same whether or not leachate recycle was imposed (110). Although enhancement may be due to more uniform nutrient distribution in the presence of water flux, this has not been demonstrated.

Recycle will not address the problems of leachate nitrogen content, because the absence of an anaerobic-transformation route for NH_4^+ implies that concentrations will increase with recycle through the refuse mass. In one study (18) a 30% increase between "fresh" and recycled leachate was recorded. A recent survey of U.K. landfill leachates (111) reported that acetogenic and methanogenic leachates contained from 194 to 3,610 and from 283 to 2,040 mg $NH_{3/4}^+$-N l^{-1}, respectively. It has been argued that to recycle such leachates risks the inhibition of decomposition processes. Because it is un-ionized ammonia that is toxic, the toxicity of ammonia is both pH- and temperature-dependent. At 20 °C, 50% of ammonia is in the form of NH_3 at pH 9.245 precisely, and for one unit decrease in pH, NH_3 concentrations decrease by a factor of 10. Moreover, toxicity increases with temperature, because at 15 and 35 °C the pKa values are 9.564 and 8.947, respectively. It is thus not possible to assess leachate ammonia toxicity without presentation of pH and temperature data, which often are lacking. Prediction is further confounded by likely concentration differences between the refuse matrix itself, interstitial water, and leachate. Adaptation of the methanogenic associations in anaerobic digesters may explain their tolerance to high concentrations ($\leq$5,000 mg $NH_{3/4}^+$-N l^{-1}) (112), which are equivalent to the total amount of nitrogen present in MSW. In one of the few studies to investigate differential effects (113), acetoclastic methanogens were shown to be more sensitive than propionigenic bacteria or SRB with threshold inhibitory levels for NH_3 of 77,105, and 123 mg l^{-1}, respectively.

Conservative elements such as Cl^- and heavy metals also accumulate. In addition, care should be taken that the additional hydraulic load does not cause structural stability problems (30). Ultimately, recirculation can be only a temporary measure for the management of leachate, which must at some point be abstracted and, if required, treated before discharge.

SUSTAINABLE WASTE MANAGEMENT

As traditionally practised, landfilling is not environmentally sustainable, in that landfills are significant sinks for a range of materials (such as glass, paper, textiles, metals, and plastics) whose manufacture and production rely on finite sources of raw materials. Moreover, the environmental impacts of landfill sites may persist for many decades. For landfills to be more environmentally sustainable, legislators and operators must reduce energy consumption, pollution of land, air, and water, and loss of amenity (2). One approach, of much recent interest, attempts the accelerated stabilization of biodegradable wastes, with concomitant benefits in increased resource (methane) generation. This could, potentially, be achieved by continuously recirculating water and/or leachate through the site. In such a "flushing bioreactor" a leachate collection and recirculation installation is required, capable of uniform leachate distribution through the refuse mass. Significant acceleration of stabilization, however, require infiltration rates (3,000–10,000 mm y^{-1}) greatly in excess of those generally recorded (50–250 mm y^{-1}), which require hydraulic conductivities greater than 10^{-7} m s^{-1}. To achieve such high conductivities require changes in operational practices, such as shredding or pulverization to produce a more homogeneous matrix, reduced compaction, and maximum site depths 20–30m (1). Although accelerated stabilization and increased gas production have been recorded at most sites where leachate recirculation has been implemented (90), leachate volumes are greater and require storage, control, and treatment measures (30). Although, overall, leachate quality does not appear to be adversely affected, without some form of aerobic-treatment stage, ammonia concentrations will accumulate, as will those of conservative species such as Cl^{-1}. Nitrification of leachate in aeration lagoons or bioreactors, and the return of nitrate to the landfill will permit denitrification to gaseous nitrogen, leading to a net loss of nitrogen and a reduction in the degree of treatment required before discharge (114). In this way the refuse mass itself is used to provide the electron donors required for denitrification, which may need to be added to a conventional denitrification system. Whether the "flushing bioreactor" can mobilize and transform ammonia concentrations to achieve final discharge levels of 5 mg l^{-1} within 30 to 50 years, as required

by the concept of sustainability, remains to be confirmed.

Although retrofitting of sites fully to accommodate accelerated "flushing" may be difficult, it may be that this is where the technology will achieve more recognition. In Europe, at least, future legislative changes aim to reduce the volume, and alter the composition, of MSW going to landfills. Given the requirement in the European Waste Landfill Directive for member states to reduce landfilling of biodegradable solid waste, by 2010, to 25% of the baseline 1993 level (115), the importance of recycling initiatives clearly will increase. Composting (aerobic) and biogasification (anaerobic) processes may be considered not only as treatment but also as recycling options, in that compost or compost/biogas, respectively, are recovered from the organic and paper fractions of MSW. Although composting technologies (1,2) are well developed, in the United Kingdom currently less than 0.5% of MSW is thus processed. Although compost can be used as a soil conditioner, fertilizer, mulch, or peat replacement, the market is so far constrained, because of the limited acceptance of waste-derived composts. Anaerobic digestion of MSW offers several advantages over composting (116), in cost (26–42% less expensive), production of biogas (CH_4/CO_2), and a stable end-product that contains fewer pathogens and weed seeds. In addition, the potential to collect biologically generated hydrogen, for use as a clean fuel, has attracted interest (117). Full-scale reactors, of various designs (batch, continuous, or two-stage continuous) and operating conditions (mesophilic or thermophilic), are in extensive use in Europe (116) despite current limitations related to the low demand for the humuslike end-product. However, the possibility of increasing biogas production, and hence profitability, by codigestion with agricultural and food-processing wastes (118) is promising, as is the drying of the end-product, in developing countries, for use as firewood substitute (116).

LASER SCANNING MICROSCOPY IN COMBINATION WITH FLUORESCENCE TECHNIQUES FOR BIOFILM STUDY

THOMAS R. NEU
UFZ Centre for Environmental Research
Leipzig-Halle, Germany

JOHN R. LAWRENCE
National Water Res. Institute
Saskatoon, Canada

Facts such as the "great plate count anomaly" in microbiology (1,2) suggest that the investigation of complex environmental communities may be best carried out using methods not involving cultivation of bacteria. These integral methods include among others, biomarkers, molecular probes, activity measurements, flow cytometry, microelectrodes, and microscopy. Comparisons of all the different microscopic methods indicate that laser scanning microscopy is best suited for the investigation of fully hydrated samples and allows the four-dimensional visualization and quantification of digitized signals of the whole microbial community (3–5).

Natural microbial communities are mostly associated with interfaces and usually referred to as biofilm systems. The definition of biofilm includes bacterial cells and their extracellular products. In addition, other cells and compounds from the environment will be associated with an interfacial microbial community (Table 1). The complexity of the biofilm architecture is dependent on physical, chemical, and biological parameters present in a specific habitat. Consequently, an environmental biofilm system will show a very different structure compared to pure culture or defined mixed culture biofilms, which have been used in many biofilm studies to date.

Table 1. Cellular and Matrix Constituents of Environmental Biofilm Systems

Cells in Biofilms	Biofilm Matrix
Prokaryotes	Particulate material
— bacteria	— geogenic and biogenic minerals
— archaea	— organic debris
	— fecal pellets
Eukaryotes	— phages, viruses
— algae	— lysed cells
— fungi	— precipitates
— protozoa	
— micrometazoa	
	Polymeric material
	— polysaccharides
	— structural proteins
	— enzymes
	— S-layers
	— nucleic acids
	— polymeric surface-active substances
	— Lipopolysaccharides, Lipoteichoic acids
	— lipids
	— chelators
	— polyphenols
	— humic substances

As a result of studying numerous environmental biofilm samples with very different properties by using laser scanning microscopy it became clear that some features are very obvious and can be easily imaged and analyzed. However, in a lot of situations the structure of interest is not visible e.g. the presence and distribution of extracellular polymeric substances (EPS) in biofilm systems. Thus it is in the imagination and skill of the scientist who has to develop a sense of "WYPIWYS" ("What You Probe Is What You See"). Consequently, the investigator has to test a variety of probes to search for the characteristic bio-physico-chemical properties of the unknown biofilm structure.

Usually, the stepwise analysis of a microbial community follows a cascade of questions. The key questions in approaching an unknown environmental sample are: (*1*) what is there, (*2*) who is there, (*3*) who is active, and (*4*) what type of activity are they doing (1,6). The first question can be answered using the intrinsic properties of the sample and general stains for typical constituents within the microbial community. The second question can be answered by employing rRNA-targeted oligonucleotide probes for in situ hybridization. In addition, new approaches with mRNA-targeted probes at the gene level may help to identify certain bacterial groups and their activities. The third question can be answered in a variety of ways. There are methods for direct activity measurements at the cell level, the determination of enzyme activity may be used as another measure, and there are several methods in which the activity of a certain gene is visualized using molecular biology techniques. The fourth question can be answered by analyzing the production or disappearance of various compounds. The tools for analysis may include enzyme assays, chemical analysis, and environmentally sensitive fluorescent probes and microelectrodes. Finally, information regarding the identity of the organisms, derived from in situ hybridization, maybe used to infer what the microorganisms may be doing.

In this entry, the sequential steps of approaching to an unknown environmental biofilm sample are discussed. Figure 1 provides an overview of the various levels of the approach and the anticipated results. The emphasis is on visualization and analysis using laser scanning microscopy (1-photon and 2-photon) as this technique allows the investigation of natural, hydrated, living samples in space and time by collecting multiple lines of information in multiple channels.

LASER SCANNING MICROSCOPY (LSM)

The potential of confocal laser scanning microscopy (CLSM) for investigations of microbial biofilms was first demonstrated in 1991 (7). In the meantime, numerous LSM applications in environmental microbiology have been published and discussed in various review articles (5,8–10).

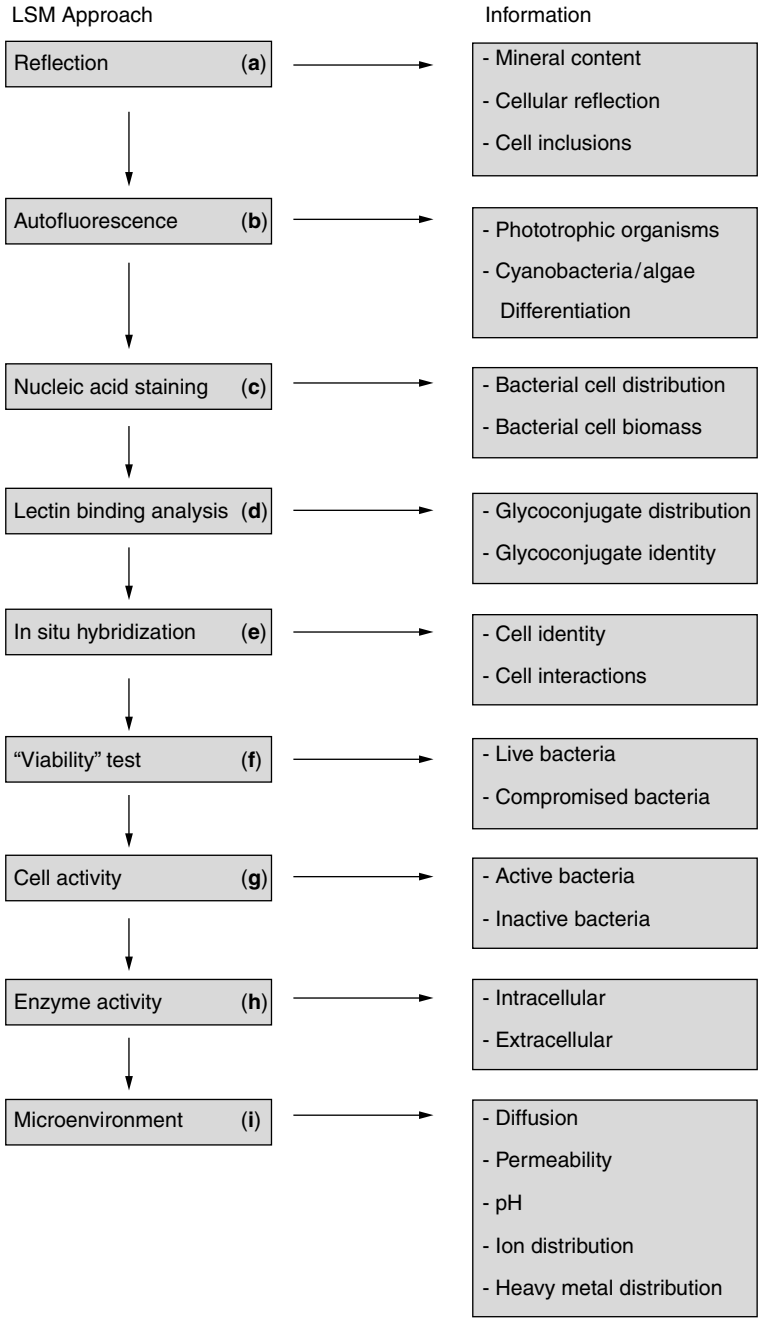

Figure 1. Laser scanning microscopy strategy to characterize an unknown biofilm sample. In the left column of the flowchart the major approaches are indicated. The letters A-I refer to the section in the text. In the right column the information gathered is listed.

The application of laser scanning microscopy allows the examination of thick biological samples in four dimensions (x, y, z, time) with the assessment of multiple parameters. Conventional confocal laser scanning microscopy uses 1-photon excitation, whereas new LSM systems may have the option of 2-photon laser scanning microscopy (2-PLSM), where 2-photons are used simultaneously for excitation of a reporter molecule. The advantages of both LSM systems are summarized in Table 2 (1-photon) and Table 3 (2-photon). Currently, most applications of LSM in microbiology use conventional 1-photon CLSM.

2-PLSM has been used in only a few studies. One group investigated defined mixed culture biofilms, which were grown in a constant depth film reactor producing very dense oral biofilms (11,12). The results confirmed previous findings from cell biological studies (13) and showed that in comparison with CLSM, the infrared laser could penetrate four times deeper into the dense biofilm structure. In another report, marine stromatolite sediments were studied after embedding in nanoplast resin (14). The study showed 2-photon imaging of DAPI-labeled bacteria and 1-photon imaging of lectin-labeled EPS compounds in different regions of the sample. A direct comparison of 1-photon and 2-photon imaging of the same biofilm location has been demonstrated very recently. Using various types of biofilm systems it could be demonstrated that 2-PLSM produced superior results

Table 2. Advantages of Confocal Laser Scanning Microscopy (CLSM)

1.	examination of fully hydrated, living, microbial communities up to several 100 μm thick
2.	noninvasive optical sectioning of samples with virtually no scattered light from out-of-focus regions
3.	sectioning in horizontal (xy), vertical (xz), and temporal (xt) dimension
4.	application of fluorescent (fluorescent mode) and nonfluorescent (reflection mode) probes
5.	simultaneous or subsequent application of multiple probes and multichannel recording of digital enhanced signals (4-fluorescence channels plus transmission and reflection)
6.	quantitative static and dynamic analyses of three-dimensional organization of polymeric aggregates, single cells, and microcolonies and complex microbial communities
7.	three-dimensional presentation and animation, for example, xyz slicer, movie, gallery view, two-dimension projection, intensity histograms, rotation, various types of stereoscopic imaging, different three-dimension projections, surface rendering

Table 3. Advantages of 2-Photon Laser Scanning Microscopy (2-PLSM)

1.	excitation only in the focal region, excitation volume is extremely small (femtoliter)
2.	caged fluorochromes are excited in extremely localized spots
3.	as a consequence, no out-of-focus bleaching and cell damage
4.	background fluorescence is also not a problem
5.	compared to 1-photon excitation, infrared has a higher depth of laser penetration (0.5–1 mm)
6.	consequently there is an inherent depth resolution
7.	less scattering and less filter problems
8.	no pinholes necessary and thus no pinhole throughput loss
9.	no UV laser necessary, no UV photo damage possible, no problems with UV optics

in terms of imaging and resolution of deep biofilm regions (Fig. 4) (Neu and coworkers, submitted). Nevertheless, 2-PLSM requires further evaluation of fluorochromes and other methodological development in order to employ this approach as a routine technique in environmental microbiology.

Direct LSM in the Reflection Mode

The laser scanning microscope (LSM) can be used in the reflection or fluorescence mode (Fig. 1, level A). Generally, in microbiological studies, the LSM is used in the fluorescence mode after applying specific fluorescent stains or other fluorescent reporter molecules. In this mode most conventional CLSMs typically equipped with an Argon/Krypton laser producing three distinct visible laser lines (488 nm, 567 nm, 647 nm) can excite three different fluorochromes. The emission signals of these fluorochromes may then be collected in the green, red, and far red part of the spectrum. This allows for either simultaneous or sequential imaging of samples using a variety of fluors. Nevertheless, the reflection signals from an unstained biofilm sample may be an additional source of information. The reflection mode can be used separately or simultaneously with other fluorescent channels. The reflection mode allows the characterization of several biofilm features. Firstly, the reflective mineral constituents of a biofilm can be recorded. The minerals adsorbed or embedded in the polymeric matrix may be of geogenic or biogenic origin (15,16). This mineral content is an important part, especially in environmental biofilm systems, and is usually not found in artificial pure or defined mixed culture biofilms. Secondly, the reflection signal of biofilm microorganisms can be imaged. Bacteria may contain reflective inclusions such as sulfur granules (17), sulfur and calcite (18) poly-beta-hydroxy butyric acid, polyphosphate, gas vesicles, and so on. In addition, it is generally known that spore-forming bacteria show a strong reflection signal. Certain bacteria may also precipitate ions on their cell surface, which may result in a reflection signal (19,20). Furthermore, environmental biofilms may contain a variety of higher organisms such as fungi or algae, also showing a reflective signal. Some of these eukaryotic biofilm organisms may have a very specific reflection signal as for example, the silicate frustules of diatoms. Several examples of reflection signals are presented in Figure 2. Thirdly, the reflective mode may be used to characterize the surface to which the biofilm is attached. By this means the surface topography and texture of the substratum can be imaged.

Direct LSM in the Fluorescence Mode

As already indicated phototrophic organisms are frequently part of environmental biofilms. The autofluorescence signal of their pigments can be valuable in the characterization of natural biofilm systems (Fig. 1, level B). In algae, the size and shape of the chloroplast can be used for taxonomic description and quantification of autotrophic organisms. The presence of two types of pigments in cyanobacteria allows the separation of their signals from green algae (Fig. 3). Nevertheless, in some cases the strong autofluorescence of algae or cyanobacteria interferes with the emission signal of fluorescent stains. If there are green algae present, the chlorophyll signal in the far red channel may preclude the use of, for example, CY5 labeled compounds, whereas the presence of cyanobacteria results in problems in the red and in the far red channel. Consequently, the detection of fluorochrome emission signals in the red (e.g., TRITC or CY3) and in the far red (e.g., CY5) channel becomes difficult as separation from pigment signals is not straightforward. Apart from these aerobic phototrophs, anaerobic phototrophic bacteria have a variety of pigments, which may be used for imaging, including bacteriochlorophylls a, b, c, d, e, and several types of carotenoids. Fluorescence of chlorophyll was used by Lawrence and coworkers to identify and localize algae in microbial mats and river biofilms (15,21). Similarly, Wiggli and coworkers used autofluorescence and CLSM to examine the distribution of photosynthetic bacteria in complex mat communities (16).

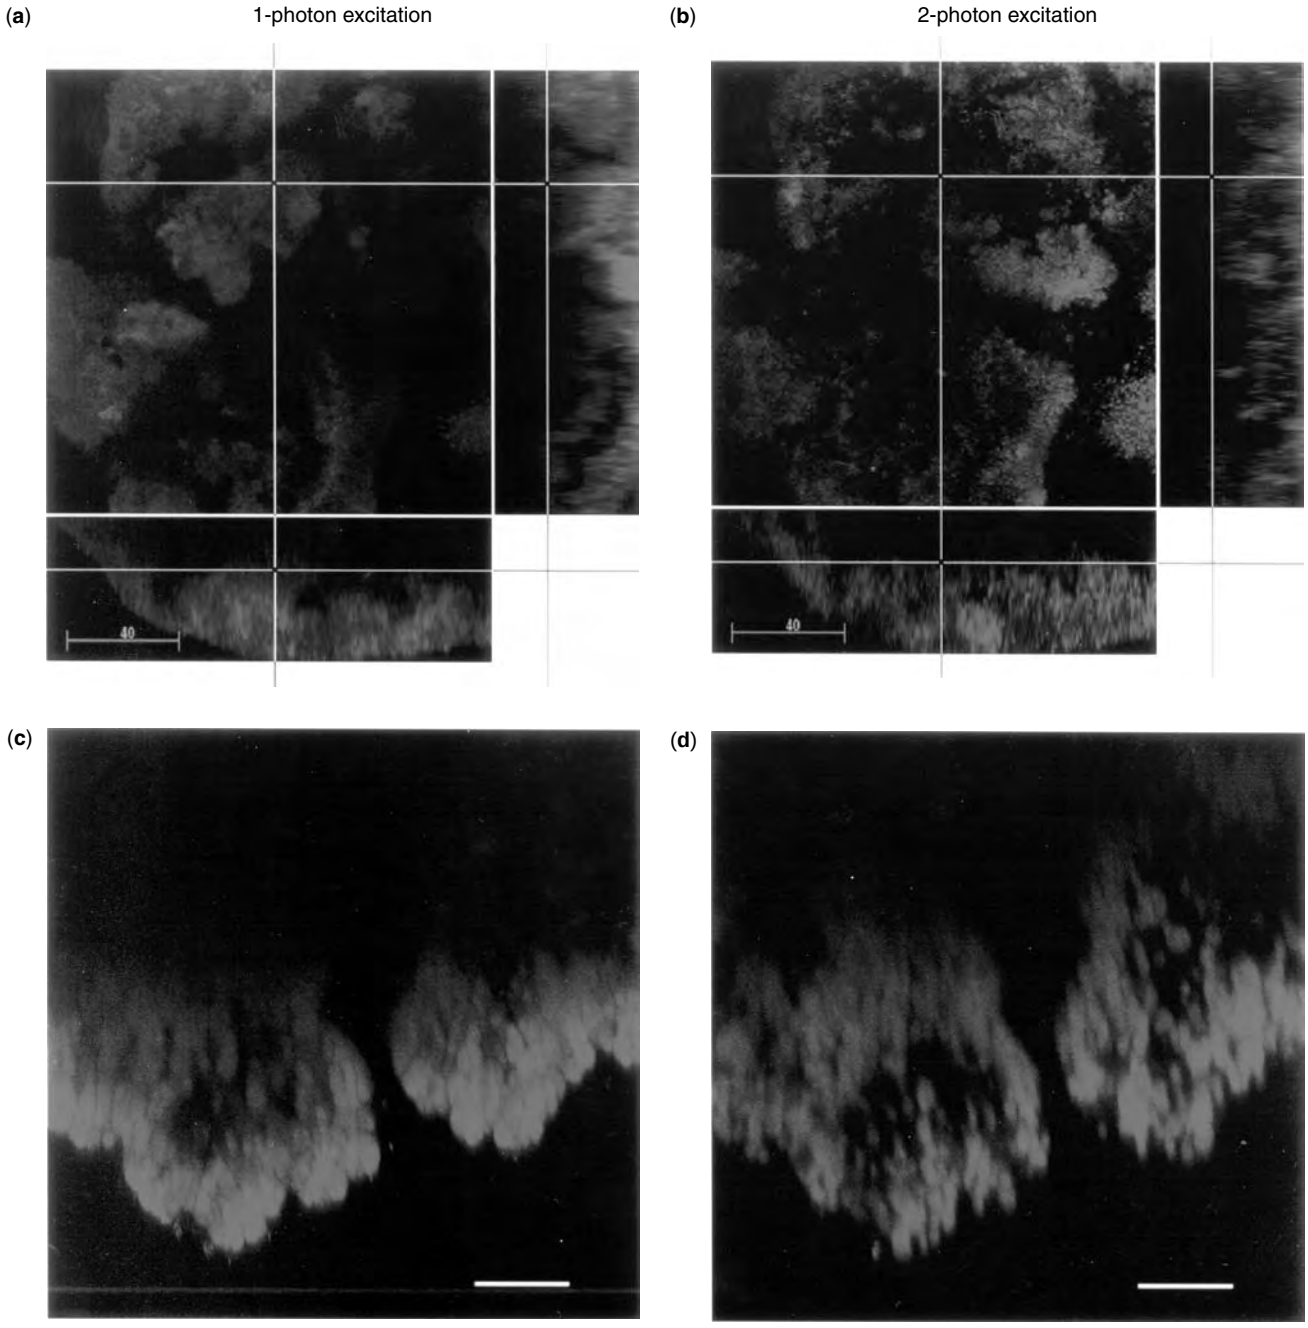

Figure 2. 2-photon (plate with 2/4 images 1p/2p). See color insert.

In addition to the phototrophic procaryotic and eucaryotic biofilm organisms certain bacteria may show an autofluorescence caused by other cellular compounds. For example, in methanogens, the autofluorescence is due to high levels of coenzyme F420, which can be used to image methanogenic aggregates (Fig. 4). Several other coenzymes are also known to show an autofluorescence signal. In cell biological studies the signal of NADP has been used as a cellular marker (22). Eubacteria may fluoresce for a variety of reasons, some cellular constituents may be fluorescent; for example, H4MPT is a coenzyme found in eubacteria, that is, a yellow fluorescent compound (23). Bacteria, in which an autofluorescence has been reported, include *Legionella*, *Vibrio parahemolyticus* (J. R. Lawrence, personal observation), *Archaeoglobus* (24), and *Thermoplasma* (25). In conclusion, depending on the habitat to be studied, and there may be many more that have not yet been examined, the autofluorescence of specific bacteria may be used for imaging. It is also necessary to assess the presence and nature of autofluorescence signals as part of the interpretation of signals resulting from application of fluorescent probes.

CLSM systems may also be equipped with nonconfocal transmitted light detection systems. The detector may

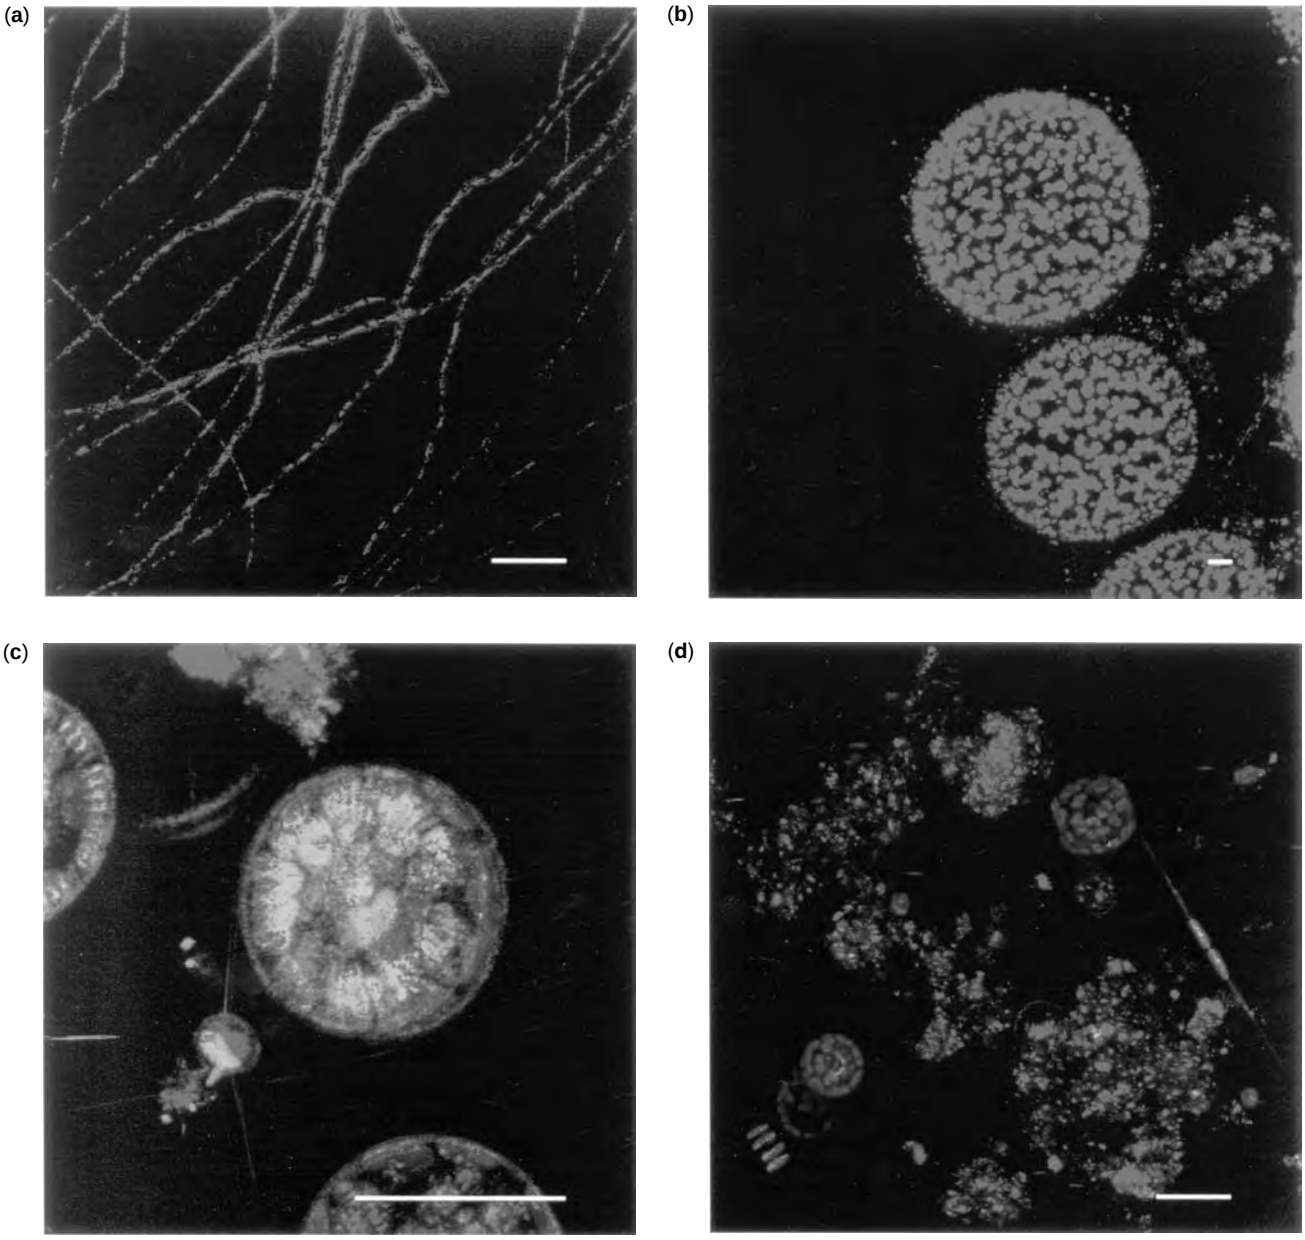

Figure 3. Reflection of diatoms, fungi, microbial mat, thiomargarita (plate with four images). See color insert.

be a photodiode or photomultiplier with a fiber-optic connection below the condenser of the host microscope. If the microscope is equipped for dark-field, phase contrast, or differential interference contrast (DIC), these images may also be digitized. Thus, confocal multichannel imaging can be combined with conventional microscopy techniques to allow correlative light microscopy of specimens under study (3). Most current LSM systems are capable of obtaining at least four images resulting from different applications of fluorescent, reflective, and transmitted light, although as many as 8+ may be obtained with additional laser options such as He Cd 442 nm (1-photon exitation), ultraviolet (1-photon excitation), or infrared (2-photon excitation).

Probes for Cell Distribution

A major application of LSM in biofilm studies is the measurement of cell distribution (Fig. 1, level C) after application of nucleic acid specific stains. Traditional stains include acridine orange (AO) and 4′6-diamidino-2-phenylindole (DAPI). However, neither is preferably employed for LSM. AO has a strong signal across the entire emission range in the green, red, and far red channels. Consequently it cannot be used in experiments with multilabeling and subsequent detection of the various signals in separate channels. In contrast, DAPI requires excitation with an expensive UV laser source, which is not readily available on most confocal laser scanning microscopes. In addition, the emission signal

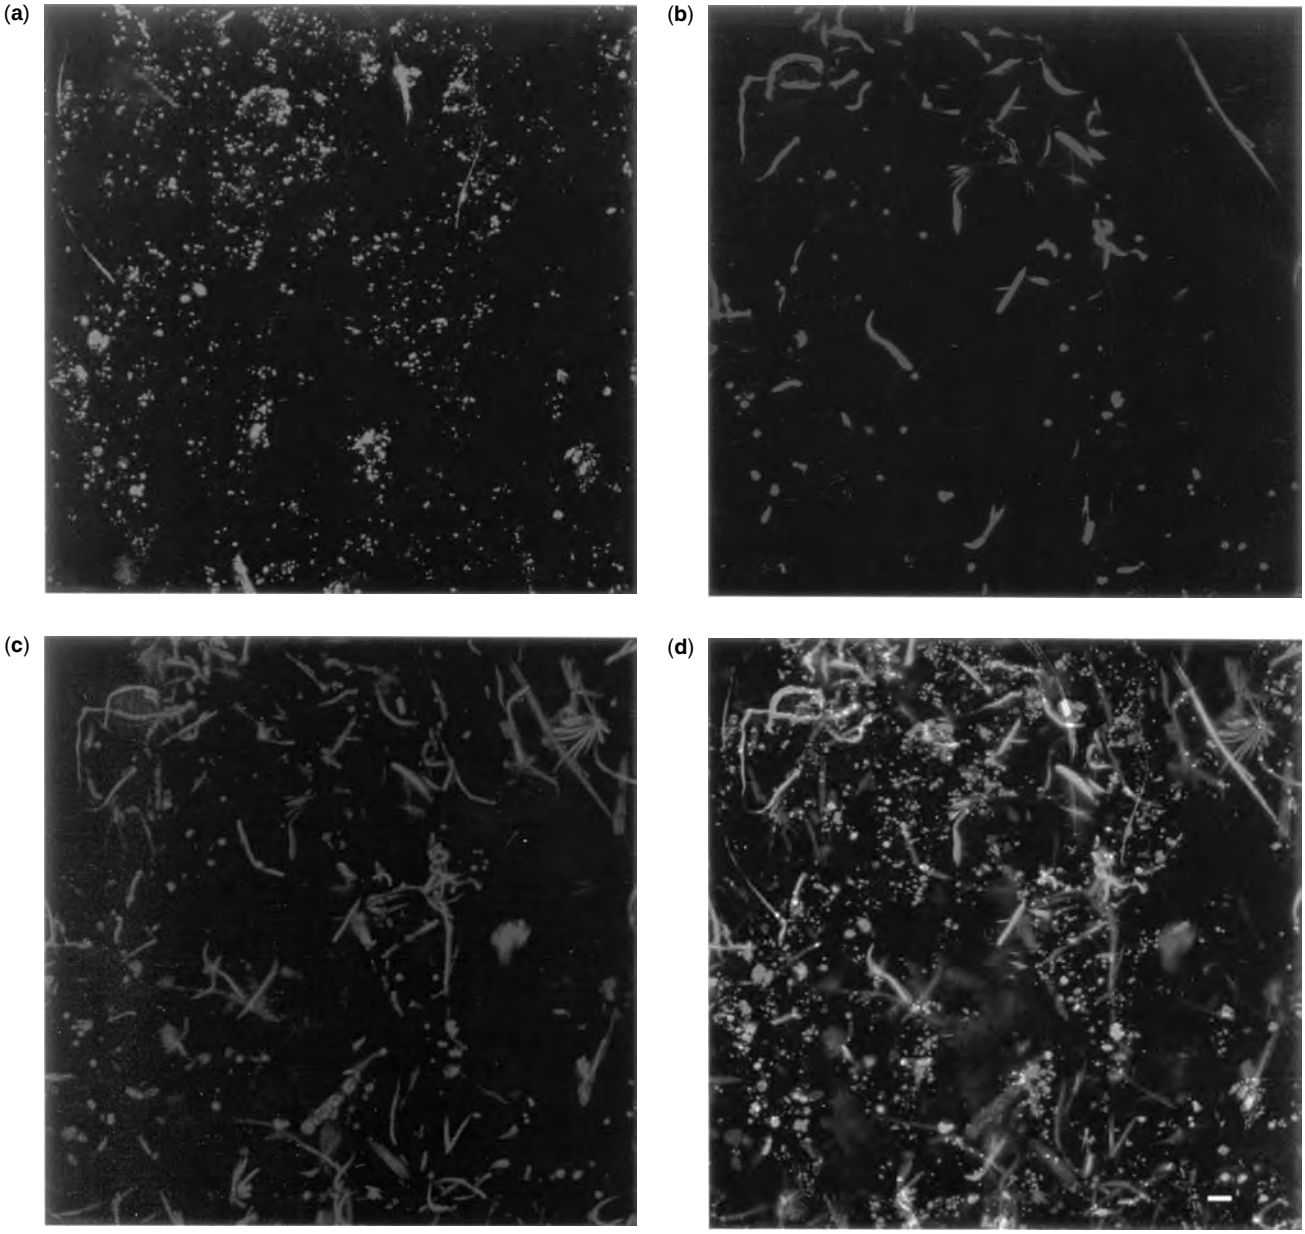

Figure 4. Autofluorescence with differentiation algae-cyanobacteria (plate with four images green-red-blue-overlay). See color insert.

of DAPI is also very broad and may interfere with emission signals in the green and even the red channel. Nevertheless, both stains have been used in numerous studies as "proven nucleic acid stains for bacterial cell counts" and their compared application has been critically reviewed (26).

In the meantime, several other options for nucleic acid specific cell labeling are available. The so-called SYTO stains (27) are now offered in all colors, including emissions in the blue, green, orange, red, and dark red. Depending on the sample properties and the other staining procedures applied, the nucleic acid stain with the appropriate emission signal can thus be selected. The labeled bacterial cells can then be easily located and quantified within the heterogenic structure of an environmental biofilm (Fig. 6). This is, however, an ever-expanding field — additional more sensitive stains such as PicoGreen or SybrGreen are available and have been employed in several studies (see references from Table 4).

Another option for staining of bacteria in biofilms, aggregates or at surfaces, is so called negative staining. This approach has been used for optical sectioning of biofilms (45). Negative stains include fluorescein, resazurin, and fluorochrome-dextran conjugates. If these are applied at appropriate concentrations the bacteria are imaged as dark objects against a bright background (7,46,47). The major advantages of this approach are lack of fading and maintenance of contrast. However, there is also significant quenching of excitation and emission signals by the high fluor concentration. Thus, the

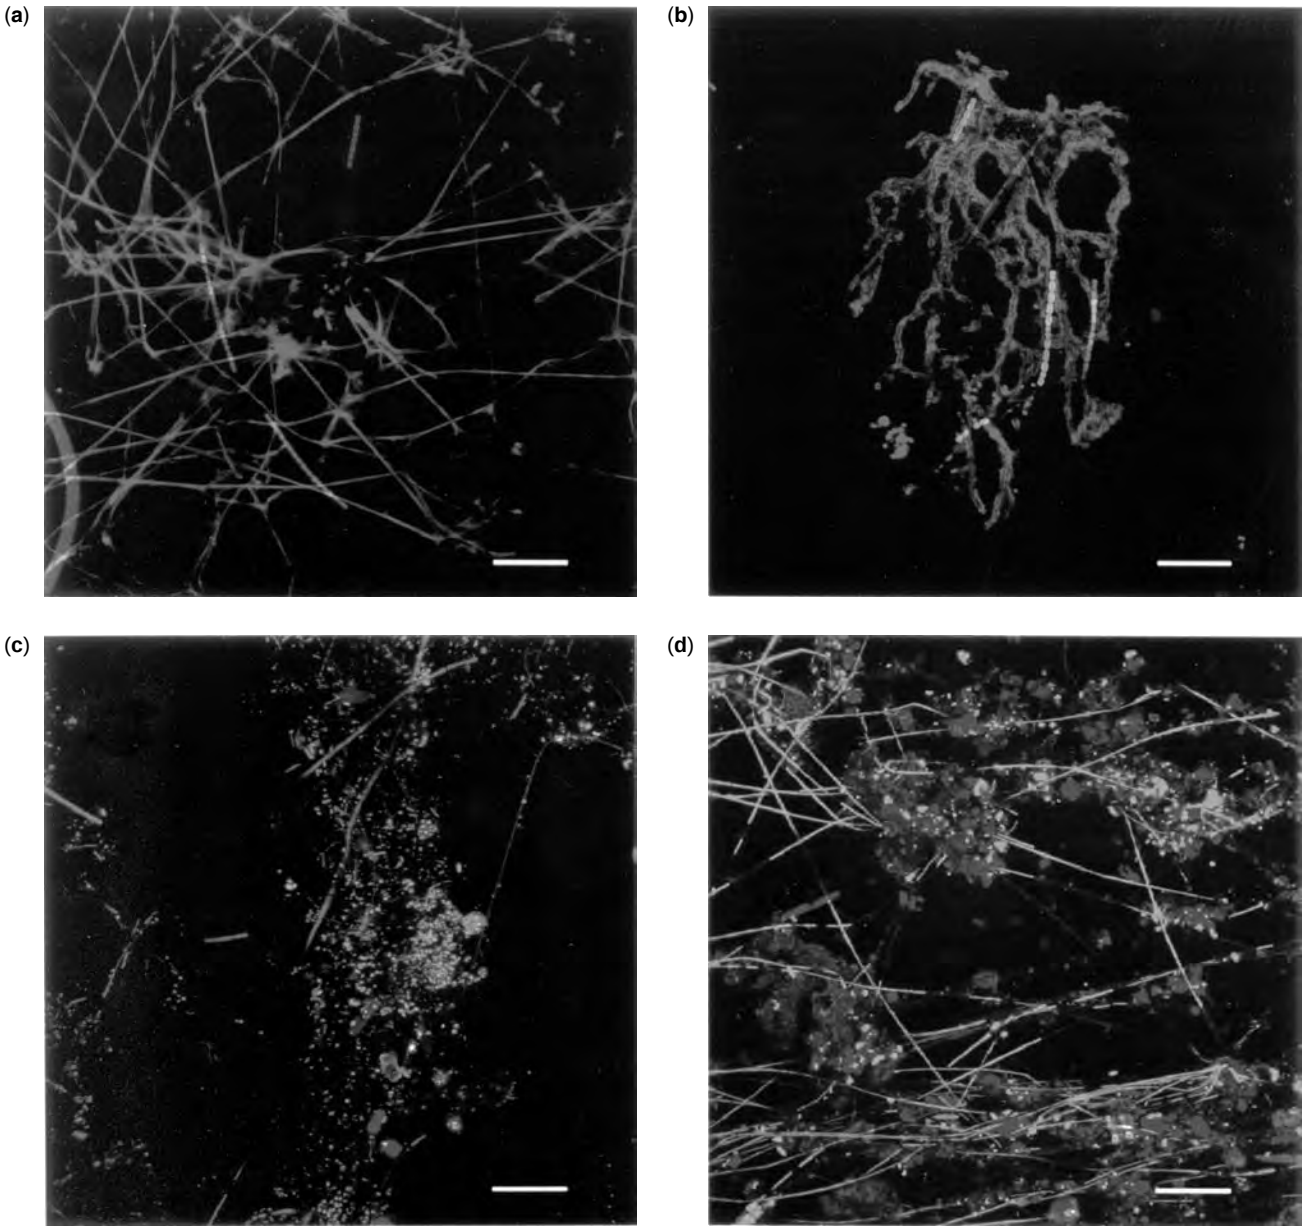

Figure 5. Bacteria and lectins 3/4 channels (plate with four images). See color insert.

microscopist has a wide range of options to consider when staining bacteria.

Probes for EPS

The term EPS (extracellular polymeric substances) stands for chemically different compounds such as polysaccharides, proteins, nucleic acids, and amphiphilic polymers. The in situ detection of these polymers remains a significant challenge (Fig. 1, level D; 48–50). In principle, several fluor conjugated probes with a specificity for each of the different polymers have to be used. Some of the stains may not only give a signal from the EPS but also result in a signal originating from the bacterial cell surface. Thus, the differentiation between cellular and extracellular signals has to be based either on the different geometric appearance of the signals or on colocalization after multiple staining and detection in different channels.

For polysaccharides there is no universal stain that will detect all types of polymers. An example of a fluorescent stain for polysaccharides is Calcofluor White M2R, specific for $(1 \rightarrow 4)$- and $(1 \rightarrow 3)$-β-D-glucan polysaccharides (51). If this type of polymer is present, it will give a very clear signal but only after excitation with a UV laser source. However, the experience to date with environmental biofilms indicates that these polymers are rarely detected. Another stain, Congo Red, is specific for similar types of polysaccharides and has an emission at 625 nm. Both stains were employed in a few microbiological studies [see (3) for literature].

Polysaccharides in environmental biofilms have been characterized by a new in situ approach employing lectin-binding-analysis. By this means, the lectin-specific glycoconjugates in the EPS can be imaged and subsequently quantified (52). A prerequisite for this staining technique is the evaluation of different types of lectins with a given biofilm sample in order to select the most appropriate lectin or most probably a panel of several lectins. This approach has been successfully used to probe for lectin-specific EPS compounds in a variety of environmental biofilm systems (Table 5). These studies have shown that lectins can be effectively used to localize EPS types not only in pure culture but also in complex biofilm systems (43,53). However, thorough evaluation of this approach is required in order to facilitate the interpretation of lectin specificity and binding patterns in biofilms (44,54). Examples for lectin-stained glycoconjugates in complex biofilms are shown in Figure 6.

Specific stains are available for proteins, some of which may be useful for proteinacious EPS compounds. Most of the protein stains have been developed for measuring proteins in solution or for detecting proteins in electrophoresis gels. Nevertheless, they may be employed to stain different kinds of proteins in biofilm systems. For example, Hoechst 2,495 has been used to label bacterial footprints on surfaces (57,58). A further option may be SYPRO protein staining, which has been employed to quantify the protein content of fixed bacterial cells by flow cytometry (59). Very recently, NanoOrange has been used as a fluorescent marker for bacterial flagella and consequently would be another stain for proteinaceous EPS compounds (60).

The presence of extracellular nucleic acids has been also demonstrated after extraction and chemical analysis of EPS compounds, which showed large amounts of nucleic acids not necessarily having their origin in cell

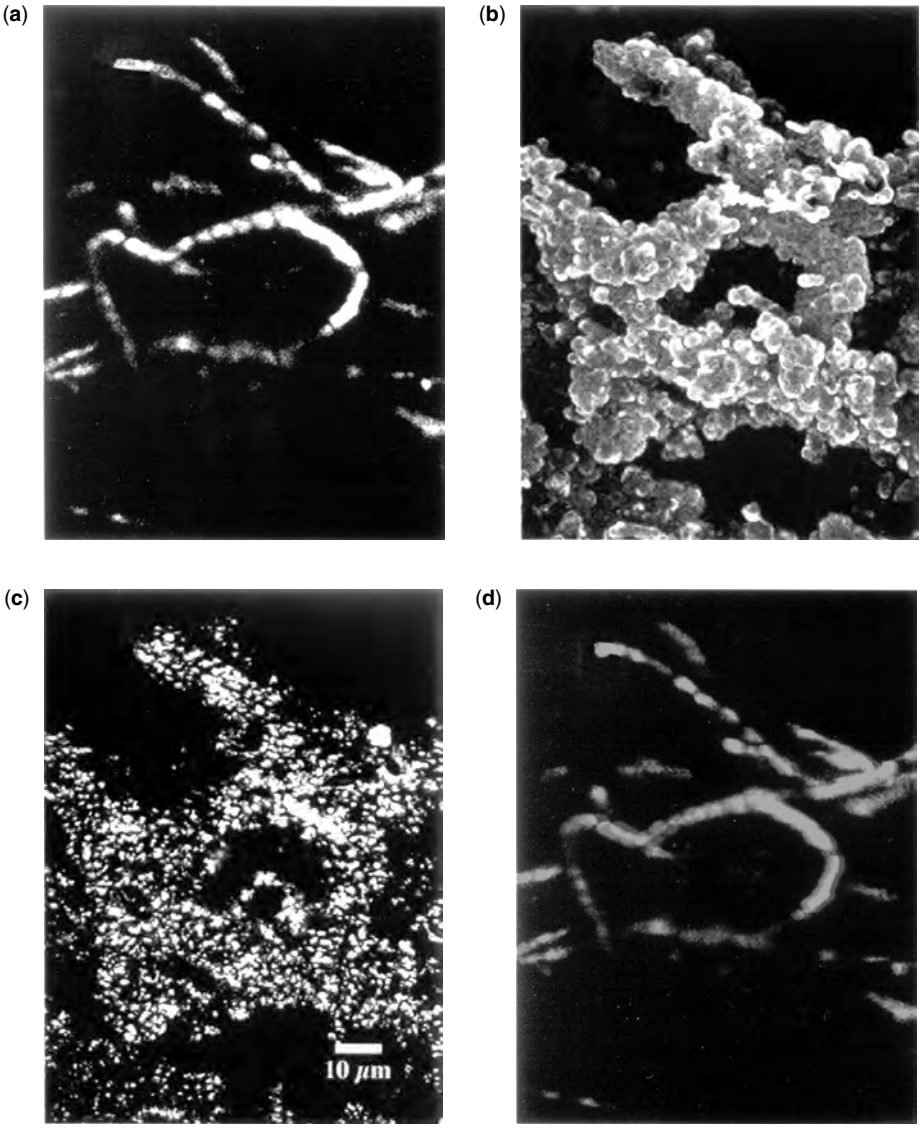

Figure 6. Stereo images (plate with red/green anaglyph and stereo pair). See color insert.

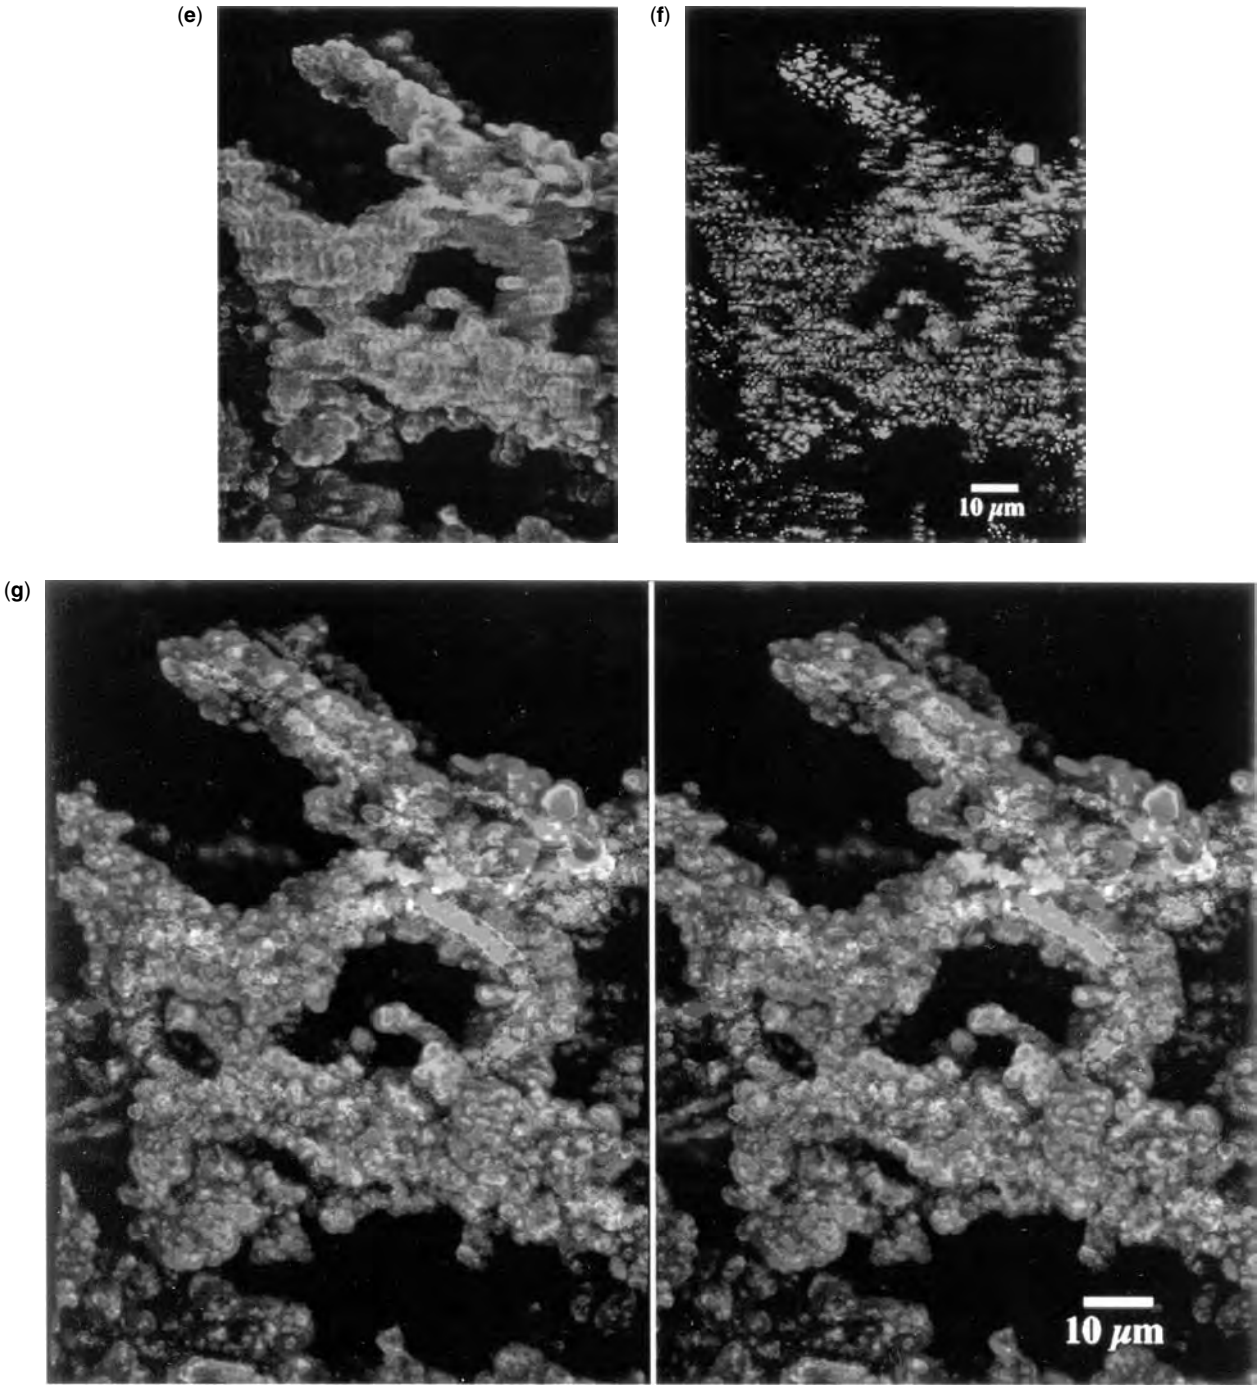

Figure 6. (*Continued*)

lysis (61). These nucleic acids, as pointed out in the preceding text, might be localized by using one of several options for fluorescent staining. A study on marine snow employed these for staining the nucleic acids associated with specific EPS compounds (62). However, the presence and lifetime of extracellular nucleic acids is still under discussion.

The charged nature of biofilm components may also be used as a target for fluorescent probes via charged (i.e., neutral anionic, polyanionic, and cationic) dextran molecules conjugated to fluorescein or other fluorochromes. These probes have proven useful for localization of charge in biofilms (53). Hydrophobicity and hydrophilicity may also be monitored through localization of the binding of fluors such as Nile Red (53) or hydrophobic/philic beads (63), whereas porosity and flow in biofilms may be evaluated through observation of the movement of fluorescent beads using confocal microscopy (64). New size

fractionated, that is, 20 nm, 40 nm, surface-modified (i.e., carboxylated, sulfonated) beads (MOLECULAR PROBES, Eugene, Oregon, http://www.probes.com) may also be used to assess the permeability and chemical nature of EPS.

An example of combining reflection, autofluorescene and fluor conjugated lectin staining is shown in Figure 6. The figure also illustrates the use of red/green anaglyphs and red/green/blue (RGB) stereo projection to simultaneously show the 3-dimensional impression of the data set(15).

Probes for Cell Identity

Antibodies. Immunologic (fluor-conjugated poly- or monoclonal antibodies) fluorescent probes can be used to assess the diversity contained in microbiological systems (Fig. 1, level E). These methods have been adapted to allow their application in various ecological studies (65). Details on preparation of antibodies are provided in various sources (66). In each system analyzed, there is always a need for optimization of technique, including blocking to prevent nonspecific binding, assessment of specificity, and so on. In studies in which there is extensive EPS such as biofilms, concerns may arise from lack of penetration of the antibody as well as cross reactivity with polymer and unknown bacteria in the biofilm. In Table 6, several excellent examples of using antibodies to track bacteria in biofilms are given. Good general reviews and evaluation of antibody applications in microbial ecology may be also found in Reference 67. Although antibodies are usually targeted to bind to specific cell surface structures, they have also been used to identify specific intracellular enzymes (see later in the text).

Table 4. Nucleic Acid Specific Stains and their Application

Nucleic Acid Stain	Applications (References)
AO/DAPI	numerous studies, for references see (26)
Hoechst 33,342	attached and planktonic bacteria (28) flow cytometry (29)

SYTO red	river snow (43,44)

Note: SYTO stains are listed due to their emission color.

rRNA Targeted. One of the most effective means for direct assessment of the biodiversity in natural microbial populations and complex systems is based on phylogenetic data, allowing the identification of specific bacteria (1,79,80). The technique is based on the conserved nature of 16S or 23S prokaryotic ribosomal RNA sequences and the synthesis of short, labeled, complementary, oligonucleotides to these conserved RNA regions (80). A major advantage of this approach is that it does not require per se the isolation and cultivation of specific bacteria, allowing studies of unculturable and hard-to-culture bacteria or those of unknown ecological significance (1,81). The application of fluor-conjugated probes is referred to as fluorescent in situ hybridization or FISH. This approach has been used extensively with CLSM and epifluorescence microscopy to document microbial diversity in a range of habitats. These include flocs, sludge granules (82,83), biofilms (84–86), and the rhizosphere (87). Amann and coworkers provide excellent reviews of FISH for the analysis of microbiological systems (1,88). FISH may also be combined with microautoradiography, allowing the assessment of metabolic activity of specific microbial groups (89–91).

mRNA Targeted. Specific bacteria and their activities can be visualized in situ by the detection of target mRNA sequences. The technique utilizes the ability of PCR to amplify either mRNA or genes of interest within bacterial cells. The mRNA of interest is amplified by in situ PCR and then visualized by labeled probes complementary to the amplified DNA (92,93). Prokaryotic in situ PCR (PI-PCR) or in situ reverse transcription in combination with PI-PCR may be used to image or visualize specific functional genes and their expression products (mRNAs) (94). The technique has been applied to study the diversity of sulfate-reducing bacteria in microbial mats (95). In general, these are potentially powerful techniques although they remain technically challenging in their execution.

