Still another application aimed at the treatment of mixed waste has been to couple the biodegradation of organic pollutants with chromium reduction. For example, a phenol-degrading consortium has been combined with a strain of *E. coli* that is capable of Cr(VI) reduction (61). In this manner, the phenol-degrading consortium degraded phenol into metabolites that were used by the *E. coli* strain as an electron donor for the reduction of Cr(VI).

In addition to organic substrates that serve as electron donors for Cr(VI) reduction, some bacteria can also use H_2, H_2S, and reduced Fe(II) as electron donors. For example hydrogen is used by *Desulfovibrio vulgaris* to drive the reduction of Cr(VI) to Cr(III) (62), in which case, the *c*-3 cytochrome from this organism functions as the Cr(VI) reductase. In experiments examining the use of H_2S as an electron donor, researchers have discovered a sulfate-reducing bacterial consortium that tolerates concentrations of 2,500 $mg\,L^{-1}$ of Cr(VI) and that indirectly reduces chromium by the production of H_2S gas (63). Cr(VI) reduction by an indirect mechanism also has been observed during dissimilatory iron reduction by the blue-green algae species *Shewanella*, which first

reduces Fe(III) to Fe(II), after which Fe(II) transfers electrons to Cr(VI) (51). In this process, the iron is cycled between the reduced and oxidized forms and appears to be working catalytically. Thus, there are a variety of practical methods for achieving detoxification of chromate in anaerobic soil and water.

In contrast to the reduction of Cr(VI), which depends mostly on the organic matter content of the system, the reverse reaction involving the oxidation of Cr(III) to more soluble Cr(VI) occurs most rapidly in soils or aqueous systems that are high in manganese [Mn(IV)] oxides and that contain low organic matter (64). In aqueous systems, Cr(III) appears to be oxidized chemically and occurs readily in the presence of light and Fe(III) minerals (65). In this case, chromium oxidation appears to be driven by photolysis of $FeOH_2^+$ complexes. However, this process is strongly inhibited by organic acids (66), which are thought to promote dissolution and reduction of manganese oxides to Mn(IV), such that manganese can no longer serve as an electron acceptor for the oxidation of chromium.

Redox Transformations of Manganese

Manganese can exist in several different valence states, but occurs in the environment primarily as Mn(IV) and Mn(II) minerals. Although manganese can be transformed abiotically, microorganisms are the major catalysts of manganese cycling in the environment (67). Manganese reduction is carried out by diverse microorganisms including various species of *Pseudomonas*, *Geobacter*, and *Shewanella*. For most of the bacteria that have been studied, manganese does not appear to be used as an electron acceptor for respiration and thus does not contribute to their energy metabolism (45). Nonetheless, this view may change as future studies determine whether or not microbial respiration using manganese oxides can be effectively coupled using quinones and other organic matter constituents. In addition to reduction that is driven directly by oxidoreductases, manganese also can be chemically reduced by Fe(II) and H_2S (68), and can be catalyzed by organic acids at pH values less than neutrality (69).

The opposing reaction, involving oxidation of Mn(II) minerals, can be achieved both biotically and abiotically. In contrast to most metal ions that have decreased solubilities on reduction, manganese solubility is increased by reduction of Mn(IV) to Mn(II). Thus, manganese-oxidizing bacteria are involved in the formation of manganese-precipitates, such as those that encrust iron pipes, and that generate manganese-oxides in the soil and manganese nodules in marine systems. The abiotic oxidation of Mn(II) to Mn(IV) occurs most rapidly under aerated conditions at neutral to alkaline pH, but is still very slow compared with biotic oxidation of manganese. Biological generation of manganese oxides is carried out enzymatically by a variety of manganese-oxidizing bacteria, fungi, and algae that use *c*-type cytochromes (70). As reviewed by Gounot (67), bacteria that carry out this process include the sheathed bacteria, *Leptothrix*, the budding and appendaged bacteria, *Pedomicrobium* and *Hyphomicrobium*, and many other common bacteria including *Bacillus, Pseudomonas*, and *Vibrio*. Biotically driven manganese oxidation also can occur indirectly by reaction with hydrogen peroxide, which is produced by certain bacteria.

Although manganese oxides are less abundant in soil and sediment than in iron oxides, they tend to accumulate in sites of high microbial activity and thus have a greater role in microbial processes than would be predicted simply on the basis of their relative abundance in the environment. Importantly, manganese oxides can abiotically facilitate the oxidation of a variety of carbon substrates, including organic contaminants such as toluene and atrazine. By-products of these substances may subsequently be degraded by various bacterial species and consortia that occur in the vicinity of manganese oxides. In studies on the use of Mn(IV) by a toluene-degrading consortium, toluene, an enrichment culture from a contaminated sediment was able to grow on toluene under strictly anaerobic conditions using manganese oxide as an electron acceptor (71). Of the different manganese oxides tested, the rate was slowest with crystalline manganese oxide as compared with amorphous manganese minerals. In the case of atrazine, which is now the most common pesticide pollutant in groundwater in the United States, manganese oxides can catalyze the complete degradation of the parent compound, but also generate dealkylated metabolites that can subsequently serve as substrates for atrazine-degrader organisms (72). The use of biogeochemical systems for the degradation of organic pollutants is a relatively new concept, but undoubtedly will become an increasingly important concept for bioremediation of organic contaminants in soil and sediment systems.

Methylation and Volatilization of Metals and Metalloids

As previously mentioned, microorganisms transform metals through oxidation and reduction reactions. Other transformation reactions carried out by microorganisms are methylation and demethylation. During methylation reactions, inorganic forms, are converted to organic forms and vice versa during demethylation reactions. The microbial methylation of heavy metals, such as selenium, arsenic, tin, lead, and tellurium results in the production of volatile and often toxic gases. In the early 1800s, several cases of arsenical poisoning occurred in Germany because of the use of wallpapers that contained arsenic in the pigments. The wallpapers were found to emit trimethylarsine when they became damp and moldy. The volatilization of heavy metals/metalloids from contaminated soil, sediment, and water is also of considerable interest as a remediation technique. Remediation methods, using microbially mediated volatilization, have been proposed for selenium (73,74), and mercury (75). These metals are also the most studied with respect to methylation reactions and, as such, will be the focus of this section (see Table 2 for a list of metal-alkylating microbial genera).

Methylation of Selenium. The environmental threat of elevated levels of selenium in soil and water has been recognized in many locations throughout the western United States (76). In California's San Joaquin Valley,

elevated levels of selenium in Kesterson Reservoir were linked to the death and deformity of waterfowl. In soil, sediment, and water, bacteria and fungi are the predominant selenium-methylating organisms (77). The methylation of selenium is thought to be a protective mechanism used by microorganisms to detoxify their surrounding environment. The predominant selenium gas produced by most microorganisms is dimethylselenide (DMSe) (78). In general, the formation of alkylselenides from selenium oxyanions involves a reduction and methylation step; however, the pathway by which these reactions occur is still highly debated.

The biosynthesis of methionine from homocysteine is an important transformation in the methylation of selenium. During the activated methyl cycle, homocysteine is methylated by the coenzyme methylcobalamin (CH_3B_{12}, derivative of vitamin B_{12}), yielding methionine. Methylcobalamin has been isolated from bacteria (79) and is believed to donate methyl groups to selenium, resulting in the formation of volatile alkylselenides. Thompson-Eagle and coworkers (80) found that the addition of methylcobalamin promoted the methylation of selenate [SeO_4^{2-}, Se(VI)] by a fungal isolate, *Alternaria alternata*. McBride and Wolfe (81) found that cell-free extracts of a *Methanobacterium* sp. methylated SeO_4^{2-} when methylcobalamin was present. Cell-free extracts of an enteric bacterium, *Enterobacter cloacae* SLD1a-1, isolated from seleniferous drainage water, catalyzed the formation of DMSe from selenite [SeO_3^{2-}, Se(IV)] or elemental selenium [Se(0)] when methylcobalamin was the methyl donor (82). In addition to methylcobalamin, *S*-adenosylmethionine has been identified as a cofactor in the microbial methylation of inorganic selenium (83). Doran (78) found that cell-free extracts of the soil bacterium, C*orynebacterium*, were able to methylate SeO_3^{2-} or Se(0) when *S*-adenosylmethionine was present.

Methylation of Arsenic. The bacterial methylation of inorganic arsenic has been studied extensively using methanogens. These archae are present in large numbers in anaerobic ecosystems such as sewage sludge, freshwater sediments, and composts in which organic matter is decomposing (76). Under anaerobic conditions, the biomethylation of arsenic only proceeds to dimethylarsine, which is stable in the absence of oxygen, but which is rapidly oxidized under aerobic conditions. It has been shown that at least one *Methanobacterium* sp. is capable of methylating inorganic arsenic to produce volatile dimethylarsine. Arsenate [AsO_4^{3-}, As(V)], arsenite [AsO_2^-, As(III)], and methylarsonic acid can serve as substrates in dimethylarsine formation. Inorganic arsenic methylation is coupled to the CH_4-biosynthetic pathway and may be a widely occurring mechanism for arsenic detoxification.

Cell-free extracts of a *Methanobacterium* strain, MOH, produce volatile dimethylarsine when incubated under anaerobic conditions with AsO_4^{3-}, methylcobalamin, hydrogen, and ATP (81). Whole cells of methanogens also produce dimethylarsine as a biomethylation end product of arsenic under anaerobic conditions. Cell-free extracts of *D. vulgaris* strain 8,303 also produce a volatile arsenic derivative, presumably an arsine, when incubated with AsO_4^{3-}. Interestingly, another study found that resting cell suspensions of *Pseudomonas* and *Alcaligenes*, incubated with either AsO_4^{3-} and AsO_2^- under anaerobic conditions, produced arsine, but no other arsenic intermediates were formed (84). *Aeronomonas* sp. and *Flavobacterium* sp. isolated from lake water were capable of methylating arsenic to dimethylarsinic acid, whereas the *Flavobacterium* sp. additionally methylated dimethylarsinic acid to trimethylarsine oxide (85).

Several fungi have demonstrated the ability to transform arsenic. It is well established that the fungi are able to volatilize arsenic as methylarsine compounds, which are derived from inorganic and organic arsenic species. The volatilized arsenic dissipates from the cells, effectively reducing the arsenic concentration to which the fungus is exposed. In recent studies, three different fungal species, *Candida humicola, Gliocladium roseum*, and *Penicillium* sp., were capable of converting methylarsonic acid and dimethylarsinic acid to trimethylarsine (86). In addition, *C. humicola* used AsO_4^{3-} and AsO_2^- as substrates to produce trimethylarsine. Cell-free extracts of *C. humicola* transformed AsO_4^{3-} into AsO_2^-, methylarsonic acid into dimethylarsinic acid and trimethylarsine oxide, and dimethylarsinic acid into methylarsinic acid and trimethylarsine oxide (87). Although trimethylarsine formation from inorganic arsenic and methylarsonic acid is inhibited by the presence of phosphate, its synthesis from

dimethylarsinic acid is increased in the presence of phosphate (86). Recently, Huysmans and Frankenberger (88) isolated a *Penicillium* sp. from agricultural evaporation pond water capable of producing trimethylarsine from methylarsonic acid and dimethylarsinic acid.

Methylation of arsenic is thought to occur by the transfer of the carbonium ion from *S*-adenosylmethionine (SAM) to arsenic. Incubation of cells with an antagonist of methionine inhibits the production of arsines, thus supporting the role of methionine as a methyl donor (89). The addition of either methanearsonic acid or dimethylarsinic acid to cell-free extracts yields trimethylarsine oxide (87). Further reduction of trimethylarsine oxide to trimethylarsine requires the presence of intact cells (90). Various arsenic thiols (cysteine, glutathione, and lipioc acid) are thought to be involved in the reduction step of trimethylarsine oxide to trimethylarsine (91,92). The final reduction step is inhibited by several electron transport inhibitors and uncouplers of oxidative phosphorylation (90,93). Preincubation of cells with trimethylarsine oxide increases the rate of conversion to trimethylarsine, suggesting an inducible system (90). In addition, the rate of transformation of AsO_4^{3-} to trimethylarsine is increased by preconditioning the cells with dimethylarsinic acid (93).

Methylation of Mercury. Although a number of microorganisms are capable of methylating mercury under both aerobic and anaerobic conditions (94), field studies suggest that mercury methylation occurs most rapidly under anoxic conditions (95,96). Recent evidence suggests that sulfate-reducing bacteria are the dominant mercury methylators in estuarine (97) and lacustrine (98) anoxic sediments. Aerobic bacteria that are active in methylating Hg(II) include *Pseudomonas* sp., *Bacillus megaterium, E. coli*, and *Enterobacter aerogenes*, whereas fungi include *Aspergillus niger, Neurospora crassa, Scopulariopsis brevicaulis*, and *Saccharomyces cerevisiae*. The anaerobic bacterium *Clostridium cochlearium* was found to methylate a variety of mercury compounds including HgO, $HgCl_2$, $Hg(NO_3)_2$, $Hg(CN)_2$, $Hg(SCN)_2$, and $Hg(OOCCH_3)_2$ (99).

As with selenium methylation, methylcobalamin has long been suspected as a cofactor in the microbial methylation of mercury because it is known to donate methyl groups to Hg(II) (100). Methylcobalamin is also an important coenzyme in the biosynthesis of methionine (101). In *E. coli*, methylcobalamin was found to catalyze the transfer of a methyl group to homocysteine, resulting in the formation of methionine (102). In *N. crassa*, the formation of methyl mercury (CH_3Hg^+) was stimulated by the addition of homocysteine, but was inhibited by the addition of methionine (103). Choi and coworkers (104) recently confirmed that the sulfate-reducing bacterium, *Desulfovibrio desulfuricans*, methylates Hg(II) by the coenzyme methylcobalamin. It was additionally proposed that Hg(II) might be methylated during the acetyl coenzyme A synthase reaction.

Bioremediation of Metal-Contaminated Soil Using Bioaugmentation

A variety of bacteria have been examined for their potential use in the cleanup of metal-contaminated sites, and there are numerous studies in which bacteria and consortia have been identified for use under aerobic and anaerobic conditions. Some bacteria appear to be particularly promising, but there has not yet been much commercialization of this technology. One bacterium, *Pseudomonas maltophilia* strain, which was isolated from soil at a toxic waste site in Oak Ridge, Tennessee (105), catalyzes the transformation and precipitation of numerous toxic metal cations and oxyanions including Hg(II), Cr(VI), Se(IV), Pb(II), Au(III), Cd(II), Te(IV), and Ag(I). Effective removal of the toxic metals is accomplished within one to two days for most of the metals, with silver requiring seven days. With this particular microorganism, a variety of mechanisms are involved in each of the metal transformations. The NADPH-dependent reduction of Hg(II) to Hg(0) is catalyzed by an inducible mercuric reductase. Reduction of selenite and tellurite to their insoluble elemental forms appears to be mediated by an intracellular glutathione reductase that uses bis(glutathio)Se(II) or bis(glutathio)Te(II), respectively, as pseudosubstrates. Reduction of hexavalent chromium is catalyzed by a membrane-bound chromate reductase.

In addition to mesophilic bacteria, there are also diverse hyperthermophilic microorganisms that have the ability to reduce Fe(III) with hydrogen (H_2) as the electron donor, and other metal ions. *Pyrobaculum islandicum* uses poorly crystalline Fe(III) oxide as an electron acceptor for growth on hydrogen or peptone and yeast extract as the electron donor (106). Cell suspensions of *P. islandicum* grown on hydrogen can also reduce U(VI), Tc(VII), Cr(VI), Co(III), and Mn(IV). It is speculated that these hyperthermophilic microorganisms may contribute to the speciation of metals in hydrothermal environments and could account for the formation of various minerals such as magnetite and uranium deposits at high temperatures near 100 °C. Reduction of toxic metals by this and related microorganisms also might be applied to the remediation of metal-contaminated water or waste streams (106).

Although there are many potential applications of microorganisms for bioremediation, methods involving bioaugmentation remain problematic and include the cost for the production of large quantities of inoculum that need to be transported and incorporated into the contaminated medium on site. Other problems include poor survival after release into the environment, low activity, and toxicities to mixed contaminants. Nevertheless, progress has been achieved in developing bioaugmentation technology for bioremediation of organic contaminants, which may be extended to the treatment of metal-contaminated sites (107).

HEAVY METAL TOXICITIES TO MICROORGANISMS

Elements of the Periodic Table with a density of more than 5 $g\,cm^{-3}$ are known as *heavy metals*. Although this encompasses 65 different elements, there are relatively few heavy metals that are generally regarded to be of environmental concern. These are arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc. Although each of these metals is toxic to most organisms at relatively high concentrations, copper, nickel, and zinc

also have important functions as essential trace elements (i.e., micronutrients). These and other metals such as iron and manganese are required cofactors of enzyme-catalyzed reactions. However, it should be noted that there is a fine threshold between heavy metal deficiency and toxicity, which may vary for different organisms depending on their tolerance and resistance mechanisms.

The contamination of soil with heavy metals usually occurs by direct application from sources including mine wastes, atmospheric deposition (a result of metal emissions to the atmosphere from metal smelting, fossil fuel combustion, and other industrial processes), animal manures, and sewage sludge. Surprisingly, some inorganic fertilizers contain significant quantities of heavy metal impurities. Sewage sludge, which is often used as a soil conditioner, contains useful quantities of organic matter, nitrogen, and phosphorus; however, it often contains heavy metals. The heavy metals are chelated or complexed by the organic matter, which are then released on decomposition. Heavy metal cations in soil may be present as several different forms: (*1*) as ions in soil solution, (*2*) as easily exchangeable ions, (*3*) organically bound, (*4*) coprecipitated with metal oxides, carbonates, phosphates, or secondary minerals, or (*5*) as ions in primary minerals (108–110).

Heavy metals in soils are found as various immobilized (e.g., organically bound) and nonimmobilized (e.g., in soil solution) forms. The heavy metal form is highly influenced by soil properties such as pH, oxidation-reduction state, clay content, iron oxide content, and organic matter content (111). Those metals that are immobilized are considered biologically unavailable, whereas those that are nonimmobilized are considered biologically available. Therefore, the toxicity of heavy metals to a soil microbial community will differ depending on their chemical state. A soil microbial population will experience a lower heavy metal concentration when a soil contains heavy metals largely in immobilized forms (e.g., carbonate complexes). Because all heavy metals in soil are not available, an important distinction must be made between the total extractable and biologically available heavy metal content in the soil. A heavy metal extraction from the soil recovers both biologically available and unavailable metals; therefore, the extractable heavy metal content does not reflect its biological effect.

It is well known that exposing microorganisms to heavy metals affects their growth and survival. In the early 20^{th} century, mercuric chloride ($HgCl_2$) was widely used as a general disinfectant, whereas the use of copper in Bordeaux mixture was used to control various fungal pathogens. Heavy metals inactivate cellular enzymes by combining with a component of the protein [e.g., $HgCl_2$ inactivates enzymes that contain sulfhydryl (–SH) groups]. In general, bacteria and actinomycetes (prokaryotes) are more sensitive to heavy metal–soil pollution than fungi (eukaryotes). However, bacteria are more sensitive than actinomycetes, and gram-positive bacteria are generally more sensitive than Gram-negative bacteria (112).

In soils, diverse communities of microorganisms, displaying a wide range of metabolic activities, carry out the cycling of nutrients such as carbon, nitrogen, phosphorus, and sulfur. It has been estimated that there are approximately 13,000 species of bacteria in a single gram of soil (113), and an unknown number of fungi and algae. The fertility of natural soil ecosystems is therefore highly dependent on nitrogen fixation and the turnover of soil organic matter (SOM) that is mediated by the soil microbial biomass. However, chemicals (e.g., heavy metals) that alter the biological activity of soil microorganisms can damage the functioning of the soil ecosystem for long periods of time. Affected soils often exhibit decreased microbial diversity, decreased microbial biomass, lower respiration rates per unit biomass, and manifest decreased enzyme activities.

A growing body of evidence suggests that microorganisms are far more sensitive to heavy metal pollution than the rest of the soil faunal (meso and macro) or floral community (114). Thus, the diversity and metal-tolerance of soil microbial communities is being examined as an indicator of heavy metal pollution, which could be used to define critical metal loadings for soil protection. As a result, there is considerable interest in the impact that heavy metals have on the soil microbial community. A heavy metal disturbance affects the growth, metabolism, and morphology of soil microorganisms through protein denaturation, functional disturbance, or cell membrane destruction. Several methods have been used in the past to investigate the response of microorganisms to heavy metal pollution including: (*1*) fatty acid composition, (*2*) microbial biomass size, (*3*) microfaunal composition, (*4*) respiration activity, (*5*) enzyme activity, (*6*) nitrogen fixation, (*7*) nitrogen and carbon mineralization, and (*8*) microbial carbon to soil carbon ratio.