Green Fluorescent Protein. An additional approach recently developed for tracking and enumerating specific bacterial cells in natural or complex systems is the use of bacteria labeled with green fluorescent protein (GFP) from the jellyfish *Aequorea victoria* (96). This technique is suitable for the simple enumeration of cells previously transformed with plasmids or transposons containing the *gfp* gene (97). GFP is also used extensively as a reporter system. For example, a GFP reporter system was used to detect metabolic interactions during the degradation of benzyl alcohol in mixed culture biofilms (98). The application of GFP for environmental applications has been reviewed by Errampali and coworkers (99) (See also "Green Fluorescent Protein," this Encyclopedia).

Others. Specific types of bacteria may also be detected using various fluorescent systems for Gram staining (100). These approaches have been based on differential staining such as that observed with the combination hexidium iodide and SYTO 13 staining. Karthikeyan and coworkers used the BacLight Gram stain to quantify gram-positive

and gram-negative bacteria in a complex microbial community grown on various carbon sources (101). Similarly, Wolfaardt and coworkers used a fluorescent Gram stain to identify the presence of a *Bacillus* sp. in a degradative microbial community (53). Commercial fluors for the identification of fungi such as Fun-1 (MOLECULAR PROBES) or Fungalase (ANOMERIC, U.S.A.) may also be used to provide broad indications of system biodiversity. However, as many of these probes have been developed and tested using pure batch cultures, the user must apply them with appropriate caution in assessing natural communities.

Probes for Cell Viability

In general, microbiologists define a viable cell as one capable of division, giving rise to a viable daughter cell. However, detecting and determining viability has proven to be a complex task (Fig. 1, level F). The methods tend to focus on membrane integrity, evidence of cell division, or metabolic activity. Methods such as difference imaging (102) direct determination and quantitation of cell growth (103,104) or physical viability assays [i.e., plasmolysis (103,104)] may be applied. Kogure and coworkers developed the direct viable count (DVC) method, in which bacterial samples are incubated with appropriate nutrients in the presence of an antibiotic preventing DNA-synthesis. Since other cellular functions are not affected, viable bacteria elongate and can be detected using microscopy (105). However, one step assays are becoming increasingly popular. One method gaining acceptance is the commercial two component LIVE/DEAD *Bac* Light™ viability kit (MOLECULAR PROBES). In this case there are two stains — one is a membrane permeable green fluorescing DNA-labeling probe (SYTO-9) and the other is a membrane impermeant red fluorescing DNA-labeling probe (hexidium iodide). When observed with epifluorescence or CLSM, cells with an intact membrane (living cells) appear green whereas "dead" cells fluoresce red. A number of studies have applied and assessed this staining system and others to define the numbers of viable cells in biofilms and flocs (Table 7). In most cases the LIVE/DEAD system must be checked or "ground truthed" using other methods in combination and it is clear that in complex systems interpretation may be difficult. Stains such as the SYTOX fluorescent stains (MOLECULAR PROBES), which penetrate cells that have damaged or fixed cell membranes, also offer the potential of detecting "nonviable cells" in biofilm and bioaggregate systems (106,107).

Probes for Cell Activity

5-Cyano-2,3-Ditolyl Tetrazolium Chloride. Various approaches have also been applied to assess the relative activity of a bacterial cell's electron transport system (ETS) (Fig. 1, level G). Initially the compound 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyltetrazolium chloride (INT) was applied and may be reduced by bacteria, leading to the deposition of opaque formazan crystals that are easily seen in cells (120). Alternatively, another compound, 5-cyano-2,3-ditolyl tetrazolium chloride (CTC), may be employed. CTC is soluble and nonfluorescent when oxidized but when reduced by an active bacterial respiratory system, it accumulates inside the cell as an insoluble fluorescent CTC-formazan. In the meantime, several studies have confirmed the utility of this approach in biofilm communities (121,122). The suitability of the technique has been critically evaluated recently by Sherr and coworkers (123–125). Application of these types of tetrazolium salt indicators may be complicated by factors such as their concentration, their toxicity, the temperature, microenvironment (pH and Eh), and growth phase of the cells (126). In addition, the presence of anaerobic microenvironments in biofilms may result in chemical reduction of the CTC, creating spurious fluorescent crystals.

Table 6. Immunofluorescence Techniques Employed for the Detection of Bacteria with the Cell Surface as Target

Specificity	Applications (References)
Pseudomonas	
Achromobacter	
Comamonas	
Vibrio	marine fouling (68)

Nitrobacter	nitrite oxidoreductase (76)
Pseudomonas	sugar beet root surfaces (77)
Pseudomonas	atrazin-utilizing biofilms
Ammonia oxidizers	ammonia monooxygenace

Reporter Genes. Molecular approaches may also be used to assess cell viability and growth rates. The concentration of rRNA as detected by quantitative hybridization with ribosomal probes may be used as an indicator of cellular activity (127–129). Both epifluorescence and CLSM images may be used in conjunction with digital image analyses to determine growth rates and activity levels. As with most methods, concerns exist and these include ribosome stability, steady state growth conditions, poorly characterized organisms, and the relationship between growth rate and ribosome concentration (130).

Gene expression may be monitored in situ using a number of genetically constructed expression vectors. Early studies applied fluorogenic substrates, such as methylumbelliferylgalactoside (MUG), carboxymethylfluorescein digalactoside, fluorescein β-D-galactopyranoside (FDG), or the lipophilic C_{12}FDG. GFP-based expression vector systems have been developed with stable and modifiable fluorescent characteristics, extending the potential for monitoring in situ gene expression. Sternberg and coworkers used a GFP-based gene reporter system to monitor cell activity, showing that individual *Pseudomonas putida* cells in a toluene-degrading system had different levels of activity that changed over time (130). The use of

unstable GFP forms can permit real-time analysis of gene expression (131). Thus, these reporter systems provide the opportunity to assess bacterial viability, activity, and specific gene expression in complex biofilm environments.

mRNA. It is also possible to monitor bacterial activity through detection of the expression products, the mRNAs. See in the preceding paragraph "Probes for cell identity, mRNA-targeted" on in situ PCR (PI-PCR) and in situ reverse transcription in combination with PI-PCR.

Probes for Enzyme Activity

Intracellular. The presence of specific enzymes in bacterial cells may be employed as a target to identify and localize certain bacterial groups (Fig. 1, level H). For example, immunolocalization of nitrogenase in cyanobacteria microcolonies was demonstrated using an AMCA-labeled secondary antibody. It could be shown that only a fraction of the *Trichodesmium* cells within a colony has the potential to fix nitrogen (132). Monoclonal antibodies have been used to identify nitrite oxidoreductase of nitrite-oxidizing bacteria. Comparison of the immunofluorescence technique with in situ hybridization confirmed the specificity for pure cultures as well as new environmental isolates (76).

Extracellular. A starting point and excellent overview of extracellular microbial enzyme activity may be found in a collection of manuscripts addressing a variety of aquatic environments. These include rivers, lakes, sediments, estuarine, and marine habitats (133). In addition, there are several research papers on exoenzyme activity, which are listed in Table 8. The techniques to measure enzyme activity include radioactive labeled compounds and fluorogenic substrates. The enzymatic measurements may also be combined with other staining techniques to colocalize several features simultaneously. Modeling the costs and benefits of extracellular enzyme activity showed that this is a powerful bacterial feeding mechanism in high-surface-areas such as biofilm systems (134). Furthermore, Unanue and coworkers gave evidence that hydrolytic exoenzymes may be described by a biphasic kinetic model (135).

Probes for the Microenvironment

Diffusion is a critical parameter in biofilm systems and several approaches have been used to assess permeability and porosity in biofilms (Fig. 1, level I). Fluor-conjugated, size-fractionated dextrans and other fluor conjugates have been used to examine diffusion and permeability of biofilms (146,147). In these cases the rate of change in fluorescence as determined using digital image analyses is used to calculate D_e, the effective diffusion coefficient for the EPS matrix. In addition, techniques such as fluorescence recovery after photobleaching (FRAP) may be used to assess diffusion and migration of a range of fluors and fluor conjugates in biofilms (11).

Evidence for the existence of environmental gradients within biofilms has been shown using CLSM techniques in combination with pH sensitive probes such as 5,6 carboxyfluorescein (45). Recently, Vroom and coworkers demonstrated the presence of pH gradients in biofilms using laser microscopy (11). Additional fluorescent probes such as NEWPORT GREEN may be used to assess the local distribution of heavy metals such as cadmium and nickel bound in bacterial biofilms (148).

Other Factors to Consider

Although these laser-based microscopy techniques have many advantages, there are some limitations and concerns. These may be divided into three categories: (1) sample properties such as absorption, scattering, background fluorescence, or bleaching, (*2*) fluorochrome/probe characteristics such as specificity, penetration, toxicity, and bleaching, and (*3*) instrumental parameters such as

lateral and axial resolution, laser penetration, and sampling. Some of these issues are discussed in the following section.

Resolution. The resolution of an LSM is comparable to the normal light microscope and dictated by the wavelength of light involved in imaging. Consequently, if resolution is an important factor, other microscopic techniques such as transmission or scanning electron microscopy have to be used. Furthermore, the digitized image has also a limited resolution in the form of pixels. With most LSM systems the usual pixel resolution for routine work is still 512×512, applicable to four channels. New instruments may have a pixel resolution of 2.048×2.048 or even more but this option is usually restricted to fewer channels due to memory limitations. In this high-resolution mode the LSM operates slowly and produces extremely large image files, which have to be handled by the host computer or subsequent image analyzing systems. Therefore, there is always a balance among the image size, image resolution and the end use of the image being collected.

Nyquist Sampling Frequency. For high-resolution three-dimensions imaging it is necessary to sample at least twice the spatial resolution of the optical system. In practical terms this means x and y sampling at 70 nm intervals while in the z axis, which has far poorer resolution and an interval of 150 nm is necessary. Consequently the sample will be extremely bleached and conventional CLSM may become impossible. In this case 2-photon laser scanning microscopy may offer a solution as excitation and bleaching will occur in the focal plane only (Table 3). Nevertheless, if sampling is carried out at these intervals then the data set is sufficiently continuous especially to allow correct image restoration (deconvolution). In addition, quantification of correct volumes becomes possible and subsequent processing may allow exact three-dimensional presentation of the data (149). Clearly, for large data sets such as those created by LSM imaging, extensive RAM, storage, and archiving are required, essentially there is never too much of any of the above computer components.

Restoration. Another drawback of all light microscopic systems is poor axial resolution. So far, this can only be compensated by computing intensive restoration procedures called deconvolution (150). Deconvolution has been applied in wide field microscopy (151) and especially in LSM (152) of microbiological communities. Several commercial software packages at different levels of sophistication are available for deconvolution of three-dimensional LSM data, for example, AUTO-DEBLUR (http://www.aqi.com), HAZE-BUSTER, MICROTOME (both http://www.vaytek.com), HUYGENS (http://www.svi.nl). Some of the packages calculate with an estimated point spread function, whereas others require the measurement of the point spread function before applying a deconvolution algorithm. The complex issue of confocal image restoration for subsequent quantification has been discussed in detail (153,154).

Laser Excitation/Emission. Penetration of the laser into biological samples is a function of wavelength of light, opacity of the sample, adsorption by the sample, scattering, the presence of inhomogeneities as well as the numerical aperture and working distance of the objective lens. Light wavelength is a major factor, many biological materials are more transparent to infrared (IR) wavelengths, and as indicated by Vroom and coworkers, penetration of biofilms using 2-photon IR lasers allowed four times greater penetration over conventional CLSM (11). The nature of the staining procedure and fluorochromes are also factors. For example, negative staining will result in reduced penetration due to quenching of both the excitation and emission wavelengths by the high fluorochromes concentration in the environment relative to typical positive stains.

Bleaching of Sample. Sample bleaching and loss of signal is often a problem in both epifluorescence and laser scanning microscopy. Minimizing observation and scan time, choosing the correct combination of zoom, pinhole, PMT setting, and laser intensity is essential. However, the use of antifade reagents is recommended

for many fluor applications such as FISH. One can only achieve the optimum image and performance from a LSM system in the absence of bleaching or fading. The reader is referred to the following paper dealing with these reagents (155). These reagents are highly toxic, must be used with caution, and may be ordered pre-mixed from MOLECULAR PROBES and CITIFLUOR Ltd. (London, U.K.).

Toxicity of Fluorochromes. Toxicity of the various fluorochromes and other reagents is a concern to both the user and the sample materials. This is particularly true in cases in which time course observations are being made on fully hydrated living biofilm samples. Although in many cases there is no immediate observable effect, negative impacts may be seen with some nucleic acid stains applied over extended time periods. Some fluorochromes such as CTC (1 to 20 mM) have demonstrated toxicity for microbial samples (124,126). In contrast, other fluors such as fluorescein (45) appear to have no detectable negative impacts when used on microbial biofilms. In a recent study, CELL TRACKER (MOLECULAR PROBES) has been used to stain intracellular bacteria in living host cells. It could be shown that the fluorochrome had no negative effect on the bacteria and the host cells (156).

CONCLUSION

The approach suggested will allow the assessment of major biofilm features by using confocal laser scanning microscopy in combination with a panel of fluorescent probes and reporter molecules. Nevertheless, new technical developments such as 2-photon excitation and time-resolved fluorescence are emerging techniques with significant advantages in fluorescence sensing and microscopy. Another necessity is the design of new fluorescent probes that can be excited with a variety of light sources and are highly specific in complex real-world microenvironments such as interfacial microbial communities.

Acknowledgments

Support under the Canadian-German Collaborative Agreement on Research and Development is gratefully acknowledged. Financial support of the National Water Res. Institute, Environment Canada, and the UFZ Centre for Environmental Research Leipzig-Halle is appreciated. Excellent technical assistance was provided by Ute Kuhlicke (UFZ) and George D. W. Swerhone (NWRI).

LEAF DECOMPOSITION BY FUNGI IN FRESHWATER ECOSYSTEMS.

See WATER FUNGI AS DECOMPOSERS IN FRESHWATER ECOSYSTEMS

LEGIONELLAE

BARRY S. FIELDS
Centers for Disease Control and Prevention
Atlanta, Georgia

Legionellae are gram-negative bacteria that are common to freshwater environments. These bacteria are human pathogens and cause a substantial number of cases of pneumonia in developed countries. Disease occurs when a susceptible human host inhales aerosolized water that contains the bacteria. Legionellae cause two forms of respiratory illness that are collectively referred to as *legionellosis* (1,2). The more severe form is named *Legionnaires' disease* in reference to the infamous 1976 outbreak that occurred during an American Legion convention in Philadelphia. The milder, flulike illness caused by these bacteria is named *Pontiac fever* after the first documented outbreak, which occurred at a health department in Pontiac, Michigan (1). Currently, there are 43 species comprising 65 distinct serogroups in the genus *Legionella* (3,4). Species identification and differentiation are performed serologically or by DNA hybridization (5). One species of *Legionella*, *L. pneumophila*, causes approximately 90% of all documented cases of legionellosis (6). Although there are now 15 serogroups of *L. pneumophila*, 82% of all legionellosis cases are caused by *L. pneumophila* serogroup 1. Approximately one-half (i.e., 20) of the 43 species of Legionellae have been associated with human disease. It is likely that most of the legionellae can cause human disease under the appropriate conditions; however, these infections are infrequently reported because they are rare and because of the lack of diagnostic reagents.

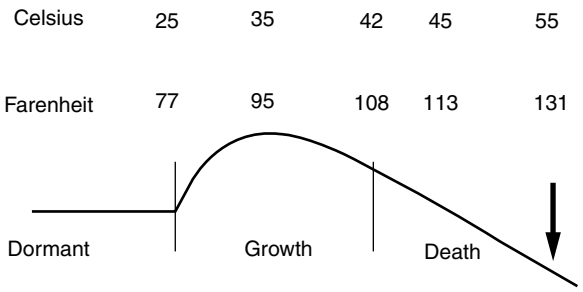

Figure 1. Temperature range of legionellae.

Incidence studies of community-based pneumonia have estimated that between 10,000 and 15,000 cases of legionellosis occur annually in the United States (7). The disease is a major concern of public health professionals and individuals involved with maintaining building water systems. Legionellosis is generally considered a preventable illness because controlling or eliminating the bacterium in certain water reservoirs will prevent cases of the disease. This concept of preventable illness has resulted in a number of guidelines aimed at reducing the risk of legionellosis in building water systems and in a growing industry based upon the litigation of Legionnaires' diseases cases. Although the disease can be effectively treated with appropriate antimicrobial agents, controlling the bacteria in freshwater environments has proven much more difficult. The factors that lead to outbreaks or cases of Legionnaires' disease are not completely understood, but certain events are considered prerequisites for infection. These include the presence of the bacterium in an aquatic environment, amplification of the bacterium to an unknown infectious dose, and transmission of the bacteria via aerosol to a human host that is susceptible to infection (8).

Water is the major reservoir for legionellae, and the bacteria are found in freshwater environments worldwide (9). Legionellae have been detected in as many as 40% of freshwater environments by culture and in up to 80% of freshwater sites tested by polymerase chain reaction (PCR) (10,11). Natural freshwater environments do not usually act as reservoirs for outbreaks of legionellosis. *Legionella pneumophila* multiplies at temperatures between 25 °C and 42 °C with an optimal growth temperature of 35 °C (Fig. 1). Most cases of legionellosis can be traced to artificial aquatic environments where the water temperature is higher than the ambient temperature. Legionellae probably have existed in freshwater environments for a very long time, whereas only in the past century has industrial technology created environments that result in increased transmission to humans. As stated in the 1992 Institute of Medicine report (12), "Emerging Infections: Microbial Threats to Health in the United States"; "technology and industry can cause, or at least contribute to, the emergence of infectious disease." This is precisely the case with Legionnaires' disease. Legionnaires' disease may be regarded as a consequence of altering the environment for human benefit. Some outbreaks of legionellosis have been associated with construction, and it was originally believed that the bacteria could survive and be transmitted to humans via soil. However, legionellae do not survive in dry environments, and these outbreaks are more likely the result of massive descalement of plumbing systems because of the changes in water pressure during construction (13,14).

Presence of the bacteria in an aquatic environment and the water temperature are the two factors that can increase the risk of Legionnaires' disease. However, these bacteria require a distinct combination of nutrients to amplify in an environment. Initially, the unusual nutritional requirement of legionellae appeared to contradict the pervasiveness of the bacteria in aquatic environments. The levels of nutrients that legionellae require would rarely be found in freshwater and, if present, would serve only to amplify faster-growing bacteria that would compete with the legionellae. However, these nutrients represent an intracellular environment, not soluble nutrients commonly found in fresh water. Legionellae survive in aquatic and in some moist soil environments as intracellular parasites of free-living protozoa (15,16). Legionellae have been labeled *protozoonotic*, a term that appears to suit their natural history (17). Legionellae have been reported to multiply in 14 species of amoebae, 2 species of ciliated protozoa, and one species of slime mold, whereas growth of legionellae in the absence of protozoa has been documented only on laboratory media (15,18,19). Protozoa naturally present in environments implicated as sources of Legionnaires' disease can support intracellular growth of legionellae in vitro (20). *Legionella* can infect and multiply intracellularly in both protozoa and human phagocytic cells (15,21). It appears that protozoa are the natural hosts of legionellae, whereas human phagocytic cells occasionally become ill-fated surrogates. Understanding the crucial role of protozoa in the ecology of legionellae is critical to the development of successful prevention strategies. The ecology of legionellae is not limited to the bacteria's interaction with protozoa. Legionellae are known to exist within biofilms found in building water systems and these biofilm-associated legionellae are more easily detected than their planktonic counterparts (22). A true understanding of the ecology of legionellae will require studies of these organisms as they interact with complete microbial communities, not as independent inhabitants of freshwater environments.

Inhalation of legionellae in aerosolized droplets is the primary means of transmission for legionellosis (23) and these aerosolized droplets must be of a respirable size (1–5 m). No person-to-person transmission of Legionnaires' disease has been documented. A number of devices have been implicated as sources of aerosol transmission of legionellae. These sources are of two general types: those producing aerosols of contaminated potable water including showers, tap water faucets, and respiratory therapy equipment; and those from nonpotable water such as cooling towers and evaporative condensers, whirlpool spas, decorative fountains, ultrasonic mist machines, and humidifiers (23). Meaningful identification of sources of transmission requires a multidisciplinary approach including epidemiology, molecular epidemiology, and microbiologic techniques including water and, occasionally, air sampling.

DETECTION OF LEGIONELLAE IN THE ENVIRONMENT

Rationale for Testing Environmental Samples

Environmental isolates of legionellae can be obtained from water or air samples, although water is the primary source of the organism (11). These bacteria can be found only in air samples after a contaminated water source has been aerosolized. Air sampling is of limited value because legionellae do not survive drying and these procedures are technically demanding. Most water samples tested for legionellae are collected either to identify a reservoir associated with cases of legionellosis or as part of a strategy to prevent cases of legionellosis (24). There is considerable controversy concerning the public health benefits of monitoring certain environments for legionellae. These viewpoints are best summarized by guidelines for healthcare facilities where there is a more susceptible population and greater need for control measures. There are at least two general strategies for preventing healthcare-associated legionellosis, especially in facilities where no cases or only sporadic cases of the illness have been detected. The first is an environmental surveillance approach, with periodic culturing of water samples from the hospital's potable water system for the purpose of detecting *Legionella* spp. (25,26). If any sample is culture-positive, diagnostic testing is recommended for all patients with healthcare-associated pneumonia. In-house testing is recommended in particular for facilities with transplant programs. When $\geq$30% of the samples obtained are culture-positive for *Legionella* spp., the healthcare facility's potable water system is decontaminated (27). The basic premise for this approach is that no cases of healthcare-associated legionellosis can occur if *Legionella* spp. are not present in the potable water system, and, conversely, if *Legionella* spp. are cultured from the water, cases of healthcare-associated legionellosis could potentially occur. Additionally, when physicians are informed that the potable water system of the hospital is culture-positive for *Legionella* spp., they are more inclined to order the necessary tests for legionellosis. A potential advantage of using this approach in these situations is that periodically culturing a limited number of water samples is less costly than routinely performing laboratory diagnostic testing for all patients who have healthcare-associated pneumonia. There may be an even greater advantage for healthcare facilities that house organ transplant patients because of the great susceptibility of these patients.

The main argument against this approach is that, in the absence of cases, the relationship between the results of water cultures and the risk for legionellosis remains undefined (24). *Legionella* spp. are sometimes present in water systems of buildings, often without being associated with known cases of disease. In a study of 84 hospitals in Québec, 68% of the water systems were found to be colonized with *Legionella* spp. and 26% were colonized at greater than 30% of sites sampled; cases of Legionnaires' disease, however, were not frequently reported from these hospitals (27).

Interpretation of the results of periodically culturing of water might be confounded by differing results among the sites sampled within a single water system and by fluctuations in the concentration of *Legionella* spp. at the same site. In addition, the risk for illness after exposure to a given source might be influenced by a number of factors other than the presence or concentration of organisms. These factors include (*1*) the degree to which contaminated water is aerosolized into respirable droplets, (*2*) the proximity of the infectious aerosol to the potential host, (*3*) the susceptibility of the host, and (*4*) the virulence properties of the contaminating strain (8). Thus, data are insufficient to assign a level of risk for disease even on the basis of the number of colony-forming units detected in samples from the healthcare environment in immunocompetent patient-care areas. Conducting environmental surveillance would obligate hospital administrators to initiate water-decontamination programs if *Legionella* spp. are identified. Because of these problems, periodic monitoring of water from the hospital's potable water system and from aerosol-producing devices is not widely recommended in general patient-care areas (28).

Collection and Culture of Water Samples

The number and types of sites that should be tested to detect legionellae must be determined on an individual basis. This is because of the diversity of plumbing and heating, ventilation, and air-conditioning (HVAC) systems in a variety of institutions that may be sampled. These institutions can include industrial facilities, hotels, hospitals, retirement homes, public facilities, and domestic environments. An environmental sampling protocol addressing selection of the appropriate sites to sample within a hospital was published in 1987 (29). An amended version of this protocol is listed in Table 1. This protocol can serve as a prototype for identifying sites that should be sampled in a variety of institutions. Generally, any water source that may be aerosolized should be considered as a potential source for the transmission of legionellae. The bacteria are rarely found in municipal water supplies and tend to colonize plumbing systems and point-of-use devices. To colonize a system, the bacteria must multiply and this

Table 1. Abbreviated Protocol for Sampling Environmental Sites for Legionellae

Category	Examples
Potable water	Incoming water line Water softener/demineralizer Water heaters Holding tanks
Potable water final outlets	Showers Sinks Whirlpools (including filter) Humidifiers Decorative fountains Misters
HVAC system	Cooling towers Evaporative condensers
Hospital associated	Water used for respiratory therapy Ice makers

requires temperatures above 25 °C (5). Therefore, legionellae are most commonly found in hot water systems. The bacteria do not survive drying (13), and so condensate from air-conditioning equipment, which frequently evaporates, is not a likely source.

Two primary sample types should be collected when sampling for legionellae: water samples and swabs of point-of-use devices or system surfaces (11,30). Collection of at least 1 liter of water allows concentration of the sample if necessary. If the water source has recently been treated with chlorine or bromine, 0.5 ml of 0.1 N sodium thiosulfate may be added to each 1-liter sample to neutralize the disinfectant.

Swabs allow sampling of biofilms, which frequently contain legionellae. These can be taken from various points within plumbing systems or from surfaces of basins of cooling towers or spas. Swabs of faucet aerators and shower heads should be taken in conjunction with water samples from these sites and should be taken with the aerator or the showerhead removed. The swabs can be streaked directly onto an agar plate or submerged in a small volume of water taken at the same time to prevent drying during transportation to the laboratory.

All samples should be transported to the laboratory in insulated coolers as protection against extreme heat or cold. Samples that will not be processed within 24 hours from the time of collection should be refrigerated.

Pretreatment of Water Samples

A schematic representation of methods for processing water samples for culture is shown in Figure 2. The procedure chosen depends on the expected degree of total bacterial contamination in a particular sample. Water samples are either concentrated and processed directly or subjected to a selective procedure such as acid or heat treatment. Potable waters generally have low bacterial concentrations and are either cultured directly or concentrated to detect legionellae. Nonpotable waters, such as those from cooling towers, generally do not require concentration because of their high bacterial concentrations.

Samples may be concentrated 10-fold or more by using either filtration or centrifugation. Filtration is used more frequently, although either procedure can be used successfully (11,30,31). Water should be filter-concentrated in a biological safety cabinet, using 0.2-μm-pore-size polycarbonate filters. Polycarbonate membranes allow suspended particles to collect on the filter surface without being trapped as with matrix-type filters. The filter membrane is then resuspended into a volume of the sterile water and vortexed for 30s. Samples may be concentrated by centrifugation at $1000 \times g$ for 10 min, removing all but 10 ml of the supernatant, and vortexing (31).

A selective procedure is required to reduce the number of non-*Legionella* bacteria before culturing some water samples with high total bacterial concentrations. Non-*legionellae* bacteria can be selectively killed by either acid pretreatment or incubation at 50 °C for 30 minutes (32,33). Legionellae are more resistant to lower pH and brief exposures to higher temperatures than many other freshwater bacteria. For acid pretreatment, the sample is mixed and incubated with an acid buffer (pH 2.2) for 3 to 30 minutes (32). The sample is neutralized by the buffer within buffered charcoal yeast extract (BCYE) agar

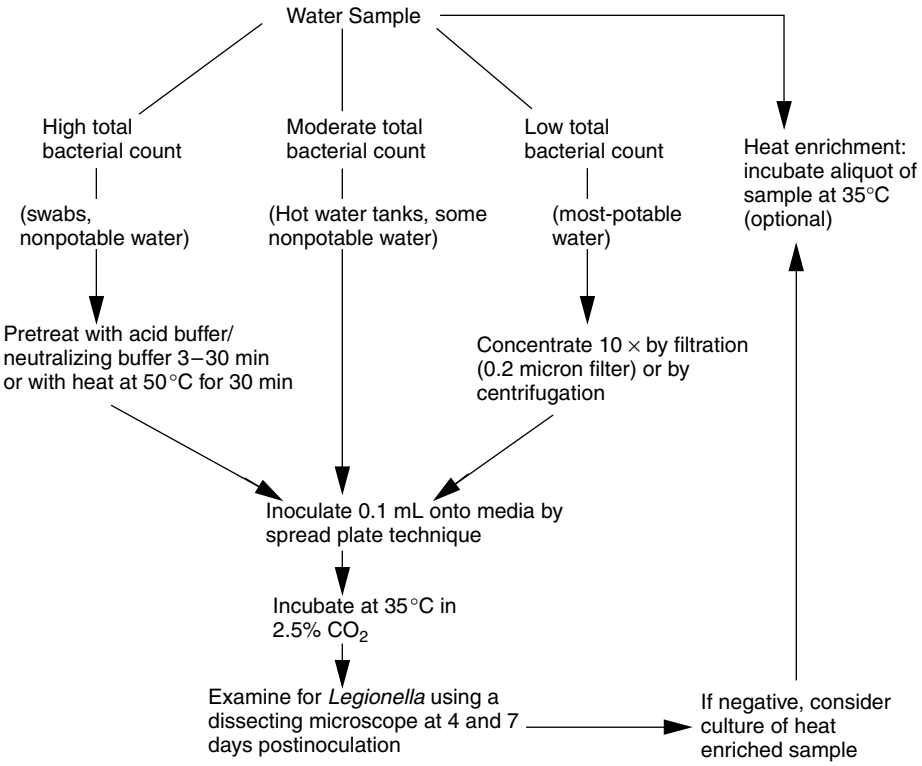

Figure 2. Overview of procedures for the culture of water samples to detect legionellae.

and therefore must be spread on the agar plate at the end of the period of incubation with the acid buffer. Heat pretreatment is accomplished by incubating 10 ml of sample in a 50 °C waterbath for 30 minutes (33).

Heat enrichment or incubation of specimens at 35 °C can improve recovery of legionellae by up to 30% (34). However, this procedure requires a considerable length of time before results can be obtained and may not be practical in many situations. Heat enrichment relies on autochthonous protozoa to amplify undetectable levels of legionellae. Aliquots of samples are incubated at 35 °C. Incubated samples can be cultured after 2 to 6 weeks.

Culture Media

Legionellae were first isolated on bacteriological agar, using Mueller-Hinton agar supplemented with hemoglobin and Iso Vitale X (MH-IH) (35). The essential component in hemoglobin was found to be a soluble form of iron, and L-cysteine is the essential amino acid provided by the Iso Vitale X. These refinements lead to the development of Feeley-Gorman agar, which provides better recovery of the organism from tissue (34). Later, starch was replaced with charcoal to detoxify the medium and the amino acid source was changed to yeast extract, resulting in charcoal yeast extract agar (36). Charcoal yeast extract agar is the base form for most media used for growing legionellae. The medium used for the culture of legionallae has been improved several times, eventually resulting in the medium currently used, BCYE (36,37,38). The most widely used form of BYCE agar is supplemented with α-ketoglutarate (37,38). Table 2 lists the primary components of BCYE agar and the supplements added for various purposes (36,39,40,41).

Table 2. Components and Supplements of BCYE Agar for Culturing Legionellae from the Environment

Component	Concentration	Purpose
Charcoal	2.0 g/liter	Base component
Yeast extract	10.0 g/liter	Base component
ACES[a] buffer	10.0 g/liter	Base component
Ferric pyrophosphate	0.25 g/liter	Base component
L-cysteine	0.4 g/liter	Base component
Potassium α-ketoglutarate	1.0 g/liter	Base component
Agar	17.0 g/liter	Base component
Glycine	3.0 g/liter	Selective agent
Polymyxin B	50–100 U/ml	Selective agent (gram negative)
Vancomycin or cefamandole	1–5 g or 4 mg/liter	Selective agent (gram positive)
Anisomycin or cycloheximide	80 μg/ml (for either)	Selective agent (fungal)
Bromocresol blue	10 mg/liter	Indicator dye
Bromocresol purple	10 mg/liter	Indicator dye
Bovine serum albumin	10 g/liter	Supplement for some fasitidious legionellae

Note: [a]N-(2-Acetamido)-2-aminothanesulfonic acid.

Culture of environmental samples requires the use of selective and nonselective media in conjunction with previously described selection procedures (11). Most laboratories use multiple plates for each sample, including a BCYE agar plate, a BCYE agar plate containing three antimicrobial agents, and a BCYE agar plate containing the three antimicrobial agents plus glycine (Table 2). These media can be prepared with or without the indicator dyes, which impart a color specific for certain species of *Legionella* (40). Although the majority of *Legionella* spp. grows readily on BCYE agar, some require supplementation with bovine serum albumin to enhance growth. *L. micdadei* and several strains of *Legionella bozemanii* show a preference for BCYE with 1.0% albumin (39). All agar plates are inoculated with 0.1 ml of sample by the spread plate technique and incubated at 35 °C in a humidified 2.5% CO_2 atmosphere or candle extinction jar.

Identification of Legionellae

Colonies of legionellae require approximately 72 hours to appear on BCYE agar and may require 7 days or longer. Ideally, plates should be examined after 4 days of incubation and a second time after 7 and 10 days before discarding incubation. Plates should be examined with a dissecting microscope and a light source to detect bacterial colonies resembling legionellae. After approximately 4 days of incubation, these colonies are 2 to 4 mm in diameter, convex, and round with entire edges. The center of the colony is usually a bright white with a textured appearance that has been described as *cut-glass-like* or *speckled*. The white center of the colony is often bordered with blue, purple, green, or red iridescence. Some species of legionellae produce colonies that exhibit blue–white or red autofluorescence (33). The primary isolation plates can be examined with long-wave UV light to detect these autofluorescent colonies.

Colonies resembling legionellae can be presumptively identified on the basis of their requirement for L-cysteine by subculture on blood agar or BCYE agar without L-cysteine. Subcultured colonies that grow on BCYE agar, but not on blood agar or BCYE without L-cysteine, are presumed to be legionellae. Legionellae are relatively inert in many biochemical test media, hence, these tests are of limited value in identification of these bacteria. Definitive identification is usually accomplished by using a direct fluorescent antibody (DFA) or slide agglutination test with specific antisera (30). Identification can also be accomplished using fatty acid analysis and DNA hybridization (5).

Air Sampling

Examination of water samples is the most efficient microbiological method for identifying sources of legionellae. Air sampling is an insensitive means of detecting these bacteria and therefore, it is of limited value in environmental sampling for legionellae. In certain instances, it may be beneficial to demonstrate the presence of legionellae in aerosol droplets associated with suspected reservoirs of the bacterium. Air sampling has been used to better define

the roles of certain devices such as showers, faucets, and evaporative condensers in disease transmission (42). It is usually used to establish the presence of the legionellae in aerosol droplets and occasionally to quantitate or determine the size of particles containing legionellae. Information regarding particle size and numbers of viable bacteria can be calculated using these procedures, but this approach requires much more stringent controls and calibration (30). Samplers should be placed in locations representative of human exposure, and investigators should wear an Occupational Safety and Health Administration-approved respirator if sampling involves exposure to potentially infectious aerosols.

Methods that have been used to sample air for legionellae include impingement in liquid by using an all-glass impinger (AGI), impaction of solid medium by using Andersen samplers, and the use of settle plates (42). Except for settle plates, these methods require a vacuum source and a means of controlling airflow. Several configurations of air sampling equipment can be used; they usually incorporate a device for controlling airflow (flowmeter-manometer) connected in the vacuum line between the sampler and vacuum source.

AGIs with the stem 30 mm from the bottom of the flask have been used successfully to sample for legionellae (42). These samplers use the principle of impingement and washing of air, in which organisms are entrapped in a liquid medium. Because of the velocity at which samples are collected, clumps tend to be fragmented, leading to a more accurate count of bacteria present in the air. The disadvantages of this method are that this velocity tends to destroy some vegetative cells, it does not differentiate particle sizes, and AGIs are easily broken in the field. Yeast extract broth (0.25%) is the recommended liquid medium for AGI sampling of legionellae (30). Once the sample has been collected, the yeast extract broth may be processed by methods used for the culture of water samples.

Andersen samplers are viable particle samplers in which particles pass through jet orifices of decreasing size in cascade fashion until they hit an agar surface (43). The agar plates are then removed and incubated to culture any legionellae present. The stage distribution of the legionellae should indicate the extent to which the bacteria would have penetrated the respiratory system. The advantages of this sampling method are that the equipment is more durable, the sampler can determine the number and size of droplets containing legionellae, and agar plates can be placed directly in an incubator with no further manipulations. Both selective and nonselective BCYE agar can be used in an Andersen sampler. If the samples must be shipped to a laboratory, they should be packed and shipped without refrigeration as soon as possible.

Detection of Legionellae by DFA and PCR

Nonculture methods offer the potential of greatly increased sensitivity, however, culture remains the method of choice for detecting legionellae, primarily because nonculture methods cannot provide information regarding the viability of the bacteria. These nonculture methods include detection of the organisms with specific antisera by DFA staining and procedures to detect nucleic acids of legionellae by using PCR.

The use of DFA to detect legionellae is limited by the number of specific antisera that can be used. There are no antisera that specifically react with all *Legionella* species, a different antiserum must be used for each species or serogroup. Reports on the sensitivity and specificity of DFA testing of environmental specimens vary greatly, with most studies indicating that the test is relatively insensitive and nonspecific (44).

The use of PCR for detecting nucleic acids of legionellae in the environment has proved to be valuable in some investigations of outbreaks of legionellosis (45). A number of Legionella genes, including 5S rRNA, 16S rRNA, and *mip* genes have been used as targets for PCR (46,47). Use of PCR to detect legionellae in the environment has suggested that up to 80% of freshwaters are positive, whereas only 20 to 40% are positive by culture (10,48). This discrepancy could be because of the presence of nonviable or injured organisms, viable but nonculturable legionellae, a nonspecific reaction with unrelated organisms, or the presence of new species of legionellae (49).

Most investigations of epidemic legionellosis have used culture to detect legionellae in the environment. As a result, most of our epidemiologically relevant information concerning legionellosis is based on direct culture data. Until we possess a better understanding of the diversity and distribution of the legionellae, results from nonculture-based methods should be interpreted cautiously.

Molecular Typing Techniques

Associating an environmental isolate of *Legionella* with a clinical isolate from a patient with legionellosis usually requires a molecular subtyping procedure. *L. pneumophila* serogroup 1 (Lp1) accounts for most of the cases of legionellosis (23). However, Lp1 can be divided into a number of subtypes by using various techniques, indicating that this is a fairly heterogeneous serogroup (50). Identification of the bacterium, even to the serogroup level, is not sufficient to implicate an environmental isolate as the source of disease.

Initially, legionellae were identified to the serogroup level during investigations of legionellosis. This form of serologic subtyping uses polyvalent or monoclonal antisera and may be adequate for identifying reservoirs of some of the uncommon legionellae causing disease. The variety of strains and distribution of Lp1 necessitate more elaborate subtyping procedures to discriminate within these bacteria. Several groups of monoclonal antibodies have been developed for this purpose (51). An international panel of seven monoclonal antibodies was proposed in 1986 (51,52). Although much information has been gained through the use of this panel, several of the cell lines have been lost and most of these reagents are no longer available. Use of these monoclonal antibodies has identified 10 type strains within Lp1. The ability to differentiate Lp1 into 10 subtypes has greatly improved our ability to correctly identify sources of disease. For example, several outbreak investigations have found Lp1 in both the potable water system and cooling towers

of a particular institution (42,53). Differentiation with monoclonal antibodies indicated that the epidemic strain had colonized only one of these systems (either cooling tower or potable systems) indicating that the presence of Lp1 in the other system was not causing disease at that site. Without this level of subtyping, it would be much more difficult to confidently confirm the source of transmission.

Recent investigations have shown that the use of monoclonal antibodies may not be sufficient for discriminating between disease-causing strains and other environmental isolates of Lp1 (54). Molecular techniques such as pulsed-field gel electrophoresis (PFGE), arbitrarily primed PCR (AP-PCR), and amplified fragment length polymorphism (AFLP) are able to discriminate within monoclonal subtypes of Lp1 and identify sources of disease-causing strains (50,55). These techniques appear to complement the use of monoclonal antibodies and are the most recent of several techniques that separate strains based on DNA polymorphism (50). Other techniques used to discriminate between isolates of legionellae include restriction fragment length polymorphism analysis, plasmid analyses, electrophoretic alloenzyme typing, and RNA/DNA probing of DNA digests (56,57). PFGE, AP-PCR, and AFLP offer better discrimination and are less labor-intensive than these other techniques.

PREVENTION OF LEGIONELLOSIS

It is unlikely that legionellae can be eradicated from aquatic environments, even on a limited scale, because they are integral members of the aquatic microbial community. The bacteria are ubiquitous in freshwater environments, and they are present in relatively low concentrations in most water supplies. They are rarely isolated from water treatment facilities. The difficulty in detecting legionellae in water treatment plants and municipal water supplies is probably because of the lower temperatures of these waters. Higher concentrations of legionellae are more frequently present in warm and thermally altered environments where they have increased potential contact with humans (58). To minimize the number of cases of legionellosis, many countries have produced guidelines or codes of practice relating to the control of legionellae. However, research to substantiate these practices is scarce, and the prevailing rationale for these recommendations is primarily empirical (59). There is no single established protocol to prevent legionellosis. The two primary approaches for controlling this disease are (*1*) maintaining building waters systems as to limit colonization and growth of the bacteria and (*2*) intervention measures if cases of legionellosis are associated with a particular environment. Table 3 list guidelines for the control and prevention of legionellosis from U.S. Federal agencies, State and Local government agencies, and nonprofit professional organizations.

Traditional means of eliminating legionellae from a particular reservoir include use of oxidizing biocides, such as chlorine and bromine and heat eradication. Additional alternative measures include UV irradiation, copper–silver ionization, monochloramine, and ozonation (60–63). Two of these procedures, copper–silver ionization and use of monochloramine have received favorable attention recently. Kool and coworkers published a case-control study that compared disinfection methods for drinking water supplied to 32 hospitals that had outbreaks of Legionnaires' disease with the disinfection method used in 48 control hospitals (64). Hospitals supplied with free chlorine were 10 times more likely to have reported outbreaks of Legionnaires' disease than those using monochloramine as a disinfectant. The authors suggest that 90% of nosocomial outbreaks may be prevented by the use of monochloramine for residual disinfection. Copper–silver ionization was documented to control legionellae at several

hospitals, however, long-term efficacy of this procedure has not been documented (65). Further studies are needed to determine the efficiency of both of these procedures.

As previously mentioned, temperature is a critical factor in the ability of legionellae to colonize reservoirs in which they are amplified. Other microorganisms and factors critical to the growth of legionellae are almost universally present in freshwater environments, and it is temperature that governs the numbers of these bacteria. An Australian study of cooling towers found that legionellae colonized or multiplied in towers with basin temperatures above 16 °C and multiplication that became explosive at temperatures above 23 °C (59). Conversely, legionellae are killed at temperatures between 44 and 55 °C, and it has been suggested that potable hot water systems be maintained at temperatures between 55 and 60 °C, to prevent growth of the bacteria (63). This may be impractical for many institutions, especially hospitals, where the potential for scalding of patients exists or where state regulations are prohibitive.

Effective prevention strategies will require a multidisciplined approach to identify more effective decontamination techniques and approaches to prevent amplification of these bacteria in reservoirs.

LEGIONELLA IN THE ENVIRONMENT: PERSISTENCE, EVOLUTION, AND PATHOGENICITY

OMAR S. HARB
University of Pennsylvania
Philadelphia, Pennsylvania

YOUSEF ABU KWAIK
University of Kentucky
Lexington, Kentucky

The environment has always been at the crux of the evolutionary process at both the macro and micro levels. Organisms are constantly faced with the challenge of adapting to environmental changes and to other inhabitants of their ecosystems. One outcome of such adaptation appears to have been the rise of pathogenic microbes that are a major source of morbidity and mortality to humans and animals. A common theme for many of those bacterial pathogens is their ability to infect and survive within free-living amoebae (1,2). In addition to allowing bacteria to replicate and increase in numbers, amoebae provide a protective barrier between such microbes and adverse extracellular conditions (3). Important human and animal pathogens such as *Mycobacterium avium* (4,5), *Chlamydia pneumonia* (6,7), and *Listeria monocytogenes* (8) are capable of infecting and surviving within protozoa. Moreover, a link may exist between the ability of these pathogens to infect amoebae and their ability to infect mammalian cells (2,9). An example of this comes from studies that showed that an avirulent strain of *Mycobacteria*, *Mycobacterium smegmatis*, cannot infect the same amoebae that the virulent strain, *M. avium*, can (4). Studies investigating members of the *Legionella* species and their interaction with the environment and amoebae have been most revealing (2,10–15). Over the past two decades a clear link between legionellae and their environments, and their ability to cause disease in humans has been established. This article discusses the important aspects of the critical role played by the environment in the evolution, persistence, and pathogenicity of legionellae. In addition, the molecular ecology of legionellae within amoebae is highlighted as a model for understanding the pathogenicity of legionellae to mammalian cells.

LEGIONELLAE; HISTORICAL PERSPECTIVE AND PUBLIC HEALTH ISSUES

Historical Perspective

Legionellae became known following a notorious outbreak of a mysterious respiratory illness in the summer of 1976 that affected 182 people in Philadelphia, Pennsylvania, of whom 29 died (16,17). Because the disease mostly affected attendees of an American Legion convention, it was called Legionnaires' disease. Several months following this outbreak, the causative agent of Legionnaires' disease was isolated and determined to be a rod-shaped facultative intracellular gram-negative bacterium (16). This bacterium was subsequently classified as a new species (*Legionella pneumophila*) and placed in a new genus, *Legionella* (18). Interestingly, it was subsequently determined that several outbreaks and sporadic cases of pneumonia with unknown etiologies dating back to as early as 1947 were indeed caused by legionellae and the bacterium was isolated as early as 1943 (19–22). Most of the Legionellaceae are motile by means of polar or lateral flagella (23–25). *Legionella* possess some unique features that may be useful in their identification, such as their utilization of amino acids as a sole carbon source (26) and their requirement for L-cysteine for growth on artificial media (27).

Since the initial description of *L. pneumophila*, 42 species of legionellae have been discovered (19,28–30). Many of the Legionellaceae such as *Legionella longbeachae*, *Legionella bozemanii*, and *Legionella micdadei* cause disease in humans (31–35). In addition, several *Legionella*-like amoebal pathogens that can also cause disease in humans have been described (19,31). A link between the environment and the ability of legionellae to cause disease became apparent soon after the 1976 outbreak of Legionnaires' disease when the source of infection

was determined to be a water-chilled air-conditioning system (17). This was followed by the discovery that legionellae are ubiquitous within both natural (water and soil) and "unnatural" (artificial aquatic devices) environmental settings (17,36). Finally, the complexity of the relationship between the habitat of legionellae and its pathogenicity began to emerge following the discovery that legionellae are able to survive within water and soil protozoa (37).

Public Health Issues

Clinically, Legionnaires' disease is characterized as an acute pneumonia that may be associated with high fever, dry cough, chills, diarrhea, and pleuritic pain and can lead to severe multisystem manifestations if left untreated (20,38–40). Unfortunately, the initial clinical symptoms are often indistinguishable from pneumonia caused by other etiologic agents making it often difficult to dispense appropriate treatments early during infection (38,41,42). Furthermore, many hospitals often fail to detect legionellae in culture specimens or simply do not attempt to identify this bacterium (19,43). Out of all the pathogenic species of *Legionella*, *L. pneumophila* accounts for up to 80% of the cases of Legionnaires' disease (11,13,19). Furthermore, among the 15 serologically distinct groups of *L. pneumophila*, serogroup 1 accounts for up to 82% of Legionnaires' disease caused by *L. pneumophila* (44).

It is now recognized that Legionnaires' disease and a milder nonfatal form of the disease, Pontiac fever, occur sporadically or in outbreaks in both community and nosocomial settings (11,40,41). It is estimated that 10,000 to 25,000 cases of Legionnaires' disease occur annually in the United States accounting for approximately 10% of cases of community-acquired pneumonia (11,13,19,41,45). Increased risk of contracting Legionnaires' disease has been found to occur among the elderly, smokers, and immunocompromised individuals (11,40,44,46).

The number of reported cases of infection caused by legionellae is believed to be an underestimate because of the difficulty in isolating the bacteria and the similarity of the initial clinical symptoms of Legionnaires' disease to pneumonia caused by other agents (11,31,42). Furthermore, sporadic cases of Pontiac fever with its flulike symptoms or asymptomatic legionellae infections are likely to occur (47). This is accentuated by a study in which one-third of surveyed adults in South Australia showed evidence of previous silent infection by *L. pneumophila* (48). In addition, a high percentage of outpatients (36%) and dental personnel (up to 50%) exhibited elevated antibody titers to different species of *legionella* (33,49).

THE TRANSMISSION AND ECOLOGY OF LEGIONELLAE

Transmission of Legionellae

Since the 1980s, there have been hundreds of documented outbreaks of Legionnaires' disease and Pontiac fever. Transmission of legionellae occurs via inhalation of aerosolized water droplets or soil particles containing the bacterium (11,32,50–53). In most cases of legionellae infection, the source of transmission has been attributed to aerosol generating artificial devices such as cooling towers, showerheads, grocery store mist machines and whirlpools (54–58). However, mechanical aerosolization of soil particles during gardening has also been described as a mode for transmission of legionellae (32,59,60).

The nature of the aerosolized infectious particle is not known, but several possibilities exist (Fig. 1; 61). First, it is possible that free extracellular legionellae could be inhaled following aerosolization. This is supported by the fact that animals can be experimentally infected with *L. pneumophila* (62,63). In addition, legionellae can escape from its protozoan hosts (see molecular ecology of legionellae in the following text) and can survive extracellularly for prolonged periods (64). Second, it is possible that amoebae harboring legionella may constitute the infectious particle (3,65,66). Amoebae are small enough to be inhaled and provide a sanctuary for legionellae (67,68). In addition, *L. pneumophila* grown within amoebae exhibits enhanced virulence in the A/J mouse model of Legionnaires' disease (66). Third, amoebae infected with legionellae are capable of excreting vesicles containing viable bacteria. Such vesicles are able to protect legionellae from the action of biocides and can be inhaled; thus, making them likely infectious particle candidates (69,70). The later two possibilities may help explain the "infective dose paradox" (70). This paradox is based on the fact that only low concentrations of legionellae are generally present in aerosols (believed to be insufficient to cause disease) (52,62) and that transmission may occur at some distance from the aerosol-generating source (71). However, aerosolized amoebae or vesicles containing legionellae may contain several million bacteria (69,70,72).

Clearly a link exists between the appearance of Legionnaires' disease and the industrialization of our society. However, the fact that simple mechanical aerosolization of soil particles harboring the bacteria can result in infection may be a sign that transmission of legionellae to humans may be as old as gardening itself. Person-to-person transmission of Legionnaires' disease has never been documented. Furthermore, natural infection with legionellae is believed to occur only in humans, although one case of naturally occurring pneumonia in animals due to legionellae has been reported (73).

Natural Ecology of Legionellae

Since the initial discovery of *Legionella*, members of this genus have been detected in natural aquatic (marine and fresh water) and soil environments (Fig. 2). Legionellae have been isolated from diverse aquatic sources such as rivers, lakes, and hot springs (36,64,74–76). In a study that investigated the prevalence of *Legionella* spp. in Puerto Rican waters, a high incidence of several pathogenic strains of legionellae including *L. pneumophila*, *L. bozemanii*, *L. longbeachae*, and *L. micdadei* was observed (77). *Legionella pneumophila* was found most commonly and all existed in diverse environments from rainwater collected from epiphytes

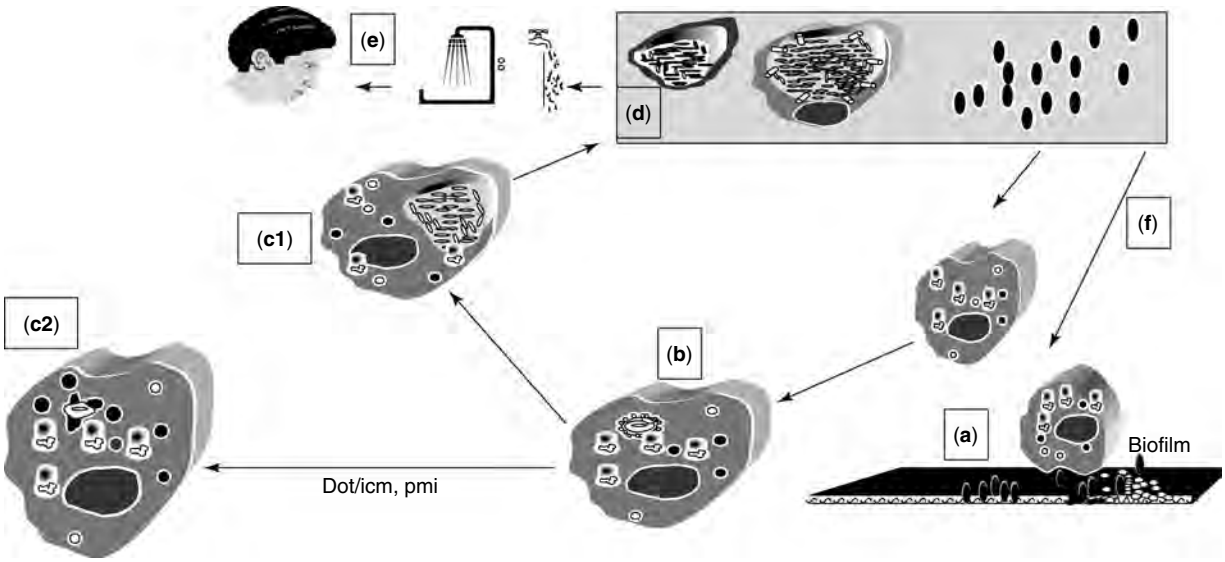

Figure 1. The environmental life cycle of *L. pneumophila* within protozoa. (**a**) *Legionella pneumophila* from biofilms with other bacteria or in suspension infecting protozoa. (**b**) Following entry, *L. pneumophila* resides in a membrane bound vacuole that recruits host cell organelles such as the mitochondria and the rough endoplasmic reticulum, and does not fuse with lysosomes. (**c1**) *Legionella pneumophila* replicates within this specialized vacuole and reaches large numbers. (**c2**) *Dot/icm* and *pmi* mutants fuse to lysosomes. (**d**) The infectious particle is not known but may include excreted legionellae-filled vesicles, intact legionellae-filled amoebae, or free legionellae that have lysed their host cell. (**e**) Transmission to humans occurs via mechanical means, such as unclear faucets and showerheads. Infection in humans occurs by inhalation of the infectious bit and establishment of infection in the lungs. (**f**) Legionellae that have escaped their host cell may survive in suspension for long periods, reinfect other protozoa, or recolonize biofilms.

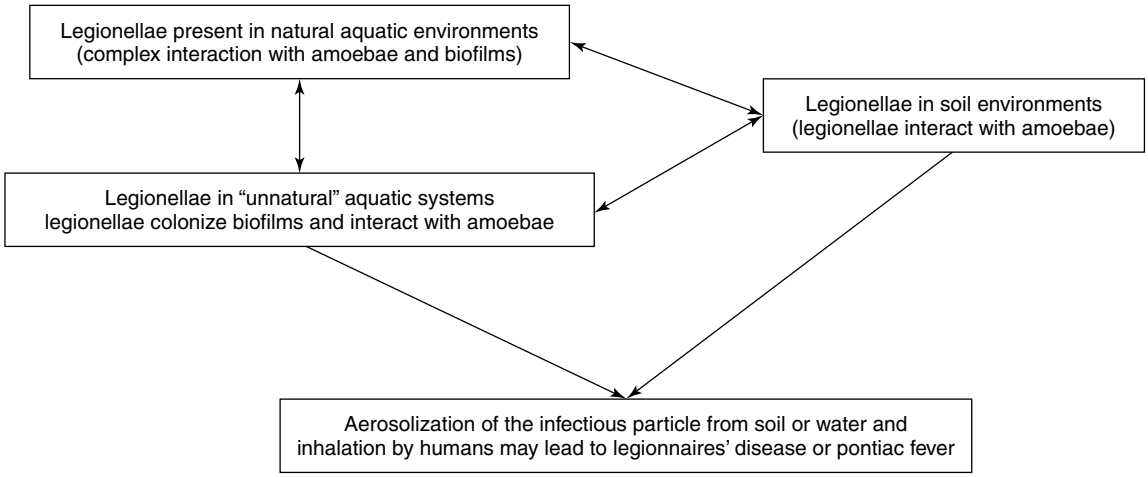

Figure 2. A diagram depicting the complex relationship of legionellae with their environments. Notice arrows between legionellae in the soil, natural aquatic environments, and "unnatural" aquatic environments are bidirectional indicating the possibility of movement of legionellae between its diverse environments. Transmission of legionellae to humans occurs from soil or artificial aquatic systems.

to sewage-contaminated coastal marine water (77). Interestingly, an average of 10^4 bacteria per milliliter of *L. pneumophila* was detected — a number sufficiently close to the estimated number of bacteria required for establishment of infection in humans (70,77).

Legionella pneumophila is able to survive high concentrations of salt (up to 3%) and no loss in viability is observed in natural seawater (78). This is interesting in light of the fact that repeated culture of *L. pneumophila* on synthetic media containing 0.65% sodium chloride allows for the isolation of salt-resistant and avirulent strains of this bacterium (79,80). Whether natural environmental exposure of legionellae to salt results in development of mutant bacterial strains is not known. However, this can

be viewed as a potential environmental factor that may contribute to the genetic diversity of legionellae.

Soil, is emerging as a potentially important reservoir for pathogenic species of this bacterium. In several studies investigating sporadic cases of Legionnaires' disease particularly in Japan and Australia and most recently in the United States, *L. longbeachae, L. pneumophila*, and *L. micdadei* were detected in potting soil (59,60,81–83). A study of potting soil in South Western Australia revealed a high rate of *Legionella* contamination (43% of sampled potting soil mixes) in particular *L. longbeachae* (59). Additionally, it is becoming clear that direct transmission of *Legionella* from soil occurs via the aerosolization of infectious particles during gardening (82–85). This is interesting in light of the common conception that transmission of *Legionella* requires mechanical aerosolization through artificial devices such as air-conditioning units or mist machines (see following text). Thus, transmission of *Legionella* to humans may not have been completely dependent on the industrialization of society.