However useful each of these microbial parameters may be in monitoring heavy metal pollution of soils no single parameter can be used universally. Combining one or more of these microbial parameters may provide a more sensitive indication of soil pollution. As mentioned previously, heavy metal affected soils show decreased microbial diversity. Decreases in biodiversity occur when species that lack tolerance to the heavy metals die off, whereas metal-tolerant species are enriched. Therefore, biodiversity of the soil microbial community could be used as a method to determine the impact of heavy metals on the environment. Classical methods involved isolating, and subsequently culturing microorganisms for identification. However, such attempts are hampered by sampling and culturing techniques, leading to bias toward certain groups within mixed microbial communities. The use of monoclonal antibodies has also improved the specificity of these methods, however, this technique is of limited applicability because of the heterogeneous nature of soil. Genetic diversity, which is always present within species, may be useful in determining the response of soil microbes to metal contamination. Individual species and strains of microorganisms have been identified by determining differences in the nucleotide sequences of the DNA. The study of population genetics is commonly known as *genetic fingerprinting* (115).

HEAVY METAL–RESISTANCE MECHANISMS

As previously mentioned, some heavy metal cations play an important role as trace elements in biochemical reactions, however, when a metal with unknown biochemical function replaces a functional metal, toxicity results. The heavy metal cations form unspecified complex compounds in the cell, which subsequently produce the toxic effects. Heavy metal cations such as Hg(II) and Cd(II) form strong toxic complexes. Even essential trace elements such as Ni(II), Zn(II), and Cu(II)become toxic at high concentrations. Therefore, intracellular concentrations of heavy metal ions must be highly regulated, and cellular heavy metal homeostasis is regulated through specific resistance mechanisms (116).

Bacterial resistance systems function by energy-dependent efflux of toxic ions. In many cases, these systems are encoded by plasmids that contain genes encoding resistance systems for toxic metal and metalloid ions (42). Plasmid-borne resistance systems include efflux systems for Ag^{+}, AsO_2^{-}, AsO_4^{3-}, Cd^{2+}, Co^{2+}, CrO_4^{2-}, Cu^{2+}, Hg^{2+}, Ni^{2+}, Pb^{2+}, TeO_3^{2-}, and Zn^{2+}. In some cases, such as with mercury and chromium, certain microorganisms employ enzymes that carry out redox transformations that result in a change in valence and reduced toxicity (117).

Arsenic

Arsenic is a metalloid of Group VA of the Periodic Table and exists in four oxidation states, +5, +3, 0, −3. Arsenic forms alloys with various metals, and covalently bonds with carbon, hydrogen, oxygen, and sulfur. Arsenate, a biochemical analog of phosphate, is transported by highly specific energy-dependent membrane pumps into the cell during assimilation of phosphate, whereas arsenite has a high affinity for thiol groups of proteins, resulting in the inactivation of many enzymes. Its similarity to phosphorus and its ability to form covalent bonds with sulfur are two reasons for arsenic toxicity. As a result, arsenic has no function as a trace element in bacteria, although some bacteria are known to use arsenate as a terminal electron acceptor during anaerobic respiration (118–121). The poisonous character of arsenic made it a very effective herbicide and insecticide.

In *E. coli*, resistance to arsenic can be achieved by two distinct mechanisms that include chromosomal and plasmid-encoded systems. Chromosomally encoded resistance occurs by the activation of a phosphate uptake pump with an increased selectivity for phosphate. In bacteria, two phosphate uptake systems are present, Pit (phosphate-inorganic transport) and Pst (phosphate-specific transport) (122). The Pit system is constitutive and does not discriminate between phosphate and arsenate. During periods of phosphate starvation or arsenatetoxicity, the Pst is activated, and the reduction in cellular arsenic is achieved by a higher affinity for phosphate. Thus, activation of the Pst system confers higher levels of resistance by virtue of the reduced uptake of arsenate.

Plasmid-determined resistance is a consequence of an accelerated efflux of arsenical and antimonal compounds but not phosphate from the cell. Three genes, named *ars* A, *ars* B, and *ars* C, are responsible for the export function in *E. coli* (123). The genes for resistance are clustered on plasmids R773 and R46. The ArsA protein is an arsenite- and antimonite-stimulated ATPase that forms a complex with the membrane-bound protein ArsB. The ArsAB complex actively exports As(III) and Sb(III) from the cell on the hydrolysis of ATP. To confer resistance to arsenate, the protein ArsC is required. The ArsC protein reduces As(VI) to As(III), which is subsequently exported by the ArsAB complex. Other *ars* C genes have been identified in the gram-positive staphylococcal plasmids pI258 and pSX267. However, the export of arsenic and antimony oxyanions is accomplished using membrane potential, rather than cellular ATP as an energy source.

Cadmium

Cadmium is a relatively rare element that is closely related to zinc, with which it is usually associated in nature. Cadmium is divalent in all its stable compounds. It has many industrial uses, including pigments in plastics, paints, and ceramics, and is used in the production of corrosion-resistant plating, alloys, and batteries. When compared with zinc, cadmium is more toxic because of its higher solubility. Poisoning through the contamination of food and drinking water by cadmium-plated containers has been reported, however, the principal human risk is from industrial exposure, primarily through the inhalation of cadmium fumes.

In *Ralstonia* sp. CH34, cadmium is accumulated by a magnesium uptake system (MIT) (124), which is also responsible for the accumulation of cadmium in other bacteria. However, resistance to cadmium in bacteria is based on cadmium efflux. Cadmium resistance in gram-negative bacteria appears to be regulated by RND (resistance, nodulation, and cell division)-driven systems such as the *Czc* and *Ncc*, which are mainly zinc (also cobalt in sp. CH34) and nickel exporters, respectively (6,125). The CadA pump from *Staphylococcus aureus* was the first example of cadmium-exporting P-type ATPase found in gram-positive bacteria (126). In other gram-positive bacteria, cadmium resistance is also mediated by proteins similar to CadA (127). Cadmium-resistance genes may also be conferred by plasmids and may co-occur with genes that confer resistance to chromium and some antibiotics (128).

Chromium

Chromium has many industrial uses and, as a result, large volumes of chromium waste in various chemical forms are discharged into the environment. Chromium can exist in oxidation states ranging from −2 to +6. However, only Cr(III) and Cr(VI) are normally found within the range of pH and redox potentials common in environmental systems. Hexavalent chromium [Cr(VI)] forms chromate (CrO_4^{2-}) and dichromate ($Cr_2O_7^{2-}$), which are toxic, mutagenic and carcinogenic, soluble over a wide pH range, and mobile in the environment. This form of chromium can

easily cross the membranes of eukaryotic and prokaryotic cells. The trivalent form, Cr(III), is considerably less toxic and is virtually nonmobile, largely because it precipitates as oxides and hydroxides at pH 5 and above. In humans, Cr(III) is incorporated into a small polypeptide, which is responsible for activating the insulin receptor tyrosine kinase. In microorganisms, no beneficial uses of chromium have been found.

Chromate is a competitive inhibitor of sulfate, and enters the cells by the sulfate-transport pathways, which is normal for many microorganisms (6). Once in the cytosol, Cr(VI) may be reduced to Cr(III), which in turn reacts with the DNA. Trivalent chromium is relatively innocuous, because biological membranes do not allow its passing. Resistance to chromium is often reported to be plasmid-related and has been found in *Pseudomonas* strains, *Streptococcus,* and *Alcaligenes*, and is also known to occur in yeast (129). Chromate resistance results from the decreased accumulation of chromium, through efflux mechanisms, by the resistant cells. A chromate resistance plasmid was isolated from *Pseudomonas mendocina* MCM B-180 (130). Incubation of the strain at 42 °C for 24 hours caused loss of chromate resistance and the plasmid pARI180. Transformation of *E. coli* DH5-alpha with the purified plasmid DNA resulted in the simultaneous acquisition of resistance to chromate and the ability to reduce hexavalent chromium. Although the microbial reduction of Cr(VI) to Cr(III) is not known to be a plasmid-determined process, it may act as an additional mechanism of resistance to chromate.

Copper

Copper easily interacts with radicals, especially that of molecular oxygen. The toxicity of copper is based on its ability to produce hydroperoxide radicals, which interact with the cellular membranes. This characteristic makes it very toxic, and many organisms are highly sensitive to copper. Copper has a role in copper/zinc superoxide dismutases, however, its most important function is in the cytochrome *c* oxidase and other related enzymes, which are oxygen-dependent, terminal oxidases in the electron-transport chain of many microorganisms (131). The purpose of copper in cytochrome *c* is to transfer electrons, which are used to reduce molecular oxygen to water. The energy that is derived during the electron transfer is used to pump protons across the cytoplasmic membrane.

Plasmid conferred resistance to copper has been described in *E. coli* (132,133), *Pseudomonas* (134), and *Xanthomonas* (135). Each of these systems is highly homologous and contain the same genes. *Pseudomonas* species contain two regulatory genes (*cop* R and *cop* S) and four structural genes (*cop* ABCD). In *E. coli*, the comparable genes are called *pco* RS and *pco* ABCD. CopS is a sensor protein found in the membrane, whereas CopR is the DNA-binding responder protein. Of the four structural proteins, CopD is an inner membrane protein, CopB is an outer membrane protein, and CopA and CopC are periplasmic proteins (Fig. 2). CopA and CopC are copper-binding proteins, which contain 11 and

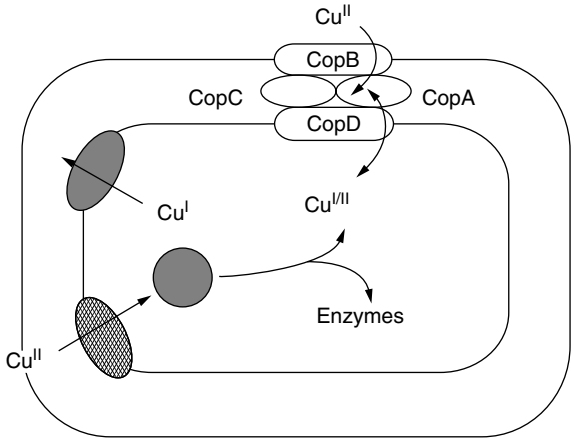

Figure 2. Copper transport and resistance in *Pseudomonas*. Hypothesized chromosomal uptake and efflux membrane transporters are shown, as well as intracellular copper-binding protein and plasmid-encoded CopABCD, the products of the copper resistance system of *P. syringae*. Adapted from Silver and Phung [123].

1 Cu^{2+} ions, respectively (134). At present, it is not clearly understood how the membrane proteins, CopB and CopD, move copper across the periplasm. In *E. coli*, plasmid copper–encoded resistance strongly interacts with chromosomally encoded functions (136). In addition, the actual resistance mechanism may depend on the growth phase (133). When copper-resistant *Pseudomonas* species are grown in the presence of high levels of copper, the bacteria turn blue (132). This occurs when copper is accumulated in the periplasm and the outer membrane, thus protecting the cell from toxic copper. However, *Xanthamonas* sp. and *E. coli* do not turn blue, implying that no copper storage is occurring in the periplasm.

In *Enterococcus hirae*, a gram-positive bacterium, resistance is conferred by the *cop* operon that contains two structural genes (*cop* A and *cop* B), both encoding a P-type ATPase. Compared with the gram-negative bacterial systems, that of *E. hirae* is the most understood copper transport and resistance system. Although it is suspected that CopA is responsible for copper uptake and nutrition, CopB is responsible for copper efflux and detoxification (137). Both proteins apparently transport silver as well (138). In addition, copper-transporting P-type ATPases have been found in a variety of organisms, including cyanobacteria, yeast, and eukaryotes. However, in *S. cerevisiae*, the P-type ATPase does not transport copper across the cytoplasmic membrane. To take up copper, Cu(II) is first reduced to Cu(I) by iron/copper-specific reductases. The Cu(I) is then bound to copper-specific protein transporters, which transport the Cu(I) into the cell (139).

Lead

Lead is a member of group IVA of the Periodic Table and exists mainly in two oxidation states, +2 and +4, and rarely occurs in its elemental state. Lead forms many salts, oxides, and organometallic compounds. Because of

its low solubility, it is largely biologically unavailable, and therefore is often not toxic to microorganisms. Lead is widely used in manufacturing, and the largest single use is the production of storage batteries. Additionally, it has been used as an automotive fuel additive, despite the fact that it is highly toxic to humans and animals. Lead affects the central nervous system, reproductive system, and blood pressure.

Although lead-tolerant gram-negative and gram-positive bacteria have been isolated, very little is known about their resistance mechanisms. Isolates belonging to the genera *Arthrobacter* and *Corynebacterium*, and species of *Alcaligenes, Bacillus*, and *Pseudomonas* have been identified (140). Lead-resistant bacteria isolated from lead-contaminated soil have been found to contain mercury- and copper-resistance genes (141). In lead-tolerant strains of *Citrobacter freudii* and *S. aureus*, lead is accumulated within the cell as lead phosphate (142,143).

Mercury

Mercury is noted for being one of the few metals that exists as a liquid at ambient temperatures and for being a potent human neurotoxin. Natural (e.g., volcanic eruptions) and anthropogenic (e.g., fossil fuel combustion) activities release large amounts of metallic mercury [Hg(0)] into the biosphere, however, it readily undergoes biotic and abiotic conversion to organic forms such as methylmercury (CH_3Hg^+). Methylmercury is water-soluble and fat-soluble, and therefore poses a threat to aquatic organisms such as fish and especially to fish consumers. Mercury pollution first received a great deal of publicity from the infamous Minamata Bay incident in Japan, where direct discharge of mercury-contaminated industrial waste led to extremely high levels of methylmercury in fish, which when eaten by humans, caused physical impairments and death.

In the environment, microorganisms are involved in the transformation of inorganic and organic mercury compounds, mostly as a detoxification mechanism. Numerous microorganisms avoid mercury toxicity by reducing ionic mercury [Hg(II)] to volatile Hg(0), which may be a potentially useful application to remove mercury from mercury-contaminated water. The reduction of Hg(II) to Hg(0) can be mediated by a number of microorganisms including enteric bacteria, *Pseudomonas* sp., *S. aureus, T. ferrooxidans, Streptomyces*, and *Cryptococcus* (144). The ability of bacteria to reduce Hg(II) is linked to mercury-resistance (*mer*) operons (122). The plasmid codes for a protein (merP) that initially binds to Hg(II) in the periplasm. The Hg(II) is then transported through the inner membrane into the cytoplasm by the membrane-bound protein merT. In the cytoplasm, Hg(II) is reduced to Hg(0) by a soluble, NADH-dependent, FAD-containing mercuric reductase. Mercuric reductase is active in the presence of excess thiols (R-SH) such as mercaptotethanol, dithiothreitol, glutathione, or cysteine. Intracellular Hg(0) is subsequently eliminated from the cell by enhanced diffusion.

Nickel

Nickel has oxidation states of +1, +2, and +3, but its preferred valence state is +3 in biological systems. In addition, it is chemically analogous to both iron and cobalt. As a result, the toxicity of nickel is similar to that of cobalt. Nickel is used principally in the production of stainless steel and other alloys because of its excellent corrosion resistance. However, nickel has carcinogenic properties and is involved in hypersensitivity reactions. Nickel dermatitis, a nickel allergy, is especially common among nickel platers and people wearing low-quality jewelry. Nickel is an essential micronutrient for many bacteria, including some acetogenic bacteria and methanogens. Nickel is a component of hydrogenase, urease, and carbon monoxide dehydrogenase, and is mainly bound to cysteine or histidine.

In bacteria, nickel enters the cell mainly by the CorA system (metal transport system), which is generally fast and unspecific (145). Two highly specific nickel transport systems are the HoxN and ABC transporters. The HoxN transporter, identified in *Ralstonia eutropha*, is part of the hydrogenase gene cluster. Uptake of nickel in this system is most probably driven by a chemiosmotic gradient. During the production of hydrogenase in *E. coli*, nickel is supplied by the ABC (ATP binding cassette) transporter and a periplasmic nickel-binding protein.

Through sequestration and/or transport, nickel can be detoxified. In *S. aureus*, nickel is bound to polyphosphate (146), and in *S. cerevisiae*, nickel is suspected to be disposed of and bound to the histidine in the vacuole (147). A proton-pumping ATPase transports nickel into the vacuole. It is suspected that other yeast and fungi probably detoxify nickel by similar mechanisms and also by mutation of the CorA uptake system (148,149). A well-known system is that of *Ralstonia* sp. strain CH34, in which an RND transporter drives nickel efflux (125,150).

Zinc

Zinc only occurs as the divalent cation Zn(II), which does not undergo redox changes under biological conditions. Zinc is a component in a number of enzymes and DNA-binding proteins, for example, zinc-finger proteins, which exist in bacteria. In humans, zinc toxicity may be based on zinc-induced copper deficiency; however, zinc is apparently less toxic than copper. In *E. coli*, the toxicity of zinc is similar to that of copper, nickel, and cobalt.

Three transporter groups contribute to the transportation of zinc. The first type of transporter system, known as CorA MIT, is responsible for transporting zinc in *S. cerevisiae* (151). This system is also present in *Archaea* and many other bacteria, but magnesium transport is not inhibited by the presence of Zn(II). The second type of transporter protein, MgtE, is chemiosmotically driven (152), and can be found in *Providencia stuartii* and several other gram-negative and gram-positive bacteria (153). The MgtE transporter is not as broadly distributed as CorA system. The third system is MgtA, which is a magnesium/zinc transporter found in *Salmonella typhimurium* (153). The MgtA system is a P-type ATPase,

which is suspected of transporting zinc better than magnesium. MgtA is regulated by magnesium starvation, which may be affected by zinc. However, this transporter is not the inducible high-specificity uptake system for Zn(II).

CONCLUSION

In the environment, unnaturally elevated levels of heavy metals exist as a result of a variety of anthropogenic activities. Heavy metals considered to be of concern are arsenic, chromium, cadmium, copper, lead, mercury, nickel, selenium, and zinc. Although a number of metals are toxic at excessive concentrations, all cellular life requires certain heavy metals as micronutrients. In aquatic and terrestrial environments, heavy metal and metalloid transformations are largely carried out as a direct result of microbial activities. Microorganisms influence the fate of metals by a number of processes including uptake into living cells, adsorption on cell walls, and chelation at the cell surface by microbially produced substances. These processes convert metals into organometal complexes that can persist in the environment and slow the degradation of organic substances, or may be taken up by higher organisms, leading to food chain transfer of metal ions. Microorganisms also carry out redox transformations of metals and produce acidity that can result in the solubilization of metals. Other microbially mediated metal transformations include methylation and demethylation reactions. The methylation and subsequent volatilization of metals, or selective precipitation of metals on the cell surface, often represent detoxification mechanisms. These and additional bacterial resistance mechanisms, which function by the energy-dependent efflux of toxic ions, are in many cases encoded by plasmids. The microbial transformation of heavy metals and metalloids into insoluble elemental forms or volatile forms may have applications in remediating metal-contaminated soil and water systems. Microbial processes also can be harnessed for biomining of metals from ores, and for the extraction of metals from contaminated water.

METAL STRESSED ENVIRONMENTS, BACTERIA IN

GORDON SOUTHAM
University of Western Ontario
London, Ontario, Canada

Bacteria are ubiquitous, found not only in nearly all surface environments, but in many subsurface environments as well (1–5). They are either found attached to surfaces, for example, as biofilms (6–9) or as complex associations of particles and cells (10), gluing sedimentary material together (11), or free-floating in the surrounding medium. In either case, they do not have direct control over the aqueous chemistry of the fluid phase of the environment. This fluid phase might include intrusions of heavy metal ions either from anthropogenic, for example, mining operations (12–16), or naturally occurring, for example, sources such as hydrothermal springs (17–21). If bacteria are to survive in these metal stressed environments, they must have the capacity to avoid or detoxify their surroundings.

From a bacterial perspective, a metal-stressed environment can be defined as an external aqueous chemistry that can inhibit cell metabolism and growth or can cause cell death for example, impair enzyme function (22) or entomb/fossilize bacterial cells (9). Unless the bacteria, either individually or as a population, are able to reduce the toxic effect of the metals.

Although bacteria do not have direct control over the chemistry of the fluid phase they encounter, they exhibit tremendous molecular and metabolic diversity (23–25), some of which allows them to respond to the substances dissolved in the medium, that is, metals, and to alter the chemistry of their surrounding microenvironment to their benefit (26–28). As a case in point, bacteria exploit a wide range of redox reactions with a negative $\Delta G'_o$ to support metabolism (24); these reactions often affect the solubility of metals. This article will focus on these mechanisms that allow bacteria to persist in metal stressed environments.

BACTERIAL RESPONSES TO TOXIC HEAVY METALS

Metal Transporters

Metal-resistant bacteria will be enriched and persist in anthropogenically or naturally "contaminated" ecosystems (29). When these bacteria encounter soluble, toxic heavy metals, they exert energy to remove the metals from the inside of their cells, thus preventing toxicity. The processes involved in metal transport out of the cell include enzymatic detoxification and transport (30), ATPase-based transporters, (31) and proton/antiport systems (32) (Table 1).

Schmidt and coworkers (32) identified similar nickel- and cobalt- resistance capabilities in various bacteria isolated from metal-contaminated soil and highly polluted domestic and industrial wastes. The information for these resistance mechanisms is typically contained on a plasmid (53), which allows for the exchange of metal-resistance properties between closely related bacteria. Perhaps, the best-characterized bacterial heavy metal resistance mechanism is the ability to form plasmid-mediated membrane porters (32,33). Membrane porters are produced as a direct response to toxic heavy metals and function by transporting soluble metals out of the cell (54). Plasmids often confer resistance to a variety of metals, for example, *Alcaligenes eutrophicus* plasmid pMOL28 confers resistance to chromate, cobalt, mercury, and nickel, and plasmid pMOL30 confers resistance to cadmium, cobalt, copper, mercury, and zinc (34,35). In a separate study, Schmidt and Schlegel (36) identified plasmid-mediated resistance to cadmium, cobalt, copper, nickel, and zinc. These bacterial transporters do not change the stability (redox property) of the metal or produce stable organo-metal complexes, that is, the metal remains soluble. Therefore, the metal is still available to exert a toxic effect on nonresistant bacteria.

Transformation of Metals into Volatile Forms

Some bacteria reduce the concentration of select toxic compounds by producing volatile, typically methylated metal forms (Table 1). Examples include the formation of Hg°, methyl- and dimethyl-Hg (37–39), methyl-Cd, methyl-Pb, methyl-Sn (40), dimethyl selenide (41), elemental selenium by dissimilatory selenate reduction (SeO_4^{2-} to Se°;42), arsine (43), and dimethyl arsine (44). In environments containing these metals, their transformation into a volatile form will reduce the metal concentration in the microenvironment immediately surrounding the bacterium because metals are transferred into soil gas and potentially lost to the atmosphere. The formation of volatile metals protects metal-resistant and unresistant bacteria.

Table 1. Specific Metal Resistance Mechanisms Initiating at the Genetic Level and Occurring as a Consequence of Microbial Metabolism

Toxic Heavy Metals	Mechanism
Hg^{2+}/organomercurials	Enzymatic detoxification + transport out of the cell (30)
AsO_4^{3-}/AsO_2^{-}	Arsenate is reduced to arsenite, which is pumped out of the cell by an ATPase (31)
Cd, Co, Cr, Cu, Hg, Ni, Zn	Pumped out of cells by an H^+-antiporter/metal-specific efflux (32–36)
Cd, Hg, Pb, Sn, Se, As	Formation of volatile metal forms (37–44)
Cd, Cu, Ni, Zn,	Protein-metal chelation (45–50)
Cu, Mn	Carbohydrate-metal chelation (51,52)

Metal Complexation

The bacterial formation of organic metal-complexing agents in response to the presence of toxic metals effectively chelates the metal in solution, reducing its toxicity (Table 1). Protein-metal chelate responses to cadmium (45,46), copper (47,48), nickel (49), and zinc (46,50) have been described. These metal chelators reduce metal bioavailability and limit mineral precipitation due to the formation of a stable organo-metal complex (49). They are produced by aerobic and anaerobic bacteria, including dissimilatory sulfate-reducing bacteria (SRB) and methanogens. In these systems, the protein-metal complexes are formed as a direct response to the metal and confer metal resistance by preventing the metal from entering the cell. Carbohydrate-metal complexes have also been described (51). In the study by Kidambi and coworkers (51), alginate, a copper-chelating, uronic acid–containing capsule, was produced by *Pseudomonas syringae* in response to the presence of copper. A capsule has also been synthesized by a *Rhizobium* sp. in response to the presence of manganese (52). Capsules are chemically and structurally complex organic macromolecules, which function as a hydrated cation-exchange resin that binds metals from solution (55,56). Like the bacterial formation of volatile metal forms, organic complexation of metals also protects nonmetal-resistant bacteria from the toxic effect of soluble, ionic heavy metals.

MINERAL PRECIPITATION

The greatest liability to bacteria in metal-stressed environments is the ubiquitous presence of iron that reacts with anionic charge groups on bacterial cell surfaces, which confer a net negative surface charge on most bacteria. This interaction results in the formation of fine-grained mineral precipitates, which over time, can coalesce into a mineral "armor" surrounding the bacterium. For an organism that interacts with its environment by diffusion processes, this represents a barrier to obtaining nutrients and is deleterious to the mineralized cell. Therefore, despite the elaborate resistance mechanisms toward base metals described in the preceding sections, bacteria must be able to "deal" with mineral formation, which typically occurs in metal-containing systems.

The formation of many secondary minerals in natural and laboratory systems is catalyzed by microorganisms (57; see Tables 2 and 3). These precipitation reactions

Table 2. Secondary Minerals Known to Form on Bacterial Cells by Surface Catalysis, that is, Interaction with Net Negative Surface Charge on Bacteria

Minerals Formed
Iron-oxides (ferrihydrite, hematite, goethite; 7,60)
Hydroxy iron-sulfates (61)
Metal phosphates, phosphorite (62,63)
Fe-silicates, geothermal sediments (17)
Fe-Al-silicates, sediment bacteria (11)
Metal-sulfides, for example, millerite (11)

Table 3. Secondary Minerals Known to Form on Microbial Cell Surfaces as a Consequence of Dissimilatory Metabolic Activity and Surface Catalysis

Minerals Formed	Process
Gypsum/calcite/magnesite	Photosynthetic shift in (CO_2) from bicarbonate-containing solutions (64,65)
Iron-oxide/oxy-hydroxide	Enzymatic iron oxidation, Fe(II) to Fe(III) (66,67)
Manganese oxide	Enzymatic manganese oxidation, Mn(II) to Mn (IV) (68)
Ferromanganese Concretions (Fe-Mn oxides)	Combination of the aforementioned two systems (69)
Metal-sulfides	Dissimilatory sulfate reduction (15,16)
Metal phosphates	Phosphatase activity (70)
$Cr(OH)_3$	Dissimilatory metal reduction, chromium (VI) to chromium (III); (71)
UO_2	Dissimilatory metal reduction, uranium (VI) to uranium (IV) (59,72)

have been divided into two general categories, namely, passive and active mineralization. Passive mineralization or surface catalysis is caused by the net negative charge on most bacterial cell surfaces (58) that nucleates the precipitation of metallic cations from solution. Active surface-mediated mineralization occurs by the direct transformation of metals into unstable forms (59) or by the formation of metal-reactive by-products (15,16). These dissimilatory processes, combined with bacterial surface catalysis, are responsible for cell surface mineral formation in these systems.

Natural environments in which biomineralization occurs include freshwater (6,8,73–75), seawater (69,76), sediments (77), zones of groundwater discharge (25,26,78), mine tailings (79–85), acid mine–drainage environments (7,11,12,60,86,87), pyritic soils (88,89), bog iron deposits (90), and hydrothermal systems (17–21). The samples of metal-encrusted bacteria used in this article were adsorbed onto 200 mesh Formvar-coated copper grids or prepared for ultra thin sections by conventional embedding (91) without the addition of osmium tetroxide or uranyl acetate as heavy metal fixatives and contrasting agents. Therefore, the electron density in the samples is due to the naturally immobilized metals.

Cell Envelope Structure and Chemistry

Mineral formation generally does not occur within bacteria because of the space constraints caused by the high concentration of organic material within a cell. Therefore, the outermost surface of a bacterium, that is, the interface between a bacterium and its external environment, will typically be responsible for the precipitation of metals from solution. The chemical structure of the cell surface is related to the phylogenetic or taxonomic position of the microbe (24,92,93). The bacteria are divided into gram-positive or gram-negative (although gram-variable organisms also exist) groups on the basis of cell envelope structure and chemistry. The Archaea, like the Bacteria, have demonstrated both positive- and negative-staining characteristics using the Gram reaction. However, the Archaea possess a unique chemistry (94), antigenicity (95), and ultrastructure (96) when compared with the Bacteria. Prokaryotes, excluding those bacteria which do not possess cell walls (e.g., *Mycoplasma*, *Thermoplasma*, and *Methanoplasma*) can possess a variety of surfaces that can interact with soluble metals in the environment.

Gram-positive bacteria possess a thick (typically 15 to 25 nm), peptidoglycan-containing cell wall that provides the framework to which the secondary polymers (teichoic acids or teichuronic acids) attach (58). Peptidoglycan, the major shape-determining structure for the organism, consists of repeated β (1–4)-linked N-acetyl glucosamine-N-acetyl muramic acid dimers. The N-acetyl muramic acid residues of this polymer possess short peptide stems (4 to 5 amino acids), which may be covalently bound to other muramic acid residues on neighboring strands. This results in a three-dimensional macromolecule shaped like the bacterium (97). These carbohydrate matrices and peptide stems possess carboxylate groups, which dominate the charge density of this structure (98,99). Teichoic acids, a secondary polymer, are composed of polyalcohol-based chains joined by phosphodiester linkages (e.g., polyglycerol-phosphate in *Bacillus subtilis* 168). The phosphate moieties confer a net negative electrical charge on this polymer. Teichuronic acids, a secondary polymer produced under phosphate-limiting conditions, are composed of uronic acid polymers, which also possess anionic reactive sites (100). Gram-positive archaea can resemble gram-positive bacteria, possessing a single homogeneous layer external to the plasma membrane (101). This envelope consists of an N-acetyl talosaminuronic acid/N-acetyl glucosamine peptidoglycan-like polymer termed *pseudomurein* (found in *Methanobacterium* spp.) or of a proteinaceous layer and a heteropolysaccharide cell wall (found in *Methanosarcina* spp., which grows as irregularly shaped cells in packets).

Gram-negative bacteria possess cell envelopes, which are structurally and chemically more complicated than those of the gram-positive bacteria. External to the plasma membrane is a thin (2 to 3 nm) layer of peptidoglycan contained within a periplasm, possibly

having a gel-like consistency (102). The periplasm is bound by an outer membrane that is a lipopolysaccharide (LPS)-phospholipid-protein mosaic in which the LPS and phospholipid occur on the opposite membrane faces of the bilayer (58). The LPS is anchored to the outer membrane by its lipid moiety and extends its polysaccharide chains outward from the bacterial surface (103). The outer membrane is often cemented to the peptidoglycan by salt-bridging or covalent bonding of the outer membrane proteins. One class of these proteins forms hydrophilic pores or channels (58). The LPS and peptidoglycan of gram-negative bacteria possess a net electronegative charge, which allows interaction with soluble cations (104–106).

Additional wall layers (e.g., capsules, S-layers, or sheaths) can exist external to the gram-positive or gram-negative cell envelopes described earlier. Capsules, commonly produced by bacteria in natural systems, are highly hydrated, amorphous assemblages of polysaccharides or polypeptides that are chemically linked to the cell surface and may extend up to 1 μm from the cell (107). Because of their carboxylate groups, capsules usually possess a net negative charge, and they may also possess additional anionic reactive groups because of the presence of phosphate moieties in polysaccharide chains. The highly hydrated nature of bacterial capsules and their cell surface location allows extensive interaction between capsular material and soluble metal cations (5,56,108).

S-layers are paracrystalline cell surface assemblages consisting of proteins or glycoproteins with p2, p4, or p6 symmetry (109). They self-assemble and associate with the underlying wall through noncovalent interaction (110). S-layers are located external to the peptidoglycan-based cell wall of the gram-positive Bacteria, the LPS of gram-negative Bacteria, the pseudomurein of gram-positive Archaea (109), or the cell membrane of gram-negative Archaea (58,94,96,111–113). S-layer proteins generally possess an acidic isoelectric point (pI) and thus exhibit a net negative charge, which can interact with metallic cations.

Sheaths, which surround chains of cells, are less frequently encountered. In the bacteria, they are typically recalcitrant structures composed of homo- or heteropolymers (carbohydrate or carbohydrate and protein) and usually remain intact even after cell degradation (114). The role of these sheath structures in the enzymatic precipitation of iron and manganese will be described later. Sheaths in the archaea are covalently linked proteinaceous structures that are found on *Methanospirillum hungatei* and *Methanosaeta concilii* (115,116).

Passive Mineralization

Ion-exchange reactions play an important role in the initiation of mineral formation through competition between hydronium ions, alkaline earth ions, and heavy metals for anionic reactive sites on bacterial surfaces (117; Cell envelope structure and chemistry). An acid-base titration of *B. subtilis* cell wall demonstrated that carboxyl, phosphoryl, and hydroxyl groups could potentially interact with soluble heavy metals (118–120). Under normal growth conditions, divalent cations (usually Ca^{2+} and Mg^{2+}) contribute to the stability of teichoic and teichuronic acid polymers (100), LPS (121), and S-layers (122). It is these cation-stabilized anionic sites that are replaced by heavy metals and serve as nucleation sites for the formation of minerals outward from the bacterial cell surface. Planktonic and sessile bacteria nucleate metals from solution resulting initially in the precipitation of fine-grained minerals of 10 nm diameter (Fig. 1).

Figure 1. An unstained TEM micrograph of bacteria collected by filtration (0.45 μm) of water from the Golden Giant mine tailings pond (Hemlo gold region Marathon, Ontario, Canada). Note that some of these bacteria have precipitated fine-grained (of 10 nm size) iron-arsenic minerals (determined by EDS; data not shown) on their surface, whereas others are nonmineralized. Bar equals 1 μm.

Bacterial metal precipitation typically exceeds the stoichiometry expected per chemical reaction site within the cell envelope (123). Mineral formation results from neutralization of chemically reactive sites and proceeds by nucleation of additional metallic ions with these previously sorbed metals. These critical nuclei, stabilized by the wall, are less prone to remobilization by dissolution because the wall reduces the interfacial tension between the mineral nucleus and the bulk-water phase. Mineral growth, then, is most active at the outer surface of the bacterium where these nuclei are formed and where space constraints by the envelope polymers do not inhibit metal precipitation. Mineral growth at these nucleation sites initially prevents a bacterium from being completely encrusted in metal. This is clearly important to an organism that obtains its nutrients by diffusion. The eventual, complete mineralization of microbial surfaces produces hollow minerals that are generally the size (i.e., μm order) and shape of the cell (Fig. 2). As metal precipitation proceeds, larger aggregates of mineralized bacteria that can trap insoluble particulate material, for example, clays form (124). When iron is present, bacteria can interact with one another to form visible bacteria-iron-hydroxide flocs (125) that can enhance the immobilization of base metals (7,60,126).

Direct Red/Ox Transformation of Metals

Many bacteria possess the capacity to oxidize metals, channeling these electrons through the electron-transport chain to generate a proton-motive force (PMF) for ATP

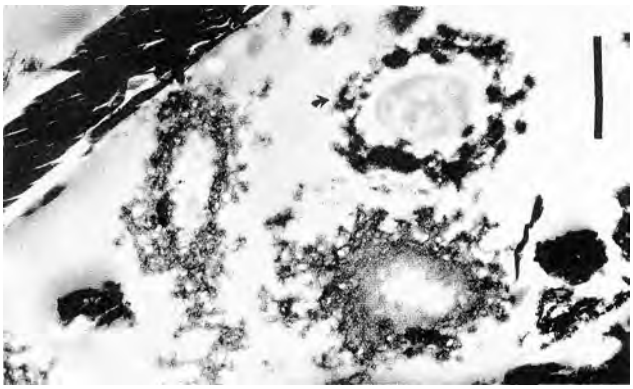

Figure 2. An unstained, ultrathin section TEM micrograph of a mineralized biofilm from the Copper Rand sulfide mine tailings pond (Chibougamou, PQ, Canada) demonstrating the presence of a mineralized bacterium (arrow), microfossils, and inorganic particulate material that has been trapped by the biofilm in this metal-stressed environment. Bar equals 1 μm.

synthesis. Other bacteria possess the capacity to use metals as electron acceptors, facilitating the oxidation of organic carbon in anaerobic respiration processes. In both physiological processes, bacteria often must deal with the inherent metal stress that results from using metals in dissimilatory metabolic reactions.

The oxidation of iron ($2Fe^{2+} + \frac{1}{2}O_2 + 2H^+ \rightarrow 2Fe^{3+} + H_2O$; 26,27,127) and manganese ($2Mn^{2+} + O_2 + 2H_2O \rightarrow MnO_2 + 4H^+$, net reaction of a two-step oxidation; 128,129) typically occurs within the aerobic/anaerobic interface in which the reduced metals encounter an oxidizing environment. In natural systems, sheaths of *Sphaerotilus* (66,67) and *Leptothrix* (68,127) are integral to the oxidative enzyme-mediated precipitation of iron and manganese because they contain the enzymes responsible for metal oxidation and they nucleate the oxidized mineral precipitates.

Dissimilatory metal-reducing bacteria are best known for their ability to use minerals for their electron acceptors resulting in the solubilization of Fe and Mn oxides (130–134) and any coprecipitated base metals. Dissimilatory metal reduction is also responsible for the bacterial cell surface precipitation of other metals, for example, $Cr(OH)_{3(s)}$ [Cr (VI) to Cr (III); 71,135] and $UO_{2(s)}$ [U (VI) to (IV); 59,72]. Although iron reduction can also result in the formation of magnetite (131) or siderite (3,136,137), reduced iron and other base metals are commonly precipitated as sulfides (138; see following text).

Reactive By-Product Catalyzed Mineral Formation

Cyanobacteria were found to precipitate gypsum or calcite in a freshwater environment, even when the bulk solution pH was too acidic to favor calcite precipitation (139). In this system, calcite formation was mediated by an increase in alkalinity at the bacteria cell surface caused by photosynthetic activity. It was also determined that the S-layer of *Synechococcus* sp., the cyanobacterium mediating this process, was responsible for nucleating these minerals from solution (64,65,140).

The basic biochemical (1) and geochemical (2) reactions mediated by dissimilatory SRB (15,16) are as follows:

$$2CH_2O + SO_4^{2-} \rightarrow H_2S + 2HCO_3^-$$

$$Fe^{2+} + H_2S \rightarrow FeS_{(s)} + 2H^+$$

The immobilization of FeS on SRB surfaces is promoted by a combination of the ionic interaction of Fe^{2+} with the anionic cell surface polymers and biogenic H_2S (Fig. 3; 49,141). Although the amorphous precipitates often found on bacterial surfaces represent the early stages in authigenic mineral formation (11,142), in SRB systems, a mineral transformation occurs rapidly after the initial metal immobilization occurs resulting in pyrite formation (143).

Bacterial phosphatase activity has been shown to release inorganic phosphate into solution and catalyze the formation of metal phosphates that nucleated on the bacterial cell surfaces perhaps with previously immobilized metals (70).

HOW DO BACTERIA SURVIVE IN A METAL-STRESSED ENVIRONMENT?

In laboratory metal binding experiments, living *B. subtilis* cells bound less metal than did non living cells (145). These experiments determined that the membrane-induced PMF, which pumps protons into the wall fabric, reduces the metal binding ability of the cell walls, probably through the competition of protons with metal ions for anionic wall sites. Therefore, the metabolic activity and the energized membranes of viable bacteria probably explains why one bacterium in a natural population is not mineralized, whereas a second adjacent bacterium that is dead or dying can be extensively

Figure 3. An unstained whole mount of a *Desulfovibrio desulfuricans* that has been cultured in the presence of 100 ppm Fe^{2+}, resulting in the precipitation of amorphous FeS (data not shown). FeS precipitation at this site is caused by the presence of a HS^-, released as a by-product of SRB metabolism, presumably forming a HS^- rich microenvironment around these bacteria. Note the extensive, electron-dense mineralization initiating at the bacterial cell surfaces. The nucleation and growth of minerals outward from the bacterial cell surface protects the cell from being completely encrusted with minerals allowing continued uptake of nutrients by diffusion. Bar equals 1 μm.

mineralized (6,9; see Fig. 1). Mineral precipitation reduces the cell surface area available for nutrient uptake (see Figs. 1–3). Consequently, those mineralized cells are starved, and as their PMF dissipates, they die. Without the competition from hydronium ions within the cell envelope, mineralization proceeds to completion, reducing the concentration of soluble, toxic heavy metals in the surrounding microenvironment. This would promote the survival of any remaining nonmineralized bacteria. The presence of nonmineralized and mineralized bacteria in a common environment may also correlate directly to the presence of metal transporters (30–36,53,54). In aerobic environments that are stressed by iron and base metals, the inability of a bacterium to pump toxic heavy metals out of the cell will result in cell death, a dissipation of its PMF, and nucleation of iron hydroxides possessing coprecipitated base metals. This overall process will protect bacteria possessing membrane transporters from biomineralization.