The "Unnatural" Ecology of Legionellae

One outcome of the industrialization of humans has been the development of new contained aquatic ecosystems that act as reservoirs for diverse species of microorganisms including protozoa, bacteria, and viruses. Such aquatic systems may provide ideal conditions for the amplification of microorganisms because the environments of such systems remain relatively stable for prolonged periods. Because species of *Legionella* are ubiquitous in nature, it is not surprising that most artificial water reservoirs are contaminated with this bacterium. In a study of the occurrence of *L. pneumophila* in hot water (up to 60 °C) obtained from nosocomial, domestic, and community sources, it was observed that more than 20% of the samples were contaminated with this bacterium (86). Several other studies investigating the prevalence of legionellae in domestic potable-water systems have revealed a high incidence of this bacterium and the capacity of such systems to generate aerosolized infectious particles (52,87–89). This raises the possibility that such water systems may be sources of sporadic infection by legionellae, although incidences of such cases are relatively low (89,90).

Recurring outbreaks of Legionnaires' disease are prevalent in nosocomial settings. In a survey of 192 hospitals in the United States, more than 60% reported at least two outbreaks of Legionnaires' disease over a six-year period (91). The source of infection in nosocomial settings is often traced back to both cooling towers and potable-water systems (91). Contamination of cooling towers may be more common than previously thought as evident from a survey of hospital cooling towers in Japan, in which 45 out of 49 samples were contaminated with various species of *Legionella* (92). Furthermore, legionellae may persist in these systems for prolonged periods following decontamination treatment (93). In a study of the water system in the University of Iowa Hospitals and Clinics, *L. pneumophila* was detected over a period of 13 years and was implicated in nosocomial outbreaks of Legionnaires' disease during the same period (94).

The widespread presence of legionellae in water supplies can be viewed in certain instances as an occupational hazard. Indeed, this may be the case for dental clinicians who are at a higher risk of being exposed to legionellae. In a study of the prevalence of legionellae-specific antibodies among dental workers, 20% tested positive compared to only 8% of a nonclinical population (95). Antibodies to *L. pneumophila* were found most commonly, followed by antibodies to *L. micdadei* and *L. bozemanii* (95). In addition, the same study revealed a strong correlation between the length of clinic exposure time and the likelihood of testing positive. The reason for this high rate of exposure to legionellae among dental workers can be traced back to the dental equipment (96,97). Such equipment contains tubing, which permits water stagnation that in turn allows for the development of biofilms where microbes can thrive (See following text). Added to this is the aerosol-generating potential of various water-cooled dental devices (97). A survey of dental waters in several areas of the United States revealed that 68% of dental units were contaminated with legionellae of which 8% contained detectable levels of *L. pneumophila* (98). This survey also indicated that 61% of potable water collected for comparison was contaminated with *Legionella* species and only 4% of those contained *L. pneumophila* (98). In addition, 20% of the contaminated dental units contained upward of 10,000 legionellae organism per milliliter, a level that was never observed in the potable water control samples (98).

The Molecular Ecology of Legionellae

The molecular ecology of legionellae can be addressed by examining the interaction of this organism with its natural microecosystem that is composed of biofilms and its natural host, free-living amoebae (2). Biofilms are complex ecological niches within which microbes reside in close proximity and communication with each other (99,100). Biofilms can form virtually anywhere and sufficient nutrients are available both on natural and synthetic surfaces upon which microbes can attach (99,100). The complexity of biofilm structure and the intricate nature of inter- and intraspecies communication that occurs within such ecosystems makes them resemble a multicellular organism (101). This feature is likely to have contributed to the diversification and coevolution of biofilm inhabitants. Two lines of evidence support this idea. First, microbes within biofilms undergo high rates of conjugation of genetic material (102,103). This phenomenon may be instrumental in bacterial evolution and diversification. *Legionella pneumophila* is naturally competent for the uptake of DNA, a fact that may have influenced the evolution of this bacterium (104). Second, protozoal grazing on bacteria within biofilms is likely to have contributed to the evolution of diverse protective bacterial responses. Several examples of bacterial adaptation to their protozoan predators exist (2). These include increased bacterial productivity to ensure survival (105), production of toxic compounds against protozoa (105,106), and the development of endosymbiotic relationships with protozoa (107–109). The latter is likely

to have contributed to the evolution of intracellular bacterial pathogens like legionellae (2).

Legionella are commonly thought to exist as intracellular parasites of amoebae in nature. However, biofilms have been shown to support the growth of *L. pneumophila* and provide a protective environment for this bacterium (110,111). Microflora within biofilms are generally more resistant to the effect of biocides, chlorination, temperature, and UV irradiation (111–114). Thus, legionellae growing on biofilms in aquatic water systems such as dental water units are likely to exhibit an increased resistance to disinfection methods (see following text). In a study by Rogers and colleagues, the growth of *L. pneumophila* in biofilms was influenced by temperature and the type of plumbing material utilized (111). *Legionella pneumophila* was most abundantly found on polybutylene surfaces at 40 °C (111). Interestingly, amoebae that support the growth of legionellae were not present at this temperature, indicating that *L. pneumophila* was able to increase in numbers in the absence of its natural amoebal hosts (111). The ability of legionellae to grow extracellularly may be attributed to nutritional support provided by other microorganisms present in the biofilm (111). For example, *L. pneumophila* is able to grow extracellularly in association with environmental isolates of *Flavobacterium breve* on media lacking the essential legionellae nutrient, L-cysteine (115). In addition, *L. pneumophila* can grow extracellularly in association with blue-green algae at 45 °C (116). Thus, legionellae are protected by biofilms, and inhabitants of these ecosystems may provide nutritional support for extracellular growth of this organism.

Since the initial discovery that legionellae can survive within free-living amoebae (37), more than 13 species of amoebae have been discovered to support their growth. (2,10,11). These include common water and soil protozoa such as species of *Acanthamoeba* and *Naegleria*, respectively (37). Interestingly, different species of *Legionella* exhibit preferential growth within certain species of protozoa (14,117). In addition, a correlation may exist between the pathogenicity of a *Legionella* species to humans and the number and types of protozoa they infect (118,119). For example, *L. pneumophila* in particular serogroup 1, which causes most cases of Legionnaires' disease, can grow in the largest variety and numbers of amoebal species (10). In comparison, *L. micdadei*, which is the second most common cause of Legionnaires' disease, can grow in *Hartmannella vermiformis*, but not in *Acanthamoeba polyphaga* (120). Another species of *Legionella*, *L. longbeachae*, which is primarily associated with soil transmission of Legionnaires' disease, does not grow within *Hartmannella vermiformis* (117), and Acanthameoba castellani (119), but grows within the ciliated protozoa *Tetrahymena pyriformis* (121).

Amoebae in the environment play an important role in the persistence of legionellae and influence their virulence to mammalian cells (2). First, Legionellae existing within protozoa are highly resistant to the action of several adverse extracellular conditions, such as elevated temperatures or toxic chemicals (122,123). *Legionella pneumophila* residing within cysts of *A. polyphaga* are resistant to the action of free chlorine, explaining why legionellae often are not eradicated following disinfection of water systems or following sewage treatment (124,125). Second, amoebae are likely to play a critical role in the amplification of legionellae in the environment. Legionellae can reach substantially large numbers within a relatively short period during intracellular growth within amoebae (126). Third, intracellular growth of legionellae within amoebae increases their virulence severalfolds toward mammalian cells (127,128). This may be a result of the fact that several virulence genes that are required by legionellae to infect amoebae are also required for the infection of mammalian cells (see following text) (2). Interestingly, following intracellular replication within amoebae *L. pneumophila* exhibits a dramatic (1,000-fold) increase in resistance to the action of antimicrobial compounds (129,130).

THE LIFE CYCLE OF LEGIONELLAE WITHIN THEIR PROTOZOAN HOST CELLS

Attachment, Entry, and Intracellular Survival

Species of *Legionella* have evolved diverse mechanisms for attachment and entry into their host cells. Attachment of *L. pneumophila* and *L. micdadei* to the amoebae *H. vermiformis* is mediated through a protozoan Gal/GalNAc lectin receptor (131,132). This event triggers a dramatic tyrosine dephosphorylation of a number of protozoan proteins including the receptor itself and several cytoskeletal proteins that include paxillin, vinculin, and focal adhesion kinase (132,133). The tyrosine dephosphorylation of these proteins is likely to be mediated through a tyrosine phosphatase and results in the disruption of the cytoskeleton (11,134). This in turn may facilitate entry of *L. pneumophila* into *H. vermiformis* through a cytoskeleton-independent receptor-mediated endocytosis (133,135). Interestingly, the ability of *L. pneumophila* to manifest the entry events requires specific gene expression by *H. vermiformis* because the inhibition of protein expression of *H. vermiformis* prevents bacterial entry (136). Analysis of *L. pneumophila* entry into another protozoan, *A. polyphaga*, revealed it to be partly mediated through a similar Gal/GalNAc lectin receptor (137). Furthermore, the pattern of tyrosine-dephosphorylated *A. polyphaga* proteins was markedly different from the observed pattern in *H. vermiformis* with only mild dephosphorylation of the putative receptor molecule (137). Thus, *L. pneumophila* may have adapted different mechanisms to invade different protozoan hosts.

The bacterial ligands utilized by legionellae to initiate interaction with protozoa have not been clearly established, although several possibilities exist. The type IV pili of *L. pneumophila* are involved in the attachment process because mutants that do not express these pili fail to adhere to *A. polyphaga* (Fig. 3; 138). Other candidate ligands include a heat-shock protein (Hsp60) and the major outer membrane protein of *L. pneumophila*, both of which are involved in the attachment of this bacterium to mammalian cells (139–141). Also, *enh* loci involved in entry into mammalian monocytes and epithelial cells may also be involved in entry into protozoa (142). Several mutants

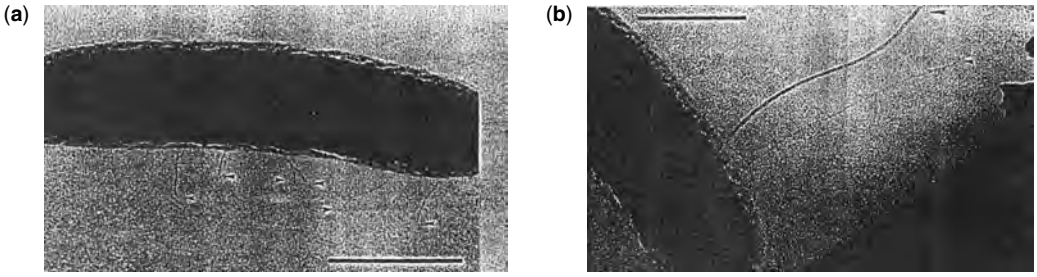

Figure 3. Electron micrographs of *L. pneumophila* expressing short pili (**a**) the long CAP pili (competence and adherence associated pili) (**b**). The two pili are expressed by different cells within the same culture, and no cells that express both pili have been detected. (Adapted from B. J. Stone and Y. Abu Kwaik, *J. Bacteriol.* **181**, 1,395–1,402 (1999)).

of *L. pneumophila* that are defective in attachment to protozoa have been recently described and should prove useful in the identification of other bacterial factors involved in the invasion process (133,137,143).

Uptake of *L. pneumophila* by its protozoan host is mediated through conventional or coiling phagocytosis (Fig. 4; 144,145). In addition, a study utilizing a flow cytometric technique revealed that *L. pneumophila* enters its host cell within five minutes of coculture with *Acanthamoeba palestinensis* (146). Following entry, *L. pneumophila* resides in a unique organelle that is surrounded by mitochondria and other vesicles (144,145,147,148). Within four hours of entry, the *L. pneumophila* phagosome becomes surrounded by the rough endoplasmic reticulum (RER) (144,145). In addition, the *L. pneumophila* phagosome is inhibited from maturation into a lysosome (11,145). The initial 4-hour period after entry precedes the replication of *L. pneumophila* and is presumed to be an adaptation period required by this bacterium to adapt to its new intracellular environment (Fig. 4; 11). The identification of several *L. pneumophila* mutants that are defective for intracellular survival within amoebae should prove useful in understanding the mechanisms used by this pathogen to parasitize its host cells (2,143). The phenotypic characteristics of the *L. micdadei* phagosome within amoebae are surprisingly different from those of the *L. pneumophila* phagosome. Studies investigating the *L. micdadei* phagosome in *H. vermiformis* have revealed that it never becomes surrounded by the RER (120,132). The importance of the phenotypic difference in the pathogenicity of legionellae is not clearly understood although it suggests heterogeneous mechanisms of intracellular parasitism by different species of legionellae (2). This is supported by the findings that *L. micdadei* does not infect another species of amoebae, *A. polyphaga*, does not exhibit pore-forming activity (see following text), and is avirulent in the A/J mouse model of Legionnaires' disease (120). In addition, *L. micdadei* and *L. pneumophila* do not share the same virulence loci (118), indicating a divergence in virulence mechanisms between these two species of legionellae.

Killing of the Host Cell

Following 24–72 hours of replication, *L. pneumophila* kills its protozoan host by a necrotic mechanism followed by release of the intracellular bacteria (149). The killing of *A. polyphaga* by *L. pneumophila* has been described to be a monophasic event in which necrosis is the only mode of bacterial-induced host cell killing (Fig. 5; 149). This is in contrast to the killing of mammalian cells by *L. pneumophila* that occurs by two mechanisms; rapid apoptosis soon after bacterial entry and necrosis before the release of the intracellular bacteria (150–153). Several studies have shown that *L. pneumophila* does not induce apoptosis in amoebae (149,154). The necrotic killing of amoebae by *L. pneumophila* is mediated through a pore formation (149). The same pore-forming activity of *L. pneumophila* is required for the killing of mammalian cells (155,156). In addition, mutants of *L. pneumophila* that are defective in pore formation cannot escape from the host cell despite reaching large (149). Expression of the pore-forming activity is triggered during

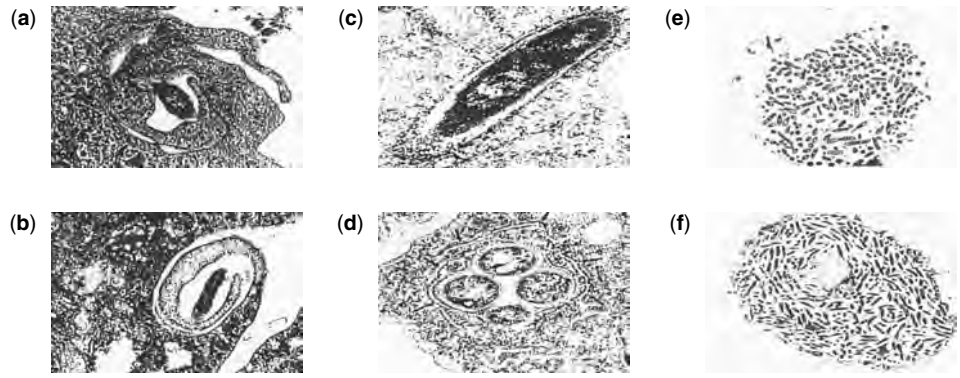

Figure 4. Electron micrographs of the infection of U937 macrophages (top panels) and *A. polyphaga* by *L. pneumophila* (lower panels). Coiling phagocytosis (**a** and **b**); formation of the RER-surrounded phagosome (**c** and **d**); and late stages of the infection (**e** and **f**). Note that in (**e**) and (**f**) there is no intact phagosomal membrane and in some cases the bacteria are making contact with the plasma membrane. (Adapted from O. S. Harb and Y. Abu Kwaik, ASM News, 66, 609–616 (2000)).

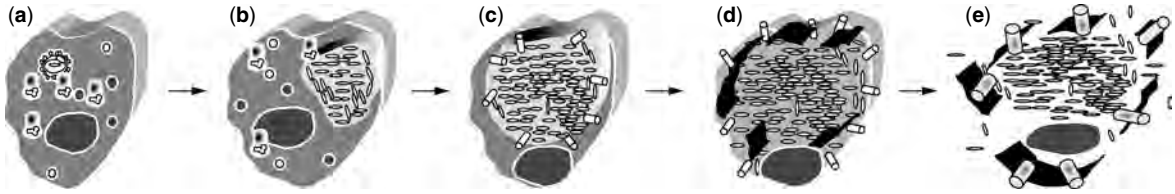

Figure 5. A model of growth phase-dependent cytolysis of *A. polyphaga* by *L. pneumophila* upon termination of intracellular bacterial replication to egress the spent host cell. During the early stages of formation of the mitochondria and RER-surrounded phagosome (**a**) and during exponential intracellular replication (**b**), expression of the pore-forming activity is turned off. This is essential to maintain integrity of the host cell, which is fundamental for intracellular bacterial proliferation. Upon transition to the postexponential phase of growth, expression of the pore-forming activity is triggered, which results in insertions of pores in the phagosomal membrane first (**c**), leading to its disruption (**d**). This is followed by insertions of the pores in the plasma membrane (**e**), leading to osmotic lysis of the cell, and release of the intracellular bacteria, which are not cytotoxic to *A. polyphaga* from an extracellular location. (Adapted from O. A. Alli and colleagues, *Infect. Immun.* **68**, 6,431–6,440 (2000)).

postexponential growth of *L. pneumophila* (149). Indeed several virulence traits of *L. pneumophila* have been described to be linked to the bacterial growth phase (157). Only postexponential phase *L. pneumophila*, in vitro, express the following traits associated with virulence: sodium sensitivity, cytotoxicity, resistance to osmotic lysis, evasion of phagosome-lysosome fusion, infectivity, and motility (flagellated) (157). Furthermore, flagellation and sodium-resistance are expressed upon macrophage lysis by intracellular *L. pneumophila* (157). Gao and colleagues, have shown that pore formation is growth phase-regulated both in vitro and in vivo (149). Interestingly, the trigger for this dramatic phenotypic change by *L. pneumophila* is thought to be nutrient starvation. In particular, depletion of five amino acids (serine, tyrosine, asparagine, proline, and threonine) appears to be crucial for the expression of these virulence traits (157). Little is known about what mediates the response to amino acid starvation by *L. pneumophila*, although a (p)ppGpp synthetase (RelA) may be involved (13,158). Thus, it is thought that *L. pneumophila* is able to repress virulence traits that are required for the invasion of and escape from its host cells during intracellular replication in the nutrient-rich intracellular environment. However, upon depletion of nutrients and entry of the bacteria into the postexponential growth phase within its host cells, the virulence traits are activated to mediate release and subsequent reinfections (13,149,157). It is likely that *L. pneumophila* may possess several effector molecules that are involved in mediating this dramatic phenotypic transformation.

Genetic Factors Required by Legionellae for Intracellular Survival Within Amoebae

Several techniques have been utilized for the identification of genetic factors necessary for the infection process of eukaryotic cells by legionellae and other intracellular bacterial pathogens (159). Such genetic analysis has allowed for a further understanding of the nature of the intracellular environment that legionellae are exposed to. Several genes involved in biosynthetic pathways are required for intracellular survival indicating that the legionellae phagosome may be deficient in or inaccessible to certain nutrients. For example, mutants of *L. pneumophila* defective in the aspartate-β-semialdehyde gene are auxotrophs for diaminopimelic acid (DAP), and can survive normally when a supplement of this compound is present on synthetic media (160). However, such mutants are defective for intracellular survival even in the presence of DAP supplement, indicating that the *L. pneumophila* phagosome is inaccessible to this compound (160). Other examples of this include the *prp* locus involved in citrate biosynthesis (161), and the Rep helicase required for survival within mammalian macrophages but not in amoebae (162). In addition, several macrophage-specific infectivity loci required for infection of mammalian cells but not protozoa have been described (163–165). The existence of these genes indicates that legionellae have evolved unique heterogeneous mechanisms for intracellular survival within different cell types.

Several genetic loci of legionellae are involved in intracellular survival of within both mammalian cells and protozoa. These include the macrophage infectivity potentiator (*mip*) gene (166), the *dot* (defect in organelle trafficking) and *icm* (intracellular multiplication) loci (167–169), the protozoan and macrophage infectivity (*pmi*) loci (143), and the *pilBCD* pilin genes (138,170). The Mip protein is a bacterial surface protein involved in the early stages of mammalian cells and protozoa infection (166) and belongs to the peptidyl-prolyl *cis*/*trans* isomerase (PPIase) family of proteins (171). However, the exact function of Mip is not known because specific mutagenesis of its PPIase activity indicated that this activity is not involved in the virulence of *L. pneumophila* (172). The *dot*/*icm* loci comprise a cluster of 23 genes that are required for the assembly of a type IV like secretion apparatus in *L. pneumophila* required for infection of both mammalian cells and protozoa (143,167,169,173,174). This secretion apparatus is involved in the proper maturation of the *L. pneumophila* phagosome (175,176), induction of apoptosis in mammalian cells (151), and assembly of a pore-forming toxin (156,169,174). The *pmi* genes consist of

89 insertion mutants of *L. pneumophila* that are all defective for intracellular survival within mammalian cells and protozoa (143). Characterization of these loci should prove useful in further understanding the virulence mechanisms of legionellae. The *pilBCD* genes of *L. pneumophila* are required for the biogenesis of type IV pili (138) and type II secretion (170). Further, *L. pneumophila* mutants of *pilBCD* are defective for intracellular survival within mammalian cells and protozoa (170,177,178).

DETECTION AND DISINFECTION OF LEGIONELLAE

Detection of Legionellae in the Environment

Several methods have been developed over the years for the detection of different species of legionellae from environmental sources. The standard method utilized for detection has been cultivation of viable legionellae on selective media (97). However, this method has several drawbacks including contamination with other bacterial species, and limited detection sensitivity and specificity. Water from environmental samples needs to be concentrated severalfolds before the detection of small numbers of bacteria is possible. In addition, supplementation of media with inhibitory compounds is often necessary to eliminate contamination (98). Perhaps, the single most important shortfall of this method is its inability to detect viable but nonculturable species of legionellae. Amplification of environmental legionellae before cultivation can be achieved via a growth cycle in amoebae (179). Steinert and colleagues were able to resuscitate a strain of *L. pneumophila* to cultivatable levels following amplification in *A. castellanii* (180).

Several immunological methods for the detection of legionellae in the environment have been developed. These include direct fluorescence detection (36,181), and the use of flow cytometry techniques (182). However, immunological detection requires the use of legionellae specific antibodies that are generally species-specific and thus is limited to the detection of only a small number of *Legionella* species. In a comparison study of culture and immunofluorescence methods for the detection of *L. pneumophila* serogroups 1 to 6 in domestic hot water supplies, Alary and colleagues showed that the indirect immunofluorescence method detected *L. pneumophila* more frequently (183). However, considerable variation existed between both methods in determining the serotype of *L. pneumophila* (183).

The most sensitive and specific methods for the detection of environmental legionellae are those that are based on the amplification of DNA fragments present in all species of legionellae. Most of these methods are based on amplification of common regions of the rRNA genes or the *mip* genes of all legionellae species using the polymerase chain reaction (PCR) technique (184–186). These methods have proven useful in the detection of legionellae from various environmental locations such as cooling towers (92), reclaimed water sources, and air (187). A drawback of the DNA amplification method is that positive results are not necessarily indicative of viable bacteria (187). Thus, the culture and imunofluorescence methods should still be utilized when the number of viable legionellae is desired (97). PCR may also lose its sensitivity in the presence of contaminants in the samples tested. However, this method is amenable to slight modifications to enhance sensitivity (92).

Disinfection of Legionellae

Eradication of legionellae from water systems is essential for controlling the occurrence of Legionnaires' disease and Pontiac fever. This is particularly important in nosocomial settings where large outbreaks of Legionellae associated diseases can occur. Several methods of disinfection have been utilized with varying degrees of success (188). First, thermal eradication was the first method utilized for the eradication of legionellae. This method involves increasing hot water tank temperatures to 60 to 70 °C followed by flushing all water outlets including faucets and showerheads for a minimum of 30 minutes. A variation of this method uses instantaneous heating systems that heat water to temperatures greater than 88 °C followed by mixing with cold water before distribution to the rest of the system (188). Thermal eradication is very useful for rapid elimination of legionellae during an outbreak and does not require any special equipment. The major disadvantage of this method is that legionellae can recolonize the water system within weeks following disinfection. In addition, it is difficult to maintain an elevated temperature in the entire water system, which may allow legionellae to survive in locations that were not sufficiently heated. Second, another method for the elimination of legionellae is by introducing copper and silver ions in the water system. Copper and silver ions are bactericidal to legionellae (188). This method is effective in the elimination of legionellae (188) and recolonization is retarded possibly because of residual ions that remain in the water system following treatment (189). The disadvantages of this method are that the concentration of copper and silver ions required to eliminate contamination may be from levels that make water unsuitable for human consumption (190). In addition, legionellae may develop resistance to the biocidal effects of copper and silver (191). Third, hyperchlorination can be used to eradicate legionellae in water systems. This method involves increasing chlorine concentrations in a water system to approximately 50 ppm (188). Although chlorine can eliminate legionellae in suspension, legionellae residing within biofilms or within amoebae will be protected. Furthermore, areas of stagnation or low circulation in the water system will not be affected by hyperchlorination (188).

All the methods utilized for disinfection are incomplete and do not provide adequate eradication of legionellae and prevention of recolonization (188). A combination of these methods and continuous surveillance of water systems for the presence of species of *Legionella* is necessary (188). Alternative means of disinfection may be achieved by further understanding the microenvironment within which legionellae survive.

CONCLUSION

The ability of legionellae to survive within a wide range of environments is indicative of its remarkable evolution. Furthermore, a clear link exists between the relationship of legionellae with its environment and it pathogenicity to humans. This, in addition to the amenability of legionellae to experimental manipulation, provides a unique opportunity for the dissection of the evolutionary process that has taken legionellae from the environment through protozoa to human cells. Indeed, some pieces of the puzzle are beginning to come together. Within biofilms, legionellae reside in a multicellular environment reminiscent of its state during the infection process of humans. Similar principles that govern the interaction of legionellae with its surroundings in biofilms may exist during the infection process in humans.

Protozoa can be viewed as an evolutionary bridge linking legionellae from the environment to humans. The interaction of legionellae with protozoa is likely to have provided the necessary conditions for the evolution of mechanisms of invasion and intracellular survival. This in turn may have been essential for its ability to invade and survive within mammalian cells. Several molecular and phenotypic similarities exist between the infection process of protozoa and mammalian cells by legionellae. Furthermore, a relationship appears to exist between the virulence of different species of *Legionella* to mammalian cells and protozoa. This may be utilized as an indicator for the potential pathogenicity of environmental microbes to humans.

The existence of novel bacterial pathogens in the environment is almost certain. Such novel pathogens may yet have to evolve mechanisms of eukaryotic parasitism or are simply waiting for the appropriate conditions for transmission to humans and animals. Understanding the intricate interactions that occur between legionellae and its environment may be essential for predicting the appearance and combating new human pathogens.

LEPTOSPIROSIS

GUY BARANTON
Institut Pasteur
Paris, France

Leptospirosis is a zoonosis associated with a bacterium that is emitted in the urine of infected vertebrates. Leptospires may survive in environmental freshwater and

contaminated hosts either by mucosal ways or through cutaneous lesions.

At the beginning, leptospirosis was confused with other infectious diseases including hepatitis, malaria, and yellow fever. The first undoubtful descriptions were in 1886 from both a French:Mathieu (1) and German:Weil (2) physicians who independently published the association of the prominent symptoms and characteristics of this disease.

Leptospirosis is clinically quite polymorphic and diverse. A large diversity of the isolates corresponds to the polymorphism of the disease at different levels, namely, epidemiologically, antigenically, and genetically.

There are some correlations between a given infective serotype and the level of gravity of the generated disease. For instance, serovars icterohaemorrhagiae or australis often lead to serious disease. However, this association is very theoretical, and finally, any serotype may drive any clinical presentation.

The first observation of the bacterium is attributable to Stimson who, in 1907, described spirochetes in the kidneys from a patient in New Orleans suffering from yellow fever (3). Probably the diagnosis was wrong and the patient had in fact contracted leptospirosis.

The first isolations of leptospires have been published in 1916 by Inada and coworkers but had been performed some years earlier (4). These authors have cultured leptospires, showed that they were responsible for experimental disease and that rats were a prominent reservoir of this bacterium.

Soon after, in Europe, German researchers (5), and also English and French ones, identified leptospires in ill soldiers in trenches in the 1st World War front, usually in France or in Belgium. The first strain (RGA) isolated by Uhlenhuth, which for years has been the reference strain of the *Leptospira* genus, was isolated near Paris (5).

In 1918, Martin and Pettit (6) described the agglutination-lysis reaction, which after being renamed micro-agglutination Test (MAT) by Babudieri in 1961 (7), remains 80 years later, the most powerful serological test in leptospirosis. This test also allowed the description of new leptospiral serotypes. Indeed, when a leptospire was isolated from a patient whose serum did not react with the already known serotypes, it suggested the infecting serotype to be a new one.

The basic taxon of serotypes is the serovar. There are about 220 pathogenic serovars. The serovars are clustered in serogroups according to their serological affinities. There are 23 pathogenic serogroups. Arbitrary criteria allow us to define each of these taxa.

More recently, genomic and genetic methods have been applied to bacteria including leptospires. Therefore, besides the aforementioned serological classification, a DNA-based taxonomy that recognizes among leptospires several complexes of species has been developed.

BACTERIOLOGY

Taxonomy

Bacteria from *Leptospira* genus belong to the *Leptospiraceae* family, which together with the *Spirochaetaceae* family, is within the Spirochaetales order (8). This group of bacteria, initially defined on morphological characters (9), is equivalent to the Spirochetes phylum as defined by Woese (10) in the phylogenetic studies of *rrs* genes coding for 16S ribosomal ARN (11).

Two nonpathogenic genera with a single species each, namely, *Leptonema illini* and *Turneria parva*, in addition to *Leptospira*, are comprised in the *Leptospiraceae* family (12).

The taxonomy within genus *Leptospira* is confusing, because of the coexistence of two classifications that do not quite correlate but are both useful (13) — a traditional classification that delineates (on fastidious and hazardous criteria of culture inhibition) two species, *Leptospira biflexa* (saprophytic) and *L. interrogans* (pathogenic), but this character may be lost when subcultured and no satisfying animal model is available.

Within the species, the leptospires are identified as serovars on serological criteria. There are currently 225 serovars identified in *L. interrogans* (more than 300 are individualized) (14). The definition of the serovar is based on an arbitrary cutoff level of antibodies in a procedure of cross-adsorption using MAT test (15). The serovars are further clustered in serogroups according to their antigenic proximity. *Leptospira interrogans* comprises 23 serogroups (14,15).

This traditional classification is hampered by many disadvantages, such as it is time-consuming, costly, and difficult to interpret (15). Such an identification is restricted to reference laboratories that need several months to confirm the identification. The interpretation itself is partially subjective and requires a complete collection of the reference serovars and corresponding experimental immune sera (one rabbit at least per strain). It is, however, often used because it is closely related to the serology diagnosis method, the MAT, which, even now, is the method allowing most of the biological diagnosis of leptospirosis. Furthermore, several serovars are associated with epidemiologically (elective host) or clinically (a given symptomatology) relevant characters.

Leptospires as other bacteria have been characterized by whole DNA/DNA hybridization (16), resulting in seven potentially pathogenic species and an unknown number of nonpathogenic species (17). Phylogenetic analysis of sequences from *rrs* genes coding for 16S ribosomal product shows that three distinct clusters of *Leptospira* species are obvious (18,19).

The first cluster comprises three validly described species (*L. biflexa*, *L. meyeri*, *L. wolbachii*) and several genomic groups of saprophytic leptospires. The second cluster comprises the seven undoubtfully pathogenic species (*L. interrogans* sensu stricto, *L. kirschneri*, *L. borgpetersenii*, *L. weilii*, *L. alexanderi*, *L. noguchii*, and *L. santarosai*). Finally, the third cluster comprises two species (*L. inadai* and *L. fainei*) (19) and probably other genomic groups. This group is diversely considered as regards to its pathogenicity.

This modern and scientific taxonomy established by standardized and universal methods has not been easily accepted by leptospirologists. However, it is also based

on the 300 delineated serovars that were distributed in the corresponding species. It is also correlated with PCR-based identification methods (20,21). Finally, it also allowed a molecular support to the serovar concept. Currently, the serovars may be identified more quickly at lower cost and more accurately by objective methods, such as ribotyping (22), pulsed field gel electrophoresis (23,24), and arbitrarily-primed PCR (25), rather than by serological cross-adsorptions. These molecular methods allow the identification of species or serovars or both (26). Only the serogroup loses its distinction because serovars belonging to the same serogroups are dispersed among several species and a species comprises serovars from distinct serogroups.

Morphology (27)

The morphology of spirochetes is typical (9) that is thin (frequining dark-field or phase contrast microscopic observation), but long bacterium. They exhibit an intense motility with a combination of translation, contraction, torsion and screw like movements.

Spirochetes are helicoidal and motile bacteria with flagella localized between the outer and inner (cytoplasmic) membranes instead of being free outside the cell. Leptospires have only one flagellum per extremity that does not overlap at the center of the cell. The cell is flexible and its motility is quite specific of spirochetes. Leptospires are also characterized by their narrow diameter of 0.1 μm, which allows them to pass through 0.45- and even 0.22 μm filters, thus complicating filtration based decontamination methods.

Leptospires are approximately 10 to 15 μm in length and the spires are very tight. Often, leptospires present a hook at each extremity. The outer membrane is three-layered and characterized by its fluidity. The cytoplasmic inner membrane is also three-layered.

- The fragile outer membrane is made of proteins, lipids, and the nontoxic lipopolysaccharide (LPS). Some immunogenic proteins of this membrane have recently been characterized (28).
- Under the periplasmic compartment is a flexible cell wall constituted by the peptidoglycan that contains muramic acid and diaminopimelate as amino acid (29).
- The two flagella inserted in the peptidoglycan comprise an axis and elements that constitute the insertion in the cell wall. A *flaB* gene coding for a 32-kD protein has been cloned (30). It forms the core of the flagellum, although a *flaA* gene codes for the sheath.

Lipids are important in proportion (15 to 25%) and some are unusual. Their composition partially reflects the medium one. Polysaccharids are essential constituents, probably playing a role in immunity (LPS) and virulence (peptidoglycan) (27).

Genome

The genome of leptospires has been studied by pulsed field gel electrophoresis. It comprises a large (5,000 kb) chromosome and another smaller mini chromosome (31,32).

Three genetic maps have been drawn concerning three serovars belonging to *L. interrogans*. They show that

- Ribosomal genes are not organized in operons and are not in equal numbers (1 *rrf* coding for 5S RNA, 2 *rrs* coding for 16S RNA, and 2 *rrl* coding for 23S RNA) (32–34).
- Physical maps differ according to each serovar (32,33,35).
- Several insertion sequences (IS) are present. Their identities differ according to the species and their number according to the serovars (35–37).
- The order of genes are quite different even for serovars close to one another (32,33,35).

These points lead to the hypothesis that the formation of a new serovar is associated with a rearrangement of chromosome fragments from a previous serovar because of the mobility of IS: deletion, insertion, inversion. Only the combinations allowing the best adaptation to a given ecological context (host serovar association) should be maintained.

In saprophytic leptospires, a phage isolated from serovar patoc (38) allows to build a shuttle vector (39). It would therefore be possible to realize genetic transfer in vitro to study the actual role of candidate-virulence genes.

Finally, in Shangai, China, a team is sequencing the whole genome of *L. interrogans* serovar lai. The complete sequence will be published in 2001.

PHYSIOLOGY — METABOLISM

Culture (27)

Optimum growth of leptospires occurs at 30 °C; however, they have been observed to grow within the range of 13 to 37 °C. Saprophytic leptospires grow at 13 °C. Hypertonicity is an adverse condition for leptospires. In optimum conditions, the doubling time is six to eight hours and the maximum density is about 10^9/ml. Mobility of leptospires increases with the medium viscosity. Culture on solid media is very slow. Growth of pathogenic leptospires require approximately 20 days before colonies can be detected.

Energy and Respiration (27)

Leptospires are aerobic bacteria with both catalase and oxidase. Their carbon source are long-chain fatty acids (and not glucides) that are used by β-oxidation. In culture, free fatty acids are toxic for leptospires and must be supplied as tweens and detoxified by Bovine Serum Albumin. Ammonium salts must be supplied or are obtained by desamination of amino acids. Saprophytes synthesize both purines and pyrimidines and normally grow in the presence of a purine analog (8-azaguanine), which, in opposition, is inhibitor for pathogenic leptospires. Glycerol and pyruvate increase growth of leptospires.

Vitamins B1 and B12, and chlorides, phosphates, calcium, magnesium, and Fe^{+++} are needed. In practice, zinc, manganese, and sulfate also are added.

Resistance to Chemical and Physical Agents (27)

Leptospires are quite sensitive to desiccation and hypertonicity. If halophile leptospires do exist, pathogenic ones are grown in 1/10 NaCl conditions as compared to physiological values. Copper Sulfate at concentrations exceeding 10 mg/L has been shown to be especially toxic to pathogenic leptospires.

Leptospires can be maintained at $-70\,^{\circ}C$ ($-20\,^{\circ}C$ for histological pieces). In culture, they are killed above $42\,^{\circ}C$ and by pH below 6.8. However, they may survive alkalinization up to 7.8. They are killed by the usual disinfectants, detergents, and most antibiotics (with the exception of rifampicin, phosphomycin, neomycin, kanamycin, and sulfamides).

Antigenic Structure

The immunodominant antigen is closer to the surface; it is the LPS carrier of the serovar specificity. It elicits protective antibodies but their activity is restricted to a given serovar (40).

Another polysacharidic antigen, close to the surface, is what is called *antigen of group* (42). This antigen, abundant in patoc serovar, serologically cross-reacts with an equivalent found in most pathogenic serovars (41). Sometimes called *TR* for "thermoresistant," this antigen is used in several diagnosis tests (TR (42), ELISA (43), Dipstick (44), etc.). Many proteins are observed in SDS PAGE electrophoresis, but few of them have been characterized or even identified (46). Recently, however, several were described and studied. A heat shock protein, Gro EL (45), and, DnaK of 72 kD has been identified (46). The endoflagellum comprises several proteins of 34 to 36 kD, which exists in the core and sheath of the endoflagellum and other pieces of endoflagellum insertion (47). These antigens exhibit cross-reactions with their homologs from other bacteria.

Finally, genes coding for *Leptospira*-specific proteins such as LipL32, LipL36, and LipL41 were cloned, sequenced, and expressed (27,48). All are lipoproteins associated with the outer or inner membrane. LipL41 is a protective antigen, mainly if injected simultaneously to OmpL1 a porin (49).

EPIDEMIOLOGY

Geographic Distribution (27)

Leptospirosis is a zoonosis, the animal spectrum of which is very large. It is therefore spread all over the world with almost no exceptions, and is found even in deserts and arctic areas. In arctic areas, they have been found in foxes and seals, and in deserts, in kangaroo-rats and gerbils.

However, its frequency differs according to the climate. Incidence is prominent in equatorial and tropical regions and decreases from temperate to boreal climates.

Another heterogeneity is observed concerning geographic distribution of leptospiral species. Indeed, the serovars associated with animal species, such as icterohaemorrhagiae serovar in rats, canicola in dogs, or hardjo and some other ones in cattle, can be found worldwide. But it has been noticed that most of the *L. interrogans* sensu stricto serovars and all those from *L. weilii* and *L. alexanderi* have been isolated in Asia (17).

Similarly, *L. borgpetersenii* is endemic in both Europe and Asia and *L. kirschneri* in Africa and Europe. In the American continent, *L. santarosai* predominates in South and Central America, although *L. noguchii* is mainly found in North America (17).

The disease usually occurs as isolated cases or in a sporadic way, although outbreaks of grouped cases (called *anademia*) may happen after rainy periods. This is the case in rural areas (Guatemala, Nicaragua), and in urban areas (Rio de Janeiro, Sao Paulo).

Seasonal Distribution of Leptospirosis (27)

Human contact with contaminated surface water from infected animals is the primary cause of leptospirosis.

Leptospires may survive for long periods (several months in freshwaters if their pH is neutral or slightly alkaline and their temperature high enough). Leptospirosis is a prominent disease in hot and damp areas such as tropical areas.

Usually, in the Northern Hemisphere, a majority of leptospirosis cases occur during the second part of the year. In contrast, in the Southern Hemisphere, the first six months of the year exhibit a recrudescence of cases. The rhythmicity of natural phenomenon such as rain, or wild animal behaviors (births, searching for a sexual partner) and sociooccupational human activities (harvests, cattle breeding, water activities during the holidays) explains this seasonality. In the tropics, transmission of infection tends to be less seasonal and can occur throughout the year. Usually, in the rainy season, temperature increases. Under these conditions, humidity rises above 70 to 80%. The subsurface soil is fully saturated, allowing leptospires to survive particularly well, and most cases occur during the most humid part of the year. However, in the driest times of the year, leptospires may not be present in the same way, but cooler nights delay the drying out process. Additionally, dry periods often are the ones when rice is irrigated and sugarcane is harvested, and workers become infected at this time and not typically in the rainy season. However, from one year to the next, large fluctuations in leptospirosis incidence happen. Meteorologic phenomena and their consequences on animal populations (mainly rodents) play a major role in these fluctuations. Catastrophic events, such as hurricanes in tropical areas, may lead to large outbreaks with hundred of cases.

RISK FACTORS (27)

Recreational activities in freshwaters such as canoeing, windsurfing, rafting, swimming, and other related activities are important risk factors in human leptospirosis.

Other more traditional risk factors, such as fishing, and hunting, also play a determining role. Occupational leptospirosis is associated with many different professions such as breeding, agriculture, fish-farming, slaughtering, veterinary, people involved in sewage, road repairs, and also in food storage and maintenance or building activities, plumbing, etc. The combination of climatic features and exposure to risk exposition may lead to high frequency of the disease. For instance, in Asia, rice culture in damp conditions increases both rodent population and water transmission, which explains that, in spite of being underestimated, leptospirosis in some areas is actually a public health problem (50). In Vietnam, it has been shown that 20% of the population presents serological evidence of a past contact with leptospires, although 2.9% probably contracted the disease per year (51). Similarly, in New Caledonia, for instance, existence of extensive cattle breeding and tropical environment contributes to a high-endemicity rate of about one per thousand (52).

In addition, these incidence rates only represent the detected cases. In La Reunion, it has been shown that the actual prevalence of the human infection was about ten times higher than the diagnosed disease (53). Although the disease was prominent in men, because of occupational activities and peridomestic environment and association with serovar icterohaemorrhagiae and serovar canicola, the antibodies prevalence was higher in women (53). Usually, the reported cases show a male predominance (60 to 90%) and a mean age of 35 to 45.

In the United States, the number of cases detected per year is rather low as compared with European countries. From 1955 to 1996, the number of human cases has ranged from 50 to 100 every year with a maximum in 1965 of 142 cases (54). Icterohaemorrhagiae (35%) is the main serogroup, followed by canicola and autumnalis. Comparatively, from 250 to 400 cases are detected every year in continental France (55).

Finally, a high risk factor for people from developed countries (where leptospirosis is usually drastically decreasing) is traveling in tropical countries. Sport or exploration trips in tropical areas, mainly in southeastern countries, represent a major risk.

The following are some examples from cases with a common source to large outbreaks resembling epidemics:

- In France, in 1950, 77 soldiers contracted Grippotyphosa leptospirosis after swimming in the Loing River (56).
- In China, in 1958, an "epidemics" of anicteric leptospirosis occurred in Wenjiang District of Sichuan Province. A careful study was focused on 852 patients. It revealed that they were mainly rice growers. Respiratory symptoms were prominent; most of the 21 patients succumbed as a result of asphyxia associated with long hemorrhages. Most of the cases were due to serovar lai belonging to the Icterohaemorrhagiae serogroup (57).
- In Washington state, in 1965, 61 people contracted leptospirosis after swimming in a river. Antibodies against pomona and autumnalis were present only among swimmers.
- In Lisboa, in 1967, a flood occurred during the night of the 25th and 26th November 1967. Many patients were later on hospitalized with typical leptospirosis symptoms (58).
- In Italy, in 1984, 33 confirmed cases of leptospirosis were recorded in Pietra Cuta, a small town in Central Italy. An inquiry revealed that a water fountain was used for drinking by most of the patients. A dead hedgehog was found in a reservoir of the fountain (59).
- In 1995, after a flood in Nicaragua, an epidemic of "hemorragic fever," which turned out to be leptospirosis, broke out mainly because of the Canicola serogroup. In the studied area 2,259 nonmalarial febrile patients were recorded (60).
- In 1996, 9 out of 26 rafters in Costa Rica suffered from leptospirosis (61).
- In the United States, in 1998, 1,194 athletes who attended one or both triathlons in Illinois and Wisconsin were under surveillance; 84 (11%) of the participants in Illinois, 20 (5%) of those in Wisconsin, and 6 (7%) of those having participated in both the events became ill with leptospirosis (62).
- In Brazil, Sao Paulo, Rio de Janeiro, and probably in other Brazilian cities, after rainfall large urban outbreaks of leptospirosis occur involving hundreds of cases with a fatality rate of 5 to 15%. Icterohaemorrhagiae serogroup is largely prominent and Canicola is also observed (63).

TRANSMISSION MECHANISMS (27)

Origins of leptospirosis transmission include contact with infected urine, contaminated freshwater and mud by infected urine or animal tissues. Pathogenic leptospires may survive several months in water, at neutral or slightly alkaline pH. Similarly, herbivorous or omnivorous animals may remain infective for years by the presence of leptospirosis in their urine. Penetration of leptospires in the host organism takes place through intact mucosa such as conjunctiva, nasopharyngeal or pulmonary mucosa in case of water inhalation. Alternatively, skin erosions or excoriations, even minute ones, represent means of access for leptospires. In several animal species, mainly domestic ones such as cattle, a congenital transmission occurs. More rarely (in pigs), venereal transmission may happen.

Interhuman transmission is exceptional, such that leptospirosis does not give birth to epidemics but rather to sporadic or clustered cases. Interhuman direct transmission cases that have been published consist of urinary, sexual, transplacentary, or even milk suckling cases.

Host Reservoirs (27)

The primary reservoir of pathogenic leptospires are animals but is extended to the environment.

The infected animals include both domestic and wild animals. Their bodies or remains may also be infective

during a limited extent of time. Infected animals excrete in their urine huge quantities of leptospires for extensive periods (years for rodents). Leptospires are able to survive for weeks or months in freshwater or muddy soil mainly when protected from light (mines, sewers, and so on.).

The contamination risk is high in damp areas where animal urine frequently contaminates the soil or surface water. Indirect transmission (by soil or water) is the preeminent way (rather than urine) for human contamination. Animal spectrum of leptospires is an extensive one but the epidemiological importance of a given species depends on several factors such as:

- receptivity of the species,
- density of animals,
- density of human population,
- way of life of both animal species and humans (occupational and/or recreational practices of humans and practices of animals).

Sometimes, a wild species has few opportunities for contact with humans but domestic animals may be used as an efficient intermediaries. Among wild mammals, rodents (rats, mice, voles, muskrats, etc.), insectivores (hedgehogs, shrews, etc.), marsupials (opossums bandicoots, spiny rats, etc.), and also bats, cervidae, and carnivores, are usual reservoirs. Rodents and insectivores are undoubtedly the natural reservoir hosts of many leptospiral serovars, particularly those in serogroups Icterohaemorrhagiae, Ballum, Grippotyphosa, and Hebdomadis.

Territory-marking carnivores are probably the second most efficient in transmission in mammals. When these wild animals are in close proximity to humans and their domestic animals, the extent of transmission depends on the intensity of farming and animal husbandry. Intraspecific transmission within livestock and dog population follows, and there can be cycles of both intra- and interspecific transmission with occasional shifts taking place as new serovars are introduced into domestic populations.

Unusual hosts, such as birds or lizards, have been recorded (64). A particular case is the one of batrachians, in the Caribbean (Trinidad, Grenada, and Barbados) in which both toads (*Bufo marinus*) and frogs harbor in their kidneys several serovars belonging mainly to Australis and Autumnalis serogroups that can also infect humans (65). These animals could be the primary hosts for endemic serovars (bim in Autumnalis serogroup (66) and bajan in Australis serogroup) (65).

Among domestic species, dogs, and also cattle, horses, and pigs play a major role.

Dogs. Dogs generally live in and around man's dwelling places, and therefore their ability to carry and transmit leptospirosis is of major public health significance. The risk of human infection from dogs is particularly important in developing countries or subtropical environments where the animals are frequently not restrained. Usually, canicola and icterohaemorrhagiae (both serovars constitute the dog vaccine valences) are the most common serovars prevalent among dogs. However, in tropical areas, the spectrum may be more diverse. Similarly, in developed countries where vaccination of dogs is common, it seems that new serovars could become infective for vaccinated dogs.

Livestock (27)

Cattle. In North America, Australia, New Zealand, and a part of Western Europe, as in many other parts of the world, interest in bovine leptospirosis is focused on serovar hardjo. It plays a major role in abortion and is harbored in the genitals and urinary tracts of cows.

Pigs. Just as serovars sejroe-hebdomadis (mainly hardjo) are particularly adapted to cattle, pomona and tarassovi serovars have a well-known association with pigs and can cause severe economical loss.

Sheep and Goats. Leptospirosis has been reported in sheep and goats from most parts of the world. Commonly reported serovars are pomona, grippotyphosa, and hardjo.

Horses and Other Equines. Interest in equine leptospirosis has developed from two main standpoints, namely, uveitis/periodic ophthalmia and abortion. Equine abortion, stillbirths, and premature live births have been diagnosed serologically, clinically, and by circumstantial evidence. Serogroups *Australis*, *Pomona*, *Hebdomadis*, and *Icterohaemorrhagiae* were involved.

VIRULENCE AND PATHOGENESIS (27)

When studying pathogenesis and virulence of *Leptospira*, the difficulty in quantifying the virulence and maintaining it stable along subcultures is a primary limitation. Such a maintenance is usually done by animal passages (guinea pigs under 150 g or hamsters under 70 g) sensitive to a lethal infection by Icterohaemorrhagiae serogroup. Other serogroups, sometimes lethal for humans (Canicola, Australis, Bataviae, Pomona, and so on), may be studied on either hamsters or *Meriones unguiculeatus*. However, both the infection (inoculation) and doses are far from those occurring in nature. In fact, the Saïmiri monkey (*Saïmiri sciureus*), naturally infected by Icterohaemorrhagiae serogroup, presents a severe disease resembling the human one and could constitute a satisfying animal model (67,68).

The first stage of the infection is the transcutaneous passage of leptospires, which remains unknown at the molecular or cellular level. Some authors consider that leptospires are able to cross healthy skin, although a cutaneous discontinuity probably facilitates the penetration (69). Mucosa surfaces are, however, considered to be usually penetrated by leptospires. Virulent leptospires escape phagocytosis and invade blood, lymphatic vessels, and then mainly the host tissues where they multiply with a generation time of about eight hours (70,71).

In BalbC mice (nonlethal model infection), specific antibodies are detected in the second day (72) (the eighth in humans) (70). This humoral immunity is transferable

to another mouse by transfer of either serum or splenic lymphocytes (73). These protective antibodies are opsonic and facilitate phagocytosis by macrophages and by neutrophiles (74). Avirulent leptospires also are killed by the complementary/antibodies system in opposition to virulent ones (75). The efficiency of human antibodies to clean leptospires is responsible for leptospirosis to constitute in humans an acute disease (76). However, in some occasions, the persistence of leptospires has been demonstrated (77–79).

At the cellular level, the mechanisms of interactions between leptospires and host cells have been first studied in the 80s using endothelial or epithelial cells. Adhesion of virulent leptospires (and not saprophytic ones) to host cells has been noticed (80). Extracellular matrix and mainly fibronectin has been shown to play a major role in adhesion (80,81). Recently, a leptospiral protein of 36 kD has been shown to be responsible for interaction with the gelatin domain of fibronectin, which could be the first step in adhesion phenomenon (82).

Virulent leptospires also induce apoptosis of macrophages, which could help them to escape to professional phagocytes at the initial step of the infection (82). In vivo (guinea pigs) apoptosis has also been evidenced in hepatocytes but not in other tissues (84). Other approaches have been directed toward identification of toxins. Preliminary experiments were not highly demonstrative and have not been reproduced (85).

The presence of several genes coding a phospholipase C (sphingomyelinase) (activity responsible for hemolysis), is a potential virulence factor (85). These genes have been cloned, sequenced, and expressed in *Escherichia coli* (86,87). They are present in the pathogenic leptospires but neither in saprophytic ones nor in *L. inadai*.

THE DISEASE

Human Leptospirosis (88–90)

Leptospirosis is a highly polysystemic and polymorphic disease. It comprises several syndromes that are diversely associated:

- Infectious syndrome, which is constant. It is characterized by a high fever reaching 40 °C in a few hours. Typically, the fever is accompanied by vasodilation of skin and mucosa. There is sometimes a brief relapse after 10 to 12 days. When untreated, the fever remains high for 7 to 10 days, and then decreases.
- Algic syndrome, which is quite frequent and characterized by myalgia, arthralgia. The intensity of pain may be severe (90,91).
- Meningeal syndrome characterized by neck stiffness, cephalalgias, and vomiting. Photophobia, hyperesthesia, and obnubilation may also be present. The CSF shows elevation of albumin and hypercytosis (89,90).
- Renal syndrome characterized by nephritis with hematury, albuminury, hyperazotemia, and oligury or anury. The duration of oligoanury may lead to renal failure and require dialysis (89,90).
- Hepatic syndrome, either clinical with icterus on skin and mucosa or subclinical. The association of icterus and vasodilation leads to a particular orange colour of the skin. Biologically, bilirubin is increased, although transaminases are subnormal (89,90).
- Hemorrhagic syndrome, which may be present on different organs such as purpura, epistaxis, digestive hemorrhages, hemoptisis, hematury and so on (92). Hemorrhages are in fact infrequent but thrombocytopenia is usual (89,90).

Other more rare symptoms may be present such as digestive pains, pulmonary syndrome (93), cutaneous rash at the end of the fever period, conjunctivitis, and infrequently cardiovascular syndrome with low blood pressure and trouble of the cardiac rhythm, which may lead to this situation.

Rarely, the disease begins with an encephalitic syndrome with coma and polysystemic failure, which is quickly lethal (94).

Evolution (89,90). At the beginning, only infectious syndromes, which are algic, and (sometimes) meningeal, are present.

After four to five days the signs of distinct organic dysfunctions appear in the kidney, and liver. They persist for five to seven days and decrease simultaneously with fever. Later on, after 12 to 15 days, a fever relapse may occur, usually isolated, but sometimes accompanied by algia or even icterus, oligury, and so on. Convalescence is long; the patient recovers slowly but usually without sequelae. Sometimes, several weeks later, ocular lesions such as uveitis or iridocyclitis may occur. All serovars from the seven pathogenic species, namely *L. borgpetersenii*, *L. interrogans*, *L. kirschneri*, *L. noguchii*, *L. santarosai*, *L. weilii*, and *L. alexanderi* are able to infect humans.

Although some serovars are known to lead to a particular clinical expression, this relationship is not absolute. The severity of the human disease also depends on the inoculum and the sensitivity of a given patient. From the influenza-like disease (grippotyphosa serovar) to the lethal multivisceral form with hemorrhagic suffusions (icterohaemorrhagiae serovar), there are many different clinical expressions. The death rate varies from 1 to 2% in developed countries and from 20 to 30% in developing countries without intensive care units. The causes of death may be encephalitis, renal failure, respiratory failure, or cardiac failure. The only sequelae that may happen are ocular such as uveitis, iridocyclitis, keratitis, and hemorrhagic retinitis, which, in rare occasions, leads to cecity (88,89).

Diagnosis

Nonspecific Biological Signs (15,27). A hyperleukocytosis with polymorphonuclear cells is usual (sometimes lymphocytosis) but not systematic. At the beginning of the disease, during the preserological phase, the following biological signs are of value and the association of two or more of them is quite significant:

- Thrombocytopenia ($<1, 50000/mm^3$)
- Increase of creatinin phosphokinase (CPK >130 UI/1) with transaminases level normal or moderately increased.
- Triglycerides elevated (>1.70 g/L) (95).
- Decrease of HDL cholesterol (<0.85 mmol/L) (95).

Specific Biological Signs (15,27). Hemoculture must be done during the first 10 days (day 0 is marked with fever onset) before antibiotherapy. Leptospires may be isolated from the CSF during the second week and from urine later on.

Direct examination. It has no value.

Culture. Current cultural methods use the medium of Ellinghausen, McCullough, modified by Johnson and Harris (EMJH), also called *tween albumin medium* (96,97). It has been commercialized and may become selective by addition of 5-Fluorouracile (98) or other antibiotics such as Fosfomycin, Rifampicin, Inoculation must be done as quickly as possible. The inoculum should represent 10% of the medium volume.

Hemoculture. It is necessary to perform several hemocultures (four to five dilutions at 10%) to decrease a possible inhibitory effect of the blood.

Urine. Filtration through 0.45 μm and 0.22 μm filters could decrease the risk of contaminating the medium by usual bacteria. Dilutions as for blood are useful and a selective medium is to be preferred.

Tubes are incubated at 30° and examined each week. A systematic subculture after 15 days is favorable. Tubes must be kept two months before concluding they are negative.

Identification (15,27). Morphological characters (dimension, terminal hooks, etc.), motility and growth on EMJH allow to confirm *Leptospira* genus. Further identification at the species level is obtained by molecular methods. The serogrouping is performed with 23 rabbit-immune sera. Finally, the serovar identification is obtained either by pulsed field gel electrophoresis or in reference centers by a complex procedure of cross-adsorption of rabbit-immune sera by reference strains.

Serological diagnosis (15,27). Many tests have been used in the past, such as complement fixation test (CFT), MAT on slides.

At present, in addition to the MAT, which is the confirmative test, the main presumptive tests still in use are ELISA (99), Dipstick (100), hemagglutination, or latex test. They are all more or less based on the same antigenic compound, that is, a secreted nonproteic determinant (thermoresistant) that is produced by most pathogenic leptospires, and also by a saprophytic serovar, Patoc strain.

The ELISA test may be revealed by anti-IgM antibodies. In these conditions, it becomes positive earlier than MAT (sixth to eighth day) and is very sensitive and specific. However, there are some caveats in the spectrum of serogroups this test is able to detect.

The MAT (15) or confirmative test consists of evaluating with the dark-field microscope the agglutination rate of suspensions of different leptospires by the serum of the patient. The panel of leptospires is representative of the main serogroups. For a reference laboratory, this panel comprises about 20 strains. The MAT becomes positive from the 8th to 10th day of the disease. Antibodies decrease from the third to sixth month but may persist at low titers for years. Therefore, it is necessary to get several samples to assess kinetics.

PCR diagnosis (27,78,79,101). Both delay and low sensitivity in culture diagnosis, and late appearance of specific antibodies, explain the reason for leptospirosis being more effectively directed by PCR-based technology.

It allows to detect about 10 leptospires. Pathogenic leptospires may be detected by PCR within 48 hours. Any tissue, including blood, urine, CSF, aqueous ocular humor, allows a quick detection of leptospires. The sooner the sampling is done, the more the PCR is positive.

In conclusion, PCR, culture, and serology are not alternative methods but should be considered as distinct and complementary methods, which must be used sequentially to allow an optimum diagnosis.

Leptospirosis in Animals (15,27)

In Dogs. Three main clinical expressions are observed:
- Febrile gastroenteritis or typhic disease.
- Nephritic leptospirosis with high fever.
- Icteric leptospirosis.

In Horses. Many different either acute or chronic clinical forms are observed:

- Hepatonephritis
- Encephalitis
- Genital: abortion
- Iridocyclitis, with relapses after long intervals

In Cattle. Again, symptoms are quite polymorphic:

- Fever, weight loss, lameness
- Orange color of the skin and mucosa
- Bloody and dark urine
- Photosensibilization (due to hepatic failure)
- Reddish colour of the milk

Usually, it occurs as a mild, slightly febrile illness with inappetence, drop in milk yield, and sometimes symptoms of mastitis (with a thicker and yellower milk tinged with bloody flecks). Abortion may take place several weeks later, most commonly around the seventh month of pregnancy.

CONTROL AND TREATMENT OF LEPTOSPIROSIS (15,27)

Prevention

Leptospires survive in freshwater or mud (102). The control of leptospirosis may depend on many different available measures, only a few of which are relevant to a given epidemiological situation. The measures enumerated later represent a large panel of possibilities. Among them, only the most specific ones, according to the locally dominant transmission route, would be efficient.

A careful study of the epidemiological conditions is required:

- to evaluate the actual prevalence frequently underestimated because of clinical polymorphism,
- to determine the predominant transmission route,
- to define the most cost-effective control measures to be implemented.

Control of Infection in Man

Rodent Control.

1. In food production or storage areas omnivorous anthropophile rodents that live in a wide range of habitats such as *Rattus* sp. and *Mus musculus*, are prevalent. This control is related to economical aspects (spoiling prevention) and other public health interests.

a. The best and safest way is preventing the entry of rats in building by reinforced doors that are kept closed, resistant ducts, and pipes.

Basic hygiene procedures are also recommended, for instance, resistant storage containers or food packaging, cleanliness of areas, food being inaccessible.

b. Rodent poisoning is difficult to employ. Rodenticides are usable but present environmental problems and human danger. In dry environment, water poisoning (anticoagulants with delayed activity) is efficient. Fumigation with carbon dioxide presents less hazards but requires air-proof premises and specialized equipment. Biological weapons, such as bacteria lethal for rats (*Salmonella typhi murium*, *Pasteurella multocida*, etc.), have been proposed and used but are dangerous for many species including man.

c. Finally, trapping is the safest method.

2. Rodent control in domestic environment Methods are similar but difficult to apply and more hazardous. Trapping is again the best compromise between efficiency and safety.

Control of Exposure in a Potentially Contaminated Environment. This requires draining for safety.

Occupational Hygiene

1. To avoid penetration of leptospires through skin and mucous membranes (conjunctiva), two measures must be used simultaneously:
   - Reducing the number of leptospires in the environment. Humid premises must be drained and ventilated.
   - Protecting the skin with the help of protective clothing, waterproof footwear, gloves, and even spectacles in highly infective conditions. Such methods are difficult to impose in warm and humid areas.

Wounds must be immediately treated and covered. Smoking, drinking, and eating must be prohibited during exposed work and in risk areas.

2. Immunization In high-risk occupational situations (sewer workers, garbage workers), vaccination could be useful, because usually a single serogroup (Icterohaemorrhagiae) is responsible.

In France, for instance, such a monovalent vaccine is recommended for sewage workers. In Paris, before vaccination of 600 to 700 people involved in sewage plants from 1951 to 1973, 29 leptospirosis cases with 3 deaths have been recorded (incidence: 180/100,000 inhabitants). From 1974 to 1981, during vaccine trials and implementation methods, seven cases (no death) occurred (rate: 40/100,000). From 1981 to 2000 (generalized vaccination), two cases due to Grippotyphosa and probably acquired elsewhere than in sewage plants, occurred (103).

A monovalent vaccine (serovar lai) is also used in China among farmers working in irrigated areas. Multivalent vaccines have been tried among rice farmers in Italy, in Spain, in Japan, and in Korea, but are not used any more. In Russia, a quadrivalent vaccine is still commercialized for people involved in agricultural and breeding activities. A human vaccine in leptospirosis is hampered by the necessity of frequent injections and mainly the narrow spectrum of immunity in terms of serogroups. Therefore, its indications are very exceptional and must be restricted to a long-lasting, high, and exposure to a unique serogroup. In case of temporary, high-risk exposure, chemoprophylaxis with doxycyclin, 200 mg taken once or twice a week, could be efficient (104).

Control of Infection in Animals: Herd Management

Rodent Control in Livestock Environment. Radient control in livestock environment is similar to that in food production areas with a supplementary dimension, which is reduction of field mice population.

Prophylaxis and Chemotherapy for Domestic Animals. The disease is eliminated by antibiotics, mainly penicillin, streptomycin, or tetracyclin. The latter two could be used as chemoprophylaxis of the carrier state. But the consequences of drug resistance on usual bacteria must be evaluated. Such practices are now discouraged.

Immunization of Domestic Animals

- Dogs should be vaccinated (usually they carry mainly canicola or icterohaemorrhagiae serovars).

- Immunization of pigs and cattle is a controversial procedure.

However, it has been practiced successfully, for instance, with pomona among cattle in the United States and a trivalent vaccine in New Zealand where it has been reported that vaccination of cattle drastically decreased infections not only in cattle but also among humans involved in breeding activities.

Isolation of Infected or Potentially Infected Animals. Newly introduced animals must be isolated. Possibly infected animals, serologically detected, must be separated from healthy ones and treated. Floors, soils, and tools must be disinfected.

Contaminated Products from Infected Domestic Animals. Animals slaughtered for food should be checked. Infected animals must be eliminated. Aborted fetuses and membranes must be destroyed. Milk is usually safe on account of its leptospiricidal action. Urine must be safely drained; waterproof floors and distant draining of effluents must be introduced. Storage areas of effluents must be inaccessible to humans and animals and treated preferentially by physical or biological procedures.

Wildlife. Ecological control of feral population is an unsolvable problem. Natural predator populations are usually decreasing; they are either actively destroyed because they are considered as noxious or intoxicated by pesticides (predatory birds).

General Control Measures in Agriculture and Farming

1. Some high-risk culture practices present unsolvable difficulties. The risk factors in particularly exposed occupations, such as sugarcane cutting (warm climate, few clothes and protection lead to many skin abrasions by leaves) may be improved, not only by mechanization, but also by prior cane burning.
2. Wet farming presents a dispersion of the risk at many steps. When possible, mainly in temperate climates, dry farming should be preferred. Animals are stabled indoors and potentially infecting contacts are reduced.

Finally, to prevent this zoonosis, the roles of occupational medicine and veterinary medicine, which can promote hygiene education, are of major importance.

Treatment (27,88,90,105)

- Sensitivity to antibiotics

Like other bacteria growing slowly on highly specific media, there are no standardized methods to study the in vitro sensitivity. Several studies have been done in quite different conditions. As other spirochetes, leptospires are resistant to sulfamides, kanamycin, neomycin, rifampicin and metronidazole. Some of these drugs are used in selective media to isolate leptospires. Other antibiotics are usually active. The concentration minimal inhibitors are, for β-lactamin, ampicillin (0.025 mg/L), cefotaxime (0.05 mg/L), ceftizoxine (0.05 mg/L), moxalactam (0.2 mg/L), and penicillin (0.39 mg/L). Tetracyclin (3.13 mg/L), and ciprofloxazin (0.2 mg/L), are less active.

An experimental study on hamsters allowed to distinguish two groups of antibiotics:

- Those curing the disease but not the urinary carrier state, such as piperacilline, doxycyclin chlortetracyclin.
- Those that quite eradicate leptospires, such as ampicillin, bacampicillin, mezlocilline, cefotaxine, and mexalactam.

In man, it has been considered that antibiotics were less efficient if administered four to five days after the beginning of the disease.

It has been shown recently by randomized studies that doxycyclin (200 mg/day for one week) (106) and penicillin (6 M intravenous/day for one week) (107) were both active on the duration of the symptoms and leptospiruria, even when initiated lately. Penicillin seemed to be more active than doxycyclin.

In conclusion, as a zoonosis, leptospirosis cannot be eradicated. But the incidence of the disease can be decreased by prophylactic measures. Its severity is decreased by early treatment and when needed hospitalization in intensive care unit.

LIPID BIOMARKERS IN ENVIRONMENTAL MICROBIOLOGY

ANDERS TUNLID
Lund University
Lund, Sweden

Microbial communities in natural environments are complex assemblages of microorganisms composed of a variety of different species of bacteria, archaea, and microeukaryotes including fungi, algae, and protozoa. Adding to this diversity is a large temporal and spatial variation in growth and activity, that is, at a given time and place only a fraction of the microbial community might be metabolically active. It is well accepted among microbial ecologists that the classical methods including isolation and culturing of microorganisms are not suitable for analyzing the diversity and activity of such communities. In most environments, less than 1% of the total number of microorganisms can be cultured. The introduction of various molecular methods have opened up new possibilities to assay the diversity and activity of microbial communities including the large fraction of the unculturable microorganisms. With the new methods, the microbial communities are assayed by extracting and analyzing specific components of the microbial cells, without the need for isolating and culturing the microorganisms. Depending on the components analyzed, they can be used as biomarkers for biomass, species diversity, and activity of microbial communities. An important group of biomarkers that have been widely used during the last few years are nucleic acids, particularly ribosomal RNA (rRNA). Analyses of rRNA has made it possible to analyze the phylogenetic and taxonomic diversity of microbial communities in natural environments (1). However, rRNA analyses provide very limited information on the phenotype and the activity of the microorganisms in the environment. Such information can be obtained by analyzing lipid biomarkers, including membrane and storage lipids of microorganisms. The use of lipids as biomarkers for microorganisms in environmental microbiology was introduced by David C. White and coworkers in the late 70s and has then been used in numerous studies and applications (2). The objective of this article is to give an overview of the lipid biomarkers used to characterize microbial communities, present the used procedures, discuss the different types of information that can be obtained, and provide some examples from environmental studies.

THE DIVERSITY OF MICROBIAL LIPIDS

The term *lipid* covers an extremely diverse range of molecular species; thus, unlike proteins, nucleic acids, and carbohydrates, it is not possible to provide a single chemical definition. Usually, lipids are defined as substances that are sparingly soluble in water but readily soluble in organic solvents such as chloroform. Lipids may be very simple molecules like fatty acids and hydrocarbons, but most microbial lipids are complex molecules containing sugars, amino acids, and phospho- or sulphogroups. A number of different systems for classifying lipids have been published, but a practical way of classifying, which reflects the procedures used for isolating lipids from environmental samples, is the division into neutral lipids (NL), glycolipids (GL), and polar lipids (PL) (Table 1; Fig. 1). A certain group of polar lipids are the lipoconjugates (LC), in which the hydrophilic part of the molecule has the dominant influence on soluble characteristics (3).

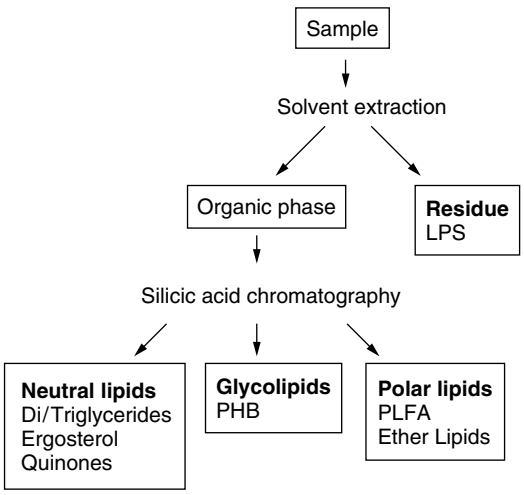

Figure 1. Scheme for analyzing lipid biomarkers in environmental samples.

Table 1. Examples of Lipid Biomarkers used in Environmental Microbiology

Lipid	Lipid Class[a]	Cellular Function	Taxonomic Distribution	References
Triglycerides	NL	Storage material	Eukaryotes	4,5
Ergosterol	NL	Membranes	Fungi	6–8
Respiratory quinones	NL	Respiratory chain/ electron transport	All cells	9,10
Hopanoids	NL	Membrane	Prokaryotes	11
Poly-β-hydroxybutyrate (PHB)	GL	Storage material	Prokaryotes	12–14
Phospholipids	PL	Membranes	All cells	15–17
Phospholipid fatty acids (PLFA)	PL	Membranes		18–20
18 : 2ω6[b]			Fungi	21,22
16 : 1ω5			AM fungi	5,23
i15 : 0, i15 : 0, i16 : 0, i17 : 0, a17 : 0			Gram-positive bacteria	19,20
10Me18 : 0			Actinomycetes	24
10Me16 : 0			*Desulfobacter*	25
15 : 1ω6, 17 : 1ω6			*Desulfobulbos*	26
i17 : 1ω7c			*Desulfovibrio*,	27
16 : 1ω8c, 16 : 1ω6c			Type I methanotrophs	28,29
18 : 1ω8			Type II methanotrophs	28,29
Phytanyl-ether lipids	PL	Membranes	*Archaea*	30,31
Lipopolysaccharides (LPS)	LC	Cell envelope	Gram-negative bacteria	32,33

[a]NL, neutral lipids; GL, glycolipids; PL, polar lipids; LC, lipoconjugate.
[b]Fatty acids are designated as total number of carbon atoms: number of double bond closest to the aliphatic end (ω) of the molecule is indicated with the geometry "*c*" for *cis* and "*t*" for *trans*. The prefixes "i" and "a" refer to iso- and anteiso branching. Other methyl-branching is indicated from the carboxylic acid end. Cyclopropal fatty acids are designated using the prefix "cy."

The diversity in the structure of microbial lipids is also reflected in the diverse cellular function of lipids. some lipids such as the triglycerides (triacylglycerols) present in eukaryotic cells and poly-β-hydroxybutyrate (PHB) found in certain prokaryotes are storage materials. A number of lipids are responsible for the structure of membranes including the phospholipids and sterols. Other lipids, such as the lipopolysaccharides (LPS) in gram-negative bacteria, participate in the organization of the cell envelope. Other lipids which are electron carriers in the respiratory chains and electron transport systems, such as the terpenoid quinones, have more special functions.

Some lipids are found in all microorganisms, such as the membrane phospholipids. Other lipids are associated with certain taxonomic groups of microorganisms (Table 1). Thus, lipids can be used as biomarkers or "signatures" for a specific group of microorganisms. More detailed information on the taxonomic distribution of microbial lipids that can provide support for the designation of specific biomarkers are found in the books by Ratledge and Wilkinson (34,35).

LIPIDS AS BIOMARKERS

There are four sorts of information that can be obtained from the analysis of lipid biomarkers in environmental samples: (*1*) microbial biomass, (*2*) community composition, (*3*) nutritional status, and (*4*) metabolic activity.

Biomass

When determining biomass by measuring the concentration of a cellular component, several requirements have to be considered: (*1*) the measured component must only occur in living microorganisms and not exist in dead cells and (*2*) the component should exist in fairly uniform concentrations in the cell (36). In environmental microbiology, particularly membrane lipids, such as phospholipids and ergosterol, have been used as markers for biomass. Phospholipids are found in the membranes of all living cells, they are not found in storage polymers, they have a relatively rapid turnover rate in aquatic sediments (15,37), and they are degraded when added to soils (38); thus, assays of phospholipids give a measure of the viable cellular biomass. The phospholipid content of microorganisms varies to some extent among different species and in response to growth conditions, which can make it difficult to convert the values of phospholipid content to cell numbers (19). However, several studies (17,33,39) have reported a good correlation between the total amount of phospholipids and the microbial biomass determined by other methods such as ATP measurements and microscopic counts.

Ergosterol is the predominant sterol in most fungi (40). It can be used as a biomarker for living fungi because it is rapidly degraded in the environment (41). Like phospholipids, the ergosterol content in fungi varies depending on species and growth conditions, and a number of different conversion factors relating ergosterol concentrations

to fungal biomass have been presented (7,8,42). Linoleic acid (18 : 2ω6) has also been proposed as a signature for fungi (21), and the soil concentration of this PLFA correlated well with the concentration of ergosterol (22). However, 18 : 2ω6 can be present in large concentrations not only in fungi but also in plants (43). Thus, 18 : 2ω6 is a good indicator for fungal biomass when plant cells are not present in the system.

Community Composition

As pointed out earlier, many lipids are associated with specific taxonomic or functional groups of microorganisms and can thus provide insights into the types of microorganisms that are present in an environmental sample. Particularly, analyses of the ester-linked fatty acids in phospholipids (PLFA) have been shown to give insights to the structure of microbial communities (18–20) (Table 1). The use of an individual PLFA as a biomarker for a specific group of microorganisms assumes in the best of cases that all members of that group contain that lipid and members of other groups of organisms do not. For example, the fatty acid 16 : 1ω5 has been used as a signature for arbuscular mycorrhizal fungi (5,23). Terminally branched fatty acids (*i* and *a*) are largely found in gram-positive bacteria, whereas cyclopropyl fatty acids are common in some gram-negative bacteria (34,35). Methyl-branching on the tenth carbon atom (such as 10Me 18 : 0) is specific for actinomycetes (24). Signature PLFA have also been identified for the sulfate-reducing bacteria (25–27) and methanogens (28,29). More extensive lists of signature PLFAs used in environmental microbiology are found in refs. (19,20).

A limitation of the PLFA method is that the occurrence of individual markers can only be derived from the analysis of isolated pure cultures. Furthermore, in most cases, there are extensive overlaps in the patterns of PLFA present in various groups of microorganisms and it is not possible to identify unique or signature PLFA. Another problem associated with the PLFA analysis is that the composition of PLFA can to a great extent depend on the growth conditions of the microorganisms. Therefore, many investigators use the "complete" PLFA profile (typically including 50 to 100 fatty acids) as a "fingerprint" of the microbial community. Using this approach, multivariate statistics such as principal component analysis (PCA) is used to simplify data and reveal patterns (44,45). For example, fingerprinted data can be used to determine the PLFAs that are most strongly correlated with an environmental variable. If the influential lipids are taxonomic biomarkers or physiological indicators (illustrated later), these changes can be interpreted as taxonomic or physiological variations.

The community composition can be further characterized by analyzing groups of lipids other than the PLFAs (Table 1). For example, methylhopanoids can be used as biomarkers for cyanobacteria (11). The composition of respiratory quinones, including the naphtoquinones and benzoquinones, vary among different groups of microorganisms and have been used as biomarkers for bacteria in environmental samples including aquatic systems, soil, and composts (9,10). Gram-negative bacteria contain unique hydroxy fatty acids in the lipid portion (lipid A) of the lipopolysaccharide (LPS) in the cell wall (46). Particularly β-OH fatty acids have been used as indicators for gram-negative bacteria in environmental samples (32,33). *Archaea* are characterized by their unique biphytanyl (archaeol) and di-biphytanyl ether lipids that are not found in other organisms (47). These lipids have been used as biomarkers for *Archaea* in sediments, hot spring mats, and soils (30,31,48,49).

Nutritional/Physiological Status

The composition and content of cellular lipids reflects the growth conditions and physiological status of an organism. Many microorganisms accumulate lipid storage polymers during conditions of unbalanced growth when sufficient levels of carbon and energy resources are present but some essential nutrient (e.g., nitrogen, phosphorus) needed for growth and division is lacking (12,50). The bacterial PHB [or PHA, poly-β-hydroxyalkanoic acid, ref. (12)] and eukaryotic triglycerides are endogenous storage polymers (Table 1), and the relative amounts of these compounds required to biomass can be used as a measure of the nutritional status of a microbial community (12–14). The diglyceride fatty acids (DGFA) are degradation products of phospholipids and have been used as indicators of dead cells (51,52). Specific patterns of PLFA can also indicate physiological stress. Exposure to toxic environments can induce the conversion of *cis* to *trans* PLFA (53), and some bacteria form a larger proportion of cyclopropane PLFA relative to their precursor (monoenoic) fatty acid in response to nutrient depletion or stress (54).

Because of a large interspecific variation in the level and metabolism of various lipids, there are potential problems in interpreting changes in patterns of PLFA to changes in nutritional and physiological status in complex assemblages of microorganisms. For example, PHB production varies widely among different species and some appear to be incapable of producing it. Likewise, the ratio of trans/cis fatty acids and cyclopropyl fatty acids to monoenoic precursors vary considerably among different bacteria (19). In spite of these difficulties, valuable information on the physiological status of microorganisms in complex environmental samples have been obtained, particularly when the information can be linked to changes in specific chemical parameters that may reflect or influence microbial growth conditions. Such an example includes the analyses of the nutritional status of microbial communities in contaminated soils (55,56).

Metabolic Activity

Lipid biomarkers can also be used to analyze the metabolic activity of specific microbial population. One strategy is to add a ^{14}C- or ^{13}C- labeled substrate to the environmental sample and to determine the degree of incorporation of the labeled substrate into the cellular lipids. The incorporation rates of ^{14}C-acetate into phospholipids can be used to measure the activity of the total microbiota (57). Labeling experiments with ^{14}C-acetate can also be used to measure the rate of synthesis of PHB and PLFA (58). Roslev and coworkers (59) developed a method for analyzing the

incorporation of various ^{14}C-labeled substrates (e.g., ^{14}C-methane and ^{14}C-phenanthrene) into PLFA biomarkers, thus making it possible to fingerprint the metabolically active part of the microbial community (59). The metabolic activity of fungi has been assayed by measuring the incorporation of ^{14}C-acetate into ergosterol (60).

There are some advantages in using ^{13}C- labeled substrates over those labeled with ^{14}C in that, stable isotopes have higher specific activities and they can be detected with high sensitivity and precision using mass spectrometry. ^{13}C-acetate and ^{13}C- methane have been used to identify metabolically active bacteria in sulfate reduction and methane oxidation in freshwater sediment (61) and to detect atmospheric methane–oxidizing bacteria in soil (62).

An alternative approach for assaying the substrate usage of various microorganisms is to measure the stable carbon isotope abundance in signature lipids using isotope ratio mass spectrometry. Stable isotope ratios have been used extensively by ecologists to study carbon usage in various organisms but have only recently been introduced for analyzing lipid biomarkers (63–65). One problem associated with this method is that δ^{13}C pattern is not uniform for different fatty acids and lipid fractions and also varies with the type of growth substrate (63). However, by δ^{13}C analysis of archaeol and 2-hydroxyarchaeol, it has been possible to detect methane consuming *Archaea* in marine sediments (65).

PROCEDURES

Generally, chemical analyses of lipid biomarkers involve the extraction of the sample with organic solvents, followed by isolation and separation with various chromatographic techniques. The procedure outlined in Figure 1 was introduced by David C. White and colleagues 20 years ago and is in large still used by most workers (15). The analyses are based on the efficient one-phase Bligh and Dyer extraction (chloroform : methanol : buffer) of the sample (66). The one-phase solvent system is then divided into two phases with the addition of one portion of chloroform and one portion of buffer. The lipids are recovered in the lipid phase and the residue can be used for analysis of more polar lipid conjugates such as LPS. The extracted lipids are separated on silicic acid into three different fractions that contain NL, GL, and PL. After extraction and isolation of the various lipid classes, they are analyzed by gas chromatography (GC) or high-performance liquid chromatography (HPLC) (Fig. 1).

Brinch-Iversen and King (67) proposed to use dichloromethane as an alternative to the more hazardous chloroform in the Bligh and Dyer extraction medium, and this procedure has been used by numerous investigators for extracting PLFA from soils. It has also been shown that the amount of PL recovered from soils depends on the buffer used in the extraction medium (17,68). Notably, the lipid extraction procedure can also be used for extracting nucleic acids from environmental samples. Nucleic acids can be recovered from the lipid-extracted residue and used for enzymatic amplification and gene probing (69). One drawback of the Bligh and Dyer extraction procedure is that it is relatively labor-intensive and slow, taking up to 24 hours for the initial extraction. Macnaughton and coworkers (70) showed that the extraction step could be significantly accelerated by using a pressurized hot solvent extractor. Another way of accelerating the analyses of lipid biomarkers is to use solid-phase extraction (SPE) columns to fractionate the lipids (71).

Ergosterol can be extracted with the Bligh and Dyer mixture and recovered in the NL fraction (72). More often, it is directly extracted by methanol, saponified, and analyzed by HPLC using a UV detector (6,7,41). More recently, Montgomery and coworkers (8) introduced a microwave-assisted extraction method to isolate ergosterol from soils. Respiratory quinones can be recovered in the NL fraction and analyzed by HPLC (9). Alternatively, they can be directly extracted from environmental samples (soil, sediment, activated sludge) using a mixture of hexane : water (10).

The ester-linked fatty acids in PLFA and di/triglycerides are usually transesterified to methyl esters by mild alkaline methanolysis, and the obtained fatty acid methyl esters (FAME) are analyzed by capillary gas chromatography using a flame ionization (FID) detector. Environmental samples usually contain a complex mixture of PLFA, for example, 30 to 50 fatty acids are typically identified in samples from soils and sediments. FAME can at least initially be identified by comparing the GC retention times with those of standard fatty acids; however, in most cases mass spectrometry (MS) is needed for identification of the FAME (36). Methyl esters of fatty acids have electron impact (EI) spectra that, in most cases, give information on the carbon chain length, presence of methyl branches, hydroxy groups, unsaturations, and cyclopropyl groups. The position of double bonds in monoenoic fatty acids can be conveniently determined in FAME by analyzing their dimethyl disulfide adducts with GC/MS (73). For most applications, the sensitivity of the aforementioned GC/FID procedure is appropriate. However, the sensitivity in the analysis of PLFA can be significantly improved by using the mass spectrometer as a detector (74).

Zelles have introduced a more extended scheme for analyzing PLFA in soils (20,75). According to this method, the saponified products obtained after the mild alkaline methanolysis of the PL fraction are separated into six different fractions using various SPE columns. These fractions include both ester-linked and amide-linked fatty acids. Using this procedure, it has been possible to identify from 190 to 360 different PLFA in various soil samples (20,75).

The biphytanyl (archaeol) and di-biphytanyl ether lipids of *Archaea* can be analyzed in environmental samples by HPLC (76). Methods have also been developed that analyze archaeols using GC-FID (31,49).

APPLICATIONS IN ENVIRONMENTAL MICROBIOLOGY

The use of lipid biomarkers in environmental microbiology has increased significantly during the last few years. PLFA analysis has become a standard method to characterize microbial communities in both soils and

aquatic environments. The following section will provide some recent examples on the application of lipid biomarker analysis in environmental microbiology.

Soils

Analysis of lipid biomarkers have been used to identify the effects on various cultivation and management practices on microbial communities in agricultural soils. Bardgett and coworkers used PLFA analysis to show that the cessation of fertilizer input to temperate grassland soils can induce a rapid shift from bacterial to fungal dominance in the soil microbial community (77). Further analysis of grassland soils along a fertility gradient verified that the fungal to bacterial ratio was highest in the unfertilized and lowest in the fertilized soils (78). This investigation also showed seasonal differences in the PLFA pattern that were related to soil mineral-N and soil moisture content. PLFA analysis have also been used to compare the microbial community compositions between organic and conventional farming systems (79).

The effects of fertility gradients on the structure and biomass of the microbial community have also been examined in boreal coniferous forest stands (80). Although the total microbial biomass and respiration rate were unchanged along the fertility gradient, shifts in the PLFA patterns indicated gradual changes in the structure of the microbial community. The relative abundance of fungi decreased and that of bacteria increased with increasing fertility. In addition, the structure of the bacterial community changed along the gradient. In another study, the PLFA method was used to demonstrate that the spatial pattern of the microbial community structure in a forest stand were related to the position of trees (81). Spruce trees had a much stronger influence on PLFA patterns than birch trees. PLFA analysis was recently used to examine microbial community changes during primary succession on a glacier forefront (82). The lipid data indicated that the biomass increased over successional time and that the microbial community shifted from bacterial-dominated to fungal-dominated.

A number of studies have characterized methane-oxidizing bacteria in soils using PLFA biomarkers (cf. Table 1). Sundh and coworkers (83) found a good correlation between the concentration of the PLFAs specific for type I and type II methanotrophic bacteria and the potential methane-oxidizing bacteria in boreal peatland soils. Such a correlation was not found in a podzolic soil profile (84). Bull and coworkers (62) added $^{13}CH_4$ to a forest soil system and found by PLFA analysis that a new methanotroph, similar at the PLFA level to known type II methanotrophs, was the predominant soil microorganism responsible for atmospheric methane oxidation.

Analysis of soil PLFA patterns has been used to detect heavy-metal effects on forest soils with low pH and high organic content, and in agricultural soils with neutral pH and low organic matter content, both in the laboratory experiments (85,86) and in field studies (87–89). In all these cases, the analysis of the PLFA pattern detected metal effects at similar or sometimes lower contamination levels compared with measurements of microbial biomass and activity. Thus, the fingerprinting PLFA analysis proved to be a sensitive measurement of heavy-metal effects irrespective of soil type and type of metal pollution (44).

Aquifers

Lipid-based methods have proven to be a valuable tool for characterizing the structure and activity of microbial communities in contaminated and pristine aquifers (19). PLFA biomass analysis has indicated trends in the distribution of microorganisms in aquifers. Several investigations have shown that the viable microbial biomass decreases with depth from the soil surface, because of the decrease in available carbon with depth (90–92). The biomass at contaminated sites is usually higher than at pristine sites, and a correlation between biomass and contaminant concentrations has been observed in several sites (55,56).

The ratio of PHB to PLFA has been analyzed in a number of aquifer studies. In groundwater from a granite aquifer, a high ratio was interpreted as a sign of nutrient limitations (93). Other studies have indicated that pristine, oligotrophic aquifers have higher PHB/PLFA ratios than contaminated and more nutrient-rich groundwater (19). The physiological status of the microbial communities in aquifers have also been examined by analyzing the *trans*/*cis* and cyclopropyl/monoenoic ratios of PLFA. Ludvigsen and coworkers (55) observed lower values of these ratios near a landfill indicating that microbial growth was enhanced by contact with the leachate. PLFA analysis of aquifer samples suggested relationships among the structure of the microbial communities, sediment types, and sample locations (55,90,92). Methanotrophs and sulfate-reducing bacteria tend to be more abundant near the contamination source (55,56,92).

Aquatic Environments

A significant part of the early applications of lipid biomarkers was done on microbial communities in aquatic environments and sediments (2,4,12,15,18,21,25,26,57,58,72). Lipid biomarkers have been used in studies examining the role of archaea in anaerobic methane utilization. Hinrichs and coworkers (65) identified isotopically depleted lipid biomarkers and archaeal 16S rRNA genes occurring together in cold seep sediments in which anaerobic oxidation of methane (AOM) is supposed to occur. Further studies of this and other sediments confirmed the presence of extremely depleted archaeal lipids, in addition to identifying isotopically depleted bacterial fatty acids and glycerol ethers, most probably originating from the AOM syntrophic partners (94). One of these partners has been identified as sulfate-reducing bacteria (95).

Isotope-labeled substrates (^{13}C) in combination with PLFA analysis were used to identify populations involved in acetate and propionate consumption in anoxic brackish sediments (96). The data showed that acetate and propionate were consumed by different specialized groups of sulfate-reducing bacteria. The acetate-labeling pattern was similar to known species of sulfate-reducing bacteria but that of propionate did not resemble any known strain.

Pollution and Bioremediation

PLFA analyses have been used to indicate microorganisms involved in the methylation of mercury in mercury-polluted lake sediments (97,98). In both investigations, the microbial community composition was strongly related to mercury methylation potential. A high correlation was found between the methylation potential and the abundance of 10Me16 : 0, which is a biomarker for *Desulfobacter* spp. (25).

Several groups have recently used isotope-labeled substrates and PLFA analysis to characterize the part of the microbial community metabolizing various pollutants. Roslev and coworkers added ^{14}C-labeled phthalate (PA) and di-(2-ethylhexyl) phthalate (DEHP) to sludge-amended soils and followed the metabolism using PLFA fingerprinting techniques (99). The data showed that organisms with different PLFA composition metabolized the two phthalates. Furthermore, it was concluded that DEHP is mineralized by indigenous microorganisms in sludge rather than by indigenous microorganisms in soil. Hanson and coworkers (100) added ^{13}C-labeled toluene to soils. After incubation, a significant part (85%) of the incorporated ^{13}C was detected in PLFAs contained in a toluene-metabolizing bacteria isolated from the experimental soil.

The effects of polycyclic aromatic hydrocarbon (PAH) contamination on freshwater sediments were determined using both PLFA biomarkers and nucleic acid probes of PAH–degradative genes (101). Principal component analysis of PLFA profiles indicated that moderate to high PAH concentrations altered the microbial community composition and that seasonal fluctuations were comparable in magnitude to the effects of PAH pollution. PAH–degradative genes were detected in all sites, but their frequencies were typically higher at contaminated sites. Similar methods were used to follow the degradation of PAH in a bioslurry treatment of a PAH–contaminated sediment (102). PLFA analysis revealed a threefold increase in microbial biomass and a dynamic microbial community composition. Nucleic acid analyses showed that the copy number of genes encoding PAH–degrading enzymes increased several orders of magnitude, and this shift correlated well with shifts in specific subsets of the microbial community (102).

Macnaughton and coworkers used PLFA analysis in combination with 16S rDNA denaturing gradient gel electrophoresis (DGGE) to identify the bacterial community members responsible for the bioremediation of an experimental oil spill (103). The PLFA analysis indicated a community shift from primarily eukaryotic biomass to gram-negative biomass with time. Data obtained from the DGGE and DNA sequence analysis verified the dramatic shift to a community dominated by gram-negative bacteria.

Composts and Waste Treatment

Analyses of lipid biomarkers have been used to follow microbial community dynamics during composting and anaerobic digestion of waste material. Herrman and Shann showed that PLFA profiles changed in a consistent and predictable way during composting of municipal solid waste. The PLFA profiles were characteristic of specific stages of the composting and it was suggested that such profiles could be used for evaluating the progress of material processing and product development (104). Hellman and coworkers related changes in the microbial community composition to the emission of trace gases during open-windrow composting of solid waste material (105). The emission of carbon dioxide, methane, and nitrous oxide (N_2O) increased successively during compost maturation. The microbial biomass (total amount of PLFA) showed a discontinuous decrease during the composting process. The level of ether lipids used as biomarkers for archaean methanogens increased at elevated methane concentrations. The period of enhanced nitrous oxide emission corresponded with an increase of PLFA, which is indicative of gram-positive bacteria and actinomycetes. Oude Elferink and coworkers used both 16S rRNA probing and PLFA analyses to identify sulfate reducers and *Syntrophobacter* sp. in anaerobic bioreactors while treating different wastewater (106). Although the PLFA method was regarded as a useful method for fingerprinting the microbial community, it was not suitable for an accurate characterization and identification of the sulfate-reducing bacteria in the sludge.

CONCLUSION

Analysis of lipid biomarkers provides a rapid and, in most cases, an inexpensive way for describing the biomass, structure, and physiological activity of microbial communities in environmental samples. The lipid biomarker methods and the methods analyzing nucleic acids such as rRNA have different strengths and weaknesses and thus complement one another (107). One advantage of the lipid biomarker method is that they can be quantitatively extracted from complex environmental samples and analyzed without the requirement for an amplification step like the PCR needed for most rRNA analysis. The PCR method can introduce artifacts and biases in the amplification processes leading to misinterpretation of the original sample. A disadvantage of the lipid biomarker method is that they cannot give the taxonomic resolution at a level that is obtained using the rRNA methods.

LITHOTROPHIC MICROBIAL ECOSYSTEMS IN THE SUBSURFACE

TODD O. STEVENS
Masier, Oregon

The study of microorganisms in or from the terrestrial subsurface has waxed and waned several times since the very roots of microbiology, when Leeuwenhoek first observed bacteria in well water [reviewed in reference (1)]. As subsurface resources were exploited during the industrial revolution, it became apparent that microorganisms were active in coal beds and oil fields. Nearly a century later, the ability of subsurface microorganisms to degrade or immobilize anthropogenic contaminants came under intense investigation. Most recently, with expanding exploration of the solar system, subsurface ecosystems are often regarded as the last feasible models for how living organisms could potentially exist on other Solar planets (2–5). It is now widely accepted that microorganisms persist and metabolize below the Earth's surface to depths of more than 3 km. The lower limit to the biosphere likely varies with geographic location and is probably controlled by the depth at which the geothermal gradient causes temperatures to exceed the habitable range, as well as the flux of nutrients mediated by groundwater flow and the composition of the surrounding rock.

The surface of the Earth is universally and profoundly impacted by biological oxygenic photosynthesis. Effects range from the approximately 21% O_2 content of the atmosphere to the incorporation of organic matter into the crust. Subsurface microorganisms have generally been thought to subsist by slow recycling of buried photosynthate. In fact, most studies of subsurface microorganisms have investigated their effects on fossil carbon sources. However, if primary production could occur in situ, then subsurface ecosystems might exist that are independent of biological processes at the surface. This is probably the only remaining prospect for extant living organisms on other solar system bodies, as the surface of all known extraterrestrial planets are probably devoid of liquid water, unprotected from extremes of radiation, temperature, and pressure, and hence inimical to life as we know it (6). Furthermore, the surface of the Earth may have been uninhabitable at or near the time of the origin of life because of the fainter luminosity of the young sun (7) or planet-sterilizing impact events during late coalescence of planetary materials (8). If primary production takes place underground without dependence on surface-based photosynthesis, it is possible that the earliest continuously habitable portion of the biosphere may have been the deep subsurface (4).

CHEMOLITHOAUTOTROPHY

Chemolithoautotrophic organisms obtain energy from the reaction of inorganic electron donors and electron acceptors, and produce biomass from inorganic carbon. It is at least conceivable that any of these organisms could carry out primary production in subsurface ecosystems, given an appropriate environment. Several sites where this may occur have been identified (reviewed in Ref. 5). Many chemolithoautotrophs, such as nitrifying bacteria, iron-oxidizing bacteria, and sulfur-oxidizing microorganisms, are ultimately dependent upon photosynthetic organisms to produce the O_2 needed as an electron acceptor. Others, such as methanogenic archaea and homoacetogenic bacteria, are able to grow using resources available from purely mineral sources. This makes them of particular interest as the potential foundation for pre-photosynthetic ecosystems. Until recently, anaerobic chemolithoautotrophs were not known to act as primary producers — they were discovered in the context of organic

matter degradation. In anaerobic food webs, H_2-consuming microorganisms frequently mediate the terminal electron-accepting process in the degradation of organic detritus. Their role there is the conservation of energy from organic chemical bonds, rather than primary production. Clearly, it is possible that these organisms could carry out primary production, albeit to a lesser extent than photosynthesizers, given an appropriate environment (Fig. 1). However, because the surface biosphere, and much of the subsurface, is so saturated with the products of photosynthesis, it has been difficult to identify such niches.

Energy is available to microorganisms in niches where a chemical disequilibrium exists. Most frequently, this occurs when materials in a reduced state are juxtaposed with relatively oxidized materials. In the most general terms, this occurs because the Earth is a differentiated planet in which slow mixing between the disparate components occurs at various timescales through the combined

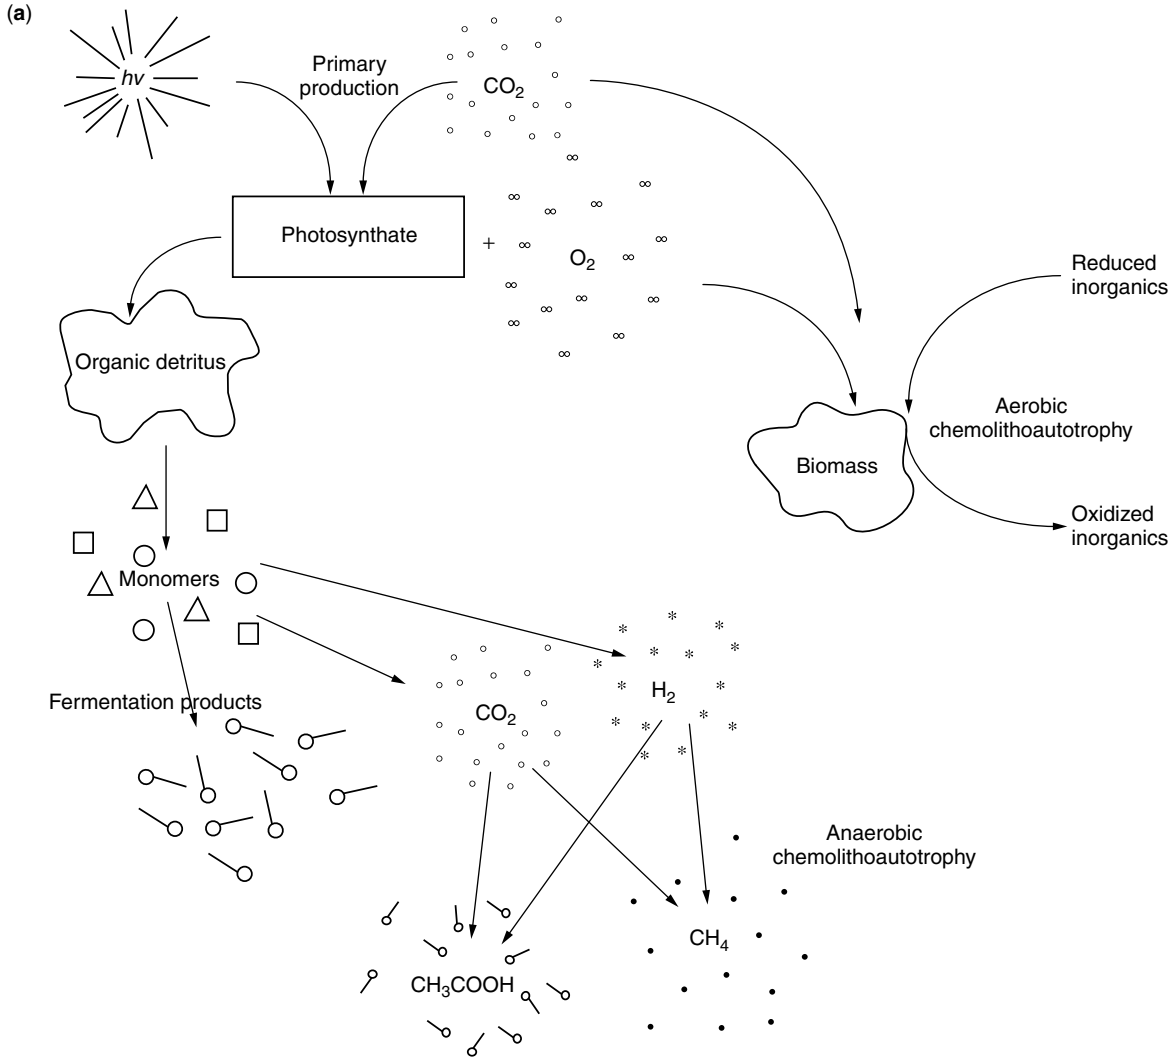

Figure 1. Ecological niches for chemolithoautotrophic microorganisms. Metabolic processes carried out by various organisms are shown as arrows. (**a**) Common niches of lithotrophs in ecosystems based on photosynthesis. Photosynthetic organisms carry out primary production and create a chemical disequilibrium, producing reduced organic matter and oxidized O_2 (from water, not shown.) Anaerobic chemolithoautotrophs conserve energy from chemical bonds of the reduced photosynthate. By consuming products of fermentation, they also improve the thermodynamic efficiency of detrital food webs. Aerobic chemolithoautotrophs depend on the other product of photosynthesis, conserving energy from reactions of photosynthetically produced O_2 with reduced inorganic compounds. (**b**) A simplified food web that might arise in environments not impacted by photosynthesis. Anaerobic chemolithoautotrophs now carry out primary production using H_2 produced as a by-product of abiotic rock-weathering reactions. Methanogenesis and acetogenesis are shown. Note that if other oxidized electron acceptors were available (e.g., Fe(III), SO_4^{2-}) other processes and complex food webs could occur. Aerobic chemolithoautotrophs (not shown) might also carry out primary production using O_2 produced by abiotic photooxidation reactions in certain subaerial environments.

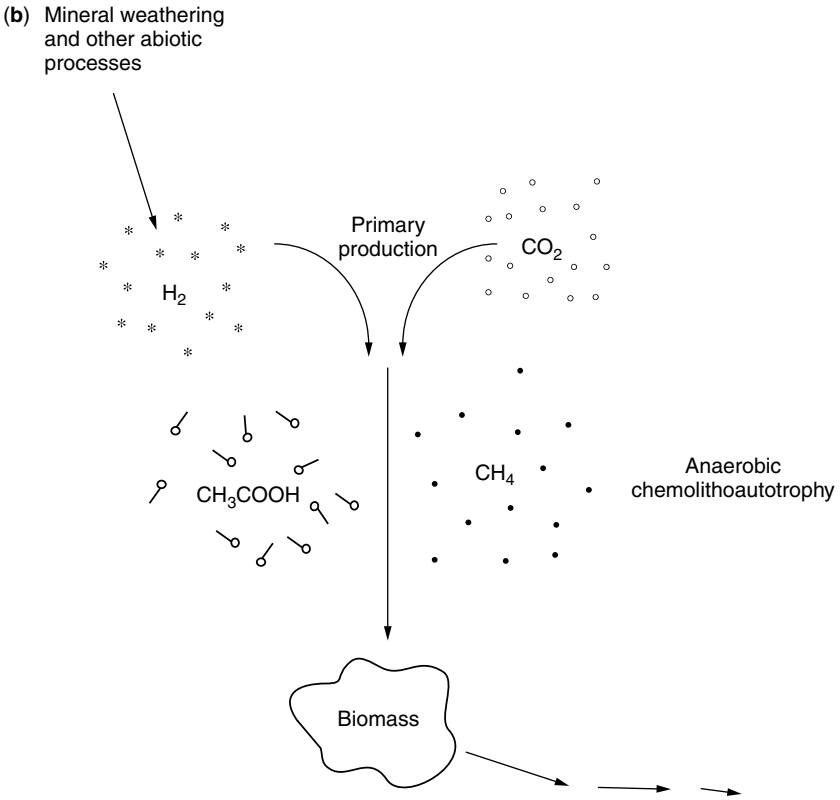

Figure 1. (*Continued*)

actions of the rock cycle (plate tectonics, erosion, volcanism), the hydraulic cycle (precipitation, runoff, groundwater flow), and subaerial processes (irradiation, lightening, aeolean flux). Reactions between the mixed materials may be thermodynamically feasible, but kinetically hindered (for example, by mineral dissolution rates) so that they remain in a state of metastability. By catalyzing these reactions at faster rates, microorganisms may be able to tap these sources of potential energy. The greatest concentrations of such exploitable energy are probably located at mixing zones where high-flux processes transport material between contrasting environments. Examples include terrestrial hot springs and mid-ocean spreading centers (9).

Igneous rocks are composed of crystalline minerals that have intruded as fluids from Earth's mantle into the crust and surface. They can be classified along a continuum from rocks containing mostly felsic (silica-rich) minerals, such as anorthosites and granites to those containing more mafic (magnesium and iron-rich) minerals, such as basalts and peridotites. These rocks are out of equilibrium with the surface environment and undergo slow reaction processes known as weathering. The more mafic minerals, which contain ferrous iron at very low redox potentials are particularly reactive.

However, as these crystalline rocks have very low solubility, weathering proceeds very slowly in most environments, and igneous rocks persist throughout the Earth's crust and over large areas of the surface. Although the weathering of igneous rocks is very slow, they are so widespread that they may constitute a very large potential energy source for microbial metabolism on a global scale. Energy flux from this source would be much more diffuse than that at high-flux mixing zones, but potentially larger in the global balance (1). However, as most igneous rocks at or near the surface are juxtaposed with the rich photosynthetically based biosphere, contributions from microorganisms growing at the expense of rock weathering may be difficult to sort out.

A MICROBIAL ECOSYSTEM IN THE COLUMBIA RIVER BASALT GROUP

A potential model system for studying microbial interactions with mafic rocks is found in the Columbia River Basalt group (CRB) in western North America. The CRB is the youngest of 12 known "flood basalt" provinces on Earth [see reference (10)]. Flood basalts were formed when so-far unknown events caused enormous volumes of magma to erupt and rapidly spread across the surface in flows that covered tens or even hundreds of thousands of square kilometers. (Many of these events have been linked to global mass extinctions in the fossil record.) In the CRB, these catastrophic flows recurred periodically over the course of a few million years and resulted in deep sequences of layered flows. These are essentially enormous volumes of almost entirely mafic rocks. The CRB covers more than 160,000 km^2 and lies up to 3 km deep, with an average thickness of 1 km. The individual flows are largely impermeable and prevent vertical groundwater flow, except through fracture zones. Zones of rubble between the flows, known as *flow tops*, are much more permeable and result in a series of aquifers with slow horizontal movement of groundwater. The time for water to flow from recharge

zones to deep aquifers in the central CRB has been estimated at greater than 30,000 years. Reaction with ferrous minerals removes oxygen from the groundwater relatively rapidly, and the deep old waters are anoxic, reducing, and mostly somewhat alkaline.

The CRB groundwaters also contain relatively large populations of microorganisms (11,12) and water pumped from the CRB frequently contains more than 10^5 entrained cells per milliliter. Most of these aquifers fall into one of three types. Shallow aerobic aquifers, generally less than 500 m deep, have not yet become strongly reducing. Deep carbonate-dominated aquifers contain relatively high concentrations of dissolved methane (up to 100 mM) and hydrogen gas (frequently around 1 μM). Deep chloride-dominated aquifers contain relatively high concentrations of sulfate (up to 2 mM) and sulfide. Higher numbers of methanogenic archaea can be recovered from the methane-containing aquifers, whereas higher numbers of sulfate-reducing bacteria can be recovered from the sulfide-containing aquifers (11). Interestingly, homoacetogenic organisms can be recovered equally well from both types (12). Lower numbers of anaerobic heterotrophic organisms could also be recovered from both sites.

As a cautionary matter, it should be noted that microbiological samples from CRB aquifers have been obtained only by sampling water produced from wells. More reliable observations of the in situ communities would require aseptically obtained core samples, which can require considerable resources and may not yet be technologically feasible in deep igneous rocks (13–15). However, observation of secondary minerals and microfossils in ancient fracture-fill material (from nonaseptically obtained cores) suggests that anaerobic microbial ecosystems similar to those present today have been present in the CRB throughout its history (16).

In fact, the methane and sulfide in CRB groundwaters appear to be products of microbial metabolism, based on trends in concentration versus depth (depth is assumed to be a proxy for time) and stable isotope values (12). Most work to date has focused on the methane-rich aquifers. The ratios of the stable isotopes of carbon can yield important clues about the metabolic functions of gas-producing organisms (17). As CRB groundwaters age, concentrations of dissolved inorganic carbon (DIC) decline, whereas concentrations of methane increase. Simultaneously, the residual DIC becomes enriched in ^{13}C, indicating that its depletion is caused by a process with strong isotope discrimination, such as microbial metabolism. In fact, if one assumes that autotrophic methanogenesis is the sole process affecting DIC, then the predicted stable isotope values match the measured values from the aquifers very closely (12). This suggests that microorganisms within these aquifers are carrying out primary production in situ. If the microbial community was producing methane from the degradation of detrital organic matter, then increases in methane concentration would be accompanied by increases in DIC from fermentation, rather than decreases, as observed (18). Furthermore, a rather wild coincidence would be required to achieve the close match between predicted and observed isotope values. Thus, field data from the CRB suggest that autotrophic methanogens carry out primary production through methanogenesis, and associated biomass production, from hydrogen and carbon dioxide.

The frequent observation of micromolar H_2 concentrations in the CRB suggests the ready availability of this electron donor, but provides few clues as to its origin. Unlike the case with methane, there does not appear to be a trend in H_2 concentration versus depth. The geochemical literature contains reports of widespread occurrences of significant H_2 in subsurface fluids [reviewed in references (12,19)]. A number of mechanisms for H_2 formation potentially exist in the subsurface [reviewed in reference (19)]. The possibility that reduced minerals in basalt react with water to produce H_2 was investigated in a series of laboratory experiments (12,19). (Such reactions are well known for ultramafic rocks, which are richer in ferrous silicate minerals than is basalt, and that produce H_2 during conversion to serpentinite during the weathering process(es) known as *serpentinization* (20).) In fact, reaction of CRB-basalt with water in the laboratory produced H_2 gas under anaerobic conditions. Experiments with different minerals present in basalt showed that the reactive components were the ferrous silicate minerals pyroxene and olivine. The production of H_2 was controlled by temperature, pH, and dissolved ferrous iron, and was inhibited in the presence of oxygen. Interestingly, H_2 production was also kinetically inhibited by product accumulation and could be enhanced by processes that remove H_2, such as microbial metabolism. Another group (21) reported inability to repeat these results at alkaline pH values, such as are found in CRB aquifers, using undescribed basalt samples from outside the CRB. This discrepancy may be caused by some compositional difference of the basalt samples, or perhaps more likely, failure to remove traces of O_2 from the experimental vessels.

The ability of microorganisms to take advantage of this reaction has been tested in vitro in a series of laboratory microcosms (T. O. Stevens and N. Landau submitted). Microbial growth, dissimilatory metal reduction, acetogenesis, and methanogenesis have been demonstrated in microcosms that contained only inorganic carbon and ground basalt as a source of energy. Consistent with the kinetic experiments with H_2 production, microcosms containing methanogens produced between 2- and 30-fold (depending on experimental conditions) more reduced gas than abiotic control microcosms.

In summary, the evidence suggests that the slow weathering of basalt minerals in deep confined aquifers results in the production of H_2 gas. Autotrophic microorganisms use the H_2 as an electron donor for reduction of carbon dioxide. In so doing, these organisms appear to carry out primary production in the deep subsurface with no link to biotic processes at the surface, and they may support the existence of subsurface ecosystems. These hypotheses might be tested by continued synergistic field studies and laboratory experiments.

At this time, relevant field data is rather sparse, because few measurements have been made specifically to test the hypotheses. Some tentative extrapolations can be made to compare laboratory results with existing field data, though a number of questionable assumptions are

required. If one assumes a single source of methane and steady-state production, then the rate of H_2 production observed in laboratory microcosms, when normalized for surface area, agrees remarkably well with the rate required to produce the highest methane concentrations observed in the CRB aquifers (19). However, transport of atmospheric carbon dioxide through groundwater recharge does not appear to provide enough DIC to support the observed methane. Dissolution of carbonates or volcanic outgassing (both present in the region, but not quantified) could potentially provide this missing DIC source. In fact, the putative CRB ecosystem may well be DIC-limited, rather than H_2-limited, which may explain the persistence of scattered but widespread micromolar concentrations of dissolved H_2. Extrapolating from the very few data available to estimate the wetted surface area in the CRB, and assuming probably unreasonable homogeneity through time and space, one can estimate that the complete reaction of ferrous minerals in a given volume of basalt would require between 10^8 and 10^{10} years. Although a more reliable estimate would require significant new data, this appears to be consistent with the accumulation of 5 to 10% alteration products over the 10^7 year age of the CRB.

SPECIAL CASE OR WIDESPREAD PHENOMENON?

If subsurface lithotrophic microbial ecosystems constitute a quantitatively significant phenomena in Earth's biosphere, it should not be confined to a special case or location, such as the CRB. From the present data, one might predict that this sort of primary production should occur in any environment that contains sufficient ferrous silicate minerals and isolation from atmospheric oxygen [reviewed in reference (1)]. An obvious environment to look for such phenomena is seafloor basalt formations, which cover 70% of the earth. Where these rocks are hot, near seafloor spreading centers, the process of serpentinization produces voluminous hydrogen and methane abiotically (22). As the rocks cool and move away from spreading centers, there appears to be great potential for microbial reactions similar to those observed in the CRB, however, very few observations have been made in these environments, other than weathering patterns that suggest the presence of subsurface microorganisms (23,24). Peridotites are assemblages of ultramafic rocks formed by eruption of mantle materials at spreading centers. They are richer in ferrous silicate minerals than basalts, and one might predict that they provide a much greater potential for microbial activity. However, we know of no investigations to test this hypothesis. Conversely, granites are much more silica-rich and lower in ferrous minerals than are basalts, and one might predict that microbial activity would be lower in such environments. However, biotic methane and significant concentrations of autotrophic microorganisms have been observed in some deep granitic environments (25,26). It may be that other mechanisms of H_2 production are active in those environments, or that H_2 is transported by groundwater flow from adjacent and intercalated ultramafic rocks that are often associated with granites. Many soils and sediments also contain ferrous silicate minerals, derived from mechanical weathering of igneous parent material. If these soils are anoxic, the weathering of these minerals should contribute H_2 to any microbial community that is present, though it may be masked by contributions from organic matter decomposition. Such a phenomenon might be difficult to measure, though some suggestive data can be found in the geochemical literature. For example, some strata of marine sediments in the Astoria Fan at the mouth of the Columbia River have been observed to contain anomalously isotopically heavy DIC, suggesting that autotrophic methanogenesis is prevalent (27). These strata are composed largely of detrital CRB basalt deposited during cataclysmic pliestocene-age floods (28). It seems likely that the same processes hypothesized for the CRB are occurring in these sediments.

SPECULATIONS ON A BROADER SIGNIFICANCE

The importance of potential subsurface primary production can be exemplified in the following rather speculative discussions.

Though Earth's current biosphere is largely supported by photosynthetic primary production, it seems possible that primary production linked to mineral weathering may have been proportionally more important early in Earth's history [reviewed in reference (4)]. Near the time of the origin of life, more than 3.8 billion years ago, the atmosphere is thought to have contained very little oxygen, and the crust would have been dominated by igneous rocks. Thus, ecosystems similar to extant ones in the CRB and other deep subsurface environments may have been active nearer to the surface, before the evolution of photosynthesis. However, ancient subsurface ecosystems may have also been important to the evolution of the biosphere. The early earth was subjected to repeated surface-sterilizing cosmic impacts (8), and subsurface ecosystems may have provided refugia from which the surface was periodically recolonized. Similarly, phenomena known as *snowball earth* events are thought to have periodically rendered the surface uninhabitable, and may have been more frequent early in Earth's history, when the luminosity of the sun was much lower. The ability of microorganisms to persist in the subsurface over geological time may potentially have been of great importance to the survival and evolution of the biosphere.