The high surface-to-volume ratio of bacteria facilitates their growth. Because access to nutrients is based on diffusion, the greater this ratio, the greater the diffusion of nutrients into cells (105,144–147). In terms of mineralization, high surface-to-volume ratios also provide a tremendous surface-biomineralization potential when compared with eukaryotic microorganisms. For example, the eukaryotic algae typically possess a surface-to-volume ratio that is one-tenth of that of bacteria. The implications of the differing mineralization potentials are twofold. First, bacteria can precipitate more metal than could a comparable measure of eukaryotic biomass, and second, in a mineral-precipitating environment, the ability of some bacteria to precipitate the bulk of the soluble metals increases the probability that the nonmineralized bacteria will survive. Therefore, from a evolutionary/ecological perspective, mineral formation represents a resistance mechanism to the presence of toxic soluble heavy metals.

In sediments, the decomposition of organic matter does not typically include organics (most probably bacterial cell envelopes; 148) that have bound heavy metals (149,150). Bacteria-metal-clay aggregates (10 to 100 μm) are even less likely than mineralized bacteria to remobilize metals (148). This is probably because of the extremely low surface area-to-volume ratios of metal-laden flocs compared with that of individual bacteria. The preservation of bacterial microfossils suggests that metals immobilized on bacterial cell envelopes are less available for remobilization and subsequent toxicity toward other viable bacteria.

WHAT HAPPENS WHEN THE METAL STRESS IS TOO MUCH?

Paleological Significance

Although individual bacteria are extremely small, the death of large populations of bacteria through mineralization has produced geologically significant deposits of carbonates (151), iron-silica deposits (152–155), sulfides (156–158), and phosphorites (63,159–161). Note that these bacteriologic processes are still occurring. The formation of bacterial microfossils results from the cell surface immobilization of soluble heavy metals (biomineralization) by ionic interactions with or without the formation and release of chemically reactive metabolic by-products. Metal encrusted cell surfaces are resistant to remobilization and are typically the only component of the cell that is preserved, possibly, as long as several billion years. The size and shape of the microfossils are determined by bacterial morphology, which includes spherical, rod-shaped, filamentous, vibrioid, helical, and stalked structures. The identification of bacterial microfossils as hollow mineral assemblages using ultrathin section TEM requires preservation of the original biomineralization phenomenon (Fig. 4). Preservation of microfossils will result when the metals are immobilized on bacteria in a chemically and biogeochemically stable environment. However, for long-term preservation, silicification of bacteria often in association with iron results in the formation of extremely stable microfossils (17,19,162–164,165–168). In their simplest form, bacterial microfossils consist of only a mineralized cell envelope, which preserves the original bacterial morphology. Even in rare cases when both the cell envelope and the cytoplasm are mineralized, the cell envelope can be easily differentiated from the cytoplasm preserving the original cell morphology.

Contemporary Systems

Mineral precipitation is occurring in natural systems and is being exploited for bioremediation and industrial purposes. In aquatic systems, mineral growth cross-links individual bacteria-forming bacteria-mineral flocs (9) that settle through the water column (125). This promotes the transfer of once soluble metals into the sediment producing sediments rich in these metals (11). SRB also enrich sediments with base metals as metal sulfides (12). The enrichment of base metals in sediments was recognized by Timperley and Allan (169) who advocated the examination of sediments, presumably containing metal-encrusted

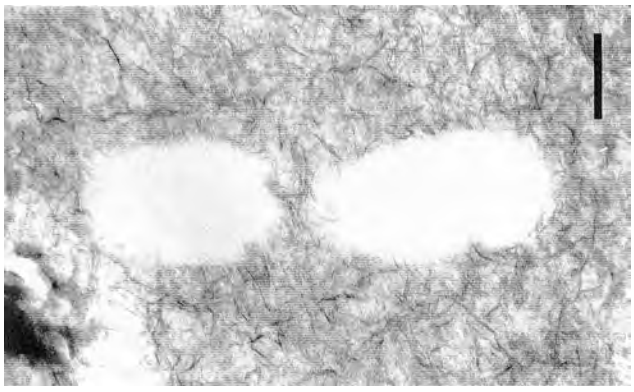

Figure 4. An unstained ultrathin section of TEM micrograph of a mineralized biofilm from the Copper Rand mine tailings pond (Chibougamou, PQ, Canada) demonstrating the presence of bacterial microfossils possessing no obvious bacterial remains. The outward growth of minerals from bacterial surfaces is inferred because the formation of hollow, bacteria-shaped structures within a geochemically precipitated iron-manganese oxide is not possible. Bar equals 0.5 μm.

bacteria, during exploration geochemistry to determine the presence of anomalous metal concentrations.

Cyanobacteria have been implicated in open ocean-whiting events (calcite precipitation; 170) by the same photosynthesis generated alkalinity and bacterial surface-active nanoenvironment described by Thompson and coworkers (65). Bacteria are also actively involved in the precipitation of silica in ambient and hydrothermal current-earth systems (11,75,163) conceivably through the precipitation of silicic acid as amorphous silica that is coprecipitated with iron (166).

CONCLUSION

Bacteria possess a wide range of responses toward toxic metals, for example, transporters, the ability to produce volatile or organic metal forms, and biomineralization. Mineral formation, resulting from surface catalysis or a combination of dissimilatory processes and surface catalysis, has produced microfossils in ancient geologic formations and is occurring in current-earth systems. Although mineralization is deleterious to individual bacteria, they are still able to persist in these mineral-forming environments. This inherent ability of bacteria to precipitate metals from solution without killing the entire population has been exploited for the reclamation of metals from contaminated water (13,14,171,172) and will no doubt play a role in the bioremediation of metal-contaminated environments in the future.

Acknowledgments

The water sample from the Hemlo gold mine was collected during an Ontario Geological Survey project. The Copper Rand mine drainage samples were collected during an environmental impact assessment for Westminer Canada Ltd. The TEM, SEM, and EDS were performed in the NSERC Regional STEM facility located in the Department of Microbiology, University of Guelph, Guelph, Ontario, Canada. I thank the editor and an anonymous reviewer for their constructive comments.

METAL TRANSFORMATIONS. See METAL (U, Fe, Mn, Hg) CYCLING

METAL (U, Fe, Mn, Hg) CYCLING

CHARLES M. MOORE
THOMAS J. DICHRISTINA
Georgia Institute of Technology
Atlanta, Georgia

Metal transformations in the environment are dominated by two fundamental processes: redox reactions and complexation by organic and inorganic compounds. By these two processes, metals are cycled among soluble, insoluble, and volatile states as well as organic and inorganic forms. In addition to strictly abiotic (chemical) reactions, metals are transformed by microbially mediated pathways. These consist of direct (enzymatic) reactions or indirect (chemical) reactions with microbially produced end-products. Microbial metal transformations represent a key component to metal cycling in natural systems.

Metal cations are classified according to their electron configuration (1,2). A-type metal cations possess electron configurations of inert gases, are distinguished by low polarizability and are termed "hard spheres" or "hard acids". A-type metal cations include elements in group I (alkali metals) and group II (alkaline earth metals), and the lanthanides and actinides, such as uranium (as $(UO_2)^{2+}$). B-type metal cations possess electron configurations that contain 10 to 12 outer-shell electrons, are highly polarizable, are termed "soft spheres" or "soft acids" and include Hg^{2+}, Au^{+}, Ag^{+}, Cu^{+}, Cd^{2+}, Zn^{2+}, and Pb^{2+}. In general, A-type metal cations are O-seeking, whereas B-type metal ions are N- and S-seeking. Some A-type metal cations (e.g., Na^{+}, Ca^{2+}, K^{+}, and Mg^{2+}) are required nutrients for cell growth. In contrast, B-type metal cations are often toxic to organisms at relatively low concentrations. Transition metal cations (e.g., Fe^{3+} and Mn^{4+}) contain one to nine outer-shell electrons, are highly redox active, and exist in multiple oxidation states in the environment. The chemical characteristics of transition metal cations lie between A- and B-type metal cations (1,2). This chapter outlines the chemical and biological pathways that contribute to the cycling of representative A-type (uranium), transition (iron, manganese), and B-type (mercury) metal cations. They also serve to illustrate the central role of metal cycling in other environmentally significant processes, including the mobilization and transport of hazardous metals and the cycling of other elements including trace metals, carbon, nitrogen, phosphorus, and sulfur.

URANIUM CYCLING

Overview

Uranium is a radioactive constituent of more than 150 naturally occurring minerals, including the most commonly found forms, uraninite (UO_2) and coffinite ($USiO_4 \cdot nH_2O$) (3). Uranium concentrations in marine waters (10 $\mu g\,kg^{-1}$) are approximately 10-fold greater than in freshwaters (4). Uranium is found in the 0, +III, +IV, +V, and +VI oxidation states, although the +IV and +V oxidation states predominate at circumneutral pH. Redox transformations and complexation reactions are important to predicting the fate and transport of uranium in contaminated subsurface aquifers. Uranyl ion (U(VI)) is highly soluble in aqueous environments, whereas uraninite (U(IV)) is highly insoluble (3). Uranium solubility is also greatly affected by complexation with a variety of organic and inorganic compounds. In aerobic environments, U(VI) is complexed by carbonates, forming highly mobile U(VI)-carbonate complexes (5). On the other hand, U(VI) is also strongly complexed by inorganic phosphate, forming highly insoluble U(VI)-phosphate complexes. Uranium mobility is also retarded by U(VI) sorption to particulate organic matter and Fe(III)- and Mn(IV)-oxides (6,7).

Uranium Oxidation

Under anoxic conditions, particulate U(IV) is thermodynamically favored. Particulate U(IV) oxidation to soluble U(VI) is rapid under aerobic conditions, with a half-life on the order of seconds at circumneutral pH (6). In Chesapeake Bay sediments, for example, particulate U(IV) is released to pore waters and bottom waters by U(IV) oxidation processes. Anoxic conditions during the summer result in reductive precipitation of U(IV) particles and minimal exchange of uranium to the bottom waters. Bay turnover in the fall, however, results in increased bottom water O_2 concentrations, enhanced U(IV) oxidation rates and subsequent release of U(VI) to the water column (8).

Neutrophilic U(IV)-oxidizing bacteria (UOB) are yet to be discovered, indicating that U(IV) oxidation in marine and freshwater environments is primarily the result of O_2-catalyzed oxidation pathways. Two acidophilic UOB, *Thiobacillus ferrooxidans* and *T. acidophilus*, oxidize U(IV) enzymatically under aerobic conditions, yet are unable to grow with U(IV) as the sole electron donor (9). Microbial U(IV) oxidation may therefore only be an important component of uranium cycling in uranium-contaminated acidic environments, such as acid mine drainage.

Uranium Reduction

In anaerobic aqueous solutions, abiotic reduction of U(VI) by inorganic reductants such as hydrogen sulfide and Fe(II) proceeds at extremely slow rates (10). However, under anaerobic conditions, U(VI) is chemically reduced to U(IV) by Fe(II) sorbed to mineral surfaces, such as hematite (10). Fe(II)-containing minerals such as pyrite (FeS_2) also reduce U(VI) under anaerobic conditions (11). Sulfidic marine sediments are therefore considered the main repository for uranium in the global uranium budget. Organic compounds are not effective chemical reductants of U(VI) at temperatures below 45 °C (10).

Sulfate-reducing bacteria (SRB) such as *Desulfovibrio desulfuricans* and *D. vulgaris* reduce U(VI) under anaerobic conditions, yet are unable to grow on U(VI) as the sole

terminal electron acceptor. U(VI)-reducing bacteria (URB) *Shewanella putrefaciens* and *Geobacter metallireducens*, on the other hand, couple U(VI) reduction to anaerobic growth (12,13). U(VI) chemical speciation is an important component to microbial U(VI) reduction. *Desulfovibrio desulfuricans* reduces U(VI) complexed to multidentate ligands (citrate, oxalate) at rates faster than U(VI) complexed to monodentate ligands (acetate). Interestingly, the opposite trend is observed with U(VI)-reducing *Shewanella alga* (14).

The contribution of microbial U(VI) reduction to uranium cycling is greatly affected by the presence of competing terminal electron acceptors. In redox-stratified marine sediments, the U(VI) reduction zone is found below the zone of Fe(III) reduction, suggesting that Fe(III) is used as a preferred terminal electron acceptor (15). U(VI) is released from estuarine sediments only after the Fe(III) and Mn(IV) oxides are reductively dissolved (16). In pure culture, U(VI) reduction by *S. alg*a (an Fe(III)- and U(VI)-reducing bacterium) is inhibited by the presence of Fe(III) oxides, which divert electron transfer from U(VI) to Fe(III) (17).

Uranium Precipitation and Biosorption

In addition to microbially mediated reductive precipitation pathways, microorganisms also immobilize U(VI) via phosphatase-associated pathways. U(VI) is precipitated at the cell surface as polycrystalline HUO_2PO_4 by complexation with inorganic phosphate liberated enzymatically from organophosphate compounds (3,18). Phosphatase-associated precipitation pathways may provide the basis for a microbial uranium detoxification system. In another indirect mechanism, U(VI) is scavenged by microbially produced siderophores that otherwise sequester low levels of Fe(II) in natural waters (18). Other microbially mediated mechanisms for uranium immobilization include direct uranium uptake or biosorption to cell surfaces (3). Direct uranium uptake results in the formation of intracellular uranium crystals (3). Extracellular uranium biosorption results from interactions between anionic sites on cell surfaces (e.g., carboxylic acid groups) and positively charged U(VI) species (19). In this manner, all microorganisms with negatively charged cell surface groups possess potential to biosorb uranium.

Hypothetical Uranium Cycle

A hypothetical uranium cycle is depicted in Figure 1. This hypothetical cycle is based on known uranium transformation pathways and does not reflect the relative contribution of each pathway to overall uranium cycling. The primary sources of U(VI) in the environment include weathering of U(VI)-bearing minerals and anthropogenic inputs. In aerobic surface waters, U(VI) is complexed to carbonates or sorbed to inorganic and organic particulate matter, which is then transported through the redox transition zone to anoxic bottom waters and sediments. Under anoxic conditions, URB produce particulate U(IV), which is stably maintained in the sediment solid phase. URB activity is inhibited by competing terminal electron acceptors, such as Fe(III) and Mn(IV). Pyrite and Fe(II) sorbed to catalytic mineral surfaces mediate the abiotic (chemical) reduction of U(VI). U(IV) is reoxidized upon exposure to oxygenated pore waters and the resulting U(VI) products freely diffuse into the water column to complete the uranium cycle.

IRON CYCLING

Overview

Iron is a transition metal that undergoes a variety of microbially and chemically mediated redox transformations and is complexed by a wide range of organic and

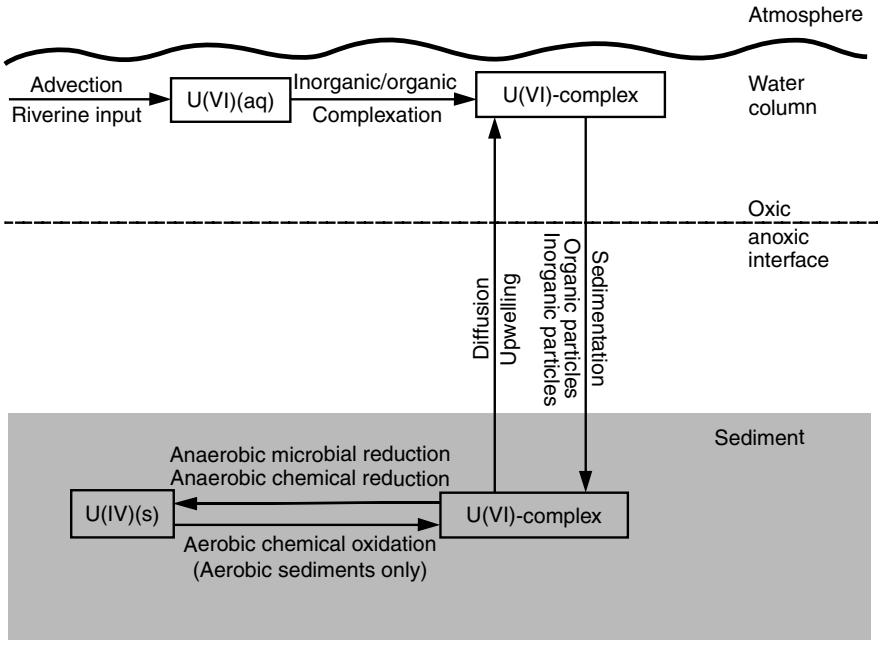

Figure 1. Hypothetical uranium cycle.

inorganic compounds. Iron redox transformations are critical to iron cycling in aqueous environments because Fe(III) is sparingly soluble at circumneutral pH, whereas Fe(II) is highly soluble (1). The predominant iron oxidation states are 0, +II and +III. Table 1 lists several common Fe(II)- and Fe(III)-bearing minerals. Iron enters marine environments via riverine input and atmospheric deposition (20). In aqueous environments at pH less than 5, Fe(II) is thermodynamically favored and is used as an electron donor by Fe(II)-oxidizing bacteria (FOB). In aqueous environments at pH greater than 5, Fe(III) is thermodynamically favored and is used as a terminal electron acceptor by Fe(III)-reducing bacteria (FRB). Fe(II) is chemically oxidized to Fe(III) by O_2 and other oxidants, including Mn(IV), whereas Fe(III) is chemically reduced to Fe(II) by organic and inorganic reducing agents. Fe(III) and Fe(II) are readily chelated by organic (e.g., EDTA, citrate, oxalate) and inorganic (e.g., PO_4^{3-}, HCO_3^-) compounds. In the following section, the biotic and abiotic pathways of iron cycling are outlined, with emphasis on microbial Fe(II) oxidation and microbial Fe(III) reduction.

Microbial Fe(II) Oxidation

FOB are isolated from aerobic environments at pH less than 5 and microaerobic environments (<10% O_2 saturation) at circumneutral pH (4). FOB are generally not found in high pH environments where Fe(III) is thermodynamically favored over Fe(II). At pH less than 5, aerobic FOB outcompete O_2 for Fe(II) substrates. At circumneutral pH, however, aerobic FOB outcompete chemical Fe(II) oxidation pathways only at low O_2 concentrations (4). Acidophilic FOB that grow by coupling Fe(II) oxidation to aerobic respiration include *T. ferrooxidans*, a common isolate of acid mine drainage (21). Leachate originating from many acid mines contains high concentrations of acid-soluble Fe(III), an indication of FOB activity (22). *Thiobacillus ferrooxidans* is also able to oxidize H_2S, S(0), $S_2O_3^{2-}$, FeS, H_2 and formate under aerobic conditions. Fe(III) oxyhydroxide precipitates are often found in spent media of Fe(II)-oxidizing *T. ferrooxidans*, suggesting that Fe(II) oxidation occurs either extracellularly or in association with the outer cell membrane. Other acidophilic FOB include *Leptospirillum ferrooxidans*, members of the genus *Mettalogenium* and the thermophilic acidophiles *Sulfolobus acidocaldarus* and *Sulfobacillus thermosulfidooxidans* (4). An as-yet uncharacterized acidophilic Archeon isolated from acid mine drainage also oxidizes Fe(II) (23). The ability to oxidize Fe(II) appears widespread in prokaryotes and may be an important component of iron cycling in aerobic/low pH, microaerobic/circumneutral pH or high-temperature environments.