It has been suggested that chemolithoautotrophic microorganisms carrying out primary production in the subsurface may be the best prospect for potential life elsewhere in the solar system (2). Surface conditions on all of the other planets in our system are probably inimical to life. A commonly invoked litmus test for the ability of an environment to harbor life is the presence of liquid water. Only on Earth can liquid water exist at the surface. Thus, ecoystems based on photosynthetic primary production, which can only occur at the surface, are unlikely in extraterrestrial settings. However, in the subsurface, geothermal gradients and lithostatic pressures ensure that if water is present, at some depth it will be in a liquid state. Subsurface water is thought to be likely on Mars, Europa, and perhaps other icy moons.

Given a potential habitat, a source of energy would be required to sustain microorganisms in such a setting. Ferrous silicate minerals like those in terrestrial basalt aquifers are ubiquitous in the solar system. They are abundant on any planet with a rocky crust. It seems almost certain that there are extraterrestrial environments where ferrous silicate minerals are bathed in liquid water. Thus, it seems possible that if microorganisms ever existed on other planets, they could feasibly persist today in habitats analogous to the CRB aquifers. However, the mere presence of basalt and water are probably not enough to sustain subsurface ecosystems. Some mechanism for circulation and atmospheric exchange is probably necessary. In the absence of circulation, the system would come to equilibrium, and no energy would be available for microorganisms. Mechanisms for large-scale subsurface circulation on Mars have been proposed (29) but few data are currently available with which to evaluate them. Perhaps the subsurface of Europa is more conducive to energy flux, as suggested by current data. A possible ocean of subsurface water would certainly allow large-scale circulation, and evident circulation of surface ices could provide a steady flow of oxidants from the surface (30).

To evaluate these possibilities, much more information is needed about both extraterrestrial environments, and about the functioning of putative analogs on Earth.

CONCLUSION

Evidence from a number of locations suggests that anaerobic chemolithoautotrophic microorganisms play major roles in some deep subsurface ecosystems. The ability of these organisms to function as primary producers of organic matter depends on the availability of abiotically derived electron donors. Weathering reactions of igneous rocks potentially could provide such a source, through a variety of mechanisms. The large extent of the CRB and the relative isolation of aquifers within it from the surface biosphere make it an appropriate environment to study such interactions. In fact, microbiological and geochemical field observations, as well as laboratory tests of these hypotheses, have provided evidence that subsurface microorganisms may carry out primary production using energy from rock weathering. Further testing of the hypotheses may require an iterative sequence of field and laboratory investigations. If these hypotheses are correct, the phenomenon may be important in understanding the origin and evolution of Earth's biosphere, and potential biospheres elsewhere.

LUCIFERASE AND GREEN FLUORESCENT PROTEIN AS BIOREPORTERS IN MICROBIAL SYSTEMS

ROBERT J. PALMER, JR.

Lyngby, Denmark

A reporter signals to the investigator that a biological event of interest is taking place. Most typically, the event is a change in gene expression and the change is ordinarily an upregulation (increase in gene expression vs. control). Thus within a population or at the single-cell level, an increase in transcriptional rate can be discerned and factors governing the expression of specific genes can be investigated. Depending on the persistence of the signal, it is possible to assess temporal changes in gene expression rather than simply an on or off state. The perfect microbial reporter system should fulfill the following criteria:

1. detectable without expensive or complicated equipment,
2. rapid linear response to gene expression,
3. directly coupled to gene expression rather than coupled through intermediate compounds/events, and
4. stable on the order of minutes but unstable on the order of hours, thereby allowing downregulation (disappearance of signal) to be detected.

Many kinds of microbial reporter systems, other than the two described here, exist (1). Some, such as ice-nucleation genes, are specific to bacteria. Others, such as the enzymatic systems β-galactosidase (*lacZ*) and β-glucuronidase (*gus*), have had broad application to eukaryotes and to bacteria. This contribution will not discuss reporters as used in eukaryotic cell culture; it will focus instead on luciferase and green fluorescent protein (GFP) as reporters in bacteria and, to a lesser extent, in microeukaryotes (e.g., yeasts). Finally, biomedical literature has not been cited because this work targets readers from environmental microbiological fields.

LUCIFERASES

Luciferases are enzymes that produce light (bioluminescence) in eukaryotes and in prokaryotes. The ecological significance of bioluminescence is very high; light production results from a suite of diverse biochemical reactions. The luminescent organism must devote large amounts of metabolic resources (ATP, reducing power, and protein synthesis) to the production of light, and the parallel development of bioluminescence (frequently through unique metabolic pathways) in many different genera supports the notion that strong evolutionary selection for bioluminescence exists. The reader is referred to the review by Wilson and Hastings (2) as a starting point in this interesting saga of the unity of nature. In the present entry the difference between bioluminescence reactions will be emphasized.

In eukaryotes, bioluminescence involves what have been historically termed *luciferin-luciferase* complexes. Luciferases are enzymes directly responsible for light production; bacterial luciferases are analogous, but not homologous, to eukaryotic luciferases. Luciferins are specialized substrates upon which luciferases act. In prokaryotic systems, fatty aldehyde intermediates from natural biosynthetic pathways are equivalent to luciferins; in naturally bioluminescent bacteria, enzymes for the regeneration of these aldehydes are synthesized as part of the luciferase operon. In prokaryotes, the luciferase gene(s) are called *lux*; in eukaryotes, they are referred to as *luc*.

Eukaryotic Luciferases

Dinoflagellates. Bioluminescence of dinoflagellates, such as *Gonyaulax*, is not well understood. The luciferin, a linear tetrapyrrole (3), is very different from other eukaryotic luciferins and it is not clear how this molecule is oxidized by the 137-kDa luciferase, both of which are contained in a special organelle, the scintillon (4). This compartment may be necessary to keep the luciferin, which is quite easily chemooxidized, in a state enzymatically compatible with the luciferase. These luciferin-luciferase complexes are thus not easily employed as bioreporters.

Coelenterates. The sea pansy *Renilla* is the organism in which coelenterate bioluminescence has been most extensively described (5). Here, and in other coelenterates, the luciferin is named *coelenterazine* (6). This polycyclic imidazole is, in the absence of calcium, bound to the luciferin-binding protein (LBP). When the concentration of free intracellular Ca^{++} rises, coelenterazine is released from the LBP and is oxidized by the *Renilla* luciferase (a 35-kDa protein) through an intermediate to coelenteramide. This oxidized (excited) molecule can emit a blue photon (480 nm) in vitro. However, in vivo, the photon is immediately captured by an accessory protein (one of several GFPs), which in turn emits green light (509 nm). The photoprotein aequorin is a stable complex of the luciferase and an oxidized coelenterazine that, in the presence of Ca^{++}, finishes the bioluminescent reaction to yield the photon. Because the reaction is Ca^{++}-dependent, aequorin has been used as a Ca^{++} reporter. In prokaryotic systems, it has been used as a probe for free Ca^{++} (7–9), to correlate putative Ca-binding proteins with Ca^{++} levels in cells (10) and to investigate Ca^{++} transients in chemotaxis (11). These authors, for the most part, recognize that their population-based measurements do not preclude the possibility that very different levels of Ca^{++} exist between

individual cells (see "Signal Detection" in the following text).

The *Renilla* luciferase component alone has been expressed as a reporter in yeast (12), and the luciferase has been expressed (but not used as a reporter) in bacteria (13). It should also be emphasized at this juncture that without the sometimes esoteric research on coelenterate bioluminescence, modern biology would not have its most exciting bioreporter, GFP. This photoprotein, best known from the bioluminescent jellyfish *Aequorea victoria*, emits green light when excited by blue light and is discussed in the latter part of this contribution.

Insects. As in coelenterates, bioluminescence in insects follows a general scheme but species-dependent variation exists, primarily in the wavelength of emitted light. Insect luciferins are assumed to be quite similar to the model molecule known from fireflies because all insect luciferases will function using firefly luciferin as a substrate (14). The luciferin, which is strikingly different from that evolved in coelenterates, is acted upon by a 62-kDa luciferase which, in turn, is very similar in organisms in the same family. The luciferase reacts with ATP and luciferin in an Mg^{++}-dependent reaction to yield the excited (oxidized) luciferin that then decays to produce a photon. The structure of the catalytic site in the luciferase is thought to regulate the wavelength of emitted light (species-dependent, from green to red) (15).

Insect *luc* genes from various sources have been expressed and produce light in many different bacteria, Gram-positive and Gram-negative. The general strategy is to have the bacterium express the *luc* gene and to supply luciferin, ATP, and Mg^{++} exogenously. *Bacillus subtilis* was used to express functional firefly and click beetle luciferases from a *lacZ* promoter (16) and click beetle *luc* was functionally expressed in *Streptococcus mutans* to yield a strain that was used in a rapid assay of antibiotic sensitivity (17). *Pseudomonas putida*, *Rhizobacterium meliloti*, *Agrobacterium tumefaciens*, and *Alcaligenes faecalis* have also been used to express functional click beetle *luc* from isopropyl β-D-thiogalactoside (IPTG)-inducible plasmid constructs (18). The ability to differentiate colonies that expressed in different wavelengths has been shown (19), and such work demonstrates the potential for environmentally or physiologically relevant use in a wide variety of microbial systems. Especially intriguing is the possibility of spectrally distinct sensing of multiple reporter systems.

Prokaryotic Luciferases

Heterodimers of ~40 kDa and ~35 kDa (α- and β-subunits, respectively; the products of the *luxA* and *luxB* genes) (20) bacterial luciferases catalyze the oxidation of a long-chain (fatty) aldehyde and reduced flavin mononucleotide ($FMNH_2$) through several intermediates (some known, some postulated) to the eventual release of a photon of blue light (about 490 nm). When comparing this reaction to the analogous situation in eukaryotes, the fatty aldehyde is analogous to luciferin.

Two general strategies exist for the use of *lux* products as bioreporters. The most common approach is to link the synthesis of a *luxAB* cassette to the promoter of interest. In this case, a fatty aldehyde (normally *n*-decanal) is usually provided externally to eliminate any possibility that the bioluminescence reaction is limited by fatty acid turnover in the cells. The second strategy is to link the entire *luxCDABE* cassette to the promoter. The reporting organism then synthesizes not only the luciferase enzyme subunits (products of *luxA* and *luxB*) but also enzymes necessary for the recycling of the fatty acid substrate (a reductase, a transferase, and a synthetase; products of *luxC*, *luxD* and *luxE*, respectively; the components of the fatty acid reductase complex) (20). Thus this approach relieves problems associated with limitation by intracellular fatty acid pools.

Signal Detection

For work with microorganisms, one must distinguish between population-based measurements (an average of signals measured from many cells simultaneously) or single-cell measurements (signal from individual cells within a population). Population measurements are generally incorporated into experiments as the single variable being measured. In contrast, single-cell measurements are most frequently done through a microscope with a camera and thus lend themselves to the simultaneous application of different microscope-based approaches (correlative microscopy) (21,22).

Light can be detected in myriad ways that distinguish themselves primarily by sensitivity. Film (photographic or X-ray) can be used; this approach is not very rapid and requires a relatively large photon flux such as obtained from a population of highly expressing cells. Spatial resolution depends on the proximity of the film to the emission source and is not high enough to detect light from single microbial cells.

Luminometers (similar in design to scintillation counters but less sensitive and therefore less costly) are the most commonly used measurement tool in luciferase detection. These devices can be quite sensitive, are inherently quantitative, and are becoming very flexible in design (23), but they lack spatial resolution on the scale necessary for single-cell microbial work.

Enhanced charge-coupled device (CCD) cameras are a good compromise between sensitivity and the ability to resolve the origin of light in two dimensions. Under proper conditions, they are as sensitive as luminometers, and they produce an image showing the origination points of the light. Quantification of the amount of light emitted is more difficult, primarily because of the potential range of emission that must be measured (from essentially zero through several orders of magnitude). This problem has been addressed by the development of "photon-counting" cameras: devices more sensitive than luminometers that use computer-assisted approaches to determine relative photon fluxes at various light origins within the image (24). Figures 1 and 2 demonstrate major advantages over most commonly used reporters afforded by the use of luciferase and a photon-counting camera: spatial discrimination in monitoring (Fig. 1 and Fig. 2a) and the ability to monitor downregulation of a gene (Fig. 2b).

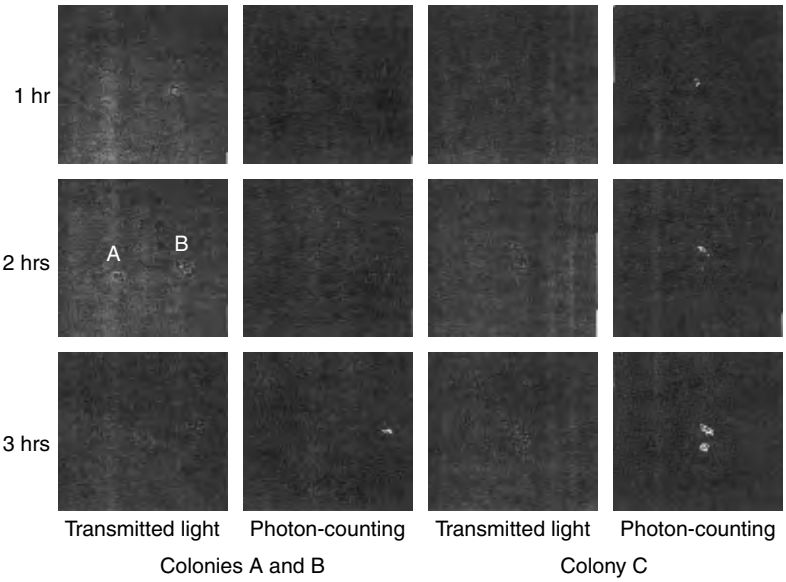

Figure 1. Spatiotemporally resolved monitoring of toluene metabolism in genetically engineered *Psuedomonas putida* cells growing in a biofilm. Transmitted light images and photon-counting images (light production) of colonies in which a chromosomally integrated fusion between the toluene-degradation gene and luciferase (*tod-lux*) responds to the presence of toluene introduced at time zero. Three colonies were monitored over the course of three hours. The columns at the left show limited growth in two colonies (transmitted light images) and no induction (light production) from colony A, whereas colony B shows increased light emission over the three-hour monitoring period. The two right columns show marked growth and high light production from a third colony in the same experiment. This colony shows two distinct centers of light production (photon-counting image at three hours). The pseudocolor scale in the photon-counting images shows low light production in black and blue, with high light production in green through red/yellow.

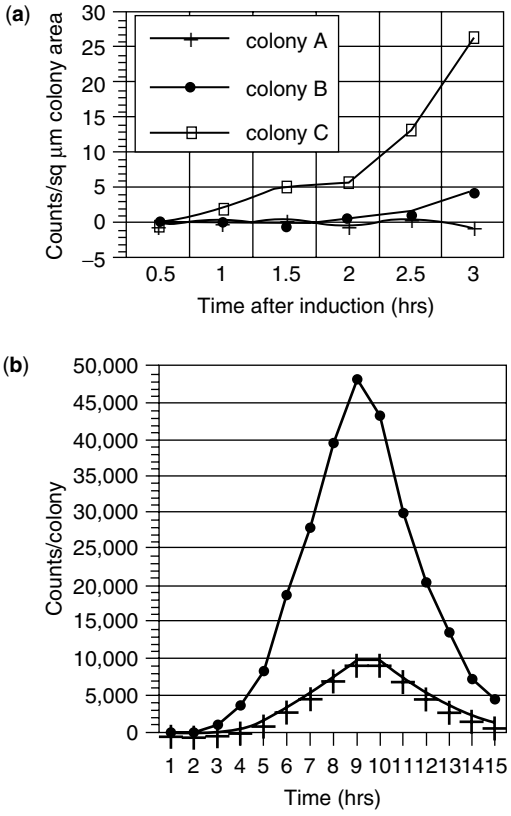

Figure 2. Quantitative interpretation of photon-counting images. (**a**) Light emission normalized to colony area for the three colonies shown in Fig. 1. (**b**) Real-time, nondestructive monitoring of up- and downregulation in two mircrocolonies of the same *tod*/*lux* reporter strain shown in Fig. 1. Light production increases from time zero (introduction of toluene). Toluene was removed after six hours of induction; light production continued to increase until nine hours, and dropped over the following six hours to preinduction levels. These data demonstrate a lag of about three hours in the response of this reporter system and show the utility of luciferase-based reporter strains as real-time biosensors.

The most sensitive detection is afforded by scintillation counters but microbiologically relevant spatial discrimination is not possible. As a result of the increasing application of these instruments for high-throughput luminescence detection, designs that incorporate the ability to read light production from individual wells within standard-format microtiter plates are available; approaches to the elimination of cross-talk between wells distinguish the instruments from one another.

Luciferase Reporters in Practice

In addition to the applications already noted, reporter systems have been applied to environmentally relevant situations, particularly to the sensing of toxins and pollutants. From a methodological standpoint, some controversy exists in the literature about the "proper" use of bioluminescence systems. Firstly, there is little consensus on the potential effects of naturally occurring variation in the myriad environmental factors known to alter bioluminescence (e.g., iron availability and oxygen concentration), on bioavailability of certain target molecules such as heavy metals, and even in the manner in which reagents are introduced in an assay (25). However, such issues seem more critical to the detailed interpretation of results than to the ability of the reporter to function when the target molecule is present. Secondly, reporters frequently respond to a suite of closely related chemicals resulting in synergistic effects when several of these effector molecules are present (26); however, in certain applications this may be advantageous. Thirdly, some assays are clearly not relevant to in situ environmental applications because they require cell lysis (27) and therefore are not capable of providing repeated measurements.

Despite these very real problems, the application of luminescence-based biosensors is on the horizon. A vast majority of work has been conducted under laboratory conditions; successful field applications of these systems remain sparse and are limited to the demonstration

of efficacy in online monitoring and process-control applications (28) and for use in mechanistic studies of bacterial contamination (29). It is also clear that reporter systems are very valuable in laboratory-based toxicity assays (30). *Luc*- and *lux*-based systems have both demonstrated potential as environmental sensors. Firefly luciferase has been expressed from a promoter of mercury resistance in bacteria to detect Hg and arsenate in environmental samples ex situ (31). The *luxAB* system and the *luxCDABE* system have been used to detect alkanes and benzene, toluene, ethylbenzene, xylene (BTEX) in ex situ samples (32,33). One example of true in situ monitoring using *lux*-based reporters is that of polyaromatic hydrocarbon (PAH) degradation in soil (34). Large (4-m deep × 2.5-m diameter) pipes were filled with PAH-contaminated soil that contained the reporter strain (*Pseudomonas fluorescens* HK44–harboring plasmid with the *luxCDABE* cassette linked to the naphthalene degradation pathway). Over a two-year period, light production of the reporter strain on soil particles was directly monitored (using a photomultiplier tube inserted into tubes in the soil), and the reduction in vapor-phase PAH levels in the soil was monitored using biosensors (the same reporter strain encapsulated in alginate) lowered into the tubes. This project not only demonstrates the utility of reporters for in situ work but also points out some of the difficulties experienced when moving from the laboratory to the field. One offshoot of this long-term field-release experiment was the development of a *lux*-based MPN assay (35) that demonstrated the presence of the plasmid-containing reporter strain over a significant background of endogenous antibiotic-resistant bacteria; the only alternative to the MPN determination was a more complicated hybridization–plating assay (34). Much effort in in situ detection studies has revolved around the development of a probe that would house immobilized whole-cell bacterial biosensors. Initially, fiber-optic-based designs were prevalent (34,36), but with the rapid development in miniaturized optoelectronics, bacterial cells and all electronic circuitry necessary to perform light measurement can be housed on a 4-mm^2 chip (37).

GREEN FLUORESCENT PROTEIN

Green fluorescent protein (GFP) is a nontoxic 238-amino acid peptide synthesized by the jellyfish *Aequorea victoria* (38,39) that emits green light at 509 nm when excited with light of 385 to 480 nm. After synthesis the protein folds and, via an autocatalytic process, three amino acid residues are modified to form intramolecular covalent cross-links (40). The protein requires only a low concentration of oxygen for maturation, and no other external factor, making it an excellent candidate as a marker in environmental microbiology (41,42). GFP was isolated in the early sixties (38) and purified a decade later (43) but was not used as a molecular marker until Chalfie and collaborators cloned it in 1994 (44). Since then, GFP has become the marker of choice for almost any biological application.

GFP Properties and Variants

Wild-type GFP has been extensively studied and characterized since Shimomura and coworkers first isolated the protein from crude jellyfish protein extracts (38). The minute amount of purified protein limited the investigation, and the detailed information available today is derived mainly from recombinant protein studies. GFP is a monomeric protein of 238 amino acids (27 kDa) with dual excitation peaks, the major peak at 395 nm and a minor peak at 470 nm. Emission is maximum at 509 nm, with a shoulder at 540 nm (38,45). This means that long-wave ultra violet (UV) light is required for efficient excitation, although blue light does excite the protein to a lesser extent. The wild-type protein has a maturation time of several hours, which makes it less interesting for gene-expression studies (41). Soon after the cloned gene was publicly available, the hunt for optimized variants commenced. One of the first useful variants described was the S65T mutant (41); the name indicates the nature of the mutation, which is a single amino acid replacement of serine 65 to a threonine residue. S65T is "red-shifted": the excitation peak is shifted toward the red end of the spectrum. S65T is still excited by blue light (488 nm) but not by long-wave UV light, whereas the emission is largely unaltered at 507 nm. Excitation with 488-nm blue light is relatively harmless for living cells when compared with the UV light required for efficient wild-type GFP emission. Furthermore, S65T has a somewhat shorter maturation time compared to that of the wild-type protein. Further refinements to the protein structure have been carried out. One of the most useful enhancements was made by Cormack and coworkers (46) who used flow cytometer–assisted cell sorting (FACS) for selection of mutants. They produced the mut1–3 mutants that are red-shifted and have significantly shorter maturation times compared to the wild type. Although the wild type takes two hours for folding of 50% of a protein pool, mut1–3 mutants have T1/2 of less than 30 minutes. Furthermore, mut1–3 mutants are brighter, that is, they have a higher quantum yield than wild-type GFP. A number of mutants with altered emission spectra have also been engineered, notably the BFP (47,48), CFP (49) and YFP (50), which emit blue, cyan, and yellow-green light, respectively. The BFP requires UV for excitation (380 nm) and emits blue fluorescence at 440 nm, whereas CFP is excited by 433 nm and 453-nm light and fluoresces at 475 and 501 nm. The YFP is excited by green light (513 nm) and emits light at 527 nm. Other physico-chemical properties of these variants are typically a higher quantum yield and shorter maturation times. For use in eukaryotic systems, codon-optimized variants that enhance translation efficiency have been engineered (Clontech, Palo Alto), but for prokaryotic systems the jellyfish codon usage works quite well. Codon-optimized mutants have been designed (e.g., for use in *Escherichia coli*), but the effects of these enhancements appear marginal (F. G. Hansen, personal communication). One last class of mutants, destabilized GFPs, deserves mention. The wild-type protein is very stable after maturation and remains intact in the cells for several days after synthesis. This obviously makes the

protein less useful for dynamic studies. Two types of destabilized proteins have been designed for use in eukaryotic or prokaryotic cells. The eukaryotic system is constructed by fusing a part of the mouse ornithine decarboxylase to the C-terminal end of the GFP protein. The tag contains a so-called PEST domain that is the target for indigenous protein degradation in higher organisms (51). In the prokaryotic setting the protein is destabilized by adding a short oligopeptide (from 3 to 10 amino acids) containing a target sequence for the ClpX protease (52). In both systems the unstable GFP-variant protein is degraded relatively rapidly, making dynamic investigations possible.

Tools for Investigating Cells Transformed with GFP

The main advantage of GFP is its visual nature, which makes it ideal for microscopic observation. Quantitative measurements of the protein are still somewhat complicated but have been achieved in a few cases. The following applications have especially benefited from the marker: epifluorescence microscopy, FACS/flow cytometry, confocal microscopy and, to a lesser extent, fluorometry.

Fluorescence microscopy of red-shifted GFP variants uses filters and light sources very similar to those needed for the observation of fluorescein-labeled specimens, but for other color variants different combinations are required. Wild-type GFP can be observed using fluorescein filter sets but fluorescence is not optimal because only the secondary excitation peak is used. Similarly, fluorescein filters can be used for flow cytometry or FACS. Using FACS machines it is possible to select mutants with higher GFP signals, for example, for selecting regulatory mutants in shotgun cloning experiments. As already mentioned, FACS was used to select some of the most frequently used GFP variants, the mut1–3 (46). These mutants were selected for higher intensity compared to the wild-type GFP. Although mercury lamps have been used as light sources in flow cytometry, a more useful configuration includes a laser light source, for example, the Argon laser line at 488 nm, which nearly coincides with the secondary excitation peak of wild-type GFP and the excitation peak of most red-shifted mutants.

The confocal microscope has been the tool of choice for investigating GFP-tagged cells. The confocal scanning laser microscope (CSLM) enables the researcher to make three-dimensional representations of thick specimens. A thorough description of the confocal microscope falls outside the scope of this chapter; details can be found in the Handbook of Biological Confocal Microscopy (53). In short, confocal microscopy is based on a conventional epifluorescence microscope, with a modification in the light path. A small pinhole is located at the focal point of a defined image plane, which allows only light from that single plane to pass. Light from planes above or below this image plane will have focal points accordingly in front of or behind the pinhole, with the result that most of the signal from these planes will not pass the aperture. In practice this means that it is possible to virtually slice the sample simply by moving the sample stage up or down and record images from the different positions. Subsequently, the slices can be combined in a computer, generating three-dimensional representations of the sample. This technique is only useful for samples of a certain size as the physical constraints on optical microscopy also apply to confocal microscopy. Single bacteria are so small that they will mainly be detected in single planes, which means that a standard microscope in many cases would be just as useful. However, for intracellular localization in large cells (eukaryotic systems) or in aggregates of cells (e.g., bacterial biofilms) or host interactions (e.g., bacterial infections), the confocal microscope is invaluable in determining the precise location of fluorescent objects. Quantitative measurements of GFP have been done using fluorometers, but several problems with this approach exist. Protein folding is not immediate or always complete, and the protein tends to precipitate to some extent. It is consequently difficult to make absolute quantitative measurements; however, it is possible to measure relative responses.

Applications of GFP

The first report on recombinant GFP expression in microorganisms was that of Chalfie and coworkers (44). They cloned the gene from the jellyfish and expressed it in *E. coli* and in the nematode *Caenorhabditis elegans*. In the bacterial system they inserted the wild-type *gfp* gene after the T7 phage promoter, and achieved green fluorescent cells. There were no other additional components than those required for expression from the T7 promoter. The excitation and emission spectra were virtually identical to those derived from the purified jellyfish protein. This work caused a revolution in the molecular biology community: since 1994, more than 3,300 scientific papers have been published that employ GFP (Science Citation Index). In the spring of 1995 the first international conference devoted to this protein was held in Palo Alto, California, and the proceedings reported initial applications of GFP in biology other than just making cells green (54). GFP is expressed efficiently in almost any bacterium, Gram-positive or Gram-negative. In higher organisms, wild-type GFP has been expressed but variants with improved codon usage which give higher efficiency of expression have been constructed.

E. coli was the first bacterium to be transformed with *gfp*, and since Chalfie's report in 1994 (44), several papers which focus on *E. coli* physiology investigated using GFP tools have been published. Numerous areas have been investigated, for example, physiological state, gene transfer, intercellular localization, identity/identification in multispecies communities, among many others. Most often, the *gfp* gene is fused to an inducible promoter such as the *lac* promoter or the T7 promoter. These promoters are often chosen for convenience of construction and because they can result in high amounts of protein. Several other prokaryotes have been used in addition to *E. coli*. The species used range from Gram-negative *Salmonella* spp. through pseudomonads to Gram-positive lactobacilli and *Bacillus* spp. Here only a few examples of the use of GFP in bacteria in environmental microbiology will be given. More comprehensive lists can be found in studies conducted by Valdivia and coworkers (55) and Errampalli and coworkers (56).

Examples of GFP as a Molecular Marker in Environmental Microbiology

Burlage and coworkers (57) were the first to use GFP in bacteria for environmental monitoring. They followed the transport of GFP-tagged *Pseudomonas* cells in a sand column. They used a Tn5 transposon to label the cells by the insertion of an expression cassette into the host chromosome. Christensen and coworkers (58,59) also used *Pseudomonas* cells to demonstrate gene-transfer events. In these experiments, a conjugative plasmid, the TOL plasmid, was labeled with the *gfp* gene fused to a repressible promoter. The donor cells also expressed the repressor protein; only when the plasmid entered repressor-free recipient cells was GFP synthesized. Tombolini and coworkers (60) labeled *Pseudomonas putida* with a Tn5 cassette containing the *gfp* gene fused to a constitutive *psb* promoter. Using this strain, GFP signal was detectable in the root hairs of *Lotus japonicus* seedlings inoculated with the *Pseudomonas* strain. *Pseudomonas* cells transformed with a stabilized plasmid-encoding GFP was used for experimental environmental monitoring in a mixed population together with unlabeled *Burkholderia* cells (61). This way it was possible to detect the presence and relative position of labeled cells in binary community. The same *Pseudomonas* strain was used for the inoculation of tomato seedlings and subsequent tracking of the cells on developing roots (61). Webb and coworkers demonstrated the utility of GFP expression in the Gram-positive *Bacillus subtilis* (62). They fused *gfp* to a spore coat protein gene, *cotE*, and demonstrated that it was possible to precisely determine the intracellular localization of the compound protein. It was also possible to show fore-spore- or mother cell–specific gene expression using promoters under the control of the sigma factor σF, a sporulation-specific transcription factor, driving GFP expression. Other Gram-positive bacteria successfully transformed with *gfp* include *Lactococcus lactis*, *Streptococcus gordonii*, and *Streptococcus bovis* (42,63). The marine bacteria *Vibrio* spp. and *Psychrobacter* spp. were tagged with GFP expressed from either a *lac* or an *npt-2* promoter by Stretton and coworkers (64). A third marine species, *Pseudoalteromonas* S91, did not show any green fluorescence when using either promoter. To achieve a fluorescence signal from this strain, the group used a promoter-probe transposon with a promoter-less *gfp* gene. This way a number of green fluorescent mutants were isolated and it was possible to identify a chitinase-negative mutant, in which the *chi* promoter was fused to the *gfp* gene, which was inducible by *N*′-acteylglucosamine (64). When the mutant cells were grown in biofilms it was found that GFP expression in mutant cells was associated with the proximal presence of a natural chitin substratum. This may be one of the first reports of determination of localized gene expression in biofilms.

Biofilm research constitutes a separate field in which GFP has proven very useful. Initially, experiments attempted simply to demonstrate the feasibility of using GFP in a living biofilm. Simple tagging to follow one species in a complex environment is still one of the prominent uses of GFP. Eberl and coworkers (65) showed an example of cell-tracking in a simple activated sewage sludge model system. They combined GFP-labeling of one particular species (*Pseudomonas putida* KT2,442) with analysis using oligonucleotide chromosomal rRNA-targeted probing. The use of GFP facilitated online tracking of a strain inoculated in a complex community, whereas subsequent fixation and probing with rDNA oligonucleotide probes made it possible to map the entire sample to establish the spatial relationship (community structure) between species. Similar tagging was used in a study of cell adhesion to activated sludge particles (66). Skillmann and coworkers (67,68) tracked tagged individual species (*Enterobacter agglomerans*) in mixed species biofilms. In these studies GFP fluorescence measurements were additionally used to quantify adhesion efficiency in an in vitro assay.

Møller and coworkers (69) used promoter fusions in model biofilm experiments to demonstrate conditional expression of catabolic pathway genes in a binary model biofilm, consisting of *Pseudomonas putida* R1 and an *Acinetobacter* sp., both capable of using benzyl alcohol as sole carbon source. They showed that commensal behavior occurs and can be measured in an intact microenvironment. When the *Pseudomonas* strain was colonizing a substratum alone the Pm promoter (responding to the presence of benzoate) was not induced on a benzyl alcohol substrate, probably because the amounts of benzoate were rapidly degraded by the strain and consequently kept at very low concentrations. Benzyl alcohol is degraded to catechol via a degradation pathway that has benzoate as an intermediate. When both strains cocolonized the substratum, Pm activity could be detected (as green fluorescence derived from the Pm-GFP cassette). The explanation offered was that *Acinetobacter* was leaking benzoate to the environment owing to a less-efficient degradation of benzoate, and *P. putida* R1 was able to use this (indicated by Pm activity). In a recent study the general physiological status of individual biofilm cells was assessed using an unstable variant of GFP (70). Using a fusion between the ribosomal RNA synthesis promoter P1 from the *E. coli* rrnB operon fused to a variant *gfp* gene, encoding a GFP protein with a half-life of 30 minutes (in batch growth experiments (52)), GFP fluorescence indicated active ribosome synthesis. The P1 promoter is growth phase–regulated, and synthesis of ribosomes occurs only in actively growing cells. Immediately before entering the stationary phase, ribosome synthesis stops. Because the GFP variant has a relatively short half-life, that is, persists only briefly after synthesis has ceased, green fluorescence could be correlated directly to cell proliferation. In the study by Sternberg and coworkers (70) it was demonstrated that cells in biofilms after a period of establishment will stop to proliferate, or do so at a relatively low rate. The same expression cassette was used by Ramos and coworkers (71) to demonstrate spatial and temporal heterogeneity of physiological activities of individual *P. putida* cells colonizing barley seedlings at the single-cell or community level.

RED FLUORESCENT PROTEIN

Recently, the red fluorescent protein (RFP) from the coral *Discosoma* sp. has been cloned (72) and made

commercially available (Clontech, Palo Alto, California). The protein has very different spectral properties than does GFP : RFP has an excitation maximum of 558 nm and an emission maximum of 583 nm. GFP variants have the drawback of spectral overlap; multiple labels based on GFP variants are difficult to differentiate. RFP, on the other hand, has a spectrum that is sufficiently different from GFP to allow easy differentiation of GFP and RFP labels in the same sample. Also, Fradkov and coworkers recently reported a gene-shuffling experiment of RFP from two different subspecies of the Discosoma coral, resulting in a red-shifted RFP with an emission maximum of 616 nm (73) which suggests that the development of spectral variants of RFP may provide a suite of different proteins just as was the case for GFP. However, RFP currently has some serious drawbacks when compared to GFP. A long maturation time and a relatively low fluorescence yield are two major factors that seem to have prevented RFP from having the same immediate application as did GFP. In *Pseudomonas aeruginosa* cells, RFP fluorescence seems to be inversely correlated to growth rate, and fluorescence is easily seen only in cells in late log or stationary phase (74). This appears to reduce the usefulness of RFP in studies of changing gene expression. The problem of low fluorescence (an unfortunate combination of low extinction coefficient and low quantum yield) can be somewhat compensated by enhancing expression efficiency (e.g., through the use of an efficient promoter). Despite these problems, RFP (alone or used in combination with other labels) is well suited as a positional marker for in vivo labeling of cells in a complex community. For example, double labels were used to show that two isogenic bacterial strains (carrying either RFP or GFP) mix very little during biofilm formation (Fig. 3) (74). Similarly, RFP-labeled cells were visualized together with GFP- and GFP-variant-labeled cells during rhizosphere colonization of tomato seedlings (75); three different populations of bacteria were differentiated.

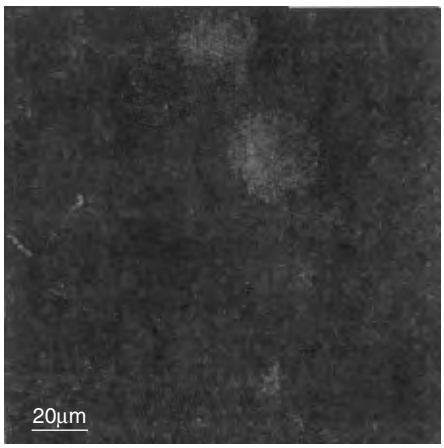

Figure 3. *Pseudomonas* sp. B13 was transformed with either GFP or RFP (chromosomal integration of the fluorescent protein gene under control of a strong promoter), and the fluorescently labeled cells were inoculated simultaneously into an in vitro biofilm growth system. This confocal micrograph shows the biofilm after five days of development. Note that the two bacterial types present in the inoculum, although isogenic except for the respective fluorescent protein gene, tend not to mix within the colonies.

CONCLUSION

Luciferases have a longer history of use than do fluorescent proteins and, although they are not simple to use, the potential rewards (real-time nondestructive data of up- and downregulation) of careful luciferase usage are great. Many problems exist in adapting luciferase-based laboratory assays for use "in the field," but the problems are no greater than those associated with any other switch from the laboratory bench to the factory. The future for luciferases is bright; the development and application of spectral variants will lead to the ability to monitor several genes simultaneously, and the push toward more sensitive detection and ultramicro (single-cell, single-chip) biosensors will assure a role for luciferases in real-world applications.

Fluorescent proteins are relatively new and extremely valuable components in the molecular microbiologist's toolbox. As with luciferases, GFP labels make nondestructive real-time monitoring of bacterial processes possible, but fluorescent protein synthesis and signal production seem to be less affected by cellular metabolic processes or extracellular conditions than for luciferases. Previous approaches to gene-expression monitoring normally required destructive (or at least system-disturbing) procedures. Currently, through the application of luciferases and GFP, the intricate three-dimensional structures of complex microbial communities can be preserved while changes in gene expression can be monitored at the level of the single cell. Although some of these proteins are suitable for only very general studies, others have been highly optimized and customized to create specialized and more informative tools. GFP has been modified with respect to spectral range, stability and maturation times to accommodate a very wide range of applications, and the recently cloned RFP is similarly under intense investigation with the aim of creating a suite of proteins similar to GFP derivatives. The number of research programs in which fluorescent proteins and luciferases play a crucial role underscores the vast impact of these small molecules on biology in general and on microbiology in particular. The impact will probably increase, and these proteins will come to be recognized as the "β-galactosidases of the 90s" and beyond.

LYME BORRELIOSIS

GUY BARANTON
Institut Pasteur
Paris, France

DEFINITION

Lyme borreliosis is a zoonosis transmitted by ticks belonging to the *Ixodes* genus (1). The infection is usually subclinical in wild animals. If accidentally transmitted to man, it leads to a two-step disease (2). The first step, an enlarging cutaneous reddish spot, *Erythema migrans* (EM), usually disappears after treatment or even spontaneously. The second step, which may occur alone, is a polymorphic and polysystemic chronic disease (2).

The disease is spread over temperature areas of the four continents in the Northern hemisphere. Although some symptoms have been known from the beginning of the twentieth century, the complete disease has been described after the discovery and first isolation in the United States in 1982 of its causal agent, a spirochete called *Borrelia burgdorferi* (3).

HISTORY

The first cutaneous symptom to have been described, now associated with Lyme borreliosis, is Acrodermatitis Chronicum Atrophicans (ACA), also called *Pick Herxheimer disease*, an extensive skin atrophy that predominates in the extremities (4). In 1910, the Swedish physician, Arvid Afzelius, published the description of the disease hallmark *Erythema migrans*, which followed a tick bite (5). Finally a third symptom has been described named *Lymphadenosis Benigna Cutis* (LBC) or pseudo lymphoma, an inflammatory nodule consecutive to a tick bite (6). Neurological symptoms were shown to accompany EM (7), LBC (8), and ACA (9). Human-to-human experimental transmission has been described by German physicians considering EM (10), ACA (11), and LBC (12). Penicillin was shown to be active on ACA (13), LBC (14), and ECM (15). In the 1950s, it was known that these three cutaneous symptoms were due to the transmission of a bacterium by a tick. Their unification in a single disease was discussed. However, decisive progress was made in the United States when Steere first described Lyme arthritis following EM cutaneous lesion (16). This evolutionary form has only been recently and infrequently reported in Europe, considering ACA (17) and EM (18). The second and definitive arguments were the association of a spirochete to Lyme disease and its isolation (19) from a tick. Such a spirochetal etiology had only been hypothesized in Europe (7,20) before its confirmation (21).

Following the isolation of the bacterium, serologic tests were made possible (1) and allowed Steere to describe in 1982 (22) the whole disease, which was further shown to include LBC and ACA (21). The spirochete responsible for Lyme borreliosis has been called *B. burgdorferi* (3).

BACTERIOLOGY

Taxonomy

An initial study by whole DNA/DNA hybridization, the golden standard in bacterial taxonomy (23), showed that three isolates:

1. B31 from a North American *Ixodes dammini* (now *scapularis*)
2. 297 in a patient's cerebrospinal fluid, and
3. IRS, a European *Ixodes ricinus*, belonged to a unique species (3). This species was unrelated to *Leptospira* genus, loosely associated with *Treponema*, but closely associated with *Borrelia* responsible for relapsing fever, although they constitute a separate and new species called *B. burgdorferi* (*B.b.*) (3).

A second study confirmed the uniqueness of Lyme disease–associated *Borrelia*. However, 9 out of the 10 isolates included in this further study were from North America and the European one was IRS isolate (24).

When considering electrophoretic profiles of many isolates from different origins, it was clear that a large polymorphism among European isolates contrasted with a relative monomorphism of North American ones (25). When considering human isolates, a certain level of homogeneity among European isolates was restored when these isolates were classified according to the tissue from which they had been isolated (25).

Similarly, when isolates from different origins were characterized by distinct molecular typing methods, they usually led to three main groups and several minor ones. It was the case for ribotyping (26,27), *RFLP* Restriction Fragments Length Polymorphism (28), *APPCR* Arbitrarily Primed PCR (29), *PFGE* Pulsed Field Gel Electrophoresis (30), and conformational polymorphic PCR (31).

Further studies by whole DNA/DNA hybridization, including isolates from the main three groups and several minor ones (32–42), led to the delineation and official naming of 10 species. Three of these, *B. burgdorferi* sensu stricto (*B.b.s.s.*), *B. garinii* (*B.g.*), and *B. afzelii* (*B.a.*), include all the isolates that have been isolated from patients (36,42). The other minor species were therefore considered nonpathogenic for humans.

It was later shown that pathogenic isolates from a given species lead to a particular evolutionary clinical presentation. Serology (43,44) and PCR identification (45) lead to these correlations between the species and the clinical presentation, although some authors disagree on the elective role of *B.b.s.s.* in arthritis (46). Indeed, the geographic predominance of a given *Borrelia* species could be correlated with the corresponding preferential organotropism locally prominent. The whole group of *Borrelia* transmitted by hard ticks (*Ixodes*) is called *B. burgdorferi* sensu lato (*B.b.s.l.*).

Morphology

Borrelia have all the features characteristic of the spirochetes (47). Compared with leptospires, *Borrelia* helicoidal cells are larger (10–20 μm) and thicker (0.2 μm). Their spires also are larger and looser. However, they also can pass through 0.45 and 0.22-μm filters.

The mobility of *Borrelia*, due to endoflagella localized in the periplasmic compartment, is a combination of translation, traction, torsion, and screwlike movements. The flexibility of the cell and the fluidity of the outer membrane are spirochetal characteristics.

Frequently, the envelope separates from the protoplasmic cylinder, leading to blebs. This process occurs in adverse conditions and is common to spirochetes. It may even lead to spherical corpuscles of small size, formed by the envelope in which the spirochete body is tightly coiled. The adverse conditions differ among spirochetes — hypertonic conditions for *Leptospira* and hypotonic ones for both *Borrelia* and *Treponema*.

Chemical Composition

Structure and chemical composition are quite homogeneous among the three pathogenic genera of spirochetes. However, there are some striking differences:

- The outer membrane is as usual composed with protein and lipids but, in opposition to *Leptospira*, *Treponema*, and *Borrelia*, do not possess lipopolysaccharides (48). Unlike *Treponema*, *Borrelia* exhibit many proteins and mainly lipoproteins at the surface of their outer membrane. Many of these have been extensively studied and will be detailed later.
- The cell wall (separated from the outer membrane by the periplasmic compartment) is constituted by the peptidoglycan that contains muramic acid and ornithine as amino acid in both *Borrelia* and *Treponema*.
- The flagella (between 6 and 10 per cell extremities) overlap at the center of the cell. As usual, they are constituted by a 41-kd flagellin core (encoded by *fla* gene), although a sheath is more external.
- Lipids are important. Fatty acids are required for the growth of *Borrelia* and are incorporated without modification into cellular lipids. It has been shown that *Borrelia* is unable to either elongate fatty acid chains to β-oxidize long-chain fatty acids.

Characteristics of the Genome of *Borrelia*

The genome of *Borrelia* is original by several features:

- The presence of a chromosome of small size (usual among parasitic bacteria) and, more unexpected, linear (49,50), which is typical of eucaryotic organisms, GC % of the genome is 27 to 33 (34–43 for *Leptospira*).
- The presence of many plasmids (up to 22), some circular and most linear (51), which are called mini chromosomes. Together, these plasmids represent in size more than one-third of the whole genome (52).
- The atypical organization of the genes coding for the ribosomal RNAs. Usually, in bacteria, these genes are encoded in an operon in a canonic order (*rrs, rrl*, and *rrf* coding respectively for 16S, 23S, and 5S rRNAs). Such operons are repeated from 1 to 10 times. In *Borrelia*, a single *rrs* gene is distantly localized from *rrl* and *rrf* genes tandemly repeated (53–55). This unique organization of ribosomal genes among bacteria allowed the design of a specific PCR, although the primers were within highly conserved genes (36).
- It has been shown that many potential or identified pseudogens (and very short open reading frames) are present in most plasmids (56). Such structures, interrupted by stop codons, reflect the fact that plasmidic genes are involved in active duplications and transformations. The observation of large families of paralogous genes (filiation of these genes is due to numerous duplications) on these plasmids reinforces the interpretation of plasticity assigned to plasmidic genes (57). Even a family of highly homologous plasmids with seven members in strain B31 is observed. They are circular plasmids of 32 kb (cp32). This cp32 family also shares homology with a small circular plasmid, cp9, and a large linear one, lp56 (56). This leads to the suggestion that linear plasmids originated from circular DNA. It has also been shown that there are homologies among the telomeric (terminal ends) sequences of some plasmids and even of the linear chromosomes (58).
- It appears that there are recombinations between the different replicons of *B. burgdorferi*, including the chromosome extremities. In conclusion, plasmidic structures are highly plastic ones involved in recombinations, genes duplications, and inactivations, revealing a fast-evolving behavior. Interestingly, the nine circular plasmids plus lp 28-2, lp54, and cp32-like portion of lp56, have been considered as 12 "ameliorated plasmids" although the 10 other linear plasmids should be "rapidly evolving" ones (59). Finally, it has been shown that cp32 has a prophage structure and could be used experimentally for DNA transfers (60).
- The discovery of the linearity and the small size of the *Borrelia* chromosome was a mystifying feature (61). The circularity of the bacterial chromosome was considered as a major difference with the linearity of eukaryotic ones. The homology of sequences in the terminal loop (hairpinlike) of the *Borrelia* chromosome and those from some linear plasmids with one telomere from African Swine Fever virus (ASFV) was surprising. ASFV is an eukaryotic virus transmitted by soft ticks that are also vectors for African relapsing fever *Borrelia* closely related with Lyme disease *Borrelia*. This suggested that a trans-kingdom genetic transfer had occurred (62).
- The genetic maps of one representative from each of the pathogenic species, *B. burgdorferi* sensu stricto, *B. afzelii*, and *B. garinii*, revealed a high level of gene order conservation (55). It could be concluded from this observation that few, if any, genetic

rearrangements occurred among and within these chromosomes.

A further study of phylogenetic trees drawn with sequence data from three genes: two chromosomal ones, *fla* and *bmp* (P39), and a plasmidic one, *ospA*, confirmed the clonal evolutionary mode of the *Borrelia* chromosome that seems to slowly diverge mainly by punctual mutations (63). Only plasmidic genes occasionally showed evidence of genetic transfers.

- In 1997, the genome of *B. burgdorferi* (stain B31) has been sequenced [by the Institute for Genome Research, TIGR (48)]. Among the expected discoveries was the identification of genes potentially associated with the virulence of *Borrelia*. Many pathogenic mechanisms have been evoked concerning *Borrelia*, but few have been confirmed. Therefore, bacteriologists expected that genes homologous to genes already known to confer virulence to other bacteria would be identified.

They were disappointed in this waiting; no clear homology with major genes previously associated with virulence was evidenced. However, many other surprising features were discovered or confirmed. Some of them are described in the paragraph on plasmids. Others are:

- The absence of many metabolic ways or steps, which is indeed expected in strictly parasitic organisms because they reduce their genomes that allow for discretion when invading a host (48). The associated loss of genes as fundamental as those responsible for amino acid synthesis is made possible by the presence of achieved products in ticks and in vertebrates. In correlation with this lack of metabolic enzymes, a high level of membrane transport systems is noticed (64).
- The large number of genes is associated with chimiotactism or motility, which accounts for more than 6% of the chromosome (48,65,66). The particular locomotion apparatus of *Borrelia* localized below the outer membrane should allow a maximal velocity in viscous environments in which external flagella of usual bacteria are inefficient.
- Also, a significant percentage of the coding genome (8%) is dedicated to lipoprotein coding (48). Most of the genes coding for lipoproteins are localized on the plasmids. Some of these lipoproteins have been carefully studied because their expression on levels are regulated according to the different steps of the transmission cycle (67). Indeed, at least two of these are associated with the colonization, either of the tick or the vertebrate host.

PHYSIOLOGY-METABOLISM

Culture

In nature, *Borrelia* live both in arthropods at ambient temperature and in vertebrates that maintain a 37 to 40 °C temperature. Therefore, they are usually grown from 25° to 37 °C; 37 °C is the optimum and growth stops at 40 °C. Due to its microaerophily, it grows best in partially filled (2/3) tubes and growth is prominent one centimeter below the surface. In culture, doubling time is 10 to 12 hours, and a maximum density of 10^9/ml may be achieved. Hypotonicity is for them an adverse condition that leads to blebs and conversion to spherical forms (47,51).

Energy and Respiration

Borrelia are microaerophilic bacteria that do not possess catalase or oxydase. Their carbon sources are carbohydrates and mainly glucose. *Borrelia* incorporates fatty acids that are required for their growth, but do not alter them.

Nitrogen Metabolism

Borrelia are not able to use ammonium salts or urea. They require a supply with amino acids to synthesize proteins. This is also why they are cultured in a medium on the basis of eukaryotic cell requirements.

Other Nutritional Requirements

The BSK II medium that is used to grow *Borrelia* is a complex and very rich medium (51,68). To the basic CMRL that is used in eukaryotic cells, culturing elements are added:

- Hepes as buffer
- Bovine serum albumine
- Normal rabbit serum
- Gelatin (providing a certain level of viscosity in the medium)
- Yeastolate
- N-acetyl-glucosamin, which is a component of chitin that composes the exoskeleton of arthropods.

Resistance to Chemical and Physical Agents

Borrelia are quite sensitive to droughness or hypotony. Similarly, they survive only in a narrow range of pH close to neutral (6.5–8).

They can stay alive in medium at 4 °C for months. Usually, they are kept in deep freezers (10% glycerol or DMSO). In culture, they are killed above 40 °C.

They are sensitive to usual disinfectants, detergents, and most antibiotics (with the exception of rifampicin, phosphomycin, neomycin, kanamycin, sulfamides, and metronidazole).

Antigenic Structure

Antigenic structure (51,69) of *B.b*.s.1. has been extensively studied with two main objectives:

- to optimize the serologic diagnosis potential, which up to now remains rather low in several conditions,
- to define protective antigens that could lead to an efficient vaccine.

The immunodominant antigens are the most outer ones — they are called Osp (Outer Surface Protein) — OspA, OspB, ..., OspF are characterized. They are encoded by plasmidic genes and are lipoproteins. Their potential roles and regulations are described in the Virulence and Pathogeny section. OspA (34–35 kd) and OspC (20–23 kd) are protective antigens (70). *dbpA* and *dbpB* are two genes present on the Lp54 plasmid (harboring also operon OspA B) encoding decorin binding proteins, which are expressed on the surface outer membrane and are protective in a syringe model but not in naturally tick-transmitted infection (71). OspE and OspF encoded by *erp* genes exhibit a certain level of protective immunity.

Many other proteins encoded by chromosomal genes are localized on the surface: P39, whose protective effect conferred by antibodies is controversial (72), and encoded by *bmp* genes or *osm28* and *p66* which are porins, the latter being inaccessible by antibodies when OspA is expressed (73,74).

In the periplasm, another immunodominant protein present is the flagellin (41 kd), encoded by the chromosomal *fla* gene (75). It is not protective.

Others that are deeper in the cell structure, such as the glycosylated p83, are less characterized (76).

EPIDEMIOLOGY AND ECOLOGY

Life Cycle of *Ixodes* Ticks (77)

Ixodes of the *ricinus* group (this *ricinus* group comprises most of the vectors of *B.b*.s.1.: *I. scapularis* and *pacificus* in the United States, *I. ricinus* in Europe, and *I. persulcatus* in Asia) are quite sensitive to droughness. They require the shadow and hygrometry maintained by forests. They cannot survive at altitudes superior to 1,200 m. Their seasonal activity is from February to March and October to November, with sometimes a decrease in summer when it is hot and dry, which determines the infection period and EM occurrence.

Their lifestyle exhibits three stages (larva, nymph, and adult) during a lifetime of 1 to 4-a maximum of 4 to 5 years. Each passage at the next stage by moult (although the third "passage" is egg formation) requires a blood meal. Thus, three (or two in males) blood meals are necessary for a complete cycle.

Larvae feed preferentially on small animals: micromammals or passerine birds (*Peromyscus leucopus* is, for instance, the main host for *I. scapularis* larvae). Nymphs feed usually on larger animals (small carnivores, horses, squirrels, hedgehogs, passerines, etc). Finally, *Ixodes* females require large mammals such as deer, wild boars, or even sheep or dogs. This point is quite important: in the United States, deer are quite necessary to an optimum success of the *I. scapularis* cycle. It explains why a Lyme borreliosis focus exists only in areas where a forest is colonized by many games, including big game.

However, not all animals are competent reservoirs, which means they are not able to harbor for a long term and transmit *Borrelia* to an uninfected tick. This ability depends on both *Borrelia* species and host species (rather than tick species, which have been experimentally shown to harbor and transmit several *Borrelia* species; see following text). Sometimes, vertebrates that are nonpermissive, for a given *Borrelia* species have a zooprophylactic effect on this particular species. Even some hosts that are nonpermissive for any *Borrelia* could play a role in actively decreasing the infection rates in ticks. This is the case for lizards in California (78).

Geographic Distribution of *Borrelia* Species

The geographic distribution of *B.b*.s.1. seems to be associated with vectors (42). Dry areas and high altitude ($>1,200$ m) are not favorable to ticks and are therefore conditions are not favorable for Lyme disease.

B.a. and *B.g*. are present in Eurasia (79), where either *I. ricinus* or *I. persulcatus* do exist (additionally in Korea *B.a*. is transmitted by *I. nipponensis* and *I. granulatus*). *B.b*.s.s. in the United States is mainly associated with either *I. pacificus* in California of *I. scapularis* in the Eastern part of the North American continent (80). In Europe, *B.b*.s.s. seems to be clearly restricted to the *I. ricinus* area; none has been isolated from *I. persulcatus* and none has been isolated from areas where *I. persulcatus* exists alone (79).

However, it has been shown experimentally that any of these vectors could harbor any of these three species, although that does not mean they are efficient vectors for the species they are not usually associated with (81). Another point, which complicates the situation, is that each *Borrelia* species may be isolated from many secondary different vectors: ticks: *Dermacentor variabilis*, *Amblyoma americanum*, *I. uriae*, *I. hexagonus*, *I. trianguliceps*, *Haemophysalis leporipalustris*, and fleas: *Ctenocephalis*, *Ctenophtalmus argyptes*, or even mosquitoes: *Aedes vexans*, and so on (82).

The association between *I. uriae*, a tick parasiting oceanic birds, and *B.g*. has been considered as being able to play a major role in disseminating *B.g*.. Indeed, *B.g*. has been isolated form *I. uriae* in colonies of transoceanic migratory birds all over the world, even in the Southern hemisphere where Lyme disease has not been clearly and unequivocally demonstrated (83–85).

In the same way, the existence of *B.b*.s.s. on two noncontiguous continents was unexpected. Surprisingly, whatever the typing method used, North American and European isolates of *B.b*.s.s. were closely related. This suggested that these two populations were evolving the same way, which supposes that exchanges are frequent. It has been shown that European population of *B.b*.s.s., as compared to North American one, reflects what is called in population genetics a "founder event." It could be inferred from sequences of *ospC*, a highly variable gene that the European population derived recently by importation from the North American one, probably by human transportation (86).

The nonpathogenic species of *B.b*.s.1. are less well-known: in the United States, *B. andersoni* is spread in the area where *I. dentatus* (vector) and the cottontail rabbit (host) are endemic (East part of the United States) (37).

B. bissettii is spread in the Southern states, from California to Florida (39). Although one isolate, 25015,

has been isolated from a *I. scapularis* in New York, the usual vector of most *B. bissettii* are *I. neotomae* and its host is *Neotoma fuscipes*. *B. bissettii* has been reported to be present and pathogenic in Europe (87), but these data are controversial and were not confirmed by other authors.

In Europe (and Asia), *B. lusitaniae* has been rarely isolated from *Ixodes* in Southern areas (Portugal, Moravia, Tunisia, etc.) (40). Potential hosts remain unknown.

B. valaisiana also is spread in both Asia (Korea, China, Japan when it has been found respectively in *I. nipponensis*, *I. granulatus* and *I. columnae*) and Europe (41,42). However, in Europe its distribution is very patchy because it is rarely isolated and its demonstration by PCR has been reported with frequency only in Ireland, Switzerland, and the Netherlands.

Borrelia and Ticks

Some parasitology features are important to appreciate ticks and *Borrelia* associations:

Ticks, when feeding, in opposition to mosquitoes, ingest not only blood but also skin cellular component and intercellular liquid. It has been shown for some viruses that infection of ticks is more frequent by co-feeding through the skin than by blood (88).

Ticks by themselves are unable to move at significant distances — less than 1 meter diameter (50 cm for larvae) (77). Therefore, after egg laying, there are patches of high density of larvae separated by large safe areas. Repartition of nymphs and adults are less known, but it is considered they also are aggregated.