Table 1. Common Iron-Containing Minerals

Mineral Name	Composition	Iron Oxidation State
Siderite	FeC_2O_3	+2
Pyrite	FeS2	+2
Hematite	α-Fe_2O_3	+3
Goethite	α-FeOOH	+3
Lepidocrocite	β-FeOOH	+3
Magnetite	Fe_3O_4	+2, +3

The neutrophilic FOB *Gallionella ferruginea* resides in Fe(II)-rich freshwaters that contain low O_2 concentrations (24). At low O_2 concentrations, *G. ferruginea* outcompetes O_2-catalyzed chemical oxidation pathways for Fe(II) substrates. During microaerobic Fe(II) oxidation, *G. ferruginea* forms stalks of twisted, bundled fibrils encrusted with Fe(III) oxyhydroxides (25). Neutrophilic FOB phylogenetically unrelated to any known lineage are enriched from iron-containing groundwaters by incubation in opposing Fe(II) and O_2 gradients (26). Other neutrophilic FOB include *Leptothrix discophora*, a freshwater isolate that contains a soluble Fe(II)-oxidizing protein (27). In the neutrophilic FOB *Metallogenium* and *Arthrobacter siderocapsulatus*, Fe(II) is oxidized by O_2 produced during H_2O_2 disproportionation by catalase. Regardless of the mechanism for Fe(II) oxidation, FOB are generally encased in precipitated Fe(III)-oxide crusts (24), which may sink to underlying sediments.

Microbial Fe(II) oxidation is also an important metabolic pathway in anoxygenic photosynthesis. Fe(II) oxidation by anoxygenic, photosynthetic FOB is postulated to be one of the first cellular energy transduction pathways on early Earth (28). In the modern biosphere, Fe(II) is oxidized by anoxygenic phototrophs, which couple reverse electron transport to carbon dioxide fixation (28). Nonphotosynthetic, anaerobic FOB derive metabolic energy by coupling Fe(II) oxidation to anaerobic respiration. For example, strains isolated from brackish-water sediments grow anaerobically by coupling Fe(II) oxidation to NO_3^- reduction (29). Geochemical evidence for NO_3^--reducing FOB is found in the suboxic zone of the Black Sea where Fe(II) and nitrate are depleted in the same depth horizon (30). Microbial Fe(II) oxidation may therefore be a significant component of iron cycling in the photic zone of anaerobic waters and in the suboxic zone of Fe(II)- and NO_3^--rich waters and sediments.

Chemical Fe(II) Oxidation

Chemical (O_2-catalyzed) Fe(II) oxidation contributes significantly to iron cycling because Fe(II) is rapidly oxidized by O_2 at pH greater than 5 (half-life on the order of seconds to minutes; (1)). In the Santa Barbara Basin, for example, Fe(II) diffusing from anaerobic sediments into the overlying anaerobic water column is rapidly oxidized by O_2 upon reaching the oxic/anoxic interface (31). The resulting Fe(III) oxide particles settle through the water column and re-enter the anaerobic sediments where they are re-reduced, released to the overlying water column and again precipitated at the oxic/anoxic interface. In this way, iron atoms are recycled hundreds to thousands of times before burial.

Chemical Fe(II) oxidation is enhanced by chemical reactions that raise pH. These reactions include NH_4^+ production during protein degradation, organic acid oxidation during microbial metabolism and CO_2 fixation (HCO_3^- removal) during photosynthesis (4). O_2-catalyzed, Fe(II) oxidation coupled to photocatalyzed, Fe(III) reduction (see following text) may form the basis of a local Fe cycle in

the photic zone of aquatic environments. Fe(II) is protected from oxidative precipitation at elevated pH and E_h by chelating agents, such as oxalate, citrate, and humic acids. Conversely, Fe(II) oxidation is promoted by microbial breakdown of Fe(II)-chelating compounds. Photochemically produced Fe(II) is also readily oxidized in a Fenton reaction with hydrogen peroxide, producing hydroxyl radical ($OH^{\bullet}$) and particulate Fe(III). $OH^{\bullet}$ produced by the photo-Fenton reaction is a potential oxidant of complex, natural organic matter that is otherwise resistant to degradation (32). The photo-Fenton reaction is postulated to be a dominant pathway for Fe(II) oxidation and organic matter degradation in the photic zone of oligotrophic seawaters (33).

Chemical Fe(II) oxidation is also an important component of iron cycling in anaerobic environments. Under anaerobic conditions at pH greater than 5, Fe(II) is rapidly oxidized to Fe(III) by Mn(IV) oxides (34). Fe(III) reduction in redox-stratified environments may therefore be masked by Mn(IV)-catalyzed (chemical) oxidation of Fe(II). Iron cycling is also tied to uranium cycling. Under anaerobic conditions, Fe(II) sorbed to Fe(III) oxide surfaces is rapidly oxidized by U(VI) to produce particulate Fe(III) and particulate U(IV) oxidation products (see preceding section on uranium cycling; (10)).

Microbial Fe(III) Reduction

The contribution of other anaerobic respiratory processes (methanogenesis, denitrification, and sulfate reduction) to carbon, nitrogen, and sulfur cycling is well documented (22). Only recently has the role of microbial (dissimilatory) Fe(III) reduction in the cycling of iron and other elements been recognized. Geochemical evidence for FRB is found in both freshwater and marine environments where Fe(II) is detected in high concentrations (35–37). In Fe(III)-rich, anaerobic marine sediments, FRB activity can account for up to 80% of the in situ rate of organic carbon oxidation. Laboratory-controlled sediment incubations demonstrate that Fe(II) production is inhibited by heat pasteurization or by addition of metabolic inhibitors and energetically more favorable terminal electron acceptors, such as O_2 and nitrate (35). Microbial Fe(III) reduction, on the other hand, suppresses less energetically favorable terminal electron-accepting processes such as sulfate reduction and methanogenesis in Fe(III)-rich, anaerobic freshwater sediments (38).

FRB couple the oxidation of inorganic substrates, such as H_2 and S(0), as well as a variety of organic carbon compounds to the reduction of Fe(III) (35,36). Respiratory electrons pass through an electron transport chain, which may terminate with Fe(III)-specific reductases. The energy released during electron transfer is coupled to generation of a proton motive force and ATP. To transfer respiratory electrons to particulate Fe(III) oxides, FRB must contact the oxide surface directly or employ electron shuttles to transport electrons to the oxide surface (39–41). Although amorphous Fe(III) oxides are more readily reduced by FRB than crystalline Fe(III) forms (e.g., hematite and goethite), differences in reduction rates are attributed to differences in reactive surface areas (42).

The ability to reduce Fe(III) is widespread in the prokaryotic world (43). FRB are found in the epsilon (e.g., *Geospirillum*) and alpha (e.g., *Rhodobacter capsulatas*) subdivisions of the proteobacteria as well as in the thermophilic gram-positive group (*Bacillus infernus*). *Geovibrio ferrireducens* and *Geothrix fermentens* form two novel FRB lineages within the Bacteria. Hyperthermophilic bacteria capable of reducing Fe(III) include *Archaeoglobus fulgidus*, a sulfate-reducing member of the Archaea (44). Microbial Fe(III) reduction is therefore a potentially important component of iron cycling in iron-rich, high-temperature environments, such as hydrothermal vents. These findings also strengthen the hypothesis that microbial Fe(III) reduction was one of the first respiratory processes to have evolved on early Earth (44).

The best-studied FRB are found in two groups of proteobacteria: facultative anaerobes in the gamma subdivision (e.g., *Shewanella putrefaciens* and acidophilic *T. ferrooxidans* (45,46)) and strict anaerobes in the delta subdivision (e.g., *Geobacter metallireducens* (46)). Most delta proteobacterial FRB completely mineralize organic carbon substrates under Fe(III)-reducing conditions, whereas their gamma proteobacterial counterparts only partially oxidize them (43). Gamma proteobacterial FRB, however, are noted for their ability to respire on a wide battery of compounds as alternate terminal electron acceptors. *Shewanella putrefaciens*, for example, respires on O_2, Fe(III), nitrate, nitrite, fumarate, Mn(IV), Cr(VI), U(VI), Tc(VII), sulfite, bisulfite, S(0), and potentially several other compounds (13,47,48). In the presence of competing terminal electron acceptors, the energetically favorable one is preferentially reduced by *Shewanella* species. For example, O_2 and nitrate are preferentially reduced before Fe(III) (49,50), whereas Fe(III) is preferentially reduced before U(VI) (17). The contribution of microbial Fe(III) reduction to the cycling of iron, uranium, and other elements in anaerobic environments is therefore greatly affected by competing terminal electron acceptors.

Microbial Fe(III) reduction is important to other environmental processes associated with iron cycling, including reductive dissolution of Fe(III)-containing clays, gleying of waterlogged agricultural soils, biomineralization of Fe(II)-containing minerals and mobilization of phosphate and trace metals sorbed to Fe(III)-oxide surfaces (35). Although iron is an essential nutrient for most microorganisms, little is known about the impact of assimilatory Fe(III) reduction on iron cycling in natural waters and sediments.

Chemical Fe(III) Reduction

Several organic compounds (e.g., cysteine and some phenols) reduce Fe(III) chemically (abiotically) at circumneutral pH (35). These compounds are generally not found in significant concentrations in the environment, however, and their role in iron cycling is minimal. Sulfide, on the other hand, is found in high concentrations in anaerobic marine environments. Fe(III) is rapidly reduced by sulfide at circumneutral pH (51) and solid phase iron monosulfides (FeS) or FeS_2 are generated via the following series

of reactions:

$$2FeOOH + H_2S + 4H^+ \rightarrow 2Fe^{2+} + S(0) + 4H_2O \quad (1)$$

$$Fe^{2+} + H_2S \rightarrow FeS + 2H^+ \quad (2)$$

$$FeS + H_2S \rightarrow FeS_2 + 2H^+ \quad (3)$$

In anaerobic sulfate-rich sediments, sulfide produced by SRB may diffuse into the Fe(III) reduction zone and outcompete FRB for Fe(III) substrates that otherwise are available for use as terminal electron acceptor (52). A more energetically favorable terminal electron-accepting process (Fe(III) reduction) is thus replaced by a less favorable one (sulfate reduction).

Photoreductive dissolution pathways may account for a significant amount of Fe(II) produced in the photic zone of the open ocean (1). In photoreductive dissolution, UV radiation catalyzes electron transfer from organic ligands to complexed Fe(III) and soluble Fe(II) is released. FRB are generally not active in the photic zone because O_2, an energetically more favorable terminal electron acceptor, is produced at high concentrations during photosynthesis. Photoreduced Fe(II) is reoxidized by photosynthetically derived O_2 in the photic zone of surficial waters, thereby driving a local iron cycle (1).

Microbial Iron Assimilation

With only two known exceptions (e.g., lactic Streptococci and *Borellia burgdorferi*) (53), all organisms require iron for use as protein cofactors. Iron-containing proteins include cytochromes, FeS proteins, catalases, peroxidases, ribonucleotide reductases, ferredoxin and transcriptional activation factors. Microorganisms have evolved numerous mechanisms for Fe assimilation. In general, these strategies include biosynthesis and secretion of low molecular weight, Fe(III)-chelating compounds (generally siderophores) that complex and solubilize Fe(III). More than 500 siderophores have been discovered in bacteria and fungi. Microorganisms that do not produce siderophores appear to be a rare exception (54). Fe(III)-siderophore complexes are transported into the cell via active transport pathways mediated by cell surface receptors with high specificity for individual Fe(III)-siderophore complexes. Iron is removed from the Fe(III)-siderophore complex either by direct reduction of the complexed Fe(III) or via degradation of the siderophore followed by Fe(III) reduction. The released Fe(II) is incorporated into proteins or stored within the microorganism for future use. Some microorganisms reduce Fe(III) prior to transporting it into the cell, whereas others take up soluble Fe(II) or Fe(III) directly from the environment (55). Microbial iron assimilation may have a significant impact on iron cycling in environments where iron is limiting or biomass concentrations are high.

Iron Cycling: A Hypothetical Model System

A hypothetical iron cycle is depicted in Figure 2. This hypothetical cycle is based on known iron transformation pathways and does not reflect the relative contribution of each pathway to overall iron cycling. The natural water

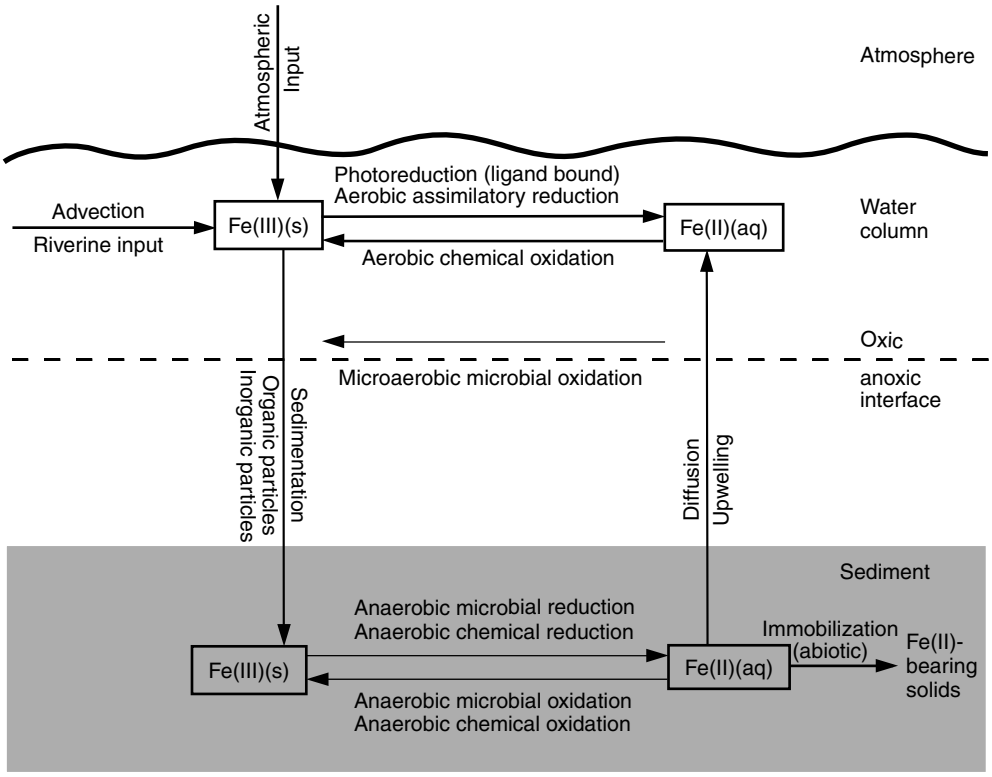

Figure 2. Hypothetical iron cycle.

system consists of aerobic surface waters, an oxic/anoxic interface and underlying anaerobic sediments. Fe(III)-bearing particles enter the system from rivers or the atmosphere. In the photic zone, Fe(III) is complexed to organic ligands and photoreduced to Fe(II). Fe(II) is oxidized to particulate Fe(III) by photosynthetically derived O_2. Fe(II) or Fe(III) may also be assimilated by the resident microbial community. Particulate Fe(III) or Fe(III) complexed by high molecular weight organic matter settles through the oxic/anoxic interface into the anoxic bottom waters. Particulate Fe(III) is reductively dissolved to Fe(II) via microbially or chemically driven pathways, releasing previously sorbed phosphate and trace metals to the water column. Fe(II) is found in a freely soluble form or is immobilized via reaction with bicarbonate or hydrogen sulfide and found as siderite ($FeCO_3$), FeS or FeS_2. Soluble Fe(II) is oxidized at the oxic/anoxic interface by microbially or chemically driven Fe(II) oxidation pathways. Particulate Fe(III) in anaerobic sediments remains buried until microbial or chemical Fe(III) reductive dissolution processes release soluble Fe(II) to the pore waters. Fe(II) is oxidized by anaerobic microbial and chemical pathways or transported upward by molecular diffusion and upwelling currents. If light penetrates the anoxic zone, anoxygenic phototrophic microorganisms oxidize Fe(II). At the oxic/anoxic interface, low dissolved O_2 concentrations provide an ecological niche for microbial Fe(II) oxidation. Photosynthetically derived O_2 drives Fe(II) oxidation in the surficial waters, whereas photocatalyzed Fe(III) reduction completes the hypothetical iron cycle.

MANGANESE CYCLING

Overview

Manganese is a redox-active transition metal that constitutes approximately 0.1% (dry weight) of the Earth's crust; it is approximately 50 times less abundant than iron. Table 2 lists common Mn-containing minerals (56). Manganese enters marine environments via riverine input and atmospheric deposition (57). The most common manganese oxidation states in the environment are +II, +III and +IV. Mn(II) is highly soluble at circumneutral pH, although not as redox reactive as Fe(II) (1). In contrast to Fe(II), Mn(II) is not readily oxidized by O_2 at pH less than 8. Under aerobic conditions and at circumneutral pH, Mn(II) is used as an electron donor by Mn(II)-oxidizing bacteria (MOB). Mn(II) is immobilized by complexation with inorganic compounds, such as bicarbonate and sulfide, producing the Mn-bearing minerals albandite and rhodocrosite:

$$Mn(II) + HCO_3^- \rightarrow MnCO_3(s) \quad \text{(albandite)} \quad (4)$$

$$Mn(II) + HS^- \rightarrow MnS\,(s) + H^+ \quad \text{(rhodocrosite)} \quad (5)$$

Mn(II) oxidation by O_2 is inhibited if Mn(II) is complexed to bicarbonate, sulfide, or humic acids (4). Mn(III), on the other hand, is highly unstable at circumneutral pH and, in the absence of complexing ligands, is rapidly disproportionated to Mn(II) and Mn(IV) via the following reaction:

$$2Mn(III) + 2H_2O \rightarrow Mn(II) + MnO_2(s) + 4H^+ \quad (6)$$

Mn(IV) is highly insoluble at circumneutral pH. Particulate Mn(IV) is used as a terminal electron acceptor by Mn(IV)-reducing bacteria (MRB). Heavy metals such as cobalt, nickel, and copper sorb to Mn(IV) oxide surfaces and are released following Mn(IV) reductive dissolution. Iron is also readily sorbed to Mn(IV) oxide surfaces, often leading to the formation of ferromanganese nodules in Fe- and Mn-rich sediments (4).

Table 2. Common Manganese-containing Minerals

Mineral Name	Composition	Manganese Oxidation State
Pyrolusite	MnO_2	+4
Hausmanite	Mn_3O_4	+2, +4
Manganite	MnOOH	+3
Rhodocrosite	$MnCO_3$	+2
Abandite	MnS	+2
Rhodonite	$MnSiO_3$	+2

Microbial Mn(II) Oxidation

Microbial Mn(II) oxidation is a potentially important component of manganese cycling in aerobic environments. In contrast to Fe(II), Mn(II) is not readily oxidized by O_2 at circumneutral pH. Mn(II) is therefore available for use as an electron donor by aerobically respiring MOB (e.g., *Hyphomicrobium manganoxidans* (58)) via the following redox reaction:

$$2Mn(II) + O_2 + 2H_2O \rightarrow 2MnO_2(s) + 4H^+ \quad (7)$$

Geochemical evidence for MOB is found in both freshwater and marine environments. For example, Mn(II) oxidation activity is detected just above the oxic/anoxic interface in Saanich Inlet (59). In other environments (4,58), Mn(IV) concretions are coated with aerobic MOB that display Mn(II)-oxidizing activity in pure culture. In addition, fossilized cells morphologically resembling extant MOB are found within Mn(IV)-bearing ores. Furthermore, Mn(II) oxidation ceases in sediment microcosms amended with metabolic inhibitors, such as azide or Hg. Aerobically respiring MOB are not detected in acidic environments: only small amounts of free energy are released during Mn(II) oxidation by O_2 at pH less than 5 (4).

Mn(IV) is oxidatively precipitated on the outer cell surface, in the periplasmic space or in the peptidoglycan layer of MOB (4). Not all MOB carry out Mn(II) oxidation for energy transduction purposes. In some MOB (e.g., *A. siderocapsulatus* and *L. discophora*), Mn(II) is oxidatively precipitated on the cell surface, forming a sheath that may protect the cell against Mn(II) toxicity, UV radiation, viral attack or heavy metal uptake. These bacteria also oxidize Mn(II) using catalase. Electrons are transferred to hydrogen peroxide, providing protection

from the excess hydrogen peroxide produced during aerobic respiration:

$$Mn(II) + H_2O_2 \rightarrow MnO_2 + 2H^+ \quad (8)$$

In spore-forming MOB (e.g., *Bacillus* SG-1), Mn(II) is oxidized by spores (and not vegetative cells), forming Mn(IV)-oxide sheaths that serve as anaerobic terminal electron acceptors for vegetative cells after germination. Freely soluble Mn(II) is not always the preferred MOB substrate. For example, *Oceanospirillum* strains only oxidize Mn(II) that is prebound to inorganic solids, such as Mn(IV) -oxides, ferromanganese nodules or clays. In contrast to their FOB counterparts, NO_3^--reducing MOB are not found in anaerobic environments. MOB are most likely unable to grow anaerobically on nitrate as terminal electron acceptor because the Mn(II)/NO_3^- redox couple yields little free energy. In addition, an anoxygenic phototrophic MOB that utilizes Mn(II) as an electron donor to drive carbon dioxide fixation is yet to be discovered.

Chemical Mn(II) Oxidation

In contrast to Fe(II), Mn(II) is oxidized slowly by O_2 at circumneutral pH (half-life on the order of months (1)). Mn(II) chemical oxidation rates are highest at high E_h (> +500 mV), pH (>8) and Mn(II) concentrations (>0.01 ppm). Mn(II) chemical oxidation rates are enhanced at circumneutral pH by the presence of Fe(III) oxide and silicate surfaces (1,60). Mn(II) chemical oxidation rates are also enhanced by pH increases associated with microbial metabolic activities, such as NH_3 production, organic acid oxidation, and carbon dioxide fixation.

Microbial Mn(IV) Reduction

Mn(IV) oxides are reduced by anaerobically respiring MRB, with Mn(II) produced extracellularly in large quantities. Geochemical evidence for MRB is found in both freshwater and marine environments where Mn(II) is detected in high concentration (35–37). Approximately 75% of organic carbon oxidation in anoxic Black Sea sediments is coupled to microbial Mn(IV) reduction (61). Mn(II) production in sediment incubations is inhibited by amendment with O_2 or metabolic inhibitors. Geochemical evidence for anaerobic NH_3 oxidation (AnAmOx) coupled to Mn(IV) reduction is also found in marine sediments (62), although a pure culture carrying out this type of metabolism is yet to be discovered.

As in dissimilatory Fe(III) reduction, anaerobic electron transport to Mn(IV) is coupled to proton translocation and ATP generation (63). Microbial Mn(IV) reduction is inhibited by O_2, which diverts electrons to aerobic respiratory pathways (facultative anaerobes only) or initiates oxidative cell damage. Facultative anaerobes capable of reducing Mn(IV) include *S. putrefaciens* and *Geospirillum barnesii*, whereas strict anaerobes include *G. metallireducens*, *D. acetoxidans*, *D. desulfuricans*, *G. fermentens*, and *B. infernus* (43). MRB couple the oxidation of H_2 and a wide range of organic carbon compounds to Mn(IV) reduction. The strict anaerobic group mineralizes organic carbon substrates, whereas the facultative group only partially oxidizes these compounds. The strict anaerobic group also couples S(0) oxidation to Mn(IV) reduction (64).

Shewanella putrefaciens reduces Mn(III) substrates under anaerobic conditions, although the role of this process in manganese cycling is unknown (65). In oligotrophic Antarctic lakes, Mn(IV) oxides are reduced under aerobic conditions by aerobic MRB belonging to the genus Carnobacteria (66). Aerobic Mn(IV) reduction is postulated to release trace metals and other nutrients that are otherwise sorbed to Mn(IV) oxide surfaces. Mn(IV) is also reduced by microorganisms during manganese assimilation. Although manganese is an essential nutrient for most microorganisms, little is known about the impact of assimilatory Mn(IV) reduction on manganese cycling in natural waters and sediments.

Chemical Mn(IV) Reduction

Mn(IV) is reduced chemically by a set of organic carbon compounds (e.g., oxalate, pyruvate, and substituted phenols) that are relatively unreactive with Fe(III) at circumneutral pH (67). These organic compounds, however, generally exist in low concentrations in the environment and their role in manganese cycling is minimal (35). In anaerobic marine sediments in which sulfate reduction is a major terminal electron-accepting process, Mn(IV) is reduced chemically by microbially produced sulfides (68):

$$H_2S + MnO_2 + 2H^+ \rightarrow Mn(II) + S(0) + 2H_2O \quad (9)$$

In addition, Fe(II)- and NO_2^--catalyzed Mn(IV) reduction reactions are potentially important to manganese cycling. Mn(IV) is reduced by Fe(II) at circumneutral pH and by nitrite under acidic conditions (34,69):

$$2Fe(II) + MnO_2 + 6H^+ \rightarrow 2Fe(OH)_3 + Mn(II) \quad (10)$$

$$NO_2^- + MnO_2 + 2H^+ \rightarrow Mn(II) + NO_3^- + H_2O \quad (11)$$

Furthermore, as Fe(III) is reduced by most if not all MRB, distinguishing between microbial and chemical Mn(IV) reduction pathways in Mn(IV)- and Fe(III)-rich environments is difficult (70). Similar to iron cycling, photocatalyzed Mn(IV) reduction is potentially significant to manganese cycling in oxygenated surface waters (1). Electron transfer to Mn(IV)-organic ligand complexes is catalyzed by UV radiation. Photoreduced Mn(II) may subsequently be reoxidized by MOB in surficial waters, thereby driving a local manganese cycle.

Manganese Cycling: A Hypothetical Model System

A hypothetical manganese cycle is depicted in Figure 3. This hypothetical cycle is based on known manganese transformation pathways and does not reflect the relative contribution of each pathway to overall manganese cycling. The natural water system is similar to the one used for the hypothetical iron cycle and is composed of a redox-stratified water column, an oxic/anoxic transition zone and

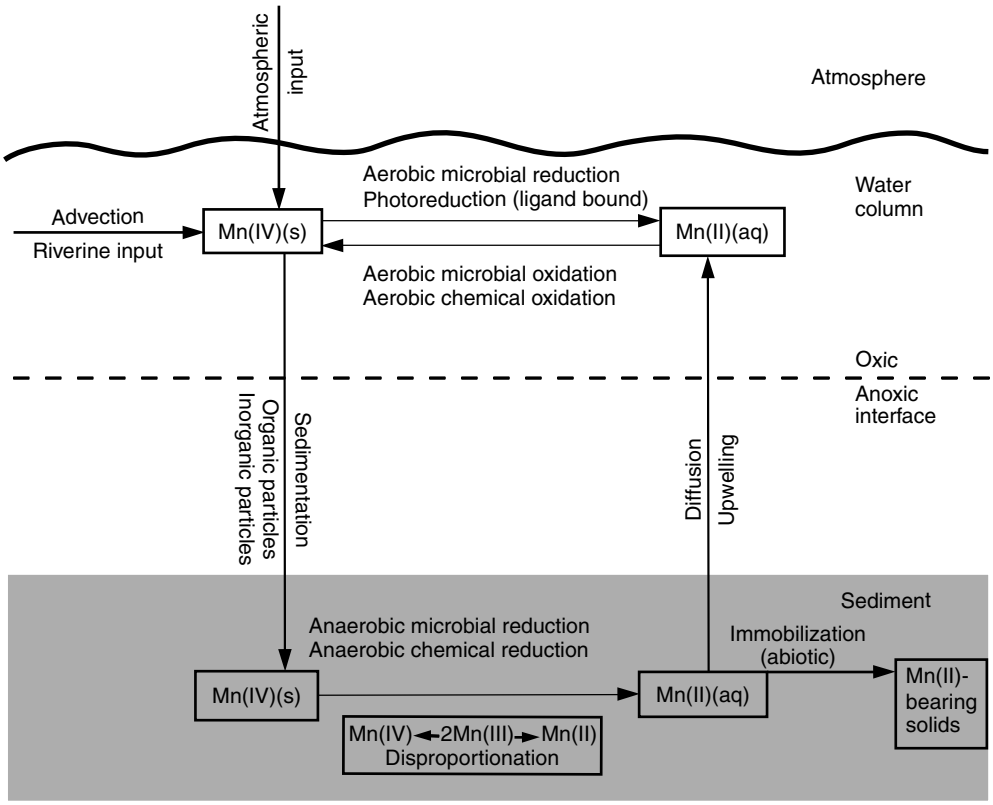

Figure 3. Hypothetical manganese cycle.

an underlying anoxic water column and sediment. Mn(IV) oxide particles are introduced into the system via riverine and atmospheric inputs. Mn(IV) oxides are complexed by organic ligands and photoreductively dissolved. Mn(IV) oxides are also reductively dissolved by aerobic MRB, with sorbed phosphate and trace metals subsequently released to the water column. Mn(IV) particles that settle through the oxic/anoxic transition zone are reduced by anaerobically respiring MRB or organic and inorganic reductants. In redox-stratified waters or sediments, the Mn(IV) reduction zone is located below the nitrate reduction zone and above the iron reduction zone. Pore water Mn(II) is either immobilized via reaction with sulfide or bicarbonate or transported back into the water column via pore water diffusion and upwelling. The manganese cycle is completed in oxygenated surface waters in which Mn(II) is oxidized by MOB to produce Mn(IV) oxides. In the absence of MOB, Mn(II) is slowly oxidized by chemical pathways. In the photic zone of surficial waters, the Mn(II) pool is fairly stable as photosynthetically derived O_2 is relatively unreactive with Mn(II).

MERCURY CYCLING

Overview

Mercury is a highly toxic metal that undergoes a myriad of microbially and chemically mediated transformations in aquatic environments and the atmosphere (71–74). Chemical speciation plays an important role in mercury toxicity, mobilization and fate. Predominant forms of mercury in natural systems include both organic and inorganic compounds, such as Hg(II), Hg(0), HgS (cinnabar), CH_3Hg^+ (monomethyl mercury; MMM), and $(CH_3)_2Hg$ (dimethyl mercury; DMM). Hg(II) and MMM are water soluble, HgS is an insoluble mineral, and both Hg(0) and DMM are highly volatile mercury gases. Mercury toxicity is magnified in natural waters as MMM is biomagnified from lower to higher trophic levels within the food chain. MMM accumulates in fish to levels one millionfold greater than ambient concentrations in the water column. Human exposure to MMM through consumption of freshwater and marine fish is now a major health concern. Cinnabar, the predominant form of mercury in nature, is formed under sulfidic conditions by Hg(II) complexation with hydrogen sulfide.

Mercury Methylation

Microbial Hg(II) methylation is a common detoxification strategy employed by microorganisms to remove mercury from their local environment (Table 3) (4,72). Mercury is removed by methylating Hg(II) in a stepwise fashion to MMM and DMM. Hg(II) is methylated to MMM at a rate three to four orders of magnitude faster than MMM is methylated to DMM. Paradoxically, mercury toxicity increases with the level of methylation (i.e., DMM > MMM > Hg(II)). MMM, however, is more easily sequestered outside the cell by sorption to clays and other negatively charged particles. DMM is extremely volatile

Bacillus megaterium	

and is degassed to the atmosphere. Hg(II)-methylating microorganisms also methylate other metals including cadmium, lead, tin, selenium, and tellurium (4). In marine sediments, SRB (and potentially several others) methylate Hg(II) via direct (enzymatic) or indirect (chemical) pathways (72,75). In the former reaction, the cobalt-containing compound cobalamin is the methylating agent, whereas in the latter, the end product of sulfate reduction (hydrogen sulfide) catalyzes the reductive methylation of MMM in the presence of humic acids. Abiotic methylation of Hg(II) to MMM by catalytic metals and humic acids is a potential pathway for mercury cycling in organic matter-rich environments (71).

Mercury Demethylation

Organomercurial compounds are demethylated to Hg(II) (and ultimately Hg(0)) via microbially and chemically mediated pathways (72). In a variety of bacteria including Staphylococci, Pseudomonads and *E. coli*, MMM is demethylated to Hg(II) and methane by mercuric lyase. Phenyl-Hg^+, a slimicidal agent used in the paper pulp industry is likewise demethylated to Hg(II) and benzene by mercuric lyase. After removal of the methyl or phenyl groups, Hg(II) is reduced to Hg(0) by Hg(II) reductase (see following text). Genes encoding mercuric lyase are often found on plasmids or transposable elements that are transferred horizontally within natural microbial communities (76). Mercuric lyase demethylates other hazardous organomercurial compounds, including ethyl-Hg, flourescein-Hg, thimerosol, and merbromin (4). MMM is decomposed by photodegradation in lake waters to unknown end-products that may or may not produce Hg(0) (77). In the atmosphere, DMM is chemically demethylated to MMM or inorganic mercury via reactions with radical species, such as OH•, Cl•, and NO_3• (73). Atmospheric DMM is also photochemically decomposed to Hg(0) and methane by UV-catalyzed reaction pathways (4).

Mercury Reduction

Microbial Hg(II) reduction is a common detoxification strategy employed by a variety of microorganisms, including strict aerobes, strict anaerobes and facultative anaerobes (Table 3). Hg(II)-reducing microorganisms produce Hg(0), a highly volatile form of mercury that is readily degassed to the atmosphere. A large body of literature is available concerning ecological and mechanistic aspects of microbial Hg(II) reduction (72,74,78). Hg(II) reduction is catalyzed by Hg(II) reductase, yet the electron transfer reaction is not linked to energy generation. Hg(II) reductases also reduce other metals including Ag(II) and Au(II). Hg(II) reductase (*mer*) genes are often found on transposons and mobilizable plasmids that are transferred horizontally within natural microbial communities (79).

In aquatic environments, Hg(II) is reduced chemically by naturally occurring humic acids in a reaction that is enhanced by exposure to natural sunlight (80). Although not yet demonstrated, humic acid-reducing microorganisms may drive Hg(II) reduction indirectly by initiating the first step in the reduction process. In the atmosphere, Hg(II) in the aqueous phase is reduced chemically by sulfite (SO_3^{2-}) and hydroperoxyl radical (HO_2•) (81). UV-catalyzed photoreduction of Hg(II)-organo or -halide complexes is not likely to occur under atmospheric conditions.

Mercury Oxidation

Chemical oxidation of Hg(0) to water-soluble Hg(II) or particulate HgO is a critical pathway for mercury cycling in the atmosphere (73,81,82). More than 95% of atmospheric mercury is in the form of Hg(0). Hg(I) is nearly undetectable in the atmosphere because it undergoes rapid disproportionation to Hg(0) and Hg(II) in the presence of common atmospheric ligands (chloride, hydroxide, sulfite). Atmospheric Hg(0) is oxidized in the aqueous phase by ozone (O_3), hydroxyl radical (OH) and chlorine ($HOCl/OCl^-$), and in the gaseous phase by nitrate radical (NO_3•) and chlorine (Cl_2). Mammals, plants and microorganisms (including *E. coli* and several soil bacteria) oxidize Hg(0) to Hg(II) using catalase and possibly other peroxidases. In *E. coli*, Hg(0) is oxidized enzymatically by KatG, a hydroperoxidase-catalase (83). The contribution of microbial Hg(0) oxidation to mercury cycling in natural waters and sediments is presently unknown.

Mercury Cycling: A Hypothetical Model System

A hypothetical mercury cycle is depicted in Figure 4. This hypothetical cycle is based on known mercury transformation pathways and does not reflect the relative contribution of each pathway to overall mercury cycling. Hg(II) (as water-soluble Hg(II) or particulate HgO) enters the natural water system via atmospheric deposition. In the water column or sediments, Hg(II) is (*1*) complexed by sulfide to form HgS; (*2*) microbially, chemically, or photochemically reduced to Hg(0); or (*3*) microbially methylated to MMM. Hg(0) is (*1*) degassed to the atmosphere, or (*2*) microbially oxidized to Hg(II). MMM is (*1*) taken up by biota, (*2*) immobilized by sorption to negatively charged particles, (*3*) microbially demethylated

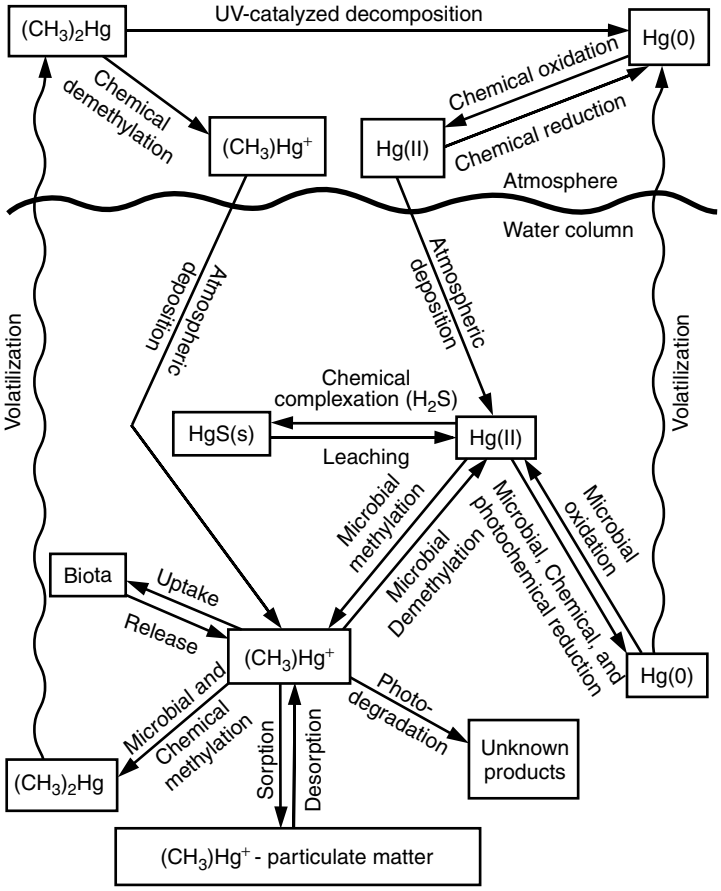

Figure 4. Hypothetical mercury cycle.

to Hg(II), (*4*) photodegraded to unknown end-products, or (*5*) microbially or chemically methylated to DMM. DMM is degassed to the atmosphere where it is chemically demethylated to (*1*) Hg(0) by UV-catalyzed pathways, or (*2*) MMM by reaction with various radical species. MMM is transported to the surface waters via atmospheric deposition. Atmospheric Hg(0) is oxidized to Hg(II) by ozone and other oxidants in the aqueous and gaseous phases. Atmospheric Hg(II) is reduced to Hg(0) by sulfite and other reductants in the aqueous phase. The mercury cycle is completed when Hg(II) re-enters the surface waters via atmospheric deposition.

The biological production of methane is part of a microbial process that catalyzes the degradation of organic compounds as part of the global carbon cycle. Methanogenesis, as the process is called, occurs in the absence of oxygen by prokaryotic microorganisms that belong to the Domain *Archaea*, which are distinguished from the *Bacteria* and the *Eukarya* by evolutionary divergence of their genomes and phenotypic characteristics such as their ability to grow in extreme environments (1). In the methanogenic process, bacteria and the methanogenic *Archaea* function as a consortium in which the bacteria catalyze the degradation of plant and animal polymers and monomers to smaller intermediate compounds that are utilized for methane production by the methanogenic *Archaea*. Methane generated from the process is oxidized back to carbon dioxide by other microbial processes and released into the atmosphere, thus completing the carbon cycle by making the carbon available for photosynthetic fixation. This process complements microbial aerobic degradation by catalyzing degradative processes in regions that lack oxygen, which include such habitats as ocean, lake, and river sediments, rice paddies, arctic tundra, submarine hydrothermal vents, sewage digestors, digestive tracts of ruminant animals, human large intestines and termite hindgut. The distribution of methanogenesis in the oceans is discussed along with the diversity, habitats, and physiology of these microbial catalysts and their potential biotechnological applications.

THE ROLE OF OCEANS IN THE GLOBAL METHANE CYCLE

Global Distribution of Methanogenesis

Biogenesis of methane in the marine environment originates from several sources including the decomposition of organic matter settling in sediments and accumulating in submarine canyons, digestive tracts of marine fauna, and from geothermal sources of hydrogen (Fig. 1). Shallow continental shelves support large populations of phototrophic macroalgae, plants, and fish that contribute to high organic loading. Methane concentrations in these regions are severalfold greater than estimated concentrations at equilibrium with air (2,3). The equilibrium concentration of methane in the water column should be approximately 2.6 nM at 19 °C on the basis of the average partial pressure of methane in the atmosphere of 2×10^{-6} atm (4). Because there are no physical barriers to prevent convection, the methane concentration at all depths should be equal to the estimated equilibrium concentration with the atmosphere if this is the sole source of methane. In one example, Scripps Canyon, a nearshore submarine canyon with high methanogenic activity due to accumulation of organic debris, the methane profile in the overlying water column ranged from 4.7 nM at the surface to 870 nM at 23 m, concentrations that are 2- to 350-fold greater than the predicted solubility equilibrium with the atmosphere (Fig. 2a). These results, in conjunction with the observation that the methane concentration increases linearly with depth, indicate that dissolved methane in the water column originates from the sediments. The inverse relationship between depth and methane concentrations probably results from two processes: diffusional fluxes as the distance between the water column and methane source increased, and biological oxidation of methane in the aerobic zones of the water column (5). The nearly twofold saturation of methane concentration at the surface above Scripps Canyon indicates that there is a net flux of methane into the troposphere as a result of biodegradation in canyon sediments by methanogenic consortia.