Transtadial transmission of *Borrelia* in ticks is rare (1%) but considering transovarial transmission when it occurs, 50 to 97% of larvae are infected (77). It leads to a mosaic of patches, few of which are highly infecting but most often safe.

In most ticks, *Borrelia* remain in the midgut laying on the mucosa. However, in some of the ticks, a generalized infection occurs and *Borrelia* disseminate in the whole body, including salivary glands (89).

Although larvae are more abundant than nymphs, it is thought that nymphs, more frequently infected (20 times more), play a prominent role in transmission (90).

- In Europe, little is known about *Borrelia* species distribution in the main vector, *I. ricinus*. It has been suggested that *B. afzelii* predominates in nymphs and *B. garinii* and *B.b.*s.s. in adults and therefore in larvae (90). A factor that contributes to further complicate vector-host *Borrelia* relationship is that several strains, which could belong to distinct species, may be present in both hosts and ticks (79,42).
- In terms of temporal distribution, it may vary according to the vector and the climate. Questing ticks are encountered from February to November.
- The pattern is either unimodal (all the season) or bimodal (the number of questing ticks temporarily decreases in summer) (91).

Tick Transmission of *Borrelia* to Hosts

When an infected tick attached to a host begins its blood meal, *Borrelia* move from the midgut and invade the whole body of the *Ixodes* tick and mainly the salivary glands (89). This process requires at least 48 hours and it has been told that removing ticks during this interval prevents the disease (92). However, in some occasions, *Borrelia* dissemination may happen before the blood meal, decreasing up to 18 hours the latency period before infection (93).

The population count of each stage is highly different. A female may lay several thousands of eggs giving birth to a multitude of larvae. Nymphs are about 10 times more frequent than adults. However, infection rates also differ — 1.6 % in larvae, 20 to 40% in nymphs, 40 to 50% in adults (77). Nymphs are thought to play a major role, considering the co-feeding infection potential. An infected nymph attached on a rodent may infect many batches of healthy larvae by a single cutaneous passage (88). This process could take place whatever the tolerance of the rodent, owing to the immune system or competent compatibility toward *Borrelia* genotypes of species.

Borrelia and Hosts

Once in nonhuman hosts, spirochetes slowly migrate through the skin without using blood or lymph circulating system (89). Later on, by blood/lymph circulating system, they invade different organs such as the heart, joints, kidneys, spleen, liver, and urinary bladder (some *Borrelia* may be isolated from urine; 94,95). In North America, *Peromyscus leucopus* (white-footed mouse) is the main reservoir for *B.b.*s.s (96).

Host-*Borrelia* species relationships are of primary importance. The coexistence of distinct species among a single vector (*B.b.*s.s., *B.g.*, *B.a.*, for instance, in *I. ricinus*) is questionable because evolutionarily it is not expected that different species occupy a single niche.

Technical difficulties, such as low efficiency of the isolation procedures, and PCR, which amplifies both living bacteria and DNA from dead bacteria, prevent a clear insight into host-*Borrelia* species associations. *B. afzelii* has been isolated from many micromammals but never from birds. In Western Europe and in Asia (Japan), *B. garinii* is primarily associated with birds (93,97,98). The same is true for *B. valaisiana* that has been detected only from birds (99). In squirrels, the predominance of *B. afzelii* and *B.b.*s.s. has been reported. In Europe, *B.b.*s.s. has been isolated only from squirrels (100) and, on one occasion, was PCR detected from a vole but no strain has been grown (101). These associations, *B.g.* and *B.v.* with birds, *B.a.* with rodents, *B.a.* and *B.b.*s.s. with squirrels, could in Europe constitute the primary or specific maintenance cycles (77).

It has been suggested that the differential sensitivity of a given *Borrelia* species to the complement of different vertebrates could play a major role in defining these cycles (102). It has indeed been shown that *B.a.* was resistant to rodent sera, whereas *B.g.* was readily lysed by rodent sera. This lytic activity could occur in the host itself and within the tick during blood meal, contributing to a reduction in population diversity in ticks.

An incompetent reservoir for a given *Borrelia* species could destroy the *Borrelia* when disseminating in the blood system by the way its humoral immune response (102).

However, in the skin of the same host, transmission of *Borrelia* during co-feeding could occur (88). This has been observed in deer and sheep that do not exhibit systemic infection.

In humans, a dead end for *Borrelia*, the evolution of the infection seems to differ from what is seen in wild hosts (103). In most occasions, the infection would not settle or remain subclinical. Often it leads to a local centrifuge progression of the *Borrelia* within the skin, leading to EM. Rarely, it may lead to delayed and invasive clinical presentations. In this case, a blood dissemination occurs, the bacteria colonize distinct organs in which they persist for months or even years (ACA).

Tick Acquisition of *Borrelia* from Hosts

The definition of a competent reservoir implies two parts — to be able to acquire *Borrelia* from the corresponding vector and to be able to transmit them efficiently to some vector. Both terms must be accurately checked.

For instance, it was believed that blackbirds (*Turdus merula*) were not competent reservoirs because, after being infected by ticks fed on rodents, they were unable to transmit *Borrelia* to healthy ticks (104). In fact, rodents usually harbor *B. afzelii* that do not infect birds. Similarly, it is not possible to get infected ticks from laboratory mice infected by *B. garinii*.

There are two ways to demonstrate the competence of a reservoir:

1. to compare the prevalence in questing ticks and in feeding ticks on a given potential reservoir in the same area. This must be done considering a single *Borrelia* species and one should differentiate co-feeding transmission from blood transmission. This method, however, showed that red squirrel transmitted only *B.b.s.s.* and *B.a.* (100).
2. The most effective way is to feed experimentally healthy (laboratory colony) ticks on tested hosts, which is called xenodiagnosis. It allowed to show that only *B.b.s.s.* and *B. afzelii* were transmitted by rodents and only *B. garinii* by blackbirds and pheasants (105).

Discovery of Lyme Disease

In the 1950s, it was known that EM, LBC, and ACA were infectious syndromes caused by bacteria, possibly spirochetes transmitted by ticks, and could be treated by penicillin. Around 1975, this knowledge was more or less forgotten, probably because of the inability to isolate the pathogen and, consequently, the nonavailability of a biological help in diagnosis. However, in the 1970s, Kelly, an American biologist, developed culture media that can allow a certain level of growth of *Borrelia* that is associated with relapsing fever (106).

In 1975, two mothers of teenagers living in the Old Lyme County (Connecticut) called the Connecticut State Health Department. They informed intelligence officers that, in the Lyme area, many teenagers, including her son, suffered from quite a rare disease — Chronic Juvenile Arthritis (CJA). A clinician from Yale University, specialized in both epidemiology and rheumatology (A.C. Steere), led a careful inquiry in Old Lyme County showing (107):

- the frequency of CJA in Lyme was 100 times higher than in all of the United States.
- when considering only woody areas, the CJA frequency became 100,000 higher
- Clinically, the syndrome observed among Lyme residents differed from CJA by several features. Steere showed that this disease, which he named Lyme arthritis, was rather due to infectious causes than to genetic ones. He determined that Lyme arthritis occurred essentially in Autumn and was not contagious (nonconcomittant outbreaks in a given family). Nutritional or toxic causes were eliminated. An extensive serologic, viral, and bacterial study did not allow the incrimination of a known pathogen. The observation that a cutaneous rash (108) preceded the arthritic symptomatology by several weeks indicates a relationship between this chronic arthritis and EM that had been described years ago in Europe. In 1970, Lyme arthritis came to be considered Lyme disease in the United States (109). Steere also noticed that cutaneous rash often occurred in parts of the body that could be in contact with the ground, assuming that a nonflying arthropod should be considered a potential vector.

Two years later, a medical entomologist, William Burgdorfer, was looking for *Rickettsiae* in *Ixodes dammini*, now called *I. scapularis*. He observed spirochetes and thought they could be associated with Lyme disease. He performed slide films directly with tick midguts. An immunofluorescence test, done with sera of patients from Lyme and then with EM European patients, confirmed this hypothesis, leading to two articles: "Lyme disease, a tick-borne spirochetosis?" (1) and "Erythema chronicum migrans, a tick-borne spirochetosis?" (110).

In 1984, Allan Barbour succeeded in growing the spirochetes in a medium called BSK (1,111), which led to serodiagnosis tests that helped describe the disease extensively. This included the specifically European symptomatologies associated with *Borrelia* species which are absent from the United States, leading to "Lyme borreliosis" being the final denomination of the disease.

Incidence of Lyme Borreliosis and Descriptive Epidemiology (112)

In the United States, where Lyme borreliosis has been a notifiable disease from the beginning, incidence of the disease increased from 1982 to 1996. In 1985, the number of cases was 2,748, and rose to 16,802 in 1998. This increase, of course, reflects increased surveillance and better awareness of the disease by practitioneers as well as some changes in case definition (in 1991) and maybe a true increase in incidence in known endemic areas.

From the 88,967 cases in the period 1992 to 1998, 92% were reported by only 10 states (in decreasing order: New York, Connecticut, Pennsylvania, New Jersey, Wisconsin, Rhode Island, Maryland, Massachusetts, Minnesota, and

Delaware). In addition, in each state a restricted number of counties reported most cases (in New York state responsible for 32.8% of 1992 to 1998, 81.9% of cases were from 5 out of 62 countries), leading to highly contrasted maps of endemic rates.

Regarding ages, the distribution is bimodal: reported incidence is higher in 5- to 9-year-old children and adults about 45 to 54. 51.9% patients are male.

Although onset of the disease may occur all over the year (from February: minimum of 1.6% to a maximum of 30.8% in July), summer is clearly the preferential season of onset (56.9% of cases occur between June and August). The onset of the disease out of the activity period of ticks reflects the cases diagnozed directly at chronic stages.

Lyme borreliosis in the United States is the most prevalent vector-borne disease. However, there are some controversies on the accuracy of the surveillance system. Indeed, as most diseases reported through a passive surveillance system, under-reporting is usual. However, considering Lyme disease, which is a highly polymorphic and chronic disease with a deficit in biological diagnosis, there is also a significant risk of overestimation. Several syndromes with not-yet elucidated etiology, such as chronic fatigue syndrome or "Yuppie's disease" in the United States, multisclerosis or Alzheimer disease in Europe, have been wrongly attributed to *B.b.s.l* (113). A wrong use of the diagnosis tests and unscientific information diffused by patients' associations, could be partially responsible for this misdiagnoses that lead to inaccurate treatments (several antibiotics over months ...). Despite these excesses, which usually are not reported, the reporting system provides an efficient picture of the disease in the United States. In addition, CDC made available a rationale for the correct use of biological tests, constituting a simple and efficient guideline.

In Europe, there are large heterogeneities within both the endemic rates and the surveillance system of Lyme borreliosis. A consensus on case definition was not obtained before 1996 (114), and in less endemic countries, no compulsory reporting system has been established.

It seems that the incidence of Lyme borreliosis is low in Western (Atlantic coast) and Southern parts (Mediterranean border characterized by drought) of Europe. In opposition, incidence is important in the North East and mainly Central Europe. Probably, Austria, Germany, and Slovenia are among the countries that report the higher number of cases.

Simultaneously, the *Borrelia* species are not equally distributed in Europe (115,42). In Western and Central Europe, *B. garinii* predominates. In Scandinavia, *B. afzelii* is predominant. In Southern Europe, the three pathogenic species are equally infrequent.

VIRULENCE AND PATHOGENESIS

Many virulence or pathogenesis mechanisms have been proposed. However, few, if any, have been confirmed.

It has been the case for hemolysins, adhesins, lectins, invasins .... Among those that are still under study (69) are

- An antigenic variation mechanism: Such an antigenic variation has been clearly characterized in relapsing fever *Borrelia* (116,117). However, *B.b.*s.l is not a blood bacterium as *Borrelia hermsii* or other *Borrelia* associated to relapsing fever. Anyway, a protein VlsE, belonging to the Vlp family (variable large protein), is the product of a plasmidic (*lp28.1*) gene *vls* that exhibits homology with the *vmp* system in *B. hermsii* (118). Multiple and independent recombinations occur between silent copies of *vls*. This phenomenon occurs in vivo independently of the immune response of mice. Such a system could lead to a selection of antigenic variants and constitutes a way to escape the immune response. Invariable regions (IR) of VlsE are useful as diagnosis antigens, one of them (IR6) being immunodominant (119).
- Similarly, it has been shown that proteins encoded by plasmidic genes *erp* analogous to ospE and F are expressed immediately after host infection eliciting early and partially protective antibodies. These proteins are expressed simultaneously to the temperature increase caused by the blood meal of the tick (from 20 to 35 °C). Again, these proteins are submitted to recombinations and could contribute to evasion from the immune system (120,121).
- One among the potential virulence factors, is well documented. It has been shown by several authors that *B.b.*s.s. was able to adsorb plasminogen on its surface (122). Plasminogen, when activated, gives birth to plasmin which is a host serine protease. These plasmin covered *Borrelia* have been shown to degrade the extracellular matrix (123). This mechanism could explain the ability of *Borrelia* together with the mobility with which it passes through membranes (invasiveness) (124).
- Finally, an imunological mechanism of pathogenicity has been evidenced which could explain chronic arthritis resistant to antibiotherapy. A nine amino acids peptide is shared in common by *ospA* from *B.b.*s.s. (125) and a *hLFA-1* peptide present on human leukocytes associated with allele DRB1 0401 from the major histocompatibility system. Antibodies elicited in certain conditions against *ospA* will act as autoantibodies responsible for articular lesions observed even after elimination of bacteria.

Regulation of the Expression of Two Lipoproteins, Potential Virulent Role and Applications (69)

Two outer membrane lipoproteins are of particular interest. OspA 31–32 kd and OspC 20–23 kd are both immunodominant and protective, which is a challenge for a bacterium (126,127). Each of these two lipoproteins illustrates a distinct strategy used by *Borrelia* to circumvent the immune response and have potential interest in diagnosis and vaccination. OspA is highly expressed within tick environment and repressed in the vertebrate host (128), whereas the opposite is true for OspC (129). The shift in regulation takes place very quickly: within the first 24 hours of the blood meal, the stimulus probably being the 37 °C of the host blood. This suggests a role for OspA restricted to tick environment.

Later on, its synthesis is quickly repressed to prevent elicitation of antibodies lethal for the bacterium. Recently, a role for OspA has been elucidated: it is an adhesin for an intestinal tick cells receptor (130). In opposition, OspC, expressed during and after the blood meal, probably should be useful in the initial host colonization because, in spite of its immunogenicity making it susceptible to initiate the killing of the bacterium, its expression is not repressed. However, after this initial phase, the bacterium survives in spite of the antibodies. The *ospC* gene exhibits a huge variability (because of mutations but also and overall to horizontal transfers of the highly variable central part of the gene) (131). This diversity could be interpreted as a mechanism to prevent serilisation of previously infected ticks by the blood of a previously infected host. The effects of the diversifying mechanism (analogous to the diversifying selection observed in immunoglobulins synthesis, for instance) is such that in a given place, there may be isolated bacteria bearing almost all the repertoire of *ospC* genotypes.

Recently, it has been shown that, among this whole repertoire, only a fraction of genotypes is able to infect humans. A further reduced fraction is able to lead to invasive (disseminating to deep organs after blood invasion) and chronic forms of the disease (132,103).

SYMPTOMATOLOGY (2)

Lyme borreliosis is often described in three phases. This model comes from syphilis and is sometimes artificial.

Presently, it seems more suitable to distinguish only an early and limited phase and a late and disseminated phase. These two stages usually are successive. However, each one may appear alone (133).

Early Phase

Erythema Migrans (EM). Although the blood meal of the tick requires at least a fixation of the parasitic acarian for five days, sometimes it remains unnoticed: larvae are very small and some localizations are hidden (folds, hair ...)

From 10 days to one week after the tick bite, a reddish unelevated spot may appear around the bite. It will enlarge in a centrifugal way, the edge is often redder and the center becomes normal again, giving it a "bull's-eye" aspect. It has been shown that bacteria are present ahead of the reddish edge that represents the inflammatory response following the intra dermal progression of the motile bacteria.

This lesion is the hallmark of the disease and, when typical, requires a treatment without any other confirmation.

In some occasions, EM may be multiple either directly or more often with a delay. This could represent a migration of bacteria using the lymphatic way.

Similarly, some general signs, such as a moderate fever, asthenia, and diverse pains (head, joints, muscles) ..., could indicate a certain level of diffusion of bacteria in the whole organism.

Another infrequent kind of lesion at this stage is very rare in the United States if at all: *Lymphadenosis Benigna Cutis (LBC)* or *Pseudolymphoma*. It appears on elective areas such as the ear lobe, nose, or forehead. It is a nodular and inflammatory lesion. Histologically, it is characterized by a uniform infiltration of poorly differentiated lymphocytes. It may be easily confused with a true lymphoma. In fact, this lesion is often caused by *B.a.*, which does not exist in the United States.

Late Phase

Several weeks or even months after the tick bite, several kinds of syndromes may appear. They are usually exclusive from one another (133).

Neurological Syndrome. Typically, it consists of a meningo radiculitis. The meningitis is subacute with a moderate increase of white cells and protein.

Nevritis concerns both cranial nerves, mainly the 7th with a facial palsy, and peripheral nerves. In these cases, the symptomatology predominates on sensitivity with pain.

Neuroborreliosis is twice as frequent in Europe than in the United States (134).

— *Cardiac symptoms*. They are rare and mainly consist of auriculo-ventricular block of stades 2 or 3. In exceptional cases endocarditis, myocarditis, or even pancarditis may occur. They are not as rare in the United States (134).

— *Late cutaneous symptoms*. Several months after the tick bite, a cutaneous inflammation appears which predominates at the limbs extremities. It evolves slowly over the years, to a considerable skin atrophy that makes the venous network visible. This lesion, *Acrodermatitis Chronicum Atrophicans (ACA)*, is rare in the United States and the described cases always concerned migrants from Europe where the frequency is higher in Northern and Eastern parts (134,135).

Biological Diagnosis

In fact, the biological tests are in limited number and their results must be interpreted with circumspection.

— *The unspecific tests*. relate to blood, CSF, and joint fluid: they look for infection or signs of inflammation. However, they are usually subnormal except in CSF where a moderate pleiocytosis or lymphocytosis, and an increased protein level, may be observed (2).

Specific Tests

— *Direct tests*. Bacteriology. Direct microscopic examination is of no interest. Culture is efficient on skin biopsies (20 to 50 % positive) (136). However, it is not quite necessary since the EM observation is sufficient for diagnosis. Positive results are rare on CSF and exceptional in joint fluid or synovial tissue.

— *PCR*. PCR has exactly the same indications and results as culture. It is therefore pathognomonic

when positive, which is rare except on skin biopsies (137).

— *The antigen "research" tests*. have been discarded because of insufficient reliability.

— *Indirect tests*. Serology is the most commonly used test but presents imperfections in terms of both sensitivity and specificity.

Its extensive use and interpretation led the CDC and the American College of Physicians to promote restrictive but rational rules (138,139):

- not useful at the EM stage (the lesion itself is a positive diagnosis and serology is often negative at this stage).
- later on, presumptive methods (Immunofluorescence or preferably ELISA) should be prescribed only in case of compatible symptoms in an area where Lyme disease is known to exist.
- the western blot must be prescribed only in case of a doubtful presumptive test, it is then confirmative.

The main problems with serology are in fact false positive results (140).

Finally, the limitations encountered in all the tests may be on account of the low level of bacteria in the host body, which is a characteristic in this disease.

PREVENTION AND TREATMENT OF LYME BORRELIOSIS

Collective

There are few collective (113) prevention means and they are usually hazardous to the environment.

Elimination of rodent populations is unrealistic but landscape modification can help in reducing them. Reduction of the deer population would be an efficient method to decrease the tick population. The increase in the population of deer has been responsible for the extension of risk areas in the United States.

If deer were prevented from freely circulating in the neighborhood of houses it would limit the tick infestation of the gardens.

Up to now, the collective use of acaricids in the wild has been proposed but they have been used only on a local scale.

The repartition of permethrin impregnated cotton by a self delivery system for mice in periods of rodent nesting is efficient but cannot be recommended everywhere because of environment concerns. A more efficient way is the automatic application of acaricid on deer in specially equipped deer-feeding stations.

A biological method has been proposed with an insect parasiting tick and laboratory colonies of this insect have been settled.

Finally, only an integrated prevention associating several means: host reduction, habitat modification, and insecticide application, may be efficient in the long term.

Individual Prevention (113)

1. Behavioural measures.

- The knowledge of the high-risk areas and periods is important.
- To wear long and covering clothes with sleeves and trouser legs (recovered by socks) tightly laced is quite useful.
- The use of repellents (the main ones are NN-diethyl-mtoluamide: DEET, and permethrin which is also acaricid) on impregnated clothes is efficient.
- A careful examination of the entire body (including the head) must be carefully carried out by an observer, after a walk in the forest.

2. Vaccine.

   A vaccine based on recombinant OspA has been studied by two companies. Their results have been published in the same issue of the New England Journal of Medicine in July 1998 (141,142). Results from both formulations were more or less similar. However, only one of these companies (Smith Kline Beecham) has been commercializing the vaccine from the beginning of 1999 under the name Lymerix.

Principle: The Lymerix vaccine is made of the lipid form of recombinant (expressed in *E. coli*), OspA: L-OspA. The injection dose is 30 μg of purified L-OspA adsorbed to aluminum hydroxide.

The originality of this vaccine is that its activity takes place not in the vaccinated human subject but in the biting tick body (143).

The anti-OspA antibodies are ingested by the tick during its blood meal and allow the *Borrelia* killing during the period OspA protein is still expressed in the outer membrane of the infecting *Borrelia*.

The vaccine has been made of OspA of a *B.b.*s.s. isolate and is therefore useless elsewhere than in North America where the only pathogenic species is *B.b.*s.s.

Formulations suitable for Europe and Asia are studied but the diversity of OspA among *B.g.* is an obstacle. It has been proposed to add a second antigen such as decorin-binding proteins (DBPs). However, it has been shown that a protective immunization with DBPA is reached in mice by needle inoculation challenge but not by tick inoculation challenge (71).

- Clinical trial:

  10,936 subjects living in endemic areas were randomly divided into two groups and received different schemes of Lymerix vaccine injection. They were examined clinically and biologically. The conclusions were the following ones: a global efficiency of 76 % (definite cases) after two years (3 injections) (141).
- Conclusion

  Indeed the efficacy is not complete and the repetition of injections a constraint. Probably, a cause for immune escape of *Borrelia* is caused by the fact that, during the first days (slow feeding phase) of the

tick attachment, only minute amounts of blood are sucked, although the tick temperature rises. When most of the blood meal is obtained in the late period (in fact, last day out of 5 to 7), OspA is usually no more expressed.

3. Treatment (144).

Early Lyme disease

- It has been demonstrated that 100 mg twice daily of doxycycline is as effective as amoxycline 500 mg three times daily and cefuroxixme 500 mg twice daily to treat early localized or disseminated Lyme disease (145). Additionally, docycycline is also efficient against erlichiosis also transmitted by *Ixodes* ticks. A three weeks treatment is recommended. For children above 9 years doxycycline may be used (100 mg twice daily). For children (whatever their age, amoxillin 50 mg/kg/day in three times (500 mg dose maximum) or cefuroxime 30 or 40 mg/day twice daily (maximum: 500 mg) during three weeks.

Late Lyme disease

- When central nervous system is involved, intravenous treatment is to be preferred: either penicillin IV (24 millions Unit daily or ceftriaxone: 2 mg daily IV). For children, either a single IV dose 50–60 mg/kg/day (2 g maximum) or 200,000–400,000/kg/day (20 M maximum) are suitable for three weeks (maximum duration with ceftriaxone).
- Lyme arthritis (146): oral regimens are usually as effective as intravenous ones and they may be administered longer, which is advantageous. In adults, doxycycline 100 mg twice daily or amoxillin 500 mg four times daily for four weeks are recommended. Concerning children, a treatment similar to EM one is suitable when administered 30 days.
- Treatment-resistant Lyme arthritis (146)
- When joint swelling persists after two normal courses of treatment, it is suitable to use intra-articular steroids and non steroids anti-inflammatory.
- On some rare occasions, arthroscopy synovectomy may be suitable.

CONCLUSION

Lyme borreliosis was not recognized in the United Stated before 1976. It is now the most prevalent vector-borne disease in that country. Its emergence is in part due to the recent desire of humans to live in close contact with nature and possibly to an increasing population of deer. In addition to individual prophylactic measure, only a vaccine is able to afford active protection against the disease. Such a vaccine already exists in the United States, but it is not suitable for Europe or Asia. The need for an efficient vaccine on a global scale is the actual challenge.

MARINE BIOTECHNOLOGY

John E. Dore
University of Hawaii
Honolulu, Hawaii

The deliberate manipulation of living organisms to serve practical human needs has a long history, dating back at least as far as the rise of agriculture. Over the millennia, the tools available to humans for the control of biological processes have become more and more technologically sophisticated. Biotechnology, defined as "any technique that uses living organisms (or parts of organisms) to make or modify products, to improve plants or animals, or to develop microorganisms for specific uses (1)," is not a new concept. However, the modern biotechnology industry originated only three decades ago. Today, biotechnology combines commercial and scientific enterprises under the unifying principle of utilizing life to serve life. New tools, such as genetic engineering techniques, advanced microbial bioreactors, and natural product chemistry have contributed to rapid development in the fields of health, agriculture, manufacturing, and environmental remediation. It is therefore not surprising that "biotechnology is expected to have a dramatic effect on the world economy over the next few decades (2)."

The development of new biotechnological applications is often linked to the discovery of new organisms, novel compounds produced by organisms, or unique metabolic pathways of organisms. Marine ecosystems contain a major share of the biological resources of the planet and host highly diverse populations. Moreover, the vast majority of marine biota remains untapped as a resource for biotechnological applications. The practical application of marine organisms for the development of new products and processes comprises the burgeoning field of marine biotechnology. Although many conflicting definitions of this term may be found in the literature, the definition of marine biotechnology used here is "the application of scientific and engineering principles to the processing of materials by marine biological agents to provide goods and services (3)." Within this broad characterization lie processes involving the use of marine animals, plants, fungi, protists, algae, cyanobacteria, bacteria, and archaea; however, this article will emphasize the use of the microbes in marine biotechnology. An exhaustive review of the subject is not possible here, but selected examples from the literature will be presented. The term *marine* must also be qualified, as a number of important developments in marine biotechnology have actually been made using microorganisms from diverse aquatic environments including hot springs, hypersaline ponds, and ephemeral freshwater pools. Eight major subject areas are discussed:

- Marine natural products, including pharmaceuticals, pigments, nutritional supplements, enzymes, biomaterials, and specialty products.
- Energy production from marine organisms and the use of marine microbes to mitigate the introduction of carbon dioxide from fossil fuel combustion into the atmosphere.
- Marine bioprocesses, including environmental bioremediation and wastewater treatment, the formation and effects of biofilms, and the development of genetic engineering techniques utilizing marine microbes.
- Aquaculture, including the use of genetic engineering to enhance the growth and fecundity of cultured organisms, and the production of microbial feedstocks for aquacultured animals.
- Marine health and safety, including the prevention of marine animal diseases and human diseases of marine origin, and techniques for detecting pathogens and toxins in seafoods and marine waters.
- Marine ecology, including the identification of marine organisms, the assessment of marine ecosystem biodiversity, and the study of marine microbial metabolism.
- Marine bioprocess engineering and the steps taken to bring marine microbial products from discovery to commercialization.

- Legal aspects of marine biotechnology, including concerns over the use of genetically modified marine organisms.

MARINE NATURAL PRODUCTS

Biomass Protein

The production of foodstuffs through cultivation of marine macroalgae (seaweeds) has a long history, particularly in Japan and China (4). The red alga *Porphyra*, the brown kelps *Laminaria* and *Undaria*, and the green alga *Monostroma* are just a few food-grade examples of at least 221 seaweed species now cultivated worldwide (5,6). Tissue culture techniques are widely used for the production of enhanced strains capable of rapid growth and to control the life cycles of the farmed algae. Protoplast fusion is also used to create improved hybrid strains (5). Both the seaweeds and the microalgae grow rapidly, and are generally rich in protein, hence, both have been considered as potential sources of biomass protein for large-scale human and animal consumption. Some of the earliest attempts at the mass cultivation of microalgae were carried out to test the feasibility of low-cost high-protein food production from the green alga *Chlorella*. These efforts, carried out in the early 1950s, revealed the impracticality of using microalgae for food, mainly because of the production costs, which were far in excess of those associated with existing plant protein sources such as soybeans (4). However, the ability to mass-culture microalgae was demonstrated, and this has led to ever-improving technology and many successful efforts to commercialize the production of high-value microalgal products (7).

Pharmaceuticals and other Bioactive Compounds

Perhaps the most exciting application of marine biotechnology is the identification, production, and commercialization of novel bioactive compounds from marine organisms. Bioactive secondary metabolites have been discovered in a wide variety of marine animals, plants, and microorganisms. Some of the most significant discoveries have been natural products associated with marine invertebrates (sponges, corals, bryozoans, tunicates, etc.), including antitumor compounds, anti-inflammatory compounds, antibiotics and antiviral agents, and immunosuppressants and antiparasitic agents (8). Thousands of such bioactive compounds have been discovered, yet despite their vast potential, as of 1995 only the antiviral arabinose nucleosides ara-A and ara-C had been marketed and put into clinical use (9). Probably, the single greatest impediment to the commercialization of marine natural products is the lack of adequate supply. Natural product chemists are able to screen raw extracts for bioactivity and isolate and characterize promising compounds using relatively small quantities of source material, but clinical trials require much larger supplies and pharmaceutical production requires a renewable resource base. Environmental supplies of such metabolite-rich marine animals as gorgonians and bryozoans would quickly be wiped out if they were put into industrial-scale pharmaceutical production. One way to address this problem is to develop the requisite culture techniques for the organisms of interest. Using this approach with marine invertebrates can be very difficult, but in one notable casework is under way to reliably produce the promising anticancer drug bryostatin-1 from aquacultured bryozoans (10). Another approach to the supply problem is the chemical synthesis of the newly characterized molecules and related molecules that may show superior activity. For example, total chemical syntheses of prostaglandins created a sufficient supply of these chemicals for clinical trials, probably saving the prostaglandin-rich Caribbean gorgonian *Plexura homomalla* from being overharvested (11). Often, however, the complexity of bioactive marine compounds prevents the cost-effective development of chemical syntheses, precluding pharmaceutical companies from investing into their development as drugs.

Marine microorganisms hold enormous potential as sources for new drugs. Marine microalgae, cyanobacteria, bacteria, and fungi produce a wide range of secondary metabolites of possible pharmaceutical utility (Table 1). In some cases, interesting compounds originally isolated from the tissues of marine animals, plants, and macroalgae have later been shown to originate from commensal or symbiotic bacteria living on or in their tissues (12). In addition, several factors make production of bioactive compounds from marine microbes more attractive than production from marine animals (13). Unlike marine animals, many microbes may be cultivated readily in bioreactors under controlled environmental conditions. Such control is essential for industrial situations, where reproducible production of a metabolite is a must. Furthermore, microbes grow rapidly, allowing for strain selection of hyperproducers to be carried out on relatively short timescales, and reducing the time required for production of significant quantities of metabolites. Microbes are also more easily transformed genetically than higher organisms, enabling the cloning of genes encoding metabolite production from one organism to another whose growth can be controlled better. The hazards associated with release of transgenic organisms into the environment are also reduced when closed bioreactor technology is employed for cultivation, as opposed to the open-system outdoor technology commonly used for cultivating marine animals.

Bioactive compounds have been isolated from bacteria inhabiting a wide variety of marine environments (Table 1). For example, free-living water column *Alteromonas* sp. from the sea have yielded brominated pyrroles and other bromine-containing compounds with antibiotic properties, whereas bacteria from deep-sea sediments produced the novel cytotoxic and antiviral microlactins (12). Marine microalgae, too, have yielded bioactive compounds. A host of red-tide dinoflagellates produce cytotoxic compounds of pharmacological utility, including the antitumor and antibiotic macrolides, the antifungal goniodomin, and the sodium channel blocker saxitoxin (25). Other microalgae produce bioactive compounds, such as the green alga *Dunaliella primolecta*, which contains antiherpesvirus substances (26), and certain diatoms

Table 1. Some Useful and Potentially Useful Bioproducts from Marine Microorganisms

Product	Current/Potential Use	Organism	Type/Origin	References
Brominated pyrroles	Antibiotics	*Alteromonas* sp.	Marine water column bacterium	12
Majusculamides	Anticancer drugs	*Lyngbya majuscula*	Marine cyanobacterium	14
Hormothamnins	Anticancer drugs, fungicides	*Hormothamnion enteromorphoides*	Marine cyanobacterium	14
Cephalosporins	Antibiotics	*Cephalosporium acremonium*	Marine fungus	1
Polyunsaturated fatty acids	Dietary supplements	*Crypthecodinium cohnii*	Dinoflagellate from coastal waters	15
		Thraustochytrium spp.	Fungoid protists from various marine environments	16
β-Carotene	Dietary supplements, food colorings	*Dunaliella salina*	Green microalga from alkaline saline lakes and marine waters	17
Astaxanthin	Dietary supplements, animal feed additive	*Haematococcus pluvialis*	Green microalga from ephemeral freshwater pools	17
Thermostable polysaccharide-hydrolyzing enzymes	Starch hydrolysis, paper manufacturing	*Rhodothermus marinus*	Thermophilic bacterium from submarine hot springs	18,19
		Thermococcus hydrothermalis	Hyperthermophilic archaeon from deep-sea hydrothermal vent	20
Thermostable DNA polymerases	DNA amplification by polymerase chain reaction	*Thermus aquaticus*	Thermophilic bacterium from terrestrial hot springs	21
		Pyrococcus furiosus	Hyperthermophilic archaeon from geothermally heated marine sediments	22
Cold-adapted lipases	Cold water detergents	*Moraxella* spp.	Bacteria from Antarctic seawater	23
Polysaccharides	Gelling agents, oil recovery	*Porphyridium cruentum*	Red microalga from various marine and terrestrial systems	7, 24
Phycocyanin	Medical diagnostics	*Spirulina platensis*	Cyanobacterium from alkaline saline lakes and coastal flats	7

that produce powerful antibiotics (27). Marine fungi, while less studied than other marine microorganisms, show promise as a source of novel compounds (28); a marine fungus was the original source for the commonly used cephalosporin drugs (1). Finally, the cyanobacteria are perhaps the most intriguing group of marine microorganisms for drug discovery. Cyanobacteria produce diverse cytotoxins, potentially useful as antibiotics against gram-positive bacteria and as fungicides (29), as well as potential anticancer and HIV-inhibiting compounds (30). A number of compounds with promising anticancer and antifungal properties have been isolated from marine cyanobacteria, including the majusculamides and the hormothamnins (14). Furthermore, enhanced biomass and/or metabolite accumulation in cyanobacteria has been achieved through the careful control of environmental factors during culturing, making these organisms attractive potential candidates for pharmaceutical development (29).

Pigments and Nutraceuticals

For bioactive natural compounds, the progression from discovery to commercial pharmaceutical use can take many years, many millions of dollars, and faces substantial regulatory hurdles. The reward for success can be sole access to billion-dollar markets. On the other hand, marketing natural products as whole health foods, nutraceuticals, dietary supplements, or feed additives allows for more rapid and less expensive introduction into a less-regulated commercial arena. The industrial-scale production of marine bioproducts from both microalgae and cyanobacteria has been successfully carried out by following this commercial approach. Polyunsaturated fatty acids (PUFAs) have been shown to have beneficial health effects on human health, particularly with regard to the prevention of coronary heart disease and in supporting the proper brain development of infants (31). Fish oils are the primary dietary source of PUFAs, but recently, infant formulae rich in PUFAs

have been successfully produced from microalgae grown heterotrophically in bioreactors (15,32; Table 1). Potential new candidates for the marine biotechnological production of PUFAs include the thraustochytrids (16). Carotenoid pigments are another class of compounds that have been successfully mass-produced from microalgae, both in open ponds and raceways and in photobioreactors, to make human dietary supplements and feed additives for animal nutrition. Two prominent examples produced photoautotrophically from green algae, are β-carotene from *Dunaliella* and astaxanthin from *Haematococcus* (Table 1;17). Natural microalgal carotenoids are also becoming attractive as additives for cosmetics because of their UV light-absorbing properties. Probably the biggest success stories so far in the commercial biomanufacturing of marine microalgal products are the whole-biomass health food products from the green alga *Chlorella* and the cyanobacterium *Spirulina*, which both boast annual production figures in the thousands of tons dry weight (17).

Enzymes

One of the most significant contributions of marine biotechnology to date has been the isolation and production of novel enzymes for industrial processes and molecular biology. Many industrial processes can be improved through the use of enzymes that are active under conditions of high salt, high or low temperature, high or low pH, and/or high pressure. Marine microorganisms isolated from extreme environments have evolved the capacity to produce enzymes capable of being active under extreme conditions. For example, marine vibrio bacteria have been a source for salt-tolerant proteases used in detergents and membrane cleaning formulations (3). The bacterium *Rhodothermus marinus*, isolated from a marine hot spring, has produced industrially useful polysaccharide-hydrolyzing mannanase and cellulase enzymes that remain active at temperatures exceeding 80 °C (Table 1; 18,19). Similarly, a thermostable α-glucosidase is produced by the hyperthermophilic deep-sea hydrothermal-vent archaeon *Thermococcus hydrothermalis* (20). Thermostable DNA polymerases, such as that from the hot spring bacterium *Thermus aquaticus*, form the basis for the polymerase chain reaction (PCR), a widely used and powerful technique in molecular biology (21). A new thermostable DNA polymerase with unique properties was recently purified from the hyperthermophilic archaeon *Pyrococcus furiosus* (22). Cold-adapted enzymes from psychrophilic marine microorganisms, such as the lipases from the Antarctic marine bacteria *Moraxella* spp., are also of potential interest for use in cold water detergents and other industrial applications (23; Table 1). Some of these cold-tolerant enzymes can be cloned into yeasts for commercial production using conventional fermentation technology (33).

Polysaccharides, Biopolymers, and Biomaterials

An important area of marine biotechnology is the development and production of useful biomaterials from marine organisms. In some cases, materials derived from marine organisms have unique properties, whereas in others, bioproduction is seen as an economically viable alternative to synthetic sources. Marine macroalgae have long been used as an abundant natural source for phycocolloid polysaccharides, which are used as emulsifiers, solidifiers, stabilizers, and clarifiers in a wide variety of foods, drinks, and other products (5). Although some seaweeds are still harvested from the wild, there is an ever-increasing industry based around farming of macroalgae. Major products include agars and carrageenans from red algae and alginates from brown algae (4). Agars are of particular significance to the biotechnology industries, as they are used as substrates for microbial cell cultures and for DNA separations. Sulfated polysaccharides are another class of useful compounds, produced by the red microalga *Porphyridium cruentum* (7). Although *P. cruentum* has been successfully cultivated in large-scale photobioreactors (24), economically viable production has been elusive. Two other marine polysaccharide biomaterials of note are chitin and chitosan, both isolated from the exoskeletal wastes of crustaceans, but potentially yielded from marine fungi as well (34). These compounds are used as adhesives, biodegradable medical products, artificial membranes, and have a host of other applications because of their strength and flexibility. Natural laminated composite materials from marine mollusk shells, likened to "ceramic plywood," have been studied recently with transmission electron microscopy, potentially leading to the development of novel tough, lightweight structures (35,36). Finally, marine diatoms have been considered recently as a renewable source of high-purity silica with uniquely high surface area and porosity, for use as an alternative to zeolites and in other industrial applications (37).

Specialty Products

Three additional marine bioproducts with commercial applications, but small and specialized markets are pigment standards, isotopically labeled compounds, and fluorescent diagnostic markers. Each of these is produced from cultured microalgae. Pigment standards are used primarily for the calibration of high-performance liquid chromatographic (HPLC) analyses of pigments in environmental samples. A variety of organic compounds can be labeled with stable isotopic markers for research purposes by growing the source microalgae in a medium containing isotopically labeled nutrient salts. These compounds have potential applications as cell culture biochemicals and in diagnostic breath tests (38). Lastly, certain highly fluorescent water-soluble pigments, such as phycoerythrin and phycocyanin, are commercially produced from microalgae (7; Table 1). These compounds are useful in marker applications such as flow cytometry, fluorescence microscopy, and immunoassays.

ENERGY

Energy Production

The concept of using marine organisms as an energy source consists of two major themes: producing hydrocarbons from biomass and generating hydrogen from cultured

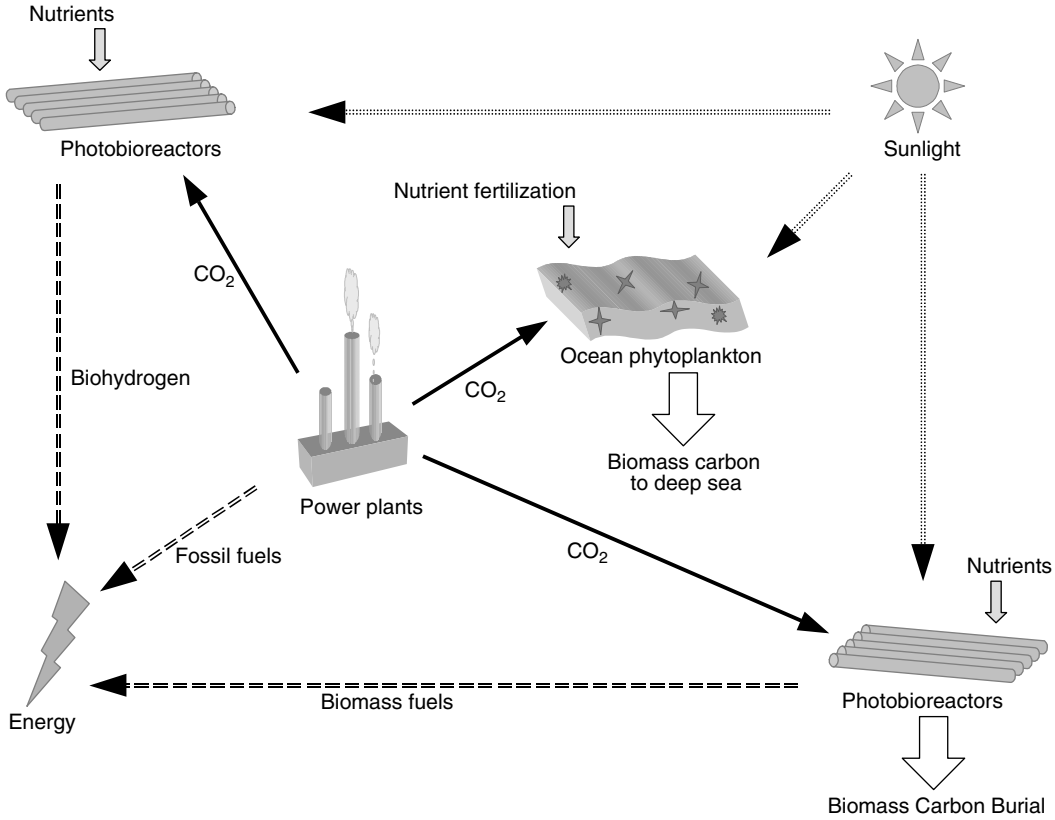

Figure 1. Schematic diagram of the potential uses of marine microorganisms in energy production and carbon dioxide mitigation.

microorganisms (Fig. 1). Neither of these approaches has yet led to commercial energy production, but because of the renewable nature of these energy sources and their relatively low impact on the environment when compared to fossil fuel combustion, research and development projects in these areas continue to increase.

Microalgae and seaweeds are the primary subjects of research into hydrocarbon production from marine biomass sources. These organisms grow rapidly by photosynthesis utilizing carbon dioxide and inorganic nutrient salts, thus could be considered as a source of renewable fuels synthesized using solar energy. Certain microalgae naturally produce energy-rich fuels. The biomass of the green alga *Botryococcus braunii*, for example, may consist of up to 86% isoprenoid hydrocarbons by dry weight (39). These compounds can easily be catalytically converted to gasoline-like fuels. Unfortunately, the mechanisms of isoprenoid production in this organism are not well understood, thus yields have been unreliable. Microalgae can also be induced to accumulate lipids via nutrient-deficient cultivation, but cost-effective conversions of these triglycerides into fuels have not been developed. The green alga *Dunaliella* will, under saline conditions, produce up to 85% by dry weight of glycerol. Glycerol is not a good fuel in itself, but could potentially be fermented to *n*-butanol and ethanol by bacteria. Production of methane via biological gasification of carbohydrates from macroalgae and microalgae has also been demonstrated, but this process has not been efficient enough to warrant large-scale development (39). Gaseous hydrocarbon production via vacuum pyrolysis of biomass, a relatively new process, has been used recently to generate fuels from the abundant and easily cultured calcifying marine microalga *Emiliania huxleyi* (40). Because of the high hydrocarbon output and the low energy input, this process holds great promise as an economically viable form of energy production for the future.

Hydrogen is attractive as a clean fuel, as it holds high potential energy and, when combusted, produces water and not carbon dioxide. Hydrogen can be produced by microorganisms via three principal processes (41). The first is through the fermentation of organic substrates by anaerobic bacteria such as *Clostridium*. This method of biological hydrogen production has the advantage of a high reaction rate, but relies upon energy-rich organic compounds as substrates, and does not completely decompose these compounds. The second process is the generation of hydrogen by photosynthetic bacteria, such as the marine bacterium *Rhodovulum*. This process also requires organic substrates as a source of hydrogen atoms, but utilizes light energy in addition to chemical energy to effect the evolution of hydrogen gas. Systems utilizing a close synergistic coupling of these first two reactions could potentially be designed for complete decomposition of organic wastes with simultaneous energy production in the form of hydrogen gas. Also, reactors utilizing immobilized enzymes from marine bacteria are possible, and preliminary data show that this technique can be carried out with a remarkably high yield of hydrogen (42). The third process for biohydrogen production is the

hydrolysis of water into hydrogen and oxygen gas by photosynthetic cyanobacteria and green algae (Fig. 1; 41). This process directly utilizes solar energy to produce clean energy-rich hydrogen gas, requires no previously existing organic substrates, and does not add to the atmospheric burden of carbon dioxide. The greatest hurdles to overcome in developing this process into an energy producing industry lie in improving the hydrogen yields from photosynthetic organisms, in designing suitable photobioreactor technologies for the cultivation of the organisms, and the efficient collection of the hydrogen they produce. Because of the recognition of the finiteness of fossil fuel resources and the climate-altering effects of their combustion, interest in the marine biotechnological development of biohydrogen production systems is active and growing (41).

Carbon Dioxide Sequestration

The steady rise of carbon dioxide in the atmosphere raises concerns about potential global warming and global climate change. Marine biotechnology has the potential to help slow the accumulation of anthropogenic carbon dioxide in the atmosphere in at least three ways (43). First, energy technologies based on marine microbes (discussed earlier) may allow for energy production with substantially reduced release of carbon dioxide. Second, mass cultures of marine microalgae and cyanobacteria may be used in carbon dioxide scrubbing schemes, to remove or recycle carbon dioxide emissions from power plants and other fossil-fuel consuming industries through photosynthesis and/or calcification (Fig. 1). Such schemes are currently the subject of novel research projects funded by the U.S. Department of Energy. Third, carbon dioxide may be removed from the atmosphere to the deep-sea. This can be accomplished through direct injection of liquid carbon dioxide to great depths via pipelines. Alternatively, stimulation of the photosynthetic productivity of oceanic phytoplankton after fertilization with iron and possibly other nutrients may result in greater export of sinking organic material to the deep sea, and genetic manipulation of other members of the marine food web might enhance such export (Fig. 1). None of these marine biotechnologies has been developed beyond the scale of pilot studies, but each has potential for helping to mitigate the global effects of fossil fuel combustion.

BIOPROCESSES

Bioremediation and Wastewater Treatment

The cleanup of pollutants from the marine environment is a pressing issue today, and one in which marine biotechnology is poised to play a vital role. The degradation of petroleum-based hydrocarbons has received the most attention in this area because of public awareness of oil spills from tankers, drilling platforms, and associated operations. The natural degradation of hydrocarbons in the marine environment is carried out principally by bacteria and fungi, but the controls on this complex process are not well understood. Nutrients, temperature, salinity, oxygen, and other environmental parameters play a role, as does the prior exposure (adaptation) of the microorganisms to hydrocarbons (44). Enhancing the activity of the natural microbial populations through the addition of fertilizers is one method of oil bioremediation. Seeding spills with laboratory-grown inocula of hydrocarbon-degrading bacteria, is another. The combination of inoculation and fertilization has also shown promise (3). Another approach is the addition of surfactants to the spill. Chemical surfactants such as synthetic detergents have been widely used to aid in the emulsification of water-hydrocarbon mixtures; however, concerns about the toxicity and lack of biodegradability of these compounds has sparked research into the use of biosurfactants for environmental cleanup operations (45). At least one marine bacterium, *Acinetobacter*, has been used for the commercial production of biosurfactants. Genetic modification of such microorganisms to enhance their petroleum-degrading capabilities may be an important future direction for bioremediation research, but introduction of such genetically modified bacteria into the environment is an issue of some concern and debate.

Two other areas of bioremediation benefit from marine biotechnological research: the degradation of pesticides, herbicides and other organic toxins, and the sequestration of toxic heavy metals. A number of marine and freshwater bacteria have been identified as having the potential to partially or completely degrade organophosphate pesticides, phenylurea herbicides, phenoxyacetate weed killers, and halogenated aromatics such as PCBs (45). Similarly, a recent study reported the isolation of a marine *Nocardioides* bacterium capable of growth on and degradation of the polyaromatic hydrocarbon phenanthrene (46). Heavy metals such as lead, uranium, silver, cadmium, and mercury are serious marine environmental problems because of their toxicity and persistence. Marine bacteria, actinomycetes, and microalgae that are resistant to such metals, and in some cases, which can accumulate the metals or convert them to less toxic forms, have been reported (3,47).

Organic toxin-degrading and heavy metal-accumulating aquatic microorganisms are of great interest not only for environmental remediation but also for the treatment of industrial liquid wastes in sludge reactors (45). Aquatic microorganisms also can be used in wastewater bioreactors for the removal of inorganic nutrients from industrial and domestic liquid wastes. Mass cultures of microalgae are used in this application in continuously mixed high-rate growth ponds at sewage treatment plants. The microalgae work in parallel with aerobic bacteria, consuming the nutrients produced from organic decomposition by the bacteria, and providing photosynthetically derived oxygen to support bacterial metabolism (48). Such synergistic bacterial-algal treatment of wastewater was one of the earliest practical applications of microalgal biotechnology.

Biofilms, Bioadhesion, and Biocorrosion

The formation of biofilms on submerged solid surfaces, and their subsequent colonization by attaching organisms, are normal marine biological processes (3,49). These films are

composed of layers beginning with organic molecules, followed by bacteria, then other microorganisms, and marine animals. Biofilms are important parts of natural aquatic ecosystems, but biofouling on the hulls of ships significantly reduces their performance and fuel efficiency, and biofilms also have been implicated as a contributing factor in corrosion of metals in marine systems. The application of marine biotechnology to biofouling research falls into three principle categories: creating an understanding of the ecological significance of biofouling and processes that control it, preventing biofouling from occurring on ships, pilings, and other submerged surfaces, and developing new compounds and materials from biofouling organisms. The interaction of biofilm-producing bacteria with marine invertebrates has been studied in some detail. For example, enzymes and polysaccharides produced by the biofilm-forming marine bacterium *Shewanella colwelliana* apparently act as cues for the settlement and attachment of oyster larvae (3). In this case, study of the bacteria and their chemical messengers could lead to microbial methods for enhancing settlement of oyster larvae in mariculture systems. Methods for the prevention of biofouling include the widespread use of antifouling paints, but these are generally toxic, and thus more environmentally friendly techniques are desired. Compounds are sought that either inactivate settlement cues or inhibit the initial colonization by bacteria. Two possibilities in this arena include the isolation and use of natural inhibitory compounds from marine organisms, and/or the development of nonstick paints that make settlement mechanically difficult (50). Finally, the study of bioadhesion in the marine environment may lead to unique water-resistant adhesives. One such adhesive already on the market, derived from the byssal threads of mussels, is being used to enhance cell attachment in tissue culture applications and may have future applications as an adhesive in surgical procedures (32).

Genetic Techniques in Marine Bioprocesses

The potential practical applications in marine biotechnology of recombinant DNA and other techniques for the genetic modification of organisms seem to be limitless. Some examples mentioned earlier include the genetic engineering of marine archaea to produce novel thermostable enzymes, and the genetic alteration of marine bacteria for the ability to degrade pollutants in the environment. Although there is no room here for an exhaustive review of the subject, a few other prominent examples of work in progress, specifically dealing with improved strains for production and/or distribution of natural products, are discussed here.

Cyanobacteria are attractive organisms for the introduction and expression of foreign genes (51). Although most attempts to genetically transform cyanobacteria have been used for basic research purposes or for use in bioremediation (52), two notable projects are under way to introduce and express genes coding for useful natural products. The first is the cloning of a mosquitocide-coding gene from a terrestrial bacterium into *Synechococcus*. The bacterium *Bacillus thuringiensis* has been known long for its insecticidal properties, stemming from several crystalline proteins. The gene coding for the most potent of these compounds (the protein CryIVD) was cloned into the cyanobacterium, which successfully expressed the gene and exhibited toxicity when eaten by *Aedes aegypti* mosquito larvae (53). This technique, when fully developed, could allow for inexpensive biocontrol of disease-carrying mosquitoes, without the use of chemical pesticides. A second notable project is the use of genetic engineering techniques to create a mutant strain of *Synechocystis* that overexpresses genes coding for the production of the carotenoid pigment zeaxanthin. Specific genes from a yeast and from *Synechocystis* were linked and expressed in the cyanobacterium, allowing zeaxanthin to become the dominant carotenoid pigment (54). These or similar mutant cyanobacteria could potentially be used to manufacture zeaxanthin for dietary supplements and other health applications.

Genetic techniques also have been applied to carotenoid production from green algae. In one example, mutants of the astaxanthin-producing alga *Haematococcus pluvialis* exhibiting resistance to carotenoid biosynthesis inhibitors were isolated and then formed into hybrids using protoplast fusion techniques (55). The new hybrid microalgae produced levels of carotenoids threefold higher than the wild-type strains. Another genetic technique for carotenoid production involved the cloning of a cDNA from *Haematococcus* into the easily cultivated *E. coli* bacterium. The resulting bacterium was able to produce the carotenoid canthaxanthin (56). Such cloning techniques hold promise for the development of bacterial fermentation-based carotenoid pigment production, a viable alternative to photosynthetic production by microalgae.

AQUACULTURE

Aquaculture is to the sea what farming is to the land. The cultivation of fish, shellfish, and crustaceans for food is a fast-growing industry. Aquaculture currently accounts for over one quarter of the fish supply for direct human consumption (57), and is likely to continue to expand as ocean fisheries decline worldwide. A variety of marine biotechnological techniques can be used to improve and enhance the aquaculture of marine organisms. Examples include genetic techniques for enhancing growth and cold tolerance, the hormonal manipulation of reproduction, the large-scale production of feedstocks through microalgal mass culture, and the integration of algal and animal production systems to increase productivity and reduce waste effluents.

Genetic Techniques in Aquaculture

At least three genetic approaches to enhancing the growth of fish have been demonstrated (3). First, foreign growth hormone genes have been fused with promoters and introduced into the eggs of commercially important fish species, resulting in transgenic offspring that grow larger than untreated control fish. Second, growth hormone genes from fish have been cloned into bacteria, which express the genes and produce large quantities of the hormone, which can then be injected into farmed fish to enhance

their growth. Third, fish gene constructs can be developed that cause overexpression of growth hormone genes when reintroduced into the fish. Similar techniques have been applied to other aquacultured animals such as abalone and oysters. Another application of genetic techniques to fish farming is the introduction of genes coding for antifreeze proteins from polar fish into fish from temperate waters, to enhance their resistance to cold. Hormones other than those promoting growth are also utilized in aquaculture, for example, to induce spawning of fish or the molting of lobster.

Microalgal Biotechnology in Aquaculture

Microalgae are a vital resource for the aquaculture industry. Various commercially important mollusks, fish, and crustaceans utilize live microalgae as food during at least part of their life cycle (58). Although natural phytoplankton populations are often used to feed aquacultured animals, this approach is fraught with problems. These problems are primarily related to the inability of the farmer to control wild phytoplankton species compositions (which can include toxic species), together with difficulties encountered in trying to exclude unwanted protists and other consumers. Microalgal production is therefore an integral component of many aquaculture operations (58). In addition to providing a food source for animals and their larvae, microalgae are also used within aquaculture ponds and tanks to help maintain oxygenation and to remove excess nutrients. If the algae are of commercial value themselves, they add to the economic potential of the operation. This sort of integrated aquaculture approach is useful for reducing wastes and for increasing the overall efficiency of the growth system. Similarly, the combined farming of fish (salmon) and seaweeds (*Porphyra* and *Gracilaria*) has been shown to be positive for optimizing the efficiency of aquaculture operations and for reducing the pollution of coastal waters with waste effluents (58,59).

HEALTH AND SAFETY

Marine biotechnology has a significant role to play in maintaining the health and safety of our marine resources. Disease prevention in wild and cultured marine organisms, as well as quality assurance in seafoods, are important areas for research and development. The rapid detection of biotoxins and human pathogens in marine environments are also critical foci.

Marine animals, particularly those raised in intensive aquaculture, are susceptible to disease. Bacteria, viruses, fungi, and protozoan infections are common problems faced by fish and shellfish. In aquaculture, diseases caused by marine vibrio and other bacteria are particularly common. The widespread use of antibiotics is undesirable, because of both high cost and the selection for resistant pathogenic strains. Because of this problem, a number of fish vaccines against bacterial pathogens have been developed using formalin-inactivated bacterial cultures (3). Also promising is the use of antimicrobial peptides isolated from natural sources to confer disease-resistance to marine animals. Certain peptides from insects and from the skin mucus of the flounder have been demonstrated to protect coho salmon from infection by the bacterial pathogen *Vibrio anguillarum* (60). Viral diseases of marine animals are also of concern in aquaculture. Important fish vaccines have been developed using recombinant DNA technology, to combat the infectious hematopoietic necrosis and infectious pancreatic necrosis viruses in salmonids (61). Diseases of shellfish caused by protozoa are also a subject of intensive biotechnological research. One such disease, caused by the parasitic protozoan *Perkinsus marinus*, nearly wiped out oyster production in Chesapeake Bay (3).

In addition to the various prevention approaches mentioned earlier, rapid early detection of pathogenic organisms is a significant weapon against marine diseases, both those affecting marine animals and those affecting humans. Most bacteria in natural samples resist attempts at culturing, thus standard plate-count methods will not reveal them. Notable human pathogens that frequently exist in a viable but nonculturable state in aquatic systems include *Vibrio cholerae* and *Salmonella enteritidis* (62). Recently, sensitive molecular methods for the detection of specific microbes in natural samples that do not rely on culturing have been developed. DNA probes, PCR amplification of specific genes, and monoclonal antibody-based tests have been successfully used for the detection of a number of human pathogens in aquatic environments, including those causing dysentery, cholera, and septicemia in humans (3). Similarly, DNA probes have been used to detect pathogens of aquacultured animals such as the shellfish parasite *Marteilia refringens* (63). A sensitive PCR assay for the salmonid pathogen causing bacterial kidney disease, *Renibacterium salmonarium*, also has been developed (64). In the near future, the use of these direct detection methods may well supplant traditional culture methods for bacterial enumeration.

Many marine toxins are produced by microalgae or bacteria and are concentrated in the tissues of organisms as they are passed up the food chain. Examples such as ciguatoxin and saxitoxin are capable of causing fatal poisoning in humans. The development of sensitive assays for marine toxins is thus of great practical interest. Puffer fish toxin (tetrodotoxin), a potent and sometimes lethal sodium channel blocker, is probably produced by bacteria associated with its namesake fish. A monoclonal antibody-based immunoassay has been recently developed to detect this toxin in biological samples (65). Similarly, a variety of bioassays, biochemical and immunoassays, and physicochemical methods are available for the detection of the diarrhetic phycotoxins responsible for shellfish poisoning (66). However, the sensitivity of such assays is only one of many important qualities. For fisherman and others with a strong stake in assuring the safety of seafood for consumption, the ease and rapidity of a toxin assay are critical parameters to consider. The simple commercially-available test kit for ciguatoxin is an excellent example of marine biotechnology research put to practical use (67). In this respect, an exciting avenue for research is the development of biosensors for the detection of marine toxins. Biosensors combine biological molecules such as enzymes or antibodies with a transducer that can convert

a biological response into an electronic signal (68). Applied marine biotechnological research in this area could lead to the development of real-time true toxicity sensors for use in the field to assess the safety of marine foodstuffs.

MARINE ECOLOGY

Fundamental research on the structure and functioning of marine ecosystems has been recently given a tremendous boost from the application of molecular biological tools. Such tools have allowed for the identification of species, and the assessment of the genetic variability within and between species, with unprecedented detail and accuracy. For example, the study of fish and invertebrate populations has benefited from the use of restriction endonuclease digestion of mitochondrial DNA. Changes in mitochondrial DNA have been used to trace genetic lineages in numerous marine animal species, from striped bass to humpback whales (69). This technique has allowed researchers to delineate and track discrete populations of animals that could not otherwise be differentiated. The phylogeny of marine animals can besimilarly determined through sequence analysis of ribosomal RNA, creating "family trees" that define the genetic relatedness of disparate species. The separation and immunological staining of individual proteins, with subsequent comparison of homologous proteins (isozyme analysis), can also be used to distinguish genetically distinct species that are morphologically identical.

The application of genetic techniques to marine microbial ecology has revolutionized the field. Evolutionary relationships between marine microorganisms are exceedingly difficult to ascertain from morphology alone, but through the use of DNA and RNA hybridization techniques, highly detailed phylogenetic trees that shed new light on microbial diversity in the sea have been created. For example, by cloning and sequencing 16S rRNA genes amplified by PCR, researchers have found that the ubiquitous bacterial genes recovered from seawater do not correspond to any cultured microbes (70). Similarly, marine archaea, previously thought to exist only in extreme environments, have been found to be abundant components of ocean plankton through the use of oligonucleotide primers specific for their rRNA genes (71). Genetic analyses of marine eukaryotes have demonstrated that the traditional separation of these organisms into algal, fungal, and protozoan groups is a gross oversimplification of the true relationships between them. For example, dinoflagellates, traditionally considered among the algae, are now thought to be more closely related to heterotrophic ciliates than to other algae such as diatoms or chlorophytes (72).

As genetic techniques in marine biotechnology are applied to microbial ecology, our view of the relationships between organisms continues to be improved. Beyond the assessment of microbial biodiversity, genetic techniques can also aid in the study of the metabolism of marine microorganisms in their environment. For example, variations in rRNA content via hybridization to 16S rRNA probes have been used to study the starvation response in marine bacteria (73). Also, gene expression in natural populations can now be assessed using mRNA analysis. This technique is now being applied to novel oceanic cyanobacteria, in order to assess their potential nitrogen-fixing activity (74). The ability to assay for gene expression should allow marine microbial ecologists to determine, better than ever before, which microorganisms in the sea are truly responsible for carrying out specific metabolic processes.

MARINE BIOPROCESS ENGINEERING

Marine organisms, particularly microorganisms, represent a vast store of genetic diversity that could potentially be used to generate thousands of unique and useful compounds. However, to date, the success rate for the progression of marine products from initial characterization through to mass production has been quite low (75). Marine bioprocess engineering represents the critical missing link between discovery and commercialization of marine bioproducts. Bioprocess engineering may be defined as "the translation of life-science discoveries into practical products, processes, or systems capable of serving the needs of society" (76). Marine bioprocess engineering is therefore an approach, based on sound scientific and engineering principles, to surmount technical and infrastructural barriers associated with the production and commercialization of marine bioproducts. The engineering of a marine bioprocess begins with compound characterization and screening, progresses through small-scale production and scale-up to industrial production, and ends with product marketing (Fig. 2). Along the way, issues of product separation and recovery, product formulation, production systems development, and market evaluation must be addressed.

Characterization and Screening

Engineering a marine bioprocess begins with the identification of a marine biological product of some potential commercial interest. In some cases, this may be a major product of the organism that can be easily identified, such as an algal polysaccharide or major pigment. In other cases, particularly with potential drug candidates, extracts from the organism are put through a series of in vitro screening procedures to identify bioactivity (Fig. 2). Screening may involve application of the extract to bacterial or fungal cultures or to various tumor cell lines or other test subjects. Wild collections or small-scale cultures usually suffice in terms of total material for this initial screening. Extracts exhibiting bioactivity are then subjected to chromatography or other separation techniques, to isolate small amounts of individual compounds. These compounds can then be characterized by GC-MS, NMR or other methods, to determine their molecular structures. Individual purified compounds are then subjected to further in vitro screening procedures to confirm their bioactivity. Promising compounds may be subjected to chemical or enzymatic combinatorial catalysis, to generate libraries of closely related compounds for additional screening.

To culture marine organisms, even at the bench scale, one needs information on the growth conditions

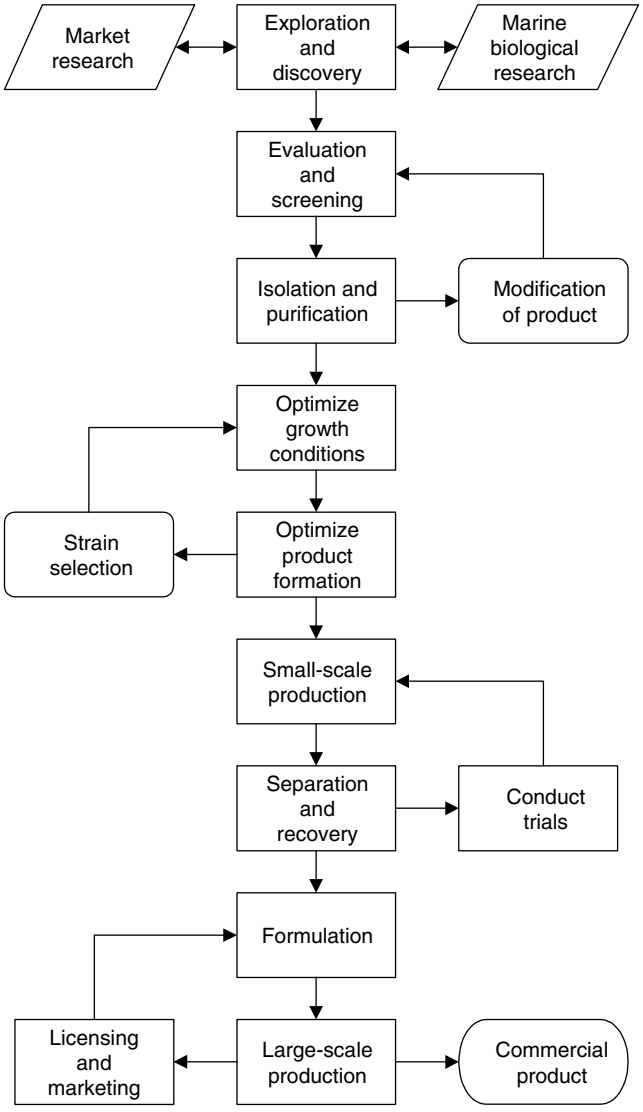

Figure 2. Conceptual flowchart for a marine bioprocess, leading from discovery to commercialization.

that the organisms require. Identifying the parameters controlling growth and affecting product formation can constitute a major research endeavor, and such attempts can sometimes prove fruitless. Product formation may require conditions very different from those favoring growth, as is the case with astaxanthin formation in the green microalga *Haematococcus pluvialis* (77). Once an organism is in culture, several techniques may be employed to generate strains capable of enhanced product formation. Classical strain selection techniques involving the handpicking of individual overproducing organisms is one approach, but can be difficult, especially with bacteria and small microalgae. In some cases, the use of automated cell sorting by flow cytometry can speed up the strain selection process, as with the selection of pigment-hyperproducing yeast mutants (78). Microbial antagonism can be used to elicit the production of bioactive compounds normally used in cell defense, by deliberately exposing cultures to foreign organisms. This strategy has been effective for the induction of antibiotic compound production by marine epibiotic bacteria (79).

Production

Marine animals, plants, and macroalgae that produce compounds of commercial interest may be harvested from the wild or cultivated in aquaculture "farms." The former approach is usually not viable for the maintenance of a steady supply of source material for industrial-scale bioproduct manufacture. The latter approach may at times be viable, but quite often the organisms of interest are difficult to reliably cultivate, and product yields are often highly variable. Marine microorganisms, on the other hand, may be cultivated in bioreactors that allow tight control over environmental parameters and isolation from potential contaminants. Marine bioprocess engineering is therefore generally more applicable to the microbes than to the multicellular life-forms. Two basic types of bioreactors are commonly employed: fermentors and photobioreactors. Fermentors are closed, environmentally controlled bioreactors, generally made of stainless steel, which are used for the heterotrophic culturing of microorganisms. Some specialized fermentors for culturing extremophiles are designed to operate at high temperatures and/or pressures. Photobioreactors are transparent versions of fermentors, usually made partly or entirely of glass or clear plastic cylinders, tubes, bags, or panels, to allow light penetration into the culture (80; Fig. 3). Photobioreactors are used for the culturing of photosynthetic organisms, principally microalgae and cyanobacteria, but in some cases other types of photosynthetic bacteria as well (81). In some instances, particularly when culturing in extreme conditions of pH or salinity, open ponds or raceways are adequate for the mass production of microalgal bioproducts (82). However, in general, the potential for close control of culture conditions and exclusion of contaminating organisms make photobioreactors the growth vessels of choice for microalgae. Light penetration is key in photobioreactor technology; hence, the ratio of surface area to volume in a large-scale photobioreactor is designed to be much greater than that of a typical fermentor. Moreover, photobioreactors must be exposed to a light source, either natural sunlight or artificial light. Artificial lighting is expensive, whereas natural sunlight, although free, is limited by latitude and weather.

Despite the wide variety of fermentor and photobioreactor designs now in use or in development, all microbial bioreactors share common features (Fig. 3). All bioreactors require some form of mixing to keep cells in suspension, some form of temperature control, and systems for introducing fresh growth medium and for effecting gas exchange (carbon dioxide and oxygen). Systems for the control of culture pH, cell concentration, and incident light levels are also frequently of use. Finally, all bioreactors must have some means for conducting harvests, either in batches or continuously. In a production plant, cultures must be effectively scaled up from the bench scale (milliliters to liters) to the full production scale (thousands of liters or more). Many aspects of environmental control that seem straightforward at bench scale become problematic at production scale, including the maintenance

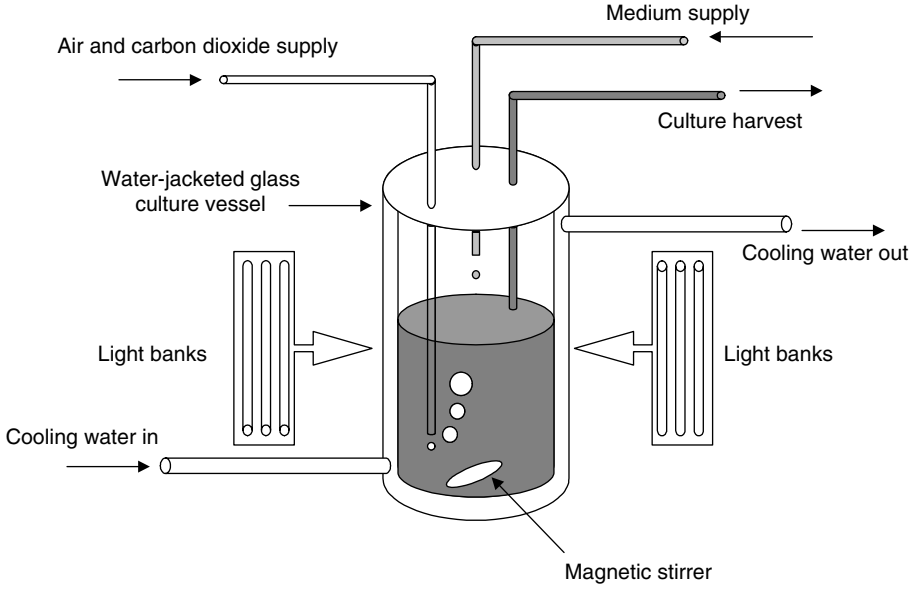

Figure 3. Schematic diagram of a simple continuous-culture laboratory-scale photobioreactor.

of sterility in bioreactors and their associated piping and pump systems, the achievement of adequate turbulent mixing, and the rapid exchange of gases. None of these problems is insurmountable, but the solutions must be carefully engineered.

Separation, Recovery, and Formulation

Once a marine microorganism is successfully growing at production scale, and is actively synthesizing the target compound, it must be processed (Fig. 2). Separating microorganisms from liquid media can be achieved by filtration, centrifugation, flocculation, or in some cases by passive settling. Each of these methods has advantages and disadvantages, and they are all expensive in practice, but in general, centrifugation is preferable for unicellular organisms. For organisms with tough cell walls, mechanical or enzymatic degradation may also be necessary to release the intracellular contents. Once the cells have been concentrated into a slurry, they can be dried and/or subjected to some sort of extraction procedure. Whole-cell products are typically dried, whereas specific compounds are usually extracted from the biomass paste with natural oils, chemical solvents, or supercritical fluids.

Formulation of marine bioproducts is an important step in the route to commercialization (Fig. 2). Microbial contamination, chemical purity, bioavailability, and consumer appeal are all characteristics to consider during the bioprocess engineering endeavor. The complete exclusion of bacteria and fungi from large-scale systems, especially outdoor photobioreactors, may not be cost-effective or may even be possible. The degree to which these organisms must be kept out of the product will depend on the end application; for example, products for animal feeds may not have regulatory requirements as strict as those for products intended for human consumption. Postprocessing sterilization or the sterile extraction of compounds may circumvent this issue entirely. The chemical purity of bioproducts also may be of great importance, particularly when compounds are extracted before packaging. For example, some drugs and nutraceuticals have geometric and stereoisomers of varying bioefficacy. Furthermore, in pharmaceutical applications, it is often critical that compounds related to the target compound not be present, as they could potentially confer toxicity upon the final product. In formulating the final product that will go to the consumer, the bioprocess engineer may also need to consider aspects of the bioavailability of the target compound in its delivery system. For example, the form (liquid/solid, oil/water, etc.) of the product and the composition of additives (stabilizers, preservatives, emulsifiers, etc.) may have a direct bearing on both storage life and on how well the target compound is assimilated into the body. Finally, the texture, odor, taste, and packaging of the end product should be appeal to the consumer.

Market Evaluation

Ultimately, the sales of the product will be the metric by which the bioprocess engineering activity is judged. It is therefore critical that careful market evaluation be carried out before too much investment is made into a new bioprocess. In a sense, market evaluation should be carried out simultaneously with product discovery (Fig. 2). Marine bioprocesses can be very expensive to engineer, thus the potential productivity of the planned operation must be commensurate with the expected demands for the product. Potentially less expensive alternative sources for the product, such as chemical syntheses or terrestrial organisms, must be scrutinized. For example, although certain microalgae are capable of synthesizing the carotenoid pigment lutein, no algal bioprocess has been developed that can compete with the inexpensive production of lutein from the petals of marigolds. Only if the marine bioproduct is destined to capture a substantial market share should

implementation proceed. Lastly, consideration of niche markets should be given in developing marine bioproducts. Potential drugs for which there is no alternative will be pursued before those of more general utility. Similarly, where currently only synthetic forms exist, a "natural" form may be perceived to be superior by the consumer.

LEGAL ASPECTS OF MARINE BIOTECHNOLOGY

Risk Assessment and Regulatory Issues

The safety of marine biotechnology for humans and for marine ecosystems is a subject of some discussion. Companies involved in marine biotechnology are both cultivating organisms introduced from foreign locations and creating genetically modified organisms with unique properties. The risks can be divided into two categories: those associated with the inanimate products of marine biotechnology and those associated with the organisms used in marine biotechnology. The former would appear to be no greater than risks associated with the products of any industry (3). No special hazards have been associated with the inanimate products of genetically modified organisms, so regulations governing their use essentially follow existing consumer safety guidelines. On the other hand, the safety of the genetically modified organisms themselves is at issue. Although the accidental generation of pathogenic organisms is exceedingly unlikely, the potential ecological consequences of the accidental release of genetically modified marine organisms into the wild are not well-understood. Marine organisms have the potential for rapid dispersal once released into the environment to a much greater extent than terrestrial organisms (83). Field tests of genetically modified marine microorganisms are likely to occur in the near future. The regulation of such modified microbes in the United States falls under the jurisdiction of the Environmental Protection Agency, whereas the Food and Drug Administration is responsible for issues regarding transgenic fish and shellfish. To date, there is no agency specifically tasked with the oversight of safety issues in marine biotechnology, although it has been proposed that such a unit be designated at the National Marine Fisheries Service (84).

Intellectual Property and Technology Transfer

Marine biotechnology, though grounded in science, is above all else a commercial enterprise. As such, much of the research and development in marine biotechnology is funded by venture capitalists or by large corporations. To these profit-minded groups, trade secrets must be jealously guarded and new technologies need to be rapidly patented. Maintaining rights to hard-won intellectual property is a key to success in the business of biotechnology, and marine biotechnology does not present an exception. Among the most significant policy issues facing government and the growing marine biotechnology industry is the issue of ownership of bioprocesses and biomaterials (85). Although apparatuses and processes have traditionally been the principle subjects of patents, the securement of intellectual property rights to both molecules and organisms is now possible. Intellectual property law, however, is not static, and is likely to be modified in coming years to adapt to rapid changes in biotechnology.

Despite the commercial emphasis of marine biotechnology, academic institutions are at the forefront of research into marine biology, ecology, and microbiology. If the combined forces of industry and academia can be brought to bear on marine biotechnological issues, society as a whole will benefit. To accomplish this, procedures and guidelines for technology transfer must be set up such that both industry and academia can feel content with their resource allocations. Excellent models for such industry/academia partnerships are to be found in the National Science Foundation's Engineering Research Centers. Among these is the newly founded Marine Bioproducts Engineering Center (MarBEC), a cooperative effort between the University of Hawaii, the University of California, and several industry partners with interests in marine biotechnology (75). Advisors from the private sector help to guide the directions for research in these centers, whereas key research results are shared with industrial sponsors. Most importantly, these centers provide the unique multidisciplinary education and training opportunities that students need to become tomorrow's leaders in the marine biotechnology industry.

CONCLUSION

The oceans cover most of the Earth's surface, yet the vast potential of their denizens as the sources for new products, processes, and research tools has hardly been tapped. The application of biotechnology to marine organisms, especially microorganisms, is beginning. Marine biotechnology is likely to yield a plethora of new drugs, health products, fuels, environmental remediation processes, advances in aquaculture, vaccines, and technologies for advanced marine research. To reach these goals will require the development of novel partnerships between academics, engineers, industrialists, legal experts, and financiers who share a common interest in finding practical uses for the unique resources of the sea.

MEROPLANKTON

CLAIRE L. SCHLESKE
University of Florida
Gainesville, Florida

Meroplankton are autotrophic and heterotrophic organisms, which occur in the water column as part of the plankton but also settle or sink to the bottom sediments and thus spend a portion of their life cycle in the benthos. These temporary plankters, sometimes referred to as tychoplankton, have both vegetative cells and resting propagules that are important in phytoplankton dynamics in both freshwater and marine environments. Resting propagules include cysts of dinoflagellates, asexual spores, or akinetes of cyanobacteria, sexually produced zygotes of *Eudorina* and *Volvox*, vegetative colonies of *Microcystis*, and resting cells of diatoms (1). Alternation from planktonic to benthic phases range from diurnal (2,3) to decadal or longer timescales (4). On short timescales, settling of vegetative cells is an adaptation to diurnal changes in light and nutrient fields. On longer timescales, the benthic phase is likely to be in the form of resting propagules.

Resting cells or resting propagules are a physiological adaptation allowing vegetative cells to survive for long periods under conditions unfavorable for growth (1). Such resting stages are common among planktonic organisms and include cysts of chyrsophytes and dinoflagellates, akinetes (asexual spores) of cyanobacteria and resting cells of diatoms. Some vegetative cells of planktonic organisms sink to the sediments at aphotic depths where light is not available for photosynthesis, and benthic resting propagules are formed. This adaptation survival strategy has ecological and evolutionary advantages (5). The alternation from planktonic to benthic habitat provides a strategy that allows populations to survive conditions unfavorable for planktonic growth by settling and forming resting propagules in the benthic environment. These propagules ensure population survival until resuspension into a planktonic environment favorable for growth. This capability of a planktonic species to survive periods when environmental factors are unsuitable for growth and to maintain a potential inoculum for growth when favorable environmental factors return is fundamental to the planktonic way of life (1).

This article is restricted to organisms that are photoautotrophic in the planktonic phase (phytoplankton) and thus does not include invertebrates with meroplanktonic stages in their life cycle.

CYANOBACTERIAL AKINETES

Akinetes are resting propagules of cyanobacteria, which form and survive in the benthic environment and play an important role in maintaining meroplanktonic populations. Benthic akinetes of the cyanobacterium *Gloeotrichia echinulata* obtain phosphorus supplies after germination on the sediments; subsequent planktonic growth can be mostly or in part supported by these accumulated reserves (6). Resuspension or direct penetration of light to

the sediments may play a role in germination of cyanobacterial populations from akinetes and their introduction into the plankton (7). Phosphorus accumulated by vegetative cells of *G. echinulata* in the benthos can account for a significant portion of internal phosphorus loading into the overlying waters when the population is recruited into the plankton (8,9). For example, internal loading from recruitment of this species in Lake Erken, Sweden ranged from 0.4 to 0.6 mg P m^{-2} d^{-1} during July and August (10). Recruitment of vegetative cells of *Aphanizomenon flos-aquae* accounted for similar rates of internal loading from the sediments in a shallow, hypereutrophic lake (Agency Lake, Oregon). Motility of cyanobacterial populations is facilitated by gas vacuoles that increase buoyancy. Not all phytoplankton populations of cyanobacteria are maintained by meroplanktonic dynamics that involve akinetes. Many populations bloom, then are maintained in low numbers in the plankton during the remainder of the year (7,11).

DINOFLAGELLATE CYSTS

Encystment by dinoflagellates is a morphological adaptation for survival in the benthic environment. Such cysts have thick resistant walls of cellulose, and their protoplasts usually contain reserves of lipid and starch, which are accumulated during a stationary growth phase (1). Stimuli for encystment in two dinoflagellates were primarily nitrogen availability coupled with a secondary influence of irradiance (12). Cysts may accumulate phosphate during the period of dormancy, providing a competitive advantage after germination and resuspension into the pelagic (13). Algal cyst dormancy may also be a temporarily transient mechanism of avoiding herbivory in the plankton (14). These results suggest an important role for dinoflagellates in the translocation of nutrients from sediments to overlying waters. The alternation between vegetative populations and the distinct resting phases of *Ceratium hirundinella* provides a classic example of a meroplanktonic dinoflagellate (1).

DIATOM RESTING CELLS

Resting cell formation as a survival strategy for diatoms that sink to aphotic waters in both freshwater and marine environments was first noted more than 100 years ago. Whipple postulated in 1895 that dormant diatoms resuspended from surficial bottom sediments during seasonal turnover of the water column in lakes provide seed populations for seasonal population blooms (4). Hensen in 1887 recognized that resting stage formation was a survival strategy in some marine diatoms (5). In the resting phase, the cytoplasmic contents of vegetative cells condense in several stages and become physiologically dormant with the resting cells containing stored nitrogen, polyphosphate, and lipid reserves (4,15,16). Resting cells of diatoms and their intermediate stages have been described from a wide variety of aquatic habitats ranging from small lakes to the deep ocean (4,5,16,17).

FORMATION AND REJUVENATION OF RESTING PROPAGULES

How rapidly and frequently resting cells and other resting propagules actually form is open to conjecture. Formation of diatom resting stages is induced by darkness and accelerated at high temperature (4). In *Aulacoseira subarctica*, it occurs at very low light levels, about one $\mu mol\, m^{-2}\, s^{-1}$ (18), with several days required for resting cell formation at 20 °C. By contrast, photosynthetic capacity of *A. subarctica* declines during dark incubation in the laboratory with little loss of metabolic competence of cells for four weeks (18). Likewise, the transitory benthic assemblage in Lake Apopka, Florida is physiologically active when incubated at 100 to 300 $\mu mol\, m^{-2}\, s^{-1}$ in three-hour light-dark bottle experiments (19). *Aulacoseira italica* is the dominant species of the autotrophic assemblage subjected to periodic resuspension in this shallow, polymictic lake. After formation, resting cells of diatoms buried in sediments retain the capability of rejuvenation for decades (4).

Numerous studies report rapid rejuvenation of physiologically inactive resting phases of diatoms (4). Resting cells of *Aulacoseira granulata* buried in the sediments of Douglas Lake, Michigan, for approximately 20 years fix carbon photosynthetically in a matter of hours after exposure to moderate light (50 $\mu mol\, m^{-2}\, s^{-1}$) (16). Resting cells of diatoms rejuvenate at rates that generally increase with temperature and light but vary among species (4). Thus, resting cells of diatoms are adapted for survival in darkness and are rejuvenated to a physiologically active state within hours after exposure to a normal light and nutrient environment (4,16).

RESUSPENSION DYNAMICS

Studies show that induced resuspension increases nutrients, phytoplankton, and suspended solids in experimental enclosures (20). Elevated phytoplankton biomass persisted for at least four to six days, whereas increased suspended solids were maintained for less than one day. Phytoplankton that persisted in these studies were generally planktonic rather than meroplanktonic species. Unpublished experimental data for resuspended meroplankton in Lake Apopka, Florida, show that cells settle slower after resuspension than other sedimentary components. Meroplanktonic populations, therefore, are maintained in a suspension longer than resuspended, inorganic solids.

The effect of experimental resuspension on population dynamics of *Aulacoseira italica* was studied in a small lake in England (21). Two areas of Blelham Tarn, a 17-ha lake, were isolated with vertical polyvinyl chloride (PVC) screens. Compressed air was used as an "air-lift pump "to destratify the enclosed areas after the water column had stratified in the summer. The late summer increase in *Aulacoseira* caused by experimental destratification in 1967 was dramatic, and this bloom was greater than many spring blooms for the previous 22 years, a period of thoroughly documented population dynamics. Results, however, were confounded by water flowing over the top

and under the bottom of the enclosures. Consequently, the response may not have been associated entirely with destratification if cold, bottom water probably passed under the PVC screens. Increased numbers of *Aulacoseira* likely resulted from nutrient-enhanced growth of a seed population that was resuspended during artificial destratification.

Resuspension and its significance on biological and chemical dynamics in temperate and subtropical lakes depend on physical and morphometric factors. Resuspension of sediments in shallow lakes likely will be more frequent and important than in deep lakes, and will not occur in temperate lakes during periods of thermal stratification or ice cover. In deep stratified lakes, resuspension occurs seasonally only during periods of isothermal mixing and during upwelling events in large lakes.

Wind-induced resuspension of bottom sediments in shallow lakes depends on wave-generated turbulence (22). Benthic sheer stress calculated from wind speed, effective fetch, and depth predicts resuspension effects on nutrients (phosphorus and nitrogen) and chlorophyll better than wind speed alone in seven shallow, New Zealand lakes (23). Such empirical relationships do not consider differential effects of resuspension related to size, density, and types of particles being resuspended (24).

Wind-induced resuspension of sediments increases phosphorus and chlorophyll in the water column (19,23,25). The residence time of resuspended particles in the water column is relatively short, on average seven hours (25), and effects on phytoplankton are highly transient (26). Because of these short residence times, resuspended particles such as small phytoplankton or nutrients may have longer effective residence times than inorganic particles. Data from New Zealand lakes show that annual mean TP concentrations including resuspension events were four times greater than means during calm periods (23). In Lake Apopka, Florida, chlorophyll concentration in the water column doubled one day following a resuspension event (19). Whether such increases in phytoplankton biomass are related to new growth resulting from resuspended nutrients or to direct resuspension of algal cells or resting propagules can be ascertained from short-interval sampling before, during, and after a resuspension event. Automated sampling of the relevant variables in situ is needed to describe the associated dynamics adequately.

TIME SCALES OF RESUSPENSION AND RECRUITMENT

Life history and survival strategies for meroplankton involve resuspension or recruitment of vegetative cells and resting propagules from the benthic environment. Physical and chemical factors in the aquatic environment play important roles in the various strategies for meroplanktonic existence. The principal physical factors are interactions between water temperature and wind-induced turbulence. In deep, thermally stratified lakes, effects of turbulence are seasonal and most important when such monomictic or dimictic lakes are homothermic. Shallow, polymictic lakes differ in that effects of turbulence depend on short-term variability in local meteorologic conditions. Algal populations with a meroplanktonic phase are planktonic only during periods of relatively high wind-induced turbulence associated with a homothermic water column. Chemical factors are important because the benthic environment is generally richer in nutrients than are overlying waters.

In shallow lakes, diurnal mixing is an important factor in phytoplankton dynamics. Thermal stratification in Lake George, Uganda, develops during the day and is then obliterated by evening winds and cooling (3). The dominant cyanobacterial populations settle toward the bottom while the water column is stratified, then are resuspended and distributed uniformly over the water column during diurnal mixing (2). Chlorophyll concentrations vary during stratified conditions from 100 μg/L in surface waters to more than 400 μg/L at depth where settling algal cells are concentrated. When the water column is not thermally stratified, chlorophyll is distributed homogeneously in the 2-m water column.

Diurnal variation in environmental factors is also important in shallow lakes and reservoirs in Brazil (27). In such systems sediment/water interactions are accentuated by diurnal mixing. As a result, wind-generated turbulence affects nutrient availability and primary productivity of phytoplankton because nutrients regenerated in the benthic environment are entrained daily and become available for phytoplankton production. Seasonal changes in rainfall cause water depth to fluctuate 2 to 4 nm and thus influence turbulence and sediment/water interactions.

Direct inoculation of meroplankton from the benthic to planktonic environment occurs in Lake Apopka, a shallow, hypereutrophic lake in north central Florida (19,28). Chlorophyll *a* in Lake Apopka is characteristic of a hypereutrophic lake, averaging 104 mg/m^3 with a coefficient of variation of 44%. Water temperature varies seasonally, but no seasonal pattern is apparent in the standing crop of phytoplankton measured as chlorophyll *a*. Bimonthly data and data collected less frequently provide little evidence for pronounced seasonal variation in phytoplankton dynamics or standing crop in the lake (19,28). Chlorophyll *a* concentrations beginning in February or March and continuing until July ranged from 100 to 200 μg/L, exceeding the range of 50 to 100 μg/L for other months of the year.

The role of wind resuspension in controlling these dynamics is evident from a plot of average daily wind speed and chlorophyll concentration. Chlorophyll is positively correlated with wind speed because meroplanktonic algae are resuspended from the sediments. Effects of wind-induced resuspension are unusual in that light attenuation also is positively correlated with increased chlorophyll concentration (28) and not affected disproportionately by nonalgal turbidity that occurs in other lakes (29). Algal standing crop increases during and after windstorms in Lake Apopka because wind-induced turbulence in the water column resuspends loosely consolidated bottom sediments and sedimented algal cells. Recent research shows that small particles including algal cells may be resuspended more readily by wind-induced turbulence than larger cells and denser sestonic materials (24).

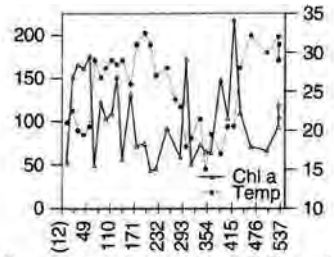

Figure 1. Surface water temperature (°C) and chlorophyll *a* concentration (μg/L) in Lake Apopka, Florida, February 1990 to July 1991 [Schelske et al. 2000 (28,47)].

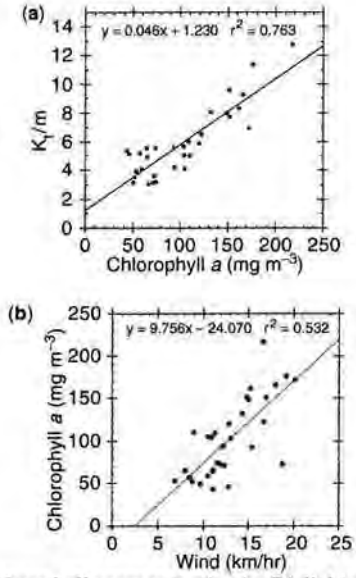

Figure 2. Chlorophyll *a* concentration (μg/L), light extinction and wind speed in Lake Apopka, Florida on data collected from February 1990 to July 1991 (28,47). (**a**) Linear regression of extinction coefficient (Kt of photosynthetically active radiation) on surface-water chlorophyll *a*. (**b**) Linear regression of surface-water chlorophyll *a* on average daily wind speed measured at Orlando International Airport [Schelske et al. 2000 (28,47)].

Phytoplankton, primarily diatoms, settle to the bottom in this lake during calm periods forming a nepheloid layer (used here as the layer of near-bottom materials that are suspended by turbulent mixing). Chlorophyll concentrations in a 5-cm thick flocculent layer of sediments near the bottom range from 2,940 to 4,230 μg/L (19), or at least 10- to 20-fold greater than the maximum in the surface water. If mixed into the water column, enough chlorophyll may be present in this layer to double the concentration found in the water column. Thus, wind resuspension plays an important role in phytoplankton dynamics in Lake Apopka.

No strong seasonal pattern in water transparency, chlorophyll, or nutrients (nitrogen and phosphorus) is apparent in Lake Apopka (28). Silica was an exception; the monthly average for 1977 to 1980 was lowest in February and March and highest in November. This seasonal pattern was related both to uptake of silica for the seasonal production of diatoms and to input of dissolved silica during periods of increased hydrologic loading.

Meroplanktonic algae in the near-bottom layer in Lake Apopka are physiologically viable and are adapted to periods of darkness or subsaturating irradiance characteristic of the lake bottom (19). Other species of diatoms with condensed cytoplasmic bodies also may be resting cells. Resting propagules in the benthic aphotic assemblage rejuvenate after short exposure to low irradiance, and when resuspended in the water column, are an important component of the phytoplankton.

Wind resuspension of nutrients and vegetative cells or resting propagules may be important in Lake Okeechobee, a shallow, subtropical, polymictic lake in Florida. *Actinocyclus normanni*, a diatom species with resting cells (4), may occur in phytoplankton samples following wind resuspension (28). *Staurosira construens*, another diatom species with resting cells, was among the ten most abundant taxa at most of the 21 stations sampled during an intensive two-year study of phytoplankton (30). Cyanobacteria, however, dominated the phytoplankton biovolume (30). *Lyngbya* sp. and pennate diatoms may be meroplanktonic and comprise a large portion of phytoplankton biomass in some regions of this shallow lake where resuspension also increases nutrients (31), inorganic turbidity and phytoplankton biomass (29) in the water column. Inorganic turbidity decreases mean light availability in the water column, resulting in lower algal production (29).

Wind resuspension of meroplankton and inorganic solids is also important in the shallow western basin of Lake Erie. The abundance of *Fragilaria crotonensis* Kitt. increased sixfold in surface waters two days after resuspension of sediments by wind-induced turbulence (32) and probably resulted from resuspension of a seed population that then expanded in surface waters. Inorganic turbidity presumably decreased soon after the wind event, allowing the planktonic population to respond to favorable nutrient and light conditions. Thus, wind-induced resuspension controlled by the frequency of storms on daily to weekly scales can be important in shallow, temperate lakes.

The role of meroplanktonic resuspension on longer timescales in deep, temperate lakes is apparent in Lake Michigan, one of the Laurentian Great Lakes. This monomictic lake (mean depth 87 m and surface area 58,000 km^2) has a large heat capacity and rarely freezes over completely. As a consequence, the period of isothermal mixing is long, extending at least from January until May in most years (28). As a result of periodic high turbulence, the water column is mixed completely during this period even at the greatest depths and is cooled below the temperature of maximum density ($<4^{circ}$C). Turbulence during storm events is adequate to resuspend sediments (33) and to mix the entire water column, entraining not only nutrients but also resting cells of diatoms and cyanobacteria (4,34).

Usually, resuspension and external loading of phosphorus in Lake Michigan tend to reset the total phosphorus concentration at approximately the same level between years, but during the unusually cold winter of 1976 to 1977, ice cover was nearly complete, and winter resuspension was minimized (33). In the spring of 1977, the average total phosphorus concentration in the water column was only five μg P/L compared to eight μg P/L in the previous year. Reduced turbulence during ice cover also influences

the abundance of meroplanktonic diatoms by shortening the period of isothermal mixing (35).

Wind resuspension of diatoms on daily to weekly scales affects phytoplankton biomass in coastal, marine environments where it is greater and more variable than in deeper, offshore waters (36). One important factor controlling variability is the frequency of wind events. Although nutrient enrichment from wind-induced upwelling and its effect on coastal phytoplankton blooms are well known, blooms of the diatom *Skeletonema costatum* develop in response to wind-induced vertical transport of diatoms from the aphotic zone to surface waters in the coastal plume of the Hudson River. Resuspended diatoms grow while being transported seaward in the plume, thereby increasing production 100 km beyond the zone of most active resuspension. Wind-induced resuspension, therefore, can affect diatom production on daily to weekly scales over a greater area than that affected directly by the wind.

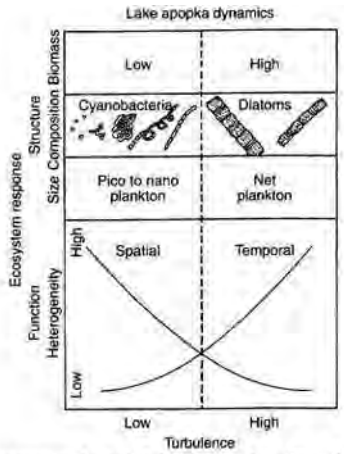

Figure 3. A conceptual model for dynamics of surface-water phytoplankton in Lake Apopka, Florida (from 19?). The model depicts ecosystem response to wind-driven, water-column turbulence in terms of function and structure of the phytoplankton community [Carrick et al. 1993, Limnology and Oceanography, (19)].

ECOLOGICAL SIGNIFICANCE OF MEROPLANKTON

The periodic appearance of meroplankton in the plankton, either from sediment resuspension or recruitment, enhances the diversity of the phytoplankton assemblage in aquatic ecosystems. The relationship between wave-induced turbulence and assemblage diversity in Lake Apopka, Florida, is illustrated with a conceptual model (Fig. 3), which has been confirmed by other studies. Wind-induced turbulence increases diversity by maintaining meroplanktonic species in the water column (37). Resuspension effects also increase the concentration of phytoplankton, bacteria, and nutrients in lakes (23,38,39). Inocula of dormant diatoms following wind-induced resuspension led to growth pulses of *Melosira* (*Aulacoseira*) in Lake Lanao, Philippines (40). After resuspension events, species are lost from the planktonic assemblage according to size and density as turbulence decreases. Small particles or picoplankton (1.5–6 μm) are resuspended by low turbulence, whereas greater turbulence is needed to resuspend larger microplankton (24). Phytoplankton populations that settle slowly under low turbulence may be maintained at low levels in the plankton throughout the year and provide an inoculum for growth when environmental conditions are favorable (11).

Sedimentation of diatoms is a life cycle strategy to enhance survivorship by incidental grazer avoidance or redistribution to more nutrient-rich waters (5). Likewise, algal cyst dormancy is also proposed as an adaptation to escape herbivory (13). Sedimentation of phytoplankton diatoms from the euphotic zone into the relatively nutrient-rich nepheloid layer in Lake Apopka, Florida, provides a mechanism to utilize relatively nutrient-rich waters at the sediment-water interface on short timescales (19, 28).

A number of studies show that diatom blooms in surface waters are an important energy source for benthic food webs. Rapid sinking of diatoms must be invoked for diatoms to reach the bottom so they can be preyed upon by benthic grazers in deep-water marine and freshwater environments. The literature reports that rapid settling of diatoms in fecal pellets of zooplankton is one mechanism for rapid transport to the bottom. A comprehensive literature review, however, concludes that the so-called "fecal pellet express "is relatively unimportant and that the most important process is aggregation of diatoms within the water column (5). Aggregated clumps of diatoms sink rapidly (sinking rates of 10 to 100 m/day) to the benthic community (41,42). These clumps are now thought to disaggregate within two weeks or less so cells can be resuspended with less turbulence than necessary for aggregated cells (43). Disaggregation also enables vegetative cells to assimilate nutrients in the benthic environment.

Mechanisms promoting rapid transport of diatoms to the benthos have not been studied as extensively in lakes as in the marine environment. Diatoms are an important food source for benthic organisms in the Laurentian Great Lakes where sedimentation of the spring diatom bloom provides a major food source for *Dioporeia affinis* (44). This amphipod apparently stores enough lipids from feeding on settled diatoms in the spring to fulfill a major component of its annual energy requirements. In these deep lakes, the spring bloom of diatoms that originates from resuspended seed populations or resting propagules is important. In shallow lakes, no adaptation for rapid sinking is required for diatoms to settle out of the euphotic zone to the bottom within a few days. In Lake Apopka, for example, most of the benthic environment is aphotic even though the mean depth is 1.7 m (28). Phytoplankton settling to the bottom may have an ecological advantage in this lake in that near-bottom waters are nutrient-rich compared to surface waters with relatively low levels of soluble inorganic nitrogen and phosphorus (28). Settling to the sediment–water interface, a site of nutrient regeneration, may be an adaptive strategy to enhance nutrient uptake and utilization by meroplanktonic populations.

LAKE MANAGEMENT IMPLICATIONS

Meroplanktonic vegetative cells or resting propagules may assimilate nutrients during the benthic phase and

store excess phosphorus (luxury uptake) that can be used for growth during the planktonic phase. The capability for luxury uptake is found also in other resting propagules. Benthic akinetes of the cyanobacterium *Gloeotrichia echinulata* utilize luxury uptake to store phosphorus supplies for planktonic growth (6). Vegetative cells of this species also accumulate phosphorus during the benthic phase of their life cycle (10,45). Phosphorus accumulation is not affected by alum treatment to reduce the exchange of phosphorus between sediments and water (9). Resting cysts of a marine dinoflagellate store phosphorus assimilated during the benthic phase, providing a competitive advantage in the planktonic phase (13), and resting cells of diatoms can be buried for decades or longer in sediments and remain viable (4).

Meroplanktonic diatoms also store phosphorus after settling to the benthic environment (28). The assimilated phosphorus, stored as polyphosphate in these cells, is a biological phosphorus sink that is not geochemically reactive (46). This biological sink is not a component of phosphorus loading models that are based only on total phosphorus concentration (46,47). If polyphosphate buried in the sediments is not reactive, loading models may underestimate sediment losses of phosphorus and over predict response times to reduced phosphorus loading (46). Burial of intact cells or propagules with stored polyphosphate, therefore, has management implications, as well as ecological significance because this process may ameliorate predicted effects of anthropogenic phosphorus loading.

Recognizing the benthic stages in meroplanktonic dynamics has additional implications for lake management. Akinetes, cysts, and diatom resting cells store phosphorus that also may be an unrecognized biological sink. Phosphorus uptake by cyanobacterial populations is not affected by alum treatment used to control the chemical exchange of phosphorus and overlying waters (9). Translocation of phosphorus from sediments to the water column occurs when cyanobacterial populations are recruited into the plankton from the sediments. Thus, controlling resuspension of akinetes is a possible lake-management strategy.

Dredging sediments containing large numbers of akinetes may help control nuisance blooms of obnoxious cyanobacteria (48) and remove phosphorus from the lake (49). Akinetes are found only in the upper sediments in lakes with a recent history of such nuisance blooms (48). Desiccation of sediments impairs the germination and recruitment of akinetes of *Anabaena circinalis* into the water column (50). Periodic drying of wetlands adjacent to lakes or drawdown of water level, therefore, may reduce cyanobacterial inocula for population growth in the water column. Relatively high sediment losses of phosphorus are important for the rapid response of Lake Apopka to decreased external loading of phosphorus (47). Polyphosphate stored in intact algal cells is the proposed mechanism for this response. These examples show that understanding meroplankton dynamics is an important component of lake management.

In summary, four mechanisms are proposed by which resuspension or recruitment of meroplankton organisms from the benthic environment affect the production and dynamics of phytoplankton in surface waters. First, entrainment of algal cells or resting propagules can increase algal biomass by direct inoculation of the water column without the response time lag required for an increase in biomass due to growth alone. Second, entrainment of algal cells or resting propagules can provide seed populations that then grow in the photic zone, provided physical and chemical conditions are favorable for growth. Third, entrainment of algal cells or resting propagules and sediments with their interstitial waters can increase the nutrient content in the water column and thereby stimulate nutrient-limited algal growth in a few days. Fourth, entrainment of either inorganic sediments or organic sediments during resuspension events can increase nonalgal turbidity, thereby decreasing light availability for phytoplankton growth and production. Fifth, translocation or recruitment of vegetative cyanobacteria from the sediment occurs when gas vacuoles develop and increase buoyancy. Four of these mechanisms depend on wind-induced turbulence and resuspension in the water column, a passive process, for development of phytoplankton populations (28). By contrast, translocation is an active process in cyanobacteria that depends on vacuole formation and increased buoyancy of vegetative cells for recruitment from the benthic environment. It is likely that more than one of these processes is important in many systems. These processes have important implications for ecological studies and management actions.

METABOLISM OF MIXTURES OF ORGANIC POLLUTANTS

Thomas Egli
Swiss Federal Institute for Environmental Science and Technology
Dübendorf, Switzerland

Most of our concepts on the biodegradation of organic chemicals originate from laboratory studies of single chemicals supplied at high concentrations to pure microbial cultures of microorganisms. For example, most of the presently used kinetic models for the prediction of the biodegradation of pollutants are based on single substrate usage. However, in wastewater and the environment, pollutant-degrading microbes are confronted with mixtures of pollutants and carbon sources of natural origin, both of which are usually present at very low concentrations.

Recently, considerable information has been collected as to how microorganisms handle the biodegradation of mixtures of organic compounds, including pollutants. In this article the most important phenomena and emerging principles with respect to utilization patterns and growth (degradation) kinetics reported for growth of microbial cultures in the presence of mixtures of carbon substrates will be presented. There is now much evidence that especially under conditions as they pertain in most ecosystems, that is, at low concentrations, microbes utilize mixtures of substrates of natural origin simultaneously with pollutants. Cells benefit from mixed substrate utilization in several ways, such as from improved growth rates, competitive advantage at low nutrient concentrations, and a better dynamic metabolic flexibility to temporary fluctuations in the spectrum of available nutrients. This has consequences on our understanding of and approach to issues such as the extent to which pollutants can be degraded in the natural environment in the presence of natural carbon sources, and how we can best stimulate and enrich a pollutant-degrading microbial population in an ecosystem.

LABORATORY VERSUS NATURE: CONTRASTING SCENARIOS FOR POLLUTANT BIODEGRADATION

As a source of carbon and energy for growth, heterotrophic microorganisms use small molecular weight–reduced carbon compounds that originate from the death and subsequent decay of other cells. In their quest for food, this class of microbes has developed the ability to utilize for growth not only organic compounds of natural origin but also a wide variety of artificial organic chemicals. As a rule, only dissolved monomers in the range of a few hundred daltons can cross the cell envelope. However, most of the decaying organic matter is present in a polymeric form and heterotrophic microbes have to rely on the extracellular enzymatic or chemical hydrolysis of these polymers into smaller portions that can be transported into the cell by means of efficient transport systems. This

hydrolysis is slow and, therefore, except for the occasional local burst, the environmental pool of organic compounds available for growth for heterotrophic microbes is small. In oligotrophic aquatic systems, typical concentrations of readily utilizable carbon sources are in the range of 1 to 10 μg of carbon L^{-1} and in eutrophic aquatic compartments they can rise transiently to reach 100 μg of carbon L^{-1} (1,2). Concentrations of individual organic pollutants in aquatic environments, including xenobiotic chemicals, are usually in the low $\mu g\,L^{-1}$ or even $ng\,L^{-1}$ range. Even in wastewater treatment plants, compounds used in large amounts, such as laundry detergents, reach peak concentrations of only a few $mg\,L^{-1}$ (3). As a consequence, in the majority of ecosystems, heterotrophic microbial growth is limited by the availability of carbon energy substrates (in addition to temperature) for most of the time (4). This scenario illustrates the growth conditions that heterotrophic microorganisms typically experience in nature (but also in well-run wastewater treatment plants): it consists of a pool of dozens or even hundreds of different natural carbon compounds and pollutants with concentrations of individual components that are extremely low.

To study the biodegradation of organic chemicals two contrasting strategies have been typically followed. On one hand, a "real-world approach" is taken in which the disappearance of a pollutant is followed in the environment (or in soil or water samples brought into the laboratory). This "black-box" approach can give realistic information about the disappearance of a chemical in a particular environment, but gives little insight into principles and mechanisms that govern the biodegradation of a compound. On the other hand, defined physiological and kinetic biodegradation studies are conducted in the laboratory under batch conditions in which pure cultures of microbial strains are supplied with high concentrations of a single chemical that serves as the only source of carbon and energy. This "ivory tower" approach contrasts strongly with the conditions these microbes experience in ecosystems as outlined earlier, but it allows investigation of the genetics and biochemistry involved in the degradation pathways for a pollutant.

In the following sections, an overview will be given first on the information available for mixed substrate growth conditions in batch cultures in which (especially at high concentrations) both sequential and simultaneous utilization of mixtures of carbon substrates is observed. This information is relevant for the degradation of pollutants at high concentrations, that is, for the treatment of special pollutant-containing wastewater, or the bioremediation of heavily contaminated environmental compartments. Subsequently, degradation strategies followed by heterotrophic microbes to deal with mixtures of carbon substrates under carbon/energy-limited conditions, as they are found in most ecosystems, are discussed. There is now considerable evidence that, as a rule, microbial cells do not specialize on one particular carbon substrate at a time but simultaneously utilize as many of the different available carbon compounds as possible, a behaviour usually referred to as *mixed substrate growth* (5,6).

BATCH CULTURE SYSTEMS: DIAUXIC GROWTH VERSUS MIXED SUBSTRATE GROWTH

Jacques Monod was the first to investigate the growth of bacterial strains in batch culture with mixtures of carbon sources (7). He was particularly attracted by the phenomenon of the two-step (diauxic) growth pattern exhibited by *Escherichia coli* when he supplied this bacterium with the two sugars, glucose and lactose (other cases of obviously "simultaneous" utilization of two sugars seemed less interesting to him). In this case, glucose was utilized first and the utilization of lactose was completely repressed until glucose had been completely consumed. A short lag followed until the cells started to grow with lactose. Subsequently, Monod and his coworkers (8) investigated the phenomenon of diauxic growth in more detail (also referred to as *carbon catabolite* or *glucose repression*). The elucidation of the molecular mechanisms leading to the controlled expression of lactose-utilizing enzymes revealed that genes for catabolic pathways are clustered (the lactose operon) and their expression is controlled in a coordinate manner. The detection of the operon was certainly a milestone in biology, but it has directed the attention away from mixed substrate utilization.

Since the detection of the mechanisms leading to carbon catabolite repression, the diauxic/sequential utilization of mixtures of carbon sources is considered to be the rule under substrate-excess conditions, rather than the exception. Nevertheless, "mixed substrate growth," that is, the simultaneous utilization of two or more carbon sources by pure microbial cultures (not to be mistaken with "cometabolism") has frequently been documented in the literature, indicating that the concept of diauxic carbon source utilization was (and still is!) incorrectly presumed to predominate under batch growth conditions. A compilation of some 50 cases (6,9) indicates that mixed substrate utilization occurs at high- and low-substrate concentrations with a wide range of different substrates, during growth under aerobic and anaerobic conditions, in gram-positive and gram-negative bacteria, Archaebacteria, and yeasts. The observations reported can be classified into two different categories:

1. A simultaneous utilization of mixtures of carbon sources supporting, on their own, only medium to low maximum specific growth rates; this frequently results in improved growth rates during growth with the mixture, and
2. Substrate mixtures that cause catabolite repression at high initial concentrations but at low concentrations these substrates are utilized simultaneously.

Simultaneous Utilization at High Substrate Concentrations

This first category of mixed carbon source utilization is well-documented in the literature [see 6), but the list given there is incomplete; more examples for pure and mixed cultures can be found in Ref. (9)]. For example, in a mixture of glucose (the carbon source supporting the highest μ_{max}) and methanol, methylotrophic yeasts utilize the two carbon sources in a clearly diauxic manner,

with glucose utilized first. However, supplied with mixtures of glycerol/methanol or xylose/methanol the two substrates are utilized simultaneously (6). For a number of microorganisms, a clear improvement of μ_{max} was observed for growth with the mixture as against growth with the individual carbon sources. In the case of *Hansenula polymorpha*, μ_{max} increased from 0.18 h^{-1} (with methanol alone) and 0.21 h^{-1} (with xylose alone) to 0.36 h^{-1} when a mixture of xylose/methanol was supplied. Similar results were reported for *Leuconostoc oenos* supplied with mixtures of glucose/citrate and glucose/fructose, and *Thiobacillus versutus* (glucose/galactose). This effect suggests that rates of breakdown for such carbon sources are not high enough to saturate the anabolic pathways with precursors for biosynthesis and that every additional compatible substrate will lead to an improvement of rate of biomass synthesis. It should be added here that an enhanced maximum specific growth rate was also observed for batch growth of *Thiosphera pantotropha* with acetate/ammonia when it was supplied with both oxygen and nitrate as mixed terminal electron acceptors (10). This effect might be attractive for bioremediation processes using denitrifying strains. Unfortunately, only limited data are available and it is therefore not yet possible to judge whether the extent of stimulation in growth rate might be predictable. Additive growth yields during the utilization of multiple substrates are usually observed but cases of enhanced (i.e., greater than additive) growth yields on account of mixed substrate utilization have been reported (11).

It was also demonstrated for both bacteria and yeasts that more than two carbon sources may be simultaneously utilized. For example, *Pseudomonas fragi* consumed glucose, lactate, citrate, asparate, and glutamate simultaneously when these were present at concentrations of 0.5 to 1.0 g L^{-1}. An interesting example is shown in Figure 1

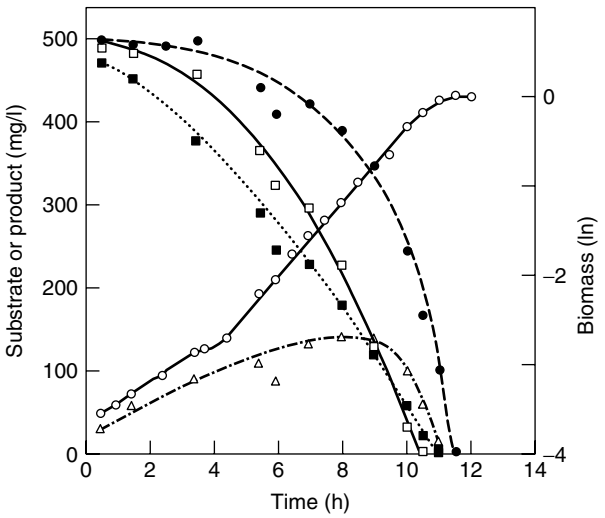

Figure 1. Batch growth of isolate NA 17 on a mixture of ethanol (●), isopropanol (■) and n-butanol (□) at 55 °C. Growth (○) is given as ln of dry weight (g L^{-1}) produced. Acetone (△) was produced during the cultivation and utilized again. Adapted from N. Al-Awadhi, Ph.D. thesis No. 8118, Swiss Federal Institute of Technology, Zürich, Switzerland 1989 with permission.

for an unidentified gram-negative thermophilic isolate, NA 17, isolated in our laboratory (12). When this bacterium was supplied with a mixture of the three solvents ethanol, isopropanol, and n-butanol, it utilized them all simultaneously. At the same time, acetone was produced from isopropanol in the early phase of growth, which was reutilized in the later phase of growth. Environmental conditions may affect the utilization pattern of substrates. For example, the yeast *Candida utilis* utilized acetate and xylose simultaneously at pH 6, but preferred acetate at pH 4.5 (probably because a significant fraction of the acetate entered the cell in the protonated form with no need for active transport). These examples demonstrate that microorganisms are able to handle quite complex combinations of substrates simultaneously.

Utilization of one substrate can enhance the degradation of a second substrate. For pure cultures, increased degradation rates for a pollutant have been reported for 2,4-dinitrophenol when glucose was added, or for benzene and *p*-xylene upon addition of toluene (9). These effects were also observed for natural populations, but it remains unclear whether or not it was based on mixed substrate utilization. However, it should be noted that the converse effect was also reported. The latter occurs probably with substrate combinations in which simultaneous utilization does not result in an enhanced growth rate, that is, in which the catabolic flux of one substrate, is able to saturate the biosynthetic capacity of a cell. Hence, whether fed with one or two substrates the total carbon assimilation rate will remain the same. Therefore, feeding a second carbon source will reduce the consumption rates for the first carbon substrate.