Estimates of the total annual methane production from the combined global continental shelf regions at less than 10 m depth range from 0.7 to 14×10^9 kilograms annually, which is equivalent to the estimated range for freshwater lakes (3,6). These regions include tidal marine marshes (7), the lower depths of sediments (8) and

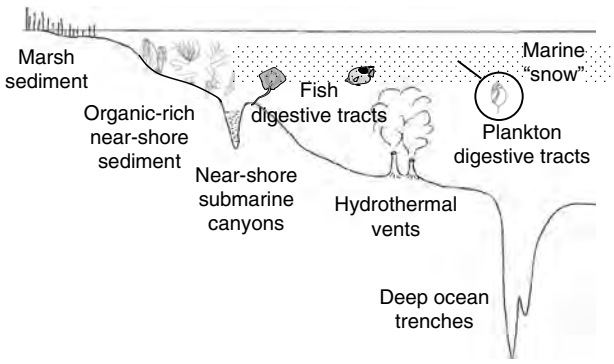

Figure 1. Sources of biological methane in the marine environment. See color insert.

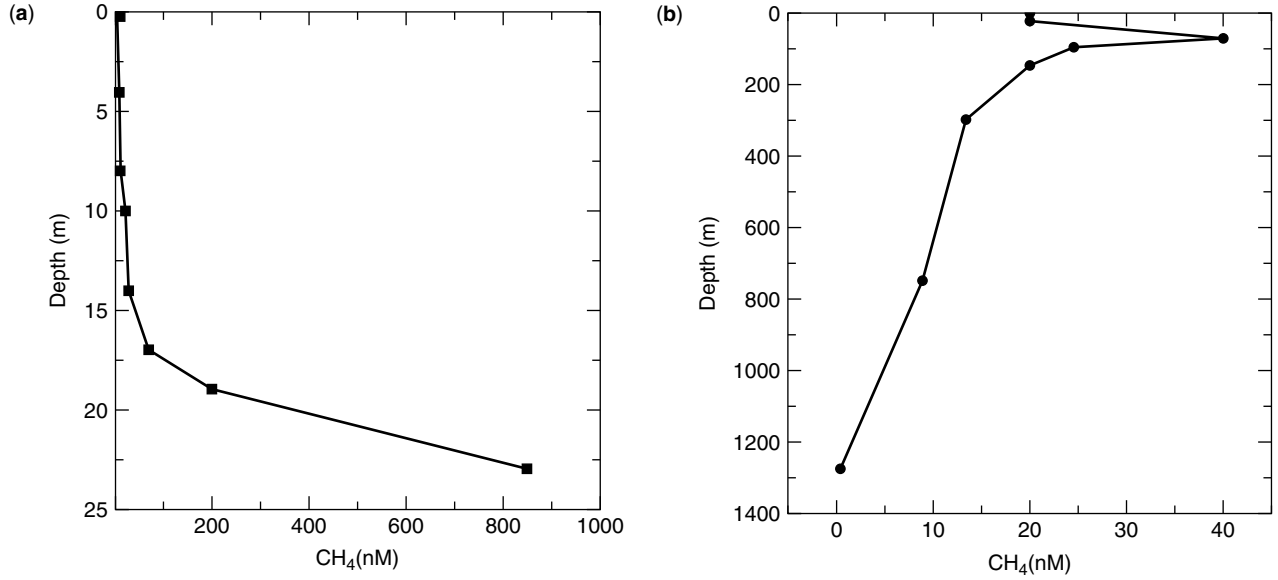

Figure 2. Dissolved methane profile in the water column above a nearshore submarine canyon near, La Jolla, CA (**a**) and in the open ocean (**b**). On the basis of data from (45) and (2).

submarine canyons, all regions that receive high organic loading (9).

Open ocean waters also show a supersaturation of methane in surface waters relative to atmospheric methane and a general decrease in dissolved methane with depth, which suggests that bacteria consume methane at lower ocean depths (Fig. 2b). Higher methane concentrations observed in the region below the surface likely result from methanogens associated with phytoplankton populations. On the basis of surface supersaturation of 1.3 and a concentration of 4.7×10^{-5} ml methane liter^{-1} seawater at the surface, the estimated total flux into the atmosphere from open oceans is 4 to 6.7×10^{9} kilograms annually (2,6). This may be an underestimate because upwelling may sweep deep, methane-rich water to the surface in some regions. Although estimates of methane release from marine sources are less than 4% of the total biogenic production released into the atmosphere annually, it is an underestimate of the total marine production because most of the methane is either oxidized to carbon dioxide or sequestered as gas hydrates.

Fate of Biogenic Methane

Most methane produced below 10 meters by marine anaerobic consortia is consumed or sequestered from the atmosphere. More than 80 % of the methane generated in marine sediments is oxidized in sulfate-rich anoxic marine upper sediments by a consortium of methanogens and sulfate-reducing bacteria closely associated in aggregates (10–12). Current reports suggest that the reaction is catalyzed via reverse methanogenesis by the methanogenic *Archaea* as a result of a thermodynamic shift, which results from sequestering of acetate and hydrogen by the sulfate-reducing bacteria. Although methane oxidation by the archaeon has been confirmed by isotopic and phylogenetic analysis, the proposed reaction mechanism has not been confirmed biochemically (12). As the remaining methane is released into the aerobic sediment zone and water column, most of it is oxidized as an energy substrate to CO_2 by the aerobic methanotrophs (13). Oxidized methane reenters the carbon cycle as bicarbonate anions dissolved in seawater or by direct release as CO_2 into the atmosphere. Although some methane escapes oxidation in eutrophic marshes and coastal waters that are supersaturated with methane or by direct release into the atmosphere through the vascular systems of aquatic plants, only a small proportion of the total global biogenic methane released annually originates from the oceans (<4%) (6,14,15). Biogenic methane is also sequestered as crystalline methane-hydrates in deep anaerobic ocean waters and sediments below 260 meters where methane can become saturating. Because the stability of methane sequestered in this form is dependent on low temperatures and high pressures, the distribution of gas hydrates is primarily restricted to deep oceans and Polar Regions. Gas hydrates are estimated to represent the largest hydrocarbon fuel reservoir on earth. However, methane sequestered as hydrates also have the potential to cause geologic instability of submarine slopes, which could lead to phenomenon such as tsunamis in the event of global changes that result in ocean warming (16). The combined processes of methane oxidation and sequestration as gas hydrates minimize the net release of biogenic methane from the oceans that would otherwise enter the atmosphere as a greenhouse gas.

DIVERSITY AND PHYLOGENY OF MARINE METHANOGENS

Isolates from the Oceans

The methanogens are classified as *Archaea*, which together with the *Bacteria* and *Eukarya* compose the three domains

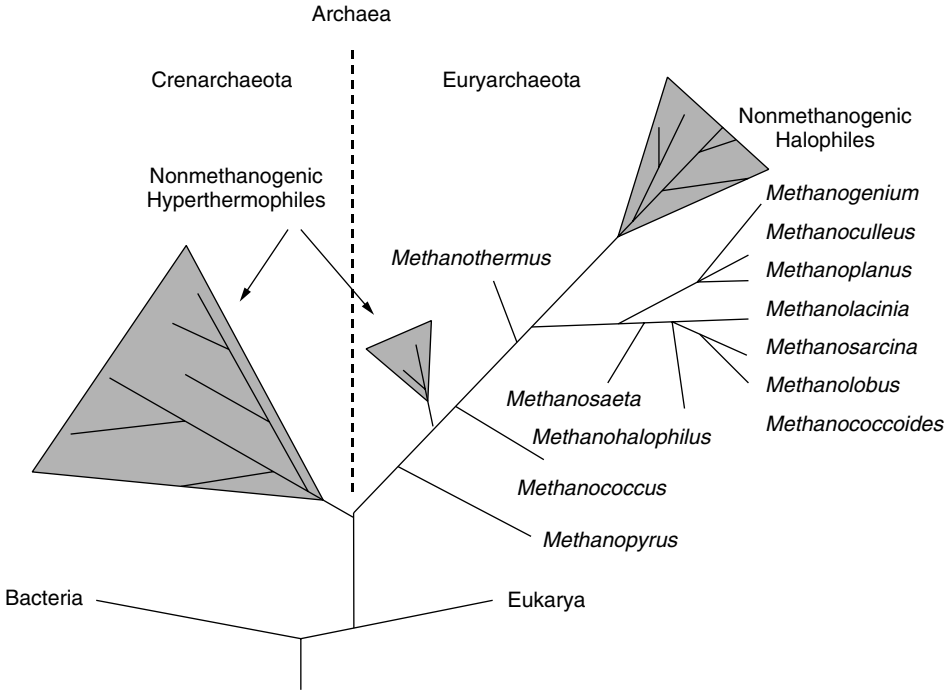

Figure 3. Phylogenetic tree of *Archaea* based on 16S rRNA gene sequence showing genera of methanogens from marine environments.

of life proposed by C. Woese on the basis of 16S rRNA sequence (Fig. 3; 1). The morphological features of the *Archaea* are similar to those of the *Bacteria*; they are unicellular microorganisms that lack a nuclear membrane and intracellular compartmentalization. However, many molecular features of the *Archaea*, which include histone-like DNA proteins, a large multicomponent RNA polymerase and the transcription initiation components, have similarity to the *Eukarya*. The *Archaea* also have characteristics that are unique from the *Bacteria* and *Eukarya*, such as nonpeptidoglycan cell walls, membranes composed of isoprenoids ether-linked to glycerol or carbohydrates and synthesis of unique enzymes and enzyme cofactor molecules. The requirement by all *Archaea* for extreme growth conditions, which include high temperatures, extreme salinity, or in the case of the methanogens, highly reduced, O_2-free environments, has redefined our perception of the boundaries of life. These revelations have fostered a renewed interest in searching for life in environments previously thought to be sterile, both on earth and extraterrestrially.

The methanogenic *Archaea* have one common attribute: they all use a methane-generating pathway for growth. However, despite their phylogenetic and catabolic coherence as a group, the methanogens are morphologically and physiologically diverse. In the marine environment, they include a wide range of morphological shapes (Fig. 4) with physiological tolerances that include psychrophiles from an Antarctic meromictic lake of marine origin that grow at 1.7 °C to extreme thermophiles from deep submarine thermal vents that grow at 113 °C; acidophiles from submarine thermal vents that grow at pH 5.0 to alkaliphiles from sediments that grow at pH 9.0; species that grow at marine saline concentrations to extreme halophiles that grow at nearly saturated NaCl concentrations in solar salterns; autotrophs that use only CO_2 for cell carbon and methyltrophs that use reduced carbon compounds.

Over one-third of more than 60 described species of methanogens are of marine origin and occur in four of the five orders within the archaeal kingdom *Euryarchaeota* (Fig. 3). Characteristics of marine methanogenic *Archaea* are described in Table 1. Species within the order *Methanobacteriales* have not been detected in marine environments. These species have a rigid cell wall composed of pseudomurein, which is chemically similar to bacterial murein and has an ultrastructure that resembles the dense monolayer cell wall of gram-positive bacteria. These species require a rigid cell wall for protection from osmotic lysis that would otherwise result from the osmotic differential between their intracellular milieu and surrounding freshwater environment. However, these species have only a limited ability to osmoregulate and become dehydrated when exposed to the higher solutes concentrations in estuarine and marine environments.

All described species in the order *Methanococcales* are marine autotrophs that grow exclusively by CO_2 reduction with H_2. These species form irregularly shaped cocci that synthesize an S-layer cell wall composed of a paracrystalline array of glycoproteins. Unlike *Methanobacteriales* that synthesize a rigid cell wall, these species have intracellular solute concentrations that are similar to seawater and are subject to osmotic lysis at "freshwater" solute concentrations. This order includes mesophilic species, as well as moderately and extremely thermophilic species.

The order *Methanomicrobiales* contains both nonmarine and marine species that are diverse in morphology and physiology. Most marine species grow as cocci and rods. In addition, *Methanoplanus* forms flat disk-shaped cells with characteristically angular ends. The cell walls in this group

are composed of a protein S-layer and these species are sensitive to osmotic shock or detergents. Species include mesophiles, moderate and extreme thermophiles. Most species grow by CO_2 reduction with H_2, but some species also use formate or secondary alcohols as electron donors for CO_2 reduction. Psychrotolerant, mesophilic and thermophilic species are included within this order.

The order *Methanosarcinales* is the most catabolically diverse phylum of methanogens. Members of this phylum grow by the dismutation or "splitting" of acetate and pyruvate, and by catabolism of the methyl groups in methanol, methylated amines, pyruvate, and dimethylsulfide. Although species of *Methanosarcina* can grow by both catabolic pathways, other genera in this order are obligate methylotrophs. All species have a protein S-layer cell wall and most species grow as irregularly shaped cocci. However, several species of *Methanosarcina* also synthesize a heteropolysaccharide matrix external to the S-layer. This external layer can be up to 200-nm thick and is composed primarily of a nonsulfonated polymer of *N*-acetylgalactosamine and D-glucuronic or D-galacturonic acids. The matrix is called methanochondroitin because of its chemical similarity to a mammalian connective tissue component, known as chondroitin. At freshwater NaCl concentrations *Methanosarcina* spp. that synthesize methanochondroitin grow in multicellular aggregates rather than as single cells, but when grown at marine salt concentrations or with high concentrations of divalent cations such as Mg^{+2}, they no longer synthesize methanochondroitin and grow as single cells. Although all species within the genus *Methanosarcina* are capable of osmoregulation that enables them to grow in both nonmarine and marine environment, only two species have been isolated from marine environments. Species within this order are psychrotolerant or mesophilic.

The order *Methanopyrales* is the most deeply branching methanogenic archaeon and presently includes only one species, the extreme thermophile *Methanopyrus kandleri*. This species is an obligate hydrogenotroph and grows as a rod with a pseudomurein cell wall surrounded by a protein S-layer, similar to that described earlier for *Methanothermus*.

Distribution of "Nonculturable" Microorganisms

In the past few years molecular probes based on 16S rRNA gene sequences have been used as phylogenetic markers to provide information on microbial populations in natural systems (17). This approach has revealed that the majority of microbes in the environment have not been isolated and described. In addition to *Bacteria*, 16S rRNA sequences with high similarities to the archaeal kingdoms *Crenarchaeota* and *Euryarchaeota* have been detected throughout the marine water column. Cultured crenarchaeotes are hyperthermophilic, sulfur-dependent and usually strict anaerobes. Cultured euryarchaeotes include methanogens, extreme halophiles, and some hyperthermophilic, sulfur-dependent species. In surveys of temperate oceans euryarchaeotes predominated near the surface and crenarchaeotes were more predominant at depth (18). In contrast, euryarchaeotes were nearly absent in Antarctic and subantarctic waters. Although reports suggest that these *Archaea* represent a significant fraction of marine phytoplankton, their physiology and ecological roles are currently unknown. Despite their requirement for anoxic, reduced environments, transient anoxic microzones in particles and or endosymbionic niches could support methanogenic euryarchaeotes within the aerobic water column. Alternatively, the picoplanktonic euryarchaeotes detected by 16S rRNA sequence analysis may consist of undescribed, mesophilic, nonmethanogenic aerobes that successfully compete with eubacterial picoplankton in the water column. The identity and physiology of archaeal picoplankton has yet to be determined.

THE METHANE CARBON CYCLE IN MARINE HABITATS

Interspecies Hydrogen Exchange

In many marine habitats methanogens depend on other anaerobes to convert complex organic matter into substrates that they can catabolize. Unlike aerobic habitats, where a single microorganism can catalyze the mineralization of a polymer by oxidation to CO_2, degradation in anaerobic habitats requires consortia of interacting microorganisms to convert polymers to CH_4. These interactions are dynamic with hydrogen-utilizing microorganisms such as methanogens affecting the pathway of electron flow, and consequently carbon flow, by a process called interspecies H_2 transfer (19). In this association, the H_2-utilizing methanogens maintain a low H_2 partial pressure that enables oxidative pathways linked to proton reduction to be thermodynamically favorable. One physiological group of microorganisms affected by interspecies H_2 transfer is the polymer degrading fermentative anaerobes. In many of these microorganisms, substrate oxidation is linked to the electron carrier nicotinamide adenine dinucleotide (NAD), which has higher redox potential (-320 mv) than H_2 (-414 mv) under standard conditions. However, if the H_2 partial pressure is maintained at a low level (<10 Pa) by H_2-utilizing microorganisms, then H_2 production from NAD by a hydrogenase becomes thermodynamically favorable. This enables the fermentative microorganisms to reoxidize NADH by reducing protons to form H_2 rather than reducing pyruvate to form dicarboxylic acids and alcohols. This synergistic process enables the fermentors to conserve ATP by synthesizing more acetate and less reduced products. In addition, the net products, acetate and H_2, serve as substrates for growth by methanogens and sulfate-reducing bacteria. The result is that carbon and electron flow is directed toward more efficient degradation by the consortium to CH_4 and CO_2.

Another physiological group of microorganisms affected by this process is the H_2-producing acetogens. These microorganisms use partially oxidized polymer products such as fatty acids and alcohols generated by fermentative microorganisms and use protons as electron acceptors. The reactions carried out by these microorganisms for growth are not thermodynamically favorable (i.e., $+\Delta G^{\circ\prime}$ under physiological growth conditions) because the H_2 they generate accumulates and growth is subsequently inhibited. However, in association with H_2-consuming

microorganisms such as the methanogens, the H_2 partial pressure is maintained at levels low enough to make the reaction thermodynamically favorable (i.e., $-\Delta G^{\circ'}$ under physiological growth conditions). Because of their dependence on the H_2-consuming microorganisms, the H_2-producing acetogens are often referred to as obligate syntrophs. The ultimate products of these consortia are H_2S or CH_4 and CO_2. CH_4 is either oxidized by methylotrophs to CO_2 as it diffuses into the aerobic zone, or it enters the atmosphere by mechanisms described below.

Competitive and Noncompetitive Substrates

In marine habitats, there is a hierarchy in the competition for H_2 as an electron donor. Because oxygen is depleted by the activities of aerobic microorganisms, an anaerobic region occurs immediately below the sediment surface if the activities of the aerobic microorganisms exceed the rate of oxygen diffusion. An anaerobic zone can even extend into the water column in regions with high organic loading. Once anaerobic, sulfate reducers and methanogens become the predominant competitors for H_2 generated by fermentative and acetogenic bacteria. In marine sediments with limited organic loading, the sulfate-reducing bacteria outcompete the CO_2-reducing methanogens by virtue of their ability to use hydrogen and acetate at lower concentrations than the methanogens (20–23). Sulfate-reducing bacteria have an apparent K_m and H_2 threshold as low as 250 and 0.9 Pa, respectively, compared with methanogens that have an apparent K_m and H_2 threshold as low as 670 and 3 Pa, respectively. At a typical H_2 threshold concentration maintained at 1 Pa by a sulfate-reducing bacterium, a methanogen would be unable to use H_2 for growth and methanogenesis. In the marine environment, in which the sulfate concentration in seawater exceeds 0.02 molar and organic nutrients are typically limited, sulfate reducers outcompete methanogens. However, in marine habitats with high organic loading, such as elevated coastal marshes, eutrophic coastal waters and submarine trenches, the high rate of hydrogen production by fermentative and acetogenic bacteria can cause the rate of SO_4^{-2} reduction to exceed the rate of SO_4^{-2} diffusion from the water column (24,25). In these environments, sulfidogenesis and methanogenesis occur concurrently.

Methanogens also generate CH_4 from methanol, methylated amines, and thiols, which are readily available in the oceans as metabolites of marine fauna and flora (Table 2). Methanol results from bacterial degradation of pectin from marine plants. Methylated amines are available from decomposition of choline and creatine or by bacterial reduction of glycine betaine and trimethylamine N-oxide, which are osmolytes excreted by marine plants and animals. The thiol dimethylsulfoxide, an osmolyte synthesized by marine macroalgae, phytoplankton, and cyanobacteria, is converted to the methanogenic substrate dimethylsulfide by bacterial reduction. Although there is evidence that some of these compounds are utilized by sulfate-reducing bacteria, they support methanogenesis in habitats that contain high SO_4^{-2} concentrations (26).