Many good carbon/energy substrates, including pollutants, also contain heteroatoms such as nitrogen, phosphorus, or sulfur groups, and when metabolized they can act as a source of both, carbon/energy and nitrogen, phosphorus, or sulfur. Because of the dual role of carbon in both dissimilation and assimilation, most of the compounds are carbon-deficient, and the cells have to excrete part of the heteroatom. In the case of C/N-compounds the degree of oxidation of the carbon skeleton, the position of nitrogen atom, and the catabolic pathway involved determine the fraction of nitrogen released (mostly in the form of ammonia). Supplied with an additional suitable carbon source, the two compounds are frequently taken up at rates such that the intracellular elemental demand is balanced and no nitrogen has to be excreted. A typical example has been reported for the utilization of the xenobiotic metal-complexing agent nitrilotriacetate (NTA) by *Chelatobacter heintzii*. When supplied with NTA as the only source of carbon, energy, and nitrogen, approximately 60% of the nitrogen in NTA was excreted in the form of ammonia and during balanced growth the release of ammonia was exactly proportional to the increase in biomass. When supplied with an additional carbon source, the uptake of both compounds was balanced, no ammonia was released and at the same time the specific growth rate increased from 0.07 h^{-1} to 0.13 h^{-1} (10). A similar effect has been observed for growth with organophosphonates and sulphonates in which surplus phosphorous and sulfur are released as phosphate, sulfite, or sulfate, respectively. This effect is

particularly important in the case in which excess ammonia, phosphorus, or sulfate represses the synthesis of the enzymes involved in the uptake and catabolism of these compounds (13).

It appears that many microorganisms are probably utilizing certain substrates only in combination with other substrates (there are many indications in the literature but rarely this has been followed up). The reasons for this phenomenon are largely unknown, perhaps, they lie in the balancing of catabolic and anabolic metabolite fluxes in the cell for avoiding the accumulation of inhibitory metabolites from one of the substrates. A typical example is the utilization of mixtures of amino acids by *E. coli* in which, for instance, serine cannot be utilized on its own but only in combination with glycine, leucine, and isoleucine (14). Therefore, testing the substrate utilization pattern of microbial isolates with the traditional single-substrate approach might not give us the full information about their catabolic capacity.

Release From Catabolite Repression At Low Substrate Concentrations

Mixtures of incompatible carbon sources, leading to diauxic growth when supplied under batch culturing conditions at high concentrations, are frequently consumed simultaneously when initial concentrations are lowered (6,10). An example is shown in Figure 2 for a culture of *E. coli* growing with a glucose/galactose mixture. This combination of sugars is utilized in a diauxic manner when supplied in the gram per liter range, however, when their initial concentration is lowered to 2 mg L^{-1} or less,

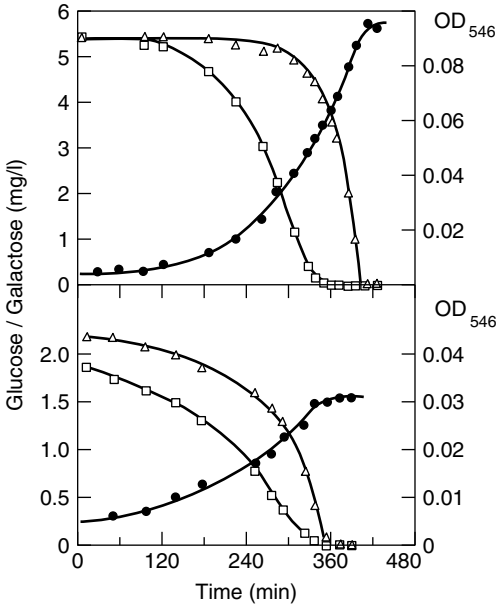

Figure 2. Batch growth of *E. coli* ML30. in a synthetic medium with different initial concentrations of glucose (□) and galactose (△). The upper panel indicates that the utilization of galactose starts as soon as the residual concentration of glucose is below approximately 2 mg L^{-1}. Growth (●) is given as optical density of the culture at 546 nm. Source of figure U. Wanner and T. Egli, *FEMS Microbiol. Rev.* **75**, 19–44 (1990) with permission.

they are consumed simultaneously (2 mg L^{-1} of a utilizable carbon source is a "feast" in the environment!). A number of other examples can be found in the literature in which the simultaneous utilization of incompatible carbon sources has been documented at low concentrations, however, only in a few cases has the transition from diauxic to simultaneous utilization been investigated systematically.

Many reports can be found in the literature in which the utilization of individual carbonaceous pollutants by a pure microbial culture has been investigated at "environmentally" low concentrations (i.e., in the low μg L^{-1} to ng L^{-1}-range) in batch culture. In contrast, mixtures of carbon compounds were considered only occasionally. For example, mixtures of acetate and phenol, or glucose and aniline were utilized simultaneously when supplied at concentrations between 1 and 10 μg L^{-1} by pure cultures of pseudomonads (9). In this context, a study reported for *Pseudomonas aeruginosa* is also interesting (15). This bacterium grew with a mixture of 45 carbon compounds added to tap water at a concentration of 1 μg L^{-1}, each, whereas none of these compounds supported growth when supplied on its own at this concentration. (However, note that it was not tested for which of the compounds were utilized and to what extent.) Such studies are usually difficult to interpret because of the interference of uncharacterized dissolved organic carbon, which is always present in cultivation media.

It has been pointed out that the effects of one substrate on the utilization of another are largely unknown (9). Nevertheless, from the information so far available, one has to assume that at the low environmental concentrations, in which growth of microorganisms also in batch systems is essentially carbon/energy-limited, carbon catabolite repression effects can be neglected and the simultaneous utilization of incompatible carbon substrates should be possible. Other effects, such as whether or not the cells are in a state in which catabolic enzyme systems are expressed sufficiently and whether or not these systems can be induced at the low concentrations, might play a far more important role than carbon catabolite repression (also illustrated later).

MIXED SUBSTRATE GROWTH IN CONTINUOUS CULTURE SYSTEMS LIMITED BY THE CARBON/ENERGY SOURCE

Although it was already recognized in the 1940s that laboratory media containing high concentrations of single carbon sources do not reflect environmental growth conditions, there were very few attempts to study the effects of low concentrations and mixtures of substrates by microbial cultures (5,6). This situation still prevails, despite the fact that it was pointed out that the concept of diauxic utilization of mixtures of carbon sources (as observed at high concentrations in batch culture) can probably rarely be applied to conditions in nature (5,16). As a more appropriate tool to investigate the behavior of microbial growth and degradation processes in the laboratory, cultivation in carbon-limited continuous culture has been suggested (4,16,17).

Within the last two decades, many studies have demonstrated that the mixtures of carbon substrates,

including pollutants, are utilized simultaneously under carbon-limited cultivation conditions in continuous culture (6). Also, for "incompatible," carbon catabolite repression–causing mixtures of carbon sources, simultaneous utilization during slow growth seems to be the rule. From these studies, a number of principles on the physiological and growth-kinetic behavior of microbial cells under environmental conditions, which are also relevant for the degradation of organic pollutants in ecosystems, can be deduced.

Substrate Utilization Patterns

The growth of methylotrophic yeasts with mixtures of glucose and methanol will be used here as an example of commonly observed microbial strategies for the utilization of diauxic substrate combinations in C-limited continuous culture. This system has been investigated in detail with respect to physiology and kinetics (6,11). Growth of methylotrophic yeasts with mixtures of glucose and methanol in batch culture results in a perfect diauxic utilization pattern with glucose utilized first and an extended intermediate lag before methanol is consumed. Repression of methanol utilization by glucose is also observed during fast growth in C-limited chemostat culture when the yeasts are fed with glucose/methanol mixtures. However, when the dilution rate is lowered, the two carbon sources are utilized simultaneously as shown for *H. polymorpha* in Figure 3a. When supplied with either methanol or glucose as the only source of carbon, a maximum specific growth rate of 0.19 h^{-1} ($\mu_{max(methanol)}$) or 0.51 h^{-1} ($\mu_{max(glucose)}$), respectively, was observed, in which the culture was washed out (D_{crit}). When the yeast was fed with a mixture of glucose/methanol (approx. 2 : 3, w/w), methanol was utilized simultaneously with glucose up to a dilution rate of 0.26 h^{-1} (i.e., considerably higher than the D_{crit} observed for growth with methanol alone!). At this dilution rate methanol started to accumulate, and at a D higher than 0.33 h^{-1}, only glucose was used for growth by the culture. Hence, growing with the "good" carbon source glucose, the yeast was able to utilize the "worse" carbon source methanol even at dilution rates exceeding $\mu_{max(methanol)}$. The dilution rate at which methanol consumption became repressed was dependent on the mixture composition fed, and this dilution rate increased with decreasing proportions of methanol in the mixture. For example, when methanol contributed only 20% of the total carbon, it was utilized up to dilution rates of almost 0.4 h^{-1} (18).

This behavior has been reported for several bacterial and yeast cultures fed with "diauxic" mixtures of carbon sources and only one exception to this rule has been observed (6). A closer inspection of the specific consumption rates for methanol during growth with single substrates or with mixtures explains this surprising effect of utilization of a substrate at dilution rates exceeding its μ_{max} (Fig. 3b). During growth with methanol alone, the maximum specific methanol consumption rate, $q_{methanol(max)}$, up to which normal growth was observed, was in the range of 0.40 to 0.45 g methanol (g dry biomass h)$^{-1}$ at a dilution rate of approximately 0.17 h^{-1}. At higher dilution rates, unbalanced growth occurred, unutilized

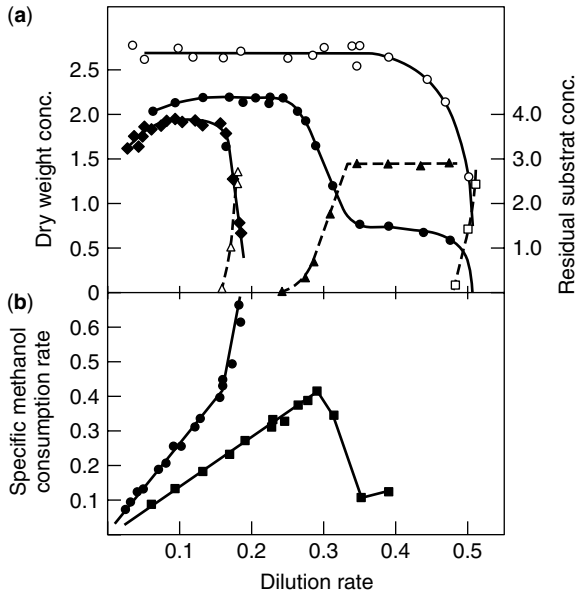

Figure 3. Growth of *H. polymorpha* as a function of dilution rate h^{-1} in carbon-limited chemostat culture supplied with either methanol, a mixture of glucose/methanol (38.2%/61.8%, w/w), or glucose as the source(s) of carbon and energy. Panel a: Dry biomass (g L^{-1}) formed with methanol alone (♦), the mixture (●), or with glucose (○); residual glucose concentration (g L^{-1}) in the culture during growth with glucose or the mixture (□); residual methanol concentration (g L^{-1}) during growth with methanol alone (△) or with the mixture (▲); panel b: Specific methanol consumption rates (g methanol (g dry biomass hour)$^{-1}$) during growth with methanol alone (●) or with the mixture (■). In all experiments, the total concentration of methanol and/or glucose in the inflowing medium was always 5 g L^{-1}. Adapted from T. Egli, C. Bosshard, and G. Hamer, *Biotechnol. Bioeng.* **28**, 1735–1741 (1986).

methanol accumulated, resulting in excessive oxidation of methanol until the system collapsed at $D = 0.19$ h^{-1}. When cultivated with the mixture at $D = 0.17$ h^{-1}, $q_{methanol}$ was only approximately half of $q_{methanol(max)}$ (Fig. 3b), and hence the methanol pathway had spare capacity to handle methanol. Consequently, the cells continued to utilize methanol when the dilution rate was increased until they consumed methanol at the maximum possible rate (with this mixture at $D = 0.28$ h^{-1}). Only when the dilution rate was further increased, and the culture was pushed beyond its methanol consumption limit, were the cells forced to switch to growth on glucose only. During growth with mixtures containing small proportions of methanol, its consumption was repressed at dilution rates above 0.35 to 0.4 h^{-1}, and the maximum capacity of the methanol catabolic pathway was never reached. This repression can be attributed to the increasing catabolite repression effect of glucose when approaching μ_{max} of 0.51 h^{-1}. Such consumption of a "slow" carbon compound at dilution rates exceeding its μ_{max} has been reported for a number of cases (6,11).

The example given was for a binary mixture of carbon sources. However, more complex mixtures containing up to 20 different substrates were shown to be degraded

simultaneously under carbon-limited continuous cultivation conditions by pure cultures (6).

Growth Kinetics With Mixed Carbon Substrates

The traditional kinetics describing microbial rates of substrate consumption and growth are based on the assumption that these processes are governed by the concentration of a single, growth-limiting substrate (19). The most widely used kinetic model (eq. 1) was proposed by Monod (7). It relates the specific rate of growth (μ) to the concentration of the growth-controlling substrate (s) via two parameters, the maximum specific growth rate (μ_{max}) and the substrate affinity constant (K_s) (the analogy to the Michaelis-Menten equation for enzyme reactions is obvious). Most of the models used for kinetic studies in the biodegradation of pollutants are based on Monod's model (19).

$$\mu = \mu_{max} \frac{s}{K_s + s} \quad (1)$$

The fact that, under environmental conditions, a microbial cell will probably utilize a variety of carbon substrates simultaneously raises the question of whether and how kinetic models based on growth rate controlled by a single substrate can be applied to a situation in the environment.

First experimental evidence for the influence of mixed substrate utilization on the kinetics of growth was observed for a culture of a *Corynebacterium* cultivated in a carbon-limited chemostat culture with mixtures of glucose and amino acids (19). When this culture was run at a constant dilution rate, the steady-state concentration of glucose was lowered when amino acids were included as carbon/energy sources in the medium. The observation that steady-state concentrations of substrates can be reduced during mixed-substrate utilization in carbon-limited chemostat cultures has been confirmed by numerous studies including various organisms and combinations of carbon substrates.

The most detailed kinetic analysis has been reported for the growth of *E. coli* with mixtures of up to six different sugars and mixtures of glucose and 3-phenylpropionate (3ppa) (20,21). An example of the response typically observed is shown in Figure 4a for growth at a constant dilution rate with different mixtures of glucose, fructose, and galactose in the feed. As expected, all three sugars were utilized simultaneously, independent of composition of the mixture. In this particular experiment, fructose always contributed around 33% to the total carbon concentration in the inflowing medium, whereas the contribution of glucose and galactose varied. With all mixtures, the steady-state concentrations of the individual sugars were reduced compared with the level measured during growth at the same dilution rate with single sugars. The concentrations of the individual sugars reflected their contribution to the total substrate supplied in the inflowing medium, that is, the steady-state concentration of fructose in the culture remained virtually constant, whereas the residual concentrations of

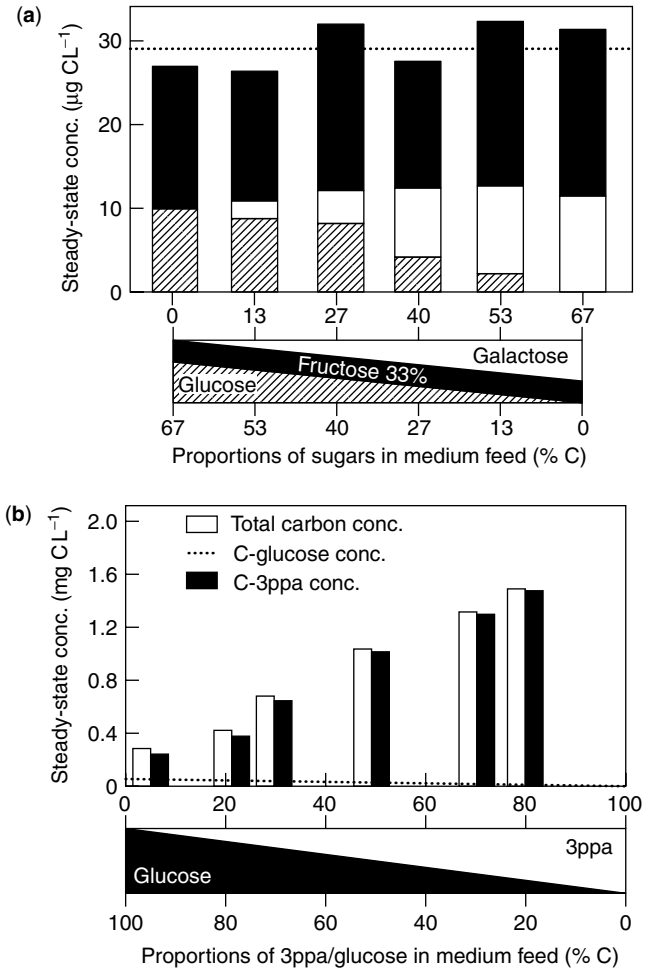

Figure 4. Mixed-substrate kinetics during growth of *E. coli* in carbon-limited continuous culture. (**a**) Growth with different mixtures of glucose, fructose, and galactose at a dilution rate of 0.30 h^{-1}. (**b**) Growth with different mixtures of glucose and 3-phenylpropionate (3ppa) at a dilution rate of 0.6 h^{-1}. In all experiments, the total carbon concentration from the mixture was such that it supported a total biomass of 45 mg dry cell weight per litre. Adapted from K. Kovářová-Kovar, and T. Egli, *Microbiol. Mol. Biol. Rev.* **62**, 646–666 (1998).

glucose and galactose were approximately proportional to the mixture fed.

Interestingly, the concentration of total organic carbon from all three sugars remained approximately constant (Fig. 3a), suggesting that the growth rate of the culture might be controlled by either the total sugar concentration, or the total available carbon in the environment. However, some of the data obtained in this series of experiments with six different sugars and for a methylotrophic yeast with glucose and methanol indicated that control of μ by a lumped parameter, such as total organic carbon, is probably only applicable to substrates with similar K_s constants and growth yields. This was confirmed for the growth of *E. coli* with mixtures of glucose and 3-phenylpropionic acid, two substrates for which the affinity constants differ significantly ($\sim$30 $\mu g\,L^{-1}$ and $\sim$700 $\mu g\,L^{-1}$

for glucose and 3ppa, respectively). In this case, the steady-state total carbon concentration in the culture originates mainly from 3ppa (Fig. 4b). Nevertheless, steady-state concentrations of both substrates were always lower during growth with single substrates and reflected their relative contribution in the feed.

It must be pointed out that the reduction of steady-state concentrations of individual substrates during mixed-substrate growth has been reported only for mixtures of sugars and the "model pollutant" 3ppa and for the solvent methanol. However, recently, this kinetic pattern was also observed for the growth of *Ralstonia eutropha* with mixtures of fructose and the pesticide 2,4-D, which indicates that it is likely that this kinetic behaviour is applicable to the degradation of pollutants in the presence of alternative carbon substrates (Rüegg, Füchslin and Egli, unpublished). Definitive statements addressing such issues will require further experimental confirmation.

A number of different kinetic models have been proposed in the literature to describe microbial growth and competition in a multisubstrate environment (21). Many of them are based on the assumption of sequential, or diauxic utilization patterns of substrates, and therefore contain inhibition terms. Nevertheless, several models have been put forward, usually derived by combining two or more Monod-terms, which can be applied to growth with mixtures of carbon sources in continuous culture. A comparison of different models using our experimental data obtained for the growth of *E. coli* with different sugar (22) and glucose/3ppa mixtures (21) was made. The model giving the most accurate description of the two sets of data is given in eq. 2,

$$\mu = \frac{\mu_{\max} \cdot \sum a_i \cdot s_i}{\mu_{\max} + \sum a_i \cdot s_i} \qquad (2)$$

where i is the number of substrates, μ is the specific growth rate predicted, $\mu_{\max}$ is the maximum specific growth rate of the best substrate, and a_i is the specific affinity for substrate i defined as $\mu_{\max,i}(K_{s,i})^{-1}$. Although such a model might be difficult to apply to a particular environmental situation (the number of substrates utilized by a cell and their concentration would have to be known), it provides a first approach to the understanding of principles of mixed-substrate growth kinetics.

Mixed-Substrate Growth and the Regulation of Pollutant-Degrading Enzyme Systems

Many enzyme systems involved in the degradation of organic pollutants are inducible and are only expressed in significant amounts in the presence of the pollutant. Hence, the questions arise as to how much pollutant is required to stimulate induction, what does the time course of this induction look like, and how are extent and rates of degradation influenced by the presence of alternative carbon substrates.

First answers to some of these questions have been obtained in an attempt to understand the degradation of the complexing agent, nitrilotriacetate (NTA), during wastewater treatment and in the environment in which a pure culture of *Chelatobacter heintzii* was grown in carbon-limited continuous culture with mixtures of NTA and glucose (23–25). The study has revealed some interesting regulatory aspects that are not only valid for this particular system but may be of use for understanding also the environmental regulation of other pollutant-degrading enzyme systems. In *C. heintzii*, NTA is degraded by an inducible NTA monooxygenase (NTA-MO), and during cultivation with glucose the activity of enzyme was close to the detection limit. Nevertheless, when a C-limited continuous culture of this bacterium was fed with glucose/NTA mixtures containing less than 1% of the carbon as NTA, the culture was able to degrade the NTA fed, although the enzyme levels did not increase significantly. Obviously, glucose did not interfere with the degradation of NTA, and the low expression level of NTA-MO was sufficient to ensure utilization of this chemical. Significant induction of NTA-MO protein and activity was observed only when the proportion of NTA in the medium feed exceeded 1% of the total carbon (Table 1).

Table 1. Expression of NTA Monooxygenase (NTA-MO) and Extent of NTA Degradation in a Carbon-limited Continuous Culture of *C. heintzii* ATCC 29,600 Grown at a Constant Dilution Rate of 0.06 h^{-1} with Different Mixtures of Glucose and NTA in the Feed. The Degree of Induction Was Assessed from Both, Specific Activity of NTA-MO in Cell Free Extract, and the Immunological Quantification of the Monooxygenase and the Oxidoreductase Proteins (Data from M. Bally, E. Wilberg, M. Kühni, and T. Egli, *Microbiology* 140, 1927–1936 (1994)

Carbon Sources in Feed	Conc. and % of Carbon Sources in Feed		Residual Conc. of Carbon Sources in Culture	Level of Expression of NTA-MO (in % of Final Level)
NTA	1 mg L^{-1}	(0.04% C)	~30 μg L^{-1}	Not induced
Glucose	2 g L^{-1}	(99.96% C)	~20 μg L^{-1}	<1%
NTA	10 mg L^{-1}	0.36% C)	~25 μg L^{-1}	not induced
Glucose	2 g L^{-1}	(99.64% C)	~20 μg L^{-1}	<1%
NTA	0.1 g L^{-1}	(3.6% C)	~30 μg L^{-1}	Induced
Glucose	1.91 g L^{-1}	(96.4% C)	~20 μg L^{-1}	~10%
NTA	1.0 g L^{-1}	(36% C)	~75 μg L^{-1}	Induced
Glucose	1.28 g L^{-1}	(64% C)	~20 μg L^{-1}	~70%

If this behaviour can be extrapolated to environmental conditions, one would expect no significant induction of NTA-utilizing enzymes in *Chelatobacter* cells growing in surface water where the contribution of NTA to the total carbon available is usually below 0.1 to 1%. However, in sewage treatment plants receiving a high load of NTA, one would expect to see an induction. Results from pure culture studies carried out in several Swiss treatment plants and model treatment plants fed with artificial sewage containing different proportions of NTA confirmed these observations (25). Although these studies are not perfect and leave considerable room for speculation, they indicate that for short-term fluctuations the degradation of NTA is probably regulated at the enzyme level rather than an enrichment of an NTA-degrading population.

It is obvious that growth conditions in wastewater treatment plants and the environment are rarely constant. Here pollutant-degrading microorganisms have to cope with changes in both concentrations and spectrum of available carbon sources. The ability to react to such changes in NTA availability was therefore also investigated for *C. heintzii* (24). When a culture growing with glucose only was suddenly switched to a medium containing NTA as the only source of carbon/energy and nitrogen, the cells exhibited a lag phase of more than a day before they started to express NTA-MO and resumed growth. This lag time was considerably reduced when the cultures were shifted from glucose to mixtures of glucose/NTA instead of NTA only. For example, shifting the cells to a mixture of 99% NTA and 1% glucose reduced the time needed for the induction of NTA-degrading capacity from some 25 to less than 10 hours, and shifts to media containing 90% glucose and 10% of NTA resulted in immediate induction. This demonstrates the important role of alternative carbon and energy sources for the metabolic flexibility of cells and their ability to induce pollutant-degrading enzyme systems. Microorganisms can be forced into a starvation response by suddenly providing a cell with a new substrate for which the enzymes are not sufficiently expressed. During starvation, all signals are set for the degradation of intracellular reserve materials, ribosomes and proteins for the generation of energy and building blocks, a state from which it takes considerable time to recover. Of course, it is essential to maintain carbon-limited conditions for a smooth induction process. Supply of high concentrations of easily degradable carbon could lead to catabolite repression of the pollutant-degrading enzyme system.

THRESHOLD CONCENTRATIONS FOR UTILIZATION AND INDUCTION

A central question concerning the fate of pollutants in the environment is that of their degradation at low concentrations. Frequently, the concentration of dissolved organic carbon of natural origin is 10 to 100 times higher than that of organic pollutants (9). On one hand, it has been demonstrated for a number of organic chemicals that they can be degraded and assimilated at concentrations of a few nano or even femto gram L^{-1}, which is far below the "threshold" concentration of 1 to 100 $\mu g\,L^{-1}$ carbon normally considered to be necessary for growth (9). On the other hand, threshold concentrations have been reported for a number of chemicals, some of them considerably higher than 100 $\mu g\,L^{-1}$, below which they were not degraded.

With respect to the utilization of pollutants at low concentrations, there is now evidence that threshold concentrations for utilization of (and growth with) particular carbon compounds are lowered by the simultaneous utilization of other carbon substrates (6,9). For example, *P. aeruginosa* grew with a mixture of 45 compounds, each present at concentrations of 1 $\mu g\,L^{-1}$, but was not able to grow with the individual compounds at this concentration. Similarly, *Salmonella typhimurium* failed to grow in a mineral medium with glucose supplied at 1 $\mu g\,L^{-1}$; however, when supported with 5 $mg\,L^{-1}$ of arabinose, glucose was still utilized at 0.5 $\mu g\,L^{-1}$. The aforementioned mixed sugar experiments for *E. coli* suggest that an individual sugar should theoretically be consumed even at minute concentrations.

With respect to threshold concentrations for utilization and induction, an interesting phenomenon was recently observed in our laboratory for the growth of *E. coli* with 3ppa (19). Cultured in glucose-limited chemostat culture, *E. coli* exhibited no detectable 3ppa-degrading activity. When low concentrations of 3ppa (0.3 and 3 $mg\,L^{-1}$) were added to the glucose feed medium (the glucose feed concentration was 100 $mg\,L^{-1}$), no degradation of 3ppa was observed. Even extended exposure for more than 100 generations did not lead to 3ppa degradation. However, if the feed concentration of 3ppa was raised to 5 $mg\,L^{-1}$ or more, degradation was induced. The data indicate a threshold concentration for the induction and utilization of 3ppa in the range of 4 $mg\,L^{-1}$. Most interestingly, once induced, the culture was able to degrade 3ppa below the threshold concentration required to trigger induction and 3ppa degradation continued, although the actual concentration of 3ppa in the reactor was always below 1 $mg\,L^{-1}$ (compare also Fig. 4b).

CONCLUSION

The data suggest a general kinetic principle, that is, multiple substrate utilization is widespread and the extent of substrate degradation depends on the number of substrates utilized, their ratio, and the growth rate. This principle has a number of important implications for the growth of heterotrophic microorganisms under carbon-limited conditions and for our conceptual thinking of pollutant biodegradation.

With respect to growth, the principle explains the puzzling observation that heterotrophic microbes can survive and even grow reasonably fast at the low substrate concentrations encountered in many oligotrophic ecosystems, such as the open ocean. Considering competition in the environment, the ability of a cell to utilize several substrates simultaneously should lead to an enhanced competitiveness. In comparison to a fastidious strain that is restricted to the utilization of one or only a few carbon substrates, the metabolically versatile strain would be able to support faster growth at the same substrate concentration (always assuming that the two strains utilize the common substrates with similar kinetic properties).

Or in other words, microorganisms could achieve the same growth rate at a lower substrate concentration and would therefore push the substrate concentration down to a lower level. There are indeed a number of examples in the literature in which nutritionally versatile strains were reported to outcompete specialist strains under mixed-substrate growth conditions, whereas the specialists won the competition for a single substrate (26). Hence, affinity for a substrate is only one component of the ecological competitiveness in the environment, another is a wide catabolic spectrum. It is frequently argued that it is not worthwhile for a cell to put efforts into the utilization of a compound that is present at too low a concentration. This argument certainly does not hold if one considers that cells utilize mixtures of substrates simultaneously. It will be the sum of carbon obtained by the cell that determines whether or not growth is possible. Therefore, it seems justified to conclude that the presence and simultaneous utilization of alternative carbon substrates enhances both the kinetics and the extent of the degradation of pollutants. However, clear data supporting this view are still scarce and a more systematic approach is required to obtain a comprehensive ecological understanding of the relationships between multiple substrate utilization, threshold concentrations, and cleanup goals.

Acknowledgments

The author would like to thank Hansueli Weilenmann, Matthias Bally, Urs Lendenmann, and Karin Kovářová for their work and many stimulating discussions on NTA biodegradation and mixed-substrate kinetics. The research on mixed-substrate kinetics was financed by grants from the Swiss National Science Foundation and from EAWAG. The financial support for the work on NTA came from Lever (Switzerland)/Unilever Merseyside (England).

The accumulation of metals in the environment due to anthropogenic activities has led to concern over the long-term fate of metal contaminants and the impact of metal accumulation on terrestrial and aquatic ecosystems. In nature, microorganisms carry out many different processes that influence the bioavailability of metals to other living organisms, and that affect their partitioning into organic and inorganic substances. Very often microbial transformations of metals are fortuitous reactions that occur as a result of microbial processes that change the physical and chemical conditions in the environment. However, various metals also have essential roles in microbial metabolism and must be carefully regulated in the cell to prevent deficiencies and toxicities. In addition to the role of metals in enzymes, some metals such as iron and manganese are used as electron acceptors for respiration by dissimilatory metal-reducing microorganisms under anoxic conditions. These redox transformations are particularly important because they change the solubility of metal ions and thus may be used to solubilize metals from ores and contaminated waste, or conversely, to precipitate metals and decrease their bioavailability. Lastly, microorganisms may carry out alkylation reactions with metals such as selenium, mercury, and arsenic that volatilize these metals. Together, all of these processes are fundamental not only for understanding the biogeochemistry of metals, but also for the development of bioremediation technology to treat metal-contaminated systems.

MICROBIAL PROCESSES AFFECTING METALS

There are many different biological processes that directly affect how metals will partition into various organic and inorganic forms that occur in nature. These include uptake of metals by living cells, sorption to the cell surface, and redox reactions that result in precipitation of solid-phase minerals or solubilization of metal ions. Prediction of the fate of metals is complicated because all of these biological processes can occur simultaneously at varying rates that depend on the species and activities of the microorganisms that are present and the particular environmental conditions. Microorganisms have a high surface-to-volume ratio, and although they comprise a very small portion of the total mass of soil and water media, they take up and adsorb significant quantities of metals over time. In reactions that are carried out by the heterotrophic microorganisms, the rates of the various reactions that are carried out by microorganisms are determined by the availability of reduced carbon in the organic substances that are used for growth. The relative amounts of metals that are taken up into living cells or that are adsorbed to the cell surface depend on the specific metal involved, the pH and ion composition of the medium, and the growth phase of the cells (1). Metals that are taken up by microbial cells may be further combined into various organic molecules that have different degradation rates and potential toxicities to other living organisms. For example, methyl mercury and organoselenium compounds represent highly toxic substances, whereas the fate and toxicities of metal ions bound to metalothioneins and cell wall components or to exopolysaccharides are less well understood. Selective precipitation of metal ions by specific functional groups on the surfaces of microbial cells can lead to the formation of nucleation sites for the precipitation of more metal ions and counter ions that result in the formation of mineral aggregates (2). The formation of metal–organic complexes also commonly leads to recalcitrance of organic molecules that may persist in the environment for long periods of time (3,4). In particular, microbial synthesis and secretion of extracellular polysaccharides affects the formation of primary organomineral complexes (<2 μm clay particles and silt size microaggregates 220 μm), which may interact with polyvalent metal ions. Because silt and clay size particles also harbor the more recalcitrant organic matter in the soil, these interactions with metal ions can help protect extracellular polysaccharides or other trapped organic matter in soil from decomposition (5). The role of microorganisms in producing and degrading organic–metal complexes is thus a key consideration in predicting the chemical form and fate of metals in the environment.

Uptake and Accumulation of Metals by Living Cells

Metal ions are taken up by cells by both passive and active transport processes. Divalent metal cations such as Mn^{2+}, Fe^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+} are all structurally very similar, having only a 14% difference in ionic diameters, and all carrying a double positive charge. To differentiate between structurally similar metal ions, heavy metal uptake systems must bind to these ions tightly. Thus, there are two general types of uptake systems for metal ions (6). The first are fast and unspecific, and are constitutively expressed because they are used for a variety of substances. These systems are usually driven by differences in the membrane potential, and are charged chemiosmotically by proton ATPase activity. The second type of heavy metal ion uptake system has high substrate specificity, and is inducible, but slower. These specific uptake systems often directly couple with ATP hydrolysis as the energy source for transport, in addition to using the chemiosmotic gradient. Usually, specific uptake systems are induced only under certain conditions such as during trace metal deficiencies. However, when these systems are expressed, they may also transport nonessential or toxic metal ions that are structurally similar to physiological ions. For example, oxyanions such as chromate (CrO_4^{2-}) and arsenate (AsO_4^{3-}), which resemble sulfate and phosphate, respectively, enter the cell by the sulfate and phosphate transport systems.

The two types of uptake systems, passive and active, can usually be distinguished by their different transport kinetics. Because there is no energy involved in the passive uptake, it occurs rapidly and metal concentrations between the outside and inside of the cell reach a steady state once equilibrium is achieved. Active uptake, on the other hand, takes longer because there is an energy requirement.

Metal Sorption to Microbial Cell Walls

Many different functional groups on the surfaces of bacterial and fungal cells can interact with metals, including carboxyl, amine, and phosphoryl groups, and various peptides. These negatively charged functional groups occur as components of structural materials in the cell wall, and are also present in the capsules of bacteria that produce exopolysaccharides. Experiments have shown that uncapsulated bacterial strains accumulate lower quantities of metals than capsulated bacteria (7). Nevertheless, capsulated cells may be better protected from metal toxicities because the production of capsular substances that adsorb metals may help prevent the entry of metals into the cell. Following a similar strategy to that of capsulated bacteria, many fungi contain melanin that binds with metals and thereby reduces their potential toxicity. Melanins contain an array of binding sites for metal ions that in melanin-pigmented fungi can increase the sorption capacity for nickel, copper, zinc, cadmium, and lead by 2.5- to 4-fold as compared with albino fungal strains without melanin (8).

Both pH and the chemical composition of the medium surrounding bacterial and fungal cells can strongly affect the accumulation of metals on the cell surface. This is because the functional groups that are responsible for the adsorption of metals are negatively charged and are protonated at low pH, which results in competition between protons and metal ions for the binding sites. In addition to protons, other cations also will interact with these anionic sites, including Na^{+}, Mg^{2+}, and Ca^{2+}, which are common in soil and aqueous media. Overall, the adsorption of metals is usually enhanced by an increase in pH, although this varies for different metal ions and microbial species (1). However, the maximum binding of metals may occur over an intermediate pH range near neutrality because at very high pH, microorganisms may change their cell surface and metals may form neutral and anionic hydrolysis species that have less affinity for negatively charged metal-binding sites.

Use of Microbial Biomass as Metal Bioadsorbents

Sorption of metals to cell surfaces has been investigated as a possible method to extract and recover metals from contaminated water. Microalgae, in particular, are being investigated for use in biofiltration because biosorbents produced from these microorganisms have a high adsorption capacity, which in some cases is comparable to that of activated carbon. Algal biomass may also be used as a source of organic acids and other soluble complexing agents that can be used as extractants. However, there are still many problems and considerations in the optimization of this technology. The sorption capacity of biomass prepared from different algae and blue-green algae can vary considerably. Adsorption characteristics also are influenced by processing the materials in different ways. For example, dried and partially mineralized biomass of the cyanobacteria *Anabaena* sp. has a 4-, 8-, and 10-fold increase in sorption capacity for cadmium, copper, and lead, respectively, as compared with the fresh biomass (9). In another example, the sorption of nickel by cyanobacteria can be increased by autoclaving (10). Thus, there are many empirical considerations in developing this technology.

Among the advantages of using microbiological materials as biosorbents, algal and cyanobacterial cells have a high surface area, are inexpensive to produce, and can be grown in large quantities in earthen ponds using sewage wastewater as a nutrient source (11). Since the early studies in the 1970s, a wide variety of cyanobacteria and green algae have been examined with the aim of identifying particular species that are effective in the adsorption of metals from wastewater. Parameters that influence sorption include the pH of the water being treated, the temperature of the medium, the presence of competing ions, the residence time, and the density of the biomass (12). To increase the selectivity of biosorbents for particular metals, it may be advantageous to use specific components of the biomass, or at least to identify the active fractions, which can subsequently be optimized through cultural procedures or appropriate processing of the biomass materials.

Biosorbents have been studied in relation to their ability to bind a wide variety of metals including zinc, cadmium, copper, nickel, and lead. They have also been studied for the sorption of radionuclides including technetium (13), cobalt and cesium (14), and americium and uranium from wastewater (15). In one investigation comparing 15 blue-green algae species, the biomass of 11 of the 15 species that were studied proved to be superior to activated carbon for the adsorption of cadmium, whereas the biomass of four other species was inferior (16). Most of the cadmium that was adsorbed by the effective algal biomass could be readily extracted using a dilute mineral acid (pH 2). This is highly advantageous because the biomass may be used repetitively to concentrate heavy metals from wastewater. Similar results have been obtained with americium and uranium, which were extracted from water using biomass produced from *Anacystis nidulans* (15). In this latter research, the optimum pH range for the sorption of both actinides was in the acidic region between 3.0 and 5.0. Under these conditions, the algal biomass was able to remove 92% of the americium (Am) and 85% of the uranium (U) from contaminated wastewater, from which 46% of the americium and 82% of the uranium originally present in the wastewater could be recovered by elution with a solution of ammonium carbonate.

Biosorbents can also be generated using fungal mycelium by-products that are generated from fermentation industries (17), and have been used to purify zinc, lead, silver, nickel, and cadmium from water in continuous-flow systems. Another application of microorganisms for the removal of metals from water effluents

is the use of constructed microbial mats. These mats contain mixed microbial communities that are grown and become embedded in glass wool supports (18). When contaminated water is passed over the mats, they rapidly remove toxic metals and metalloids including cadmium, lead, chromium, selenium, and arsenic. Metals that are removed by these mats are deposited in different forms that reflect the various microenvironments and redox gradients within the mats. In addition to the adsorption onto the cell walls that occurs in both oxic and anoxic zones, metals oxides are precipitated in the oxic zones, whereas sulfate-reducing bacteria precipitate metal sulfides in the anoxic zones.

Another process that has been investigated for the extraction of metals using microorganisms involves the use of metallothioneins and related metal-binding peptides. Metallothioneins are intercellular proteins that bind metals and contribute to cell homeostasis in the presence of potentially toxic metal concentrations. These proteins are widespread among animals and are also produced by fungi. Metal-tolerant cyanobacteria (blue-green algae) produce similar substances that are glutathionine-derived polypeptides. In developing metal-binding biomass materials, genetic engineering of microorganisms has been performed to obtain bacteria and cyanobacteria with improved metal-binding proteins that are expressed on the outer membrane of the cells (19–21). Eukaryotic metallothioneins have been expressed in *Escherichia coli* as fusions to membrane or membrane-associated proteins such as LamB, the peptidoglycan-associated lipoprotein protein (PAL), or a hybrid Lpp/OmpA carrier sequence (21). The use of different anchors enables the metallothionein to be targeted into various locations in the cell. In experiments examining different fusion proteins, each type of fusion differed in terms of expression, stability and ability to permit *E. coli* to accumulate Cd^{2+}. In similar studies with cells of a genetically engineered *E. coli* strain, JM109, which expresses metallothionein and a Hg^{2+} transport system, cells in suspension accumulated Hg^{2+} effectively at low concentrations (0–20 μM) over a broad range of pH (19). These results suggest that there is considerable potential for the genetic engineering of bacteria to remove metals from wastewater or from contaminated solutions.

MICROBIAL SOLUBILIZATION OF METALS

Factors Controlling Metal Solubilities

The solubility of inorganic metal ions and their hydrolysis species with other ions is controlled by pH, redox potential, and the ionic composition of the medium in which the metals occur. Metals may also form complexes with organic substances, and can be chelated by siderophores that are produced in response to metal deficiencies. In general, the solubility of metal ions increases by 10-, 100-, and 1,000-fold for every unit decrease in pH for mono-, di-, and trivalent metal ions, respectively. However, the total free activity in solution is also controlled by the ion-pairing with anions such as sulfate, phosphate, and carbonate. Thus, computer models are necessary to determine the speciation and solubility of metals in aqueous systems.

The solubilities of metal ions and the formation of metal complexes with organic substances have been modeled using thermodynamic models that take into account solution complexation and precipitation of solid-phase minerals. Organic acid anions and fulvic acid from dissolved organic matter, in particular, will significantly increase metal solubilities by forming metal complexes. Computer software programs that have been developed for modeling metal solubilities include GEOCHEM, MINTEK, and CHARON. The latter computer program, CHARON, takes into account interactions with both dissolved and solid organic materials that have complexing capacity for Zn^{2+}, Cd^{2+}, Cu^{2+}, Ca^{2+}, Mg^{2+}, and Al^{3+} (22).

Microorganisms directly affect the solubility of metals by their influence on pH. Acid formation by microorganisms can be accomplished by a variety of mechanisms, including respiration, release of organic acids and protons, and by mineral transformations. The most common mechanism involves simple release of carbon dioxide by heterotrophic microorganisms that use organic carbon for metabolism. Over the long term, production of carbonic acid results in the slow dissolution of rocks and minerals. In surface soil, carbonic acid production is also attributed to mycorrhizal fungi that produce carbon dioxide and enhance root-respiration rates (23). In contrast to carbonic acid, the involvement of organic acids in soil acidification is somewhat complex. Organic acids are commonly released as components of plant root exudates, but are also produced by microorganisms that grow on root exudates or that decompose organic detritus. Under aerobic conditions, organic acids such as citrate, malate, and succinate are excellent carbon sources for growth and do not accumulate (24). However, under low-oxygen conditions that commonly occur under wet soil conditions, microorganisms may transform plant-derived organic acids and other compounds into various fermentation products. These include acetic, lactic, and butyric acids that can accumulate to millimolar concentrations in microenvironments of high microbial activity. In addition to influencing pH, these substances also serve as carbon substrates that may be used to produce hydrogen or may be used by acetate-degrading anaerobic bacteria to drive dissimilatory reduction of metals (Fig. 1).

Still another process leading to the acidification of surface soil is the release of protons by microorganisms. Proton-release into the cell envelope is fundamental to microbial metabolism, and is used to generate an electrochemical potential across the cell membrane to drive synthesis of ATP. In surface soil, the relative contribution of plants and microorganisms to this process has not been easy to determine because certain microorganisms such as *Azospirillum* sp. can significantly increase proton efflux by plants and increase acidification of the rhizosphere (25).

Chemolithotrophic activity leading to soil acidification is largely because of the activity of *Thiobacillus ferrooxidans* and other iron- and sulfur-oxidizing microorganisms that produce protons as a result of the mineral-oxidation process. These bacteria typically thrive under extreme acid conditions, but are also active in normal soils that have a pH range from 3.5 to 9. The diverse bacteria and

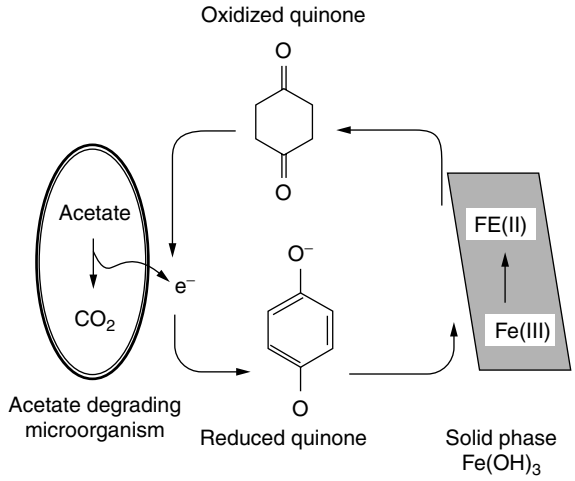

Figure 1. Dissimilatory reduction of solid phase iron minerals using quinones contained in soil organic matter as water soluble electron shuttles between bacteria and the mineral surface. Adapted after Lovely [25].

fungi that can grow well beyond this pH range include acidophilic bacteria such as *Thiobacillus thiooxidans*, which can grow at pH 1.0, and microorganisms such as *Bacillus alcalophilus*, which grows at pH 11. Recent studies on acid environments have revealed highly complex communities containing high microbial diversity including bacteria, fungi, archaea, eukaryotic algae, and even protozoa (26). The activity of acid-forming chemolithotrophs, however, generally is of concern only in soils that have exposed pyrite, or that have been amended with elemental sulfur. When large quantities of these elements are exposed, such as during mining, they can cause extreme acidification of the soil, lowering the pH to values less than 1.0 (27,28).

Bioacidification has been investigated for the leaching of metals from sewage sludge and provides a potentially useful and cost-effective method for reducing the heavy metal content of waste biosolids before application to agricultural fields or land disposal (29). In this process, elemental sulfur is added to the sludge and is converted to sulfuric acid by the oxidation of the sulfur. The lowered pH then permits solubilization and leaching of metals from the biosolids. Using an integrated process, metal-contaminated soil can be cleaned by a sequential process involving bioleaching, followed by precipitation of metal sulfides (30). In this process, soil is mixed with elemental sulfur and incubated under aerobic conditions to generate sulfuric acid. The metals contained in the leachate are subsequently stripped using an anaerobic bioreactor containing a mixed culture of sulfate-reducing bacteria that precipitate soluble metal species as solid metal sulfides. The efficacy of this treatment will vary for different metals. As shown by White and coworkers (30) in an experiment with an artificially contaminated soil, cadmium, cobalt, chromium, copper, manganese, nickel, and zinc were efficiently leached, whereas lead leaching was slow and remained incomplete over a period of 180 days. Similar results were obtained by these researchers in experiments with an industrially contaminated soil in which approximately 69% of the main toxic metals present, namely, copper, nickel, and manganese, were removed after 175 days.

Bioleaching of Metals

Microbes are increasingly being used in commercial mining operations for bioleaching of copper, uranium, and gold ores. As reviewed by Rawlings (31), direct leaching can be achieved by changing the redox state of the metal being collected to make it more soluble. In contrast, indirect leaching involves altering the redox chemistry of other metal cations that are then coupled to chemical oxidation or reduction of the harvested metal ion. This can also be combined with direct microbial attack on the mineral matrix in which the metal resides.

In addition to mining metal ores, bioleaching is being proposed as a method to treat metal-contaminated aquatic sediments. In this process, sulfur-oxidizing bacteria are used to generate sulfuric acid from elemental sulfur. As shown by Seidel and coworkers (32), in an oxic sediment with good permeability, about 60% of the total zinc, cadmium, nickel, cobalt, and manganese that was contained in a test sediment could be removed by percolation-leaching after 120 days, which was sufficient to enable the treated sediments to be reused as soil. However, the sulfur-oxidizing bacteria may take different periods of time to activate and begin producing acidity. In freshly dredged anoxic sediment, only 9% of the metals were removed. Similar processes have been used to treat metal-contaminated municipal sludges (33). A fully integrated strategy employing microorganisms it may be combine metal bioleaching with a collection of metals using bacterial biomass as biosorbents to collect the metals from the leachates. This could have many cost-advantages over the use of alternative processes that involve the use of industrially produced acids and metal chelators, followed by metal collection on cation exchange resins. Another interesting alternative is the use of activated sludge as a metal collector, which has been used with a countercurrent biosorption system for the removal of metals from aqueous effluents (34).

Metal Chelation by Organic Acids and Microbial Siderophores

Almost all microorganisms produce compounds called *siderophores* that are secreted into the environment under iron-limiting conditions that commonly occur in aerated systems at neutral to alkaline pH (35). Siderophores are produced by almost all bacteria and fungi, and there are well over 100 different types of siderophores, each of which has different metal-binding characteristics and chemical properties. Three broad classes of siderophores include the hydroxamate siderophores, catechol siderophores, and mixed ligand siderophores such as those produced by pseudomonads. Microbial siderophores are generally highly specific for iron, but as shown in some studies, may also mobilize other metals. This phenomenon has not yet been well investigated with respect to the uptake of heavy metals, primarily because very few siderophores are commercially available and they must be purified from laboratory cultures for use in experiments.

The possible function of siderophores for the deliberate uptake of essential trace metals other than iron has been investigated in only one bacterial species to date. Microorganisms require small amounts of certain transition metals that are used in metalloenzymes, including molybdenum, cobalt, nickel, and copper (36). In experiments with *Pseudomonas aeruginosa* that produces two different siderophores, pyochelin and pyoverdin, the former binds and transports Cu(II), Co(II), Mo(VI), and Ni(II), but has relatively low affinity for Fe(III) (37). In contrast, pyoverdin strongly binds iron, and its production and transport is regulated only by the availability of iron. These data suggest that siderophores may have a much broader role in metal solubilization and transport than simply for iron.

Other research has preliminarily examined the possible role of siderophores in transporting nonessential heavy metals, although the relative contribution of organic acid production, decrease in pH, and siderophores to metal solubilization in soil is not yet well understood (38). In a study with alcaligin E, the siderophore of the heavy metal-resistant *Ralstonia* sp. strain CH34 (formerly *Alcaligenes eutrophus*), the siderophore was shown to interact with cadmium and also affected its bioavailability and toxicity (39). In an alcaligin E-deficient CH34 derivative, the addition of alcaligin E stimulated growth in the presence of cadmium, which was attributed to a decrease in the bioavailability of cadmium in the presence of alcaligin E. However, alcaligin E had no influence on uptake or the cellular concentration of cadmium. Scanning electron microscopy further showed that the morphology of precipitated Cd crystals was altered by alcaligin E. Thus, alcaligin E appears to provide some protection against cadmium toxicity. In this particular study, a link between the *Ralstonia* sp. strain CH34 siderophore system and the *czc* -mediated Cd-efflux system was hypothesized.

MICROBIAL REDOX TRANSFORMATIONS OF METALS

Dissimilatory Metal Reduction

Many bacteria have the ability to reduce metals from their soluble, oxidized forms to reduced ion species that have decreased solubility or that precipitate from solution (Table 1). The energetics of metabolic reactions involving metals as electron acceptors has been reviewed (40) and can be predicted on the basis of the Gibbs free energy for the redox reaction. Metal reduction by microorganisms can involve either dissimilatory metal reduction in which the metal is used as an electron acceptor for respiration, or fortuitous processes involving nonspecific oxidoreductases (41). This latter process may be carried out by a variety of oxidoreductases such as cytochromes that function in respiration, with the difference that metal reduction does not support energy conservation and cellular growth.

Iron is used as an electron acceptor for growth of anaerobic bacteria including *Shewanella putrefaciens, Geobacter metallireducens*, and *Thiobacillus ferrooxidans*. However, with the exception of iron and manganese, heavy metals normally occur at low concentrations except in contaminated environments such as in metal ores, industrial waste, or mine tailings, and thus are not available at concentrations that would be physiologically relevant for use as electron acceptors during active growth. Even the direct use of iron as a terminal electron

Table 1. Biologically Driven Redox Transformations of Metal Ions

Metal	Reaction	Reductant	Microorganisms	Notes
As	$As^{5+} \rightarrow Ag^{3+}$		Gram positive	Reduced intracellularly before efflux by As resistance system (42)
Ag	$Ag^{+} \rightarrow Ag^{0}$			
Au	$Au^{3+} \rightarrow Au^{0}$		Fe(III)-reducing microorganisms	
Cr	$Cr^{6+} \rightarrow Cr^{3+}$	Glucose, acetate, amino acids	*Pseudomonas Bacillus* Streptomycetes Enterobacter	Cr(VI) not used for respiration.
Cu	$Cu^{2+} \rightarrow Cu^{+}$	S^{0}	Thiobacillus	Ferric ion oxidoreductase
Fe	$Fe^{3+} \rightarrow Fe^{2+}$	H_2, S^{0} organic acids alcohols	Geobacter Shewanella Desulfovibrio Thiobacillus Diverse bacteria	Fe(III) not used for respiration
Hg	$Hg^{2+} \rightarrow Hg^{0}$		Diverse bacteria	Detoxification mechanism plasmid-borne genes
Mn	$Mn^{6+} \rightarrow Mn^{4+}$ $Mn^{4+} \rightarrow Mn^{2+}$		Diverse bacteria	Mn reduction may be chemically coupled to oxidation of Fe(II)
Se	$Se^{6+} \rightarrow Se^{0}$ $Se^{6+} \rightarrow Se^{4+}$ $Se^{4+} \rightarrow Se^{0}$			Reduction of Se(VI) to Se(IV) can be used for respiration in some bacteria
Tc	$Tc^{7+} \rightarrow Tc^{4+}$		Sulfate-reducing bacteria	Fortuitous enzymatic
U	$U^{6+} \rightarrow U^{4+}$	Acetate, lactate, H_2	Geobacter, Desulfovibrio, Micrococcus,	Oxidizes *c*-type cytochromes, may be used for respiration by some bacteria
V	$V^{5+} \rightarrow V^{3+}$, V^{2+}			

acceptor for respiration by mesophilic bacteria appears to be relatively rare (43,44) because most of the aerobic bacteria that have so far been shown to reduce Fe(III) have been found to be unable to conserve energy while using this process (45). Recently, Francis and coworkers described a mesophilic bacterium that uses Fe(III) for respiration (44). In this case, a bacterium closely related to *Pantoea* (formerly *Enterobacter agglomerans*) was shown to couple the oxidation of either acetate or hydrogen to the reduction of Fe(III), Mn(IV), Cr(VI), and a quinone.

Role of Quinones in Metal Redox Transformations

For some time, metal reduction by microorganisms has been assumed to occur by direct contact of microorganisms with the surfaces of solid-phase minerals or with dissolved metal ions that are present in the solution. This view is changing rapidly because there is now much evidence that these reactions may be facilitated primarily by reduced humic substances or quinones that serve as electron shuttles for the transfer of electrons from oxidoreductase enzymes in the cell walls to nearby solid-phase minerals (46–48). After transferring electrons to metals in the vicinity of the cell, the quinones, or humic substances are regenerated to their oxidized state, and thereby can act catalytically to drive metal-reduction processes. As shown with Fe(III), even low concentrations of humic substances can significantly enhance the rate of iron reduction (49). Recent studies have focused on two Fe(III)-reducing microorganisms, *G. metallireducens* and *Shewanella alga*, which can substitute humic substances for Fe(III) as the terminal electron acceptor (49). Both *G. metallireducens* and *S. alga* conserve energy to support growth by reducing the humic substance analog, 2,6-anthraquinone disulfonate (AQDS), to 2,6-anthrahydroquinone disulfonate (AHQDS). The role of these electron-shuttles for the reduction of other metals such as chromium and uranium is now an active area of investigation. For example, the radiation-resistant bacterium, *Deinococcus radiodurans*, was recently shown to reduce Fe(III), U(VI), and Tc(VII) in the presence of anthraquinone-2,6-disulfonate (50). Recently, it has been shown that microbial reduction of metals, such as Fe(III) to Fe(II), can lead to subsequent nonenzymatic reduction of other metals, such as chromium by indirect processes (51). It remains to be investigated whether this process may also be enhanced by quinones.

Taking advantage of the fact that heavy metals have decreased solubility in their reduced forms, a variety of biological treatment processes have been proposed for the treatment of metal-contaminated soil and water. Many different organic carbon sources including glucose, organic acids, and amino acids can serve as electron donors for metal reduction. In addition to treatment of metal-contaminated sites, the ability to use metals as electron acceptors for respiration is particularly important with respect to bioremediation of organic contaminants under anaerobic conditions in sediments and subsurface environments. In the sections that follow, various methods for bioremediation of metals and organic contaminants using microbiologically driven metal-oxidoreduction reactions are summarized.

Microbiological Reduction and Detoxification of Chromium

Chromium is the seventh most abundant element on earth and is present in soil at concentrations between 5 and 3,000 $mg\,kg^{-1}$. As a result of its extensive use in industrial processes, chromium is a common metal pollutant in soil and water. Chromium can exist in the environment in different oxidation states, but most commonly occurs as Cr(III) and Cr(VI) (52). The oxidized form, Cr(VI), occurs as a water-soluble oxyanion, CrO_4^{2-}, which is a strong oxidizing agent and highly toxic to microorganisms (53,54). A variety of methods have been developed to remove chromium from water using both biosorption and bioreduction to Cr(III).

Biological reduction of the chromate ion, Cr(VI), to the chromic ion, Cr(III), can easily be achieved by indigenous soil bacteria and can be stimulated by providing an organic amendment (55). Following reduction, the chromic ion subsequently precipitates as insoluble $Cr(OH)_3$. Chromate reduction also has been studied under anaerobic conditions, in which case, Cr(VI) is reduced by bacteria that use acetate as a carbon source (56). Sulfate and nitrate both slightly inhibit this latter process, whereas oxygen causes complete inhibition. Studies aimed at the treatment of contaminated water show that nearly complete removal of Cr(VI) can be achieved by bacteria in flow-through systems containing 26 $mg\,L^{-1}$ Cr(VI) when acetate is provided at a ratio of 9 mg C mg^{-1} of Cr(VI) (57). In addition to this treatment method, there are a variety of other biological treatment methods. Among these, *Pseudomonas fluorescens* has been used to reduce Cr(VI) using citrate as a carbon source (58). Other researchers have studied *Bacillus* sp. in packed-bed bioreactors (59). In the latter case, reduction of Cr(VI) by *Bacillus* is achieved under aerobic conditions by a reductase that mediates the transfer of electrons from NAD(P)H to chromium (60). This reductase system is speculated to be a specific detoxification mechanism that differs from the dissimilatory electron-transfer mechanism used by other bacteria.