Marine Sediments

The flow of carbon in anaerobic marine sediments is shown in Figure 5. Fermentative bacteria that synthesize hydrolytic enzymes such as cellulases, proteases, amylases, and lipases catalyze degradation of complex polymers to soluble monomers. The fermentative bacteria then ferment the soluble products to H_2, CO_2, simple alcohols, and fatty acids, including significant generation of acetate due to interspecies H_2 transfer. The H_2-producing acetogenic bacteria, the second consortium group, catalyze the oxidation of alcohols and fatty acids to H_2, CO_2 and acetate. The third group, the methanogenic *Archaea* and sulfidogenic bacteria, use the simple substrates H_2, CO_2, and acetate generated by the fermentative and acetogenic bacteria, to generate CH_4 and H_2S, respectively. In habitats with limiting amounts of organic substrates, sulfidogenesis is the predominant terminal process; in eutrophic habitats, methanogenesis is predominant (27). Although the acetate-utilizing methanogens *Methanosarcina* and *Methanothrix* have been identified from marine methanogenic enrichments, isotope studies performed in sediment suggests that most of the acetate is oxidized by a H_2-producing syntroph rather than by splitting to CH_4 (28). The net result of this marine consortium is that carbon and electrons are directed toward the synthesis of CH_4 or H_2S and CO_2, which then reenter the global carbon cycle.

Table 2. Reactions and Free Energy Yields from Methanogenic Substrates

Substrate	Reaction	$\Delta G^{\circ'}$ (kJ/mol CH_4)
Carbon monoxide	$4CO + 5H_2O \rightarrow CH_4 + 3HCO_3^- + 3H^+$	−196
Formate	$4HCOO^- + 4H^+ \rightarrow CH_4 + 3CO_2 + 2H_2O$	−145
Hydrogen/carbon dioxide	$4H_2 + HCO_3^- \rightarrow CH_4 + 3H_2O$	−135
Ethanol[a]	$2CH_3CH_2OH + HCO_3^- \rightarrow 2CH_3COO^- + H^+ + CH_4 + H_2O$	−116
Hydrogen/methanol	$CH_3OH + H_2 \rightarrow CH_4 + H_2O$	−113
Methanol	$4CH_3OH \rightarrow 3CH_4 + HCO_3^- + H_2O + H^+$	−105
Trimethylamine[b]	$4CH_3NH^+ + 9H_2O \rightarrow 9CH_3 + 3HCO_3^- + 4NH_4 + 3H^+$	−76
Dimethylsulfide[c]	$2(CH_3)_2S + 3H_2O \rightarrow 3CH_4 + HCO_3^- + 2H_2S + H^+$	−49
Acetate	$CH_3COO^- + H_2O \rightarrow CH_4 + HCO_3^-$	−31
Pyruvate	$4CH_3COCOOH + 2H_2O \rightarrow 5\ CH_4 + 7CO_2$	−31

[a] other short chain alcohols utilized include propanol, isopropanol, butanol, cyclopentanol
[b] other methylated amines utilized include methylamine, dimethylamine, dimethylethylamine
[c] other methylated sulfides utilized include methylmercaptan, methylmercaptopropionate

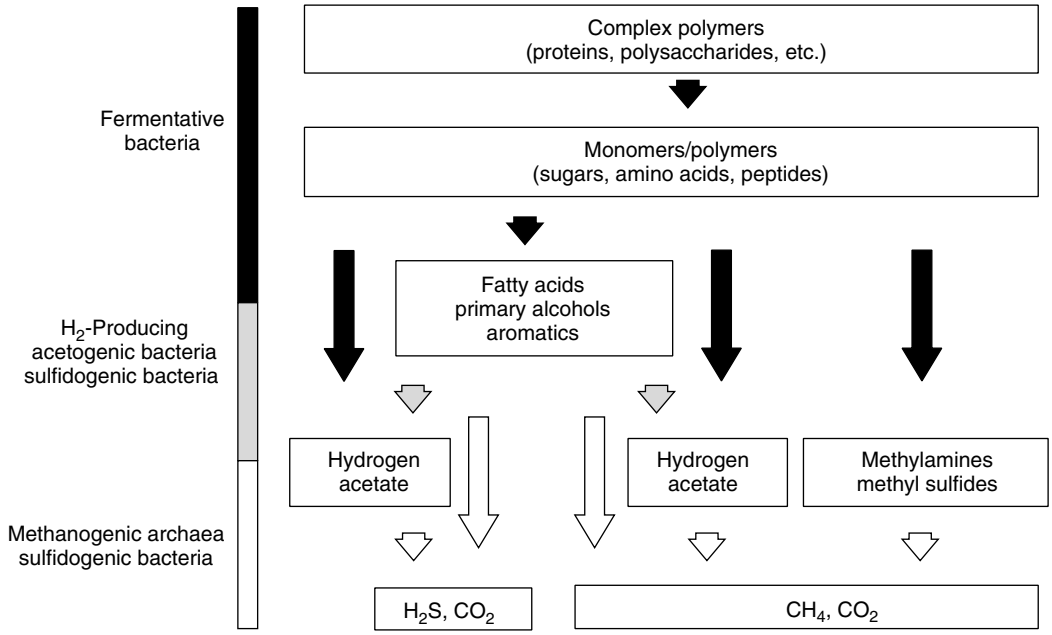

Figure 5. Carbon flow in a marine methanogenic consortium.

Hydrothermal Vents

Marine hydrothermal vents are regions in oceans where hot basalt and magma near the sea floor cause the seabed to slowly fragment (29). Seawater seeps into the fissures, mixes with hot minerals and is emitted from the vents as mineral-rich plumes. The types of vents range from warm vents that emit hydrothermal fluids above ambient temperatures to hot vents known as "black smokers" because they emit a characteristic black cloud as metal sulfides and other minerals in the 270 to 380 °C superheated plume precipitate upon mixing with the cooler seawater. Although reports on the stable isotope ratios of CH_4 ($^{13}C/^{14}C$) indicate that most methane generated from several hydrothermal vents is from geothermal decomposition of organic matter (30), several hydrogen-utilizing hyperthermophilic methanogens have been isolated near hydrothermal vents, possibly using geochemically produced H_2 that is released from the plume along with other reduced inorganic compounds or generated by bacterial decomposition of organic material in the surrounding vent community. The methanogenic *Archaea* and other lithotrophs that use hydrothermal inorganic materials serve as primary producers in this deep-sea nonphotosynthetic food chain. These microbes may be used directly as food by plankton and larger filter feeders that populate the vents. Dissolved geochemical and biogenic methane that remains in the vicinity of the vent can be utilized by methane-oxidizing bacteria associated with bivalves and sponges (31,32). The methanotrophic bacterial symbionts enable these nonfilter feeding animals to survive in the vent communities.

Ocean Water Column

Dissolved methane in the open ocean water column frequently has subsurface concentrations that are greater than the surface concentrations, which indicates that methane is generated within the water column (33). Although methane concentrations in shallow eutrophic coastal waters would be expected to be supersaturated as a result of methanogenic activity in sediments, supersaturated methane gradients in deep open waters cannot be explained by advection from submarine point sources such as anoxic sediments and abiotic hydrocarbon seeps. The only known source of methane in the open water is by methanogenic activity. It has been postulated that methane is produced in oxygenated ocean waters from the digestive tracts of fish and zooplankton, which provide anaerobic microniches for the obligately anaerobic methanogens (33). Methanogens have also been identified in close association with phytoplankton and aggregations of planktonic organic particles known as marine snow in the water column (34). Biogenic methane associated with the particles is exchanged with the water column as the particles sink causing it to become supersaturated with methane (35).

BIOTECHNOLOGICAL APPLICATIONS OF MARINE METHANOGENESIS

Natural Products

Species of methanogenic *Archaea* have adapted cellular mechanisms that enable them to survive and proliferate in marine temperature extremes ranging from sub zero in the Arctic and Antarctic oceans to near boiling in submarine hydrothermal vents. Archaeal proteins adapted to function in extreme temperatures could be a potential boon to industrial processes. Restriction endonucleases with unique recognition sequences from *Methanococcus aeolicus* have been marketed (36). As demonstrated by the commercial development of the DNA polymerases Vent™ and DeepVent™, archaeal enzymes can have

unique characteristics such as a lower error rate than conventional Taq polymerase and the ability to produce blunt end-products that can be readily ligated into any cloning vector with a blunt-end restriction site (37). As more hyperthermophilic marine vent methanogens are characterized, additional enzymes with unique features may be discovered. Hyperthermostabile proteases from methanogenic vent species have potential applications in high-temperature detergents. Only one psychrotolerant and one psychrophilic species have been described, but as additional cold-adapted methanogens are characterized, enzymes applicable to cold temperature industrial processes may also be discovered (38,39).

Archaeal bipolar lipids, synthesized by several species of marine methanogens, have unique properties because of their exceptionally high mechanical and chemical stability (40). As a consequence, the lipids have a natural resistance to oxidation and esterase (because of their ether glycerol linkage) and can be used to make liposomes that are stable over a broad range of conditions, including temperature and pH. This stability and characteristic low permeability to molecules and ions make these lipids potentially useful as vesicles in drug delivery systems and novel membranes for separation processes. Because of the thermostability of lipids from hyperthermophilic marine methanogens, the liposomes can be autoclaved to remove microbial contaminants.

Other unique biosynthetic products of the marine methanogens include small organic molecules produced as osmoprotectants (41). Unlike the extremely halophilic *Archaea*, which synthesize proteins that require high intracellular salt concentrations similar to their environment, all marine methanogens isolated thus far are halotolerant and maintain an intracellular milieu with a salt content lower than the environment. Because their proteins are denatured by salt concentrations found in seawater, these cells must remain equiosmotic with their environment by the synthesis of small organic molecules known of osmoprotectants. These molecules are often neutrally charged to minimize denaturing of proteins and often have a structure that is different from homologs used for biosynthesis to minimized perturbation of biosynthetic pathways. Both these characteristics enable marine methanogens to accumulate high intracellular concentrations of these compounds in response to the relatively high solute concentration of seawater. Some of the unique methanogen osmoprotectants include β-amino acids such as β-glutamate, β-glutamine, and N^{ε}-acetyl-β-lysine, and the phosphorylated inositol, di-*myo*-inositol-1,1'-phosphate. Besides the synthesis of these unique compounds, the biosynthetic pathways for their synthesis may be useful for in vitro biotechnological production of biopolymers.

Bioremediation

Many industrial wastes contain high concentrations of salts that can inhibit methanogenic digestors containing "freshwater" inoculum. Consortia of marine bacteria and methanogenic *Archaea* are already adapted for growth at greater solute concentrations. Because many species of marine methanogens have the ability to adapt to fluctuating solute concentrations by intracellular osmoregulation, digestors containing marine inocula are less likely to stall as a result of changes in effluent salt concentrations (42).

Marine methanogenic consortia can also degrade halogenated alkane hydrocarbons, and individual species of methanogens have been reported to dehalogenate brominated alkanes such as brominated benzoate and phenols (43). Because halogenated compounds are prevalent in the marine environment as a result of biosynthesis by a variety of marine plants and animals, this environment may be a virtually untapped source of naturally dehalogenating consortia and species for halogen waste treatment.

Alternative Energy and Chemical Sources

Marine plant biomass is a virtually unexploited renewable resource for biosynthesis of fuel and industrial chemicals. The higher water and soluble sugar content of marine biomass such as macroalgae, relative to the composition of terrestrial plants, make these resources amenable to relatively rapid rates of methanogenesis and high-energy yields by methanogenic consortia. In addition, species such as the giant marine brown kelp *Macrocyctis pyrifera* have rapid growths rates of up to 0.6 meters day^{-1}. As a result, this species could be exploited as a renewable "energy sink" for harvesting solar energy as plant biomass for microbial conversion to methane without a requirement for arable land. Another advantage of marine methane biogenesis is that microbial consortia occur naturally that can convert plant biomass to methane at efficiencies greater than 90% (Fig. 6). As an end-product for biomass conversion, the low solubility of methane in water facilitates its collection from an aqueous environment such as a fermentor and it can be transported directly as a fuel in the existing infrastructure for distributing natural gas. Furthermore, methane can be used as a precursor for biosynthesis of a variety of solvents and industrial chemicals by methanotrophic bacteria. Because depleted reserves will increase the cost of processing petroleum-based fuels and

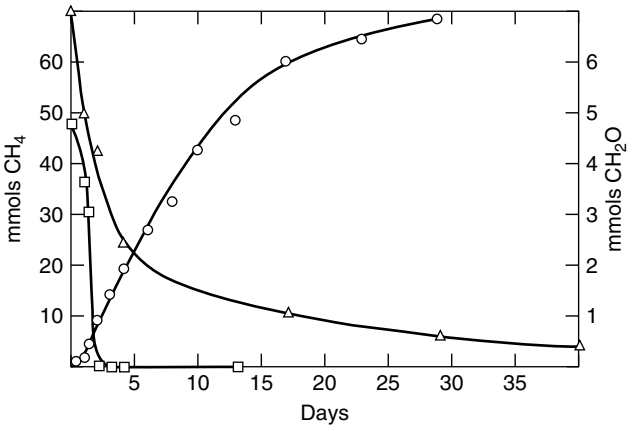

Figure 6. Methane generation catalyzed by a kelp-degrading microbial consortium in a methanogenic digestor. Symbols: soluble algal sugars alginate (△) and mannitol (□); methane (○). On the basis of data from (45).

chemicals in coming decades, synthesis of fuel and solvents from biogenic hydrocarbon sources such methane has the potential to become economically viable.

CONCLUSION

Marine methanogensis is less understood than in other habitats such as freshwater sediments, digestors, and ruminants. This is largely due to the general misperception that methanogenesis does not have a significant role in the marine environment. First, the apparent role of marine methanogenesis in the global carbon cycle is frequently underestimated because much the product synthesized by this process, methane, is oxidized as part of a microbial food chain before it can measured. Second, in many environments, sulfate reduction can outcompete methanogens for limited substrates. However, marine methanogens compete successfully in marine habitats that contain excess substrate or are sulfate depleted, which include eutrophic coastal sediments, fish, and plankton digestive tracts and in planktonic organic particles. Thus, they have specific ecological roles in the marine carbon cycle. Marine hydrogenotrophic methanogens also have a unique role as primary producers in hydrothermal vent communities that exist in the total absence of light. Methanogens isolated from marine sediments exhibit a wide range of phylogenetic diversity and 16S rRNA molecular analysis indicates that methanogenic species are ubiquitous throughout the oceans and coastal regions. Because only a small portion of these *Archaea* have been described, the oceans represent a largely untapped reservoir for natural products and processes generated by the marine methanogens.

Methanotrophic bacteria, also called *methanotrophs*, are aerobic prokaryotic microorganisms that oxidize methane for energy and growth. They are ubiquitous in nature, living in any location where air and methane are simultaneously present. Habitats include soil, sediment, wetland, lakes, and marine systems that have distinct anaerobic–aerobic interfaces where anaerobic methane production occurs on one side of the interface and methane oxidation occurs on the other side. More recent work has shown that "high-affinity" methanotrophs, which consume methane at atmospheric methane levels (~1.7 parts per million by volume), are also present in many locations in the environment where no clear methane enrichment exists. Methanotrophic bacteria are of great ecological significance because they play a major role in the global carbon cycle (1–5). Additionally, their activity in nature significantly reduces "greenhouse gas effects" by mineralizing methane, a gas that absorbs ultraviolet wavelengths more strongly than carbon dioxide (2,6–8). They have also been shown to have many biotechnological applications, such as contaminant transformation (9) and chemical product formation in biochemical engineering (10).

A number of excellent review articles exist on methanotrophic bacteria. Hanson and Hanson (11) provided an overview of methanotroph taxonomy, the role of methanotrophs in global carbon cycling, methanotroph ecology, and a summary of their contaminant transformation capabilities. Lidstrom and Stirling (12), Murrell (13), Murrell and coworkers (14), Murrell and coworkers (15), and Murrell and Radejewski (16) published further reviews on the molecular biology of the organisms and the use of molecular methods for studying methanotroph ecology. Methanotroph biochemistry was summarized in various publications, including Colby and coworkers (17), Higgins (18), Anthony (19), Lidstrom (20), and Lipscomb (21), with recent emphasis on the enzymology of soluble (sMMO) and particulate (pMMO) methane monooxygenases, the enzymes responsible for methane oxidation in these organisms.

Because of the extensive existing literature on these important organisms, this article will concentrate on recent results, especially associated with the molecular ecology of methanotrophs, their role in the nitrogen cycle, and the biochemistry of monooxygenases and related enzymes, although a general background will also be provided for completeness. The article is divided into four major topics including methanotroph classification systems (phenotypic and genotypic), methanotroph biochemistry and molecular biology, microbial ecology of methanotrophs, and biotechnological applications.

CLASSIFICATION OF METHANOTROPHS

Methanotrophs belong to a broad group of microorganisms known as *methylotrophs*. Methylotrophic bacteria can use as their sole source of carbon and energy reduced carbon substrates with no carbon–carbon bonds (20). There are two traditional subgroups of methylotrophs, namely, obligate and facultative. Obligate methylotrophs grow only at the expense of compounds without carbon–carbon bonds, and all methanotrophs belong to this subgroup. Facultative methylotrophs grow on a variety of carbon sources that include C_1 compounds; however, they cannot use methane for growth (22). Table 1 summarizes growth and cometabolic substrates used by methylotrophic bacteria.

A second more recent subgrouping for methanotrophs, low-affinity and high-affinity organisms (where "affinity" refers to their K_S for methane consumption), has been developed on the basis of results from ecological studies (8,11). The discovery of distinct high-affinity organisms has resulted from studies on ecosystems that have no methane enrichment other than atmospheric methane. Because very little is currently known about high-affinity methanotroph species, descriptions presented here largely are associated with low-affinity organisms.

Known methanotrophs are strictly aerobic, catalase- and oxidase-positive, and possess cytochromes *c*, *a*, and either *o* or *b*. With the exception of one gram-positive

Table 1. Substrates of Methylotrophic Bacteria*

Growth Substrates	Examples of Cometabolic Substrates
Methane, methanol, methylamine, dimethylamine, trimethylamine, tetramethylammonium, trimethylamine N-oxide, trimethylsulfonium, formate, formamide, carbon monoxide, dimethyl ether, dimethyl carbonate, dimethyl sulfoxide, dimethylsulfide	Ammonia, ethylene, chloromethane, bromomethane, higher hydrocarbons (ethane, propane, trichloroethylene, etc.)

*At least one methylotroph has been reported to oxidize each compound presented.

microorganism (*Mycobacterium* species ID-Y), all methanotrophs are gram-negative (20). All methanotrophs possess intracytoplasmic membranes (ICMs) and are able to form cysts, exospores, or lipid cysts as resting stages under adverse environmental conditions. Methanotrophs have a complete pathway for methane oxidation and have the ability to assimilate cell carbon as formaldehyde. All methanotrophs can use ammonia as the sole source of nitrogen; many are capable of using nitrate and nitrite; and, as discussed in the following section, some methanotrophs are capable of N_2-fixation, providing them a significant competitive advantage in some environmental settings (5,11,23–28).

Despite the aforementioned similarities, differences in morphology, fine structure, resting stages, and biochemical pathways have allowed methanotrophs to be classified into three generic groups, namely, types I, II, and X (6,21,24,25,29–31). Some features that distinguish the three major classes of methanotrophs are summarized in Table 2. Six Type I genera (*Methylococcus*, *Methylomonas*, *Methylomicrobium*, *Methylobacter*, *Methylocaldum*, and *Methylospaera*), three Type II genera (*Methylosinus*, *Methylocystis*, and *Methylocella*), and one Type X genus (*Methylococcus*) have been recognized (16). Although the cell size and shape vary within species, Type I methanotrophs generally have rod, coccoid, or ellipsoid shapes, Type II methanotrophs have rod, crescent, or pear shapes, and the Type X *Methylococcus capsulatus* (Bath) has a coccoid shape. Most isolated methanotrophs grow optimally at approximately neutral pH and at a temperature near 30 °C, whereas some methanotrophs, including *M. capsulatus* (Bath) and a few recent isolates, can grow under more extreme conditions (29,30,32–36).

Some strains of Type I and X form cysts with a fine structure that is similar to that formed by *Azotobacter*, whereas Type II methanotrophs form either exospores or lipid cysts with some exospores being resistant to pasteurization (37–41). Some Type II methanotrophs form lipid cysts, or poly-β-hydroxybutyrate structures, during periods of excess methane. These storage polymers can make up to 20 to 25% dry mass and are used as a source of reducing power under methane-limiting conditions (42). The formation of rosettes at the end of the exponential phase of growth is characteristic of some Type II species, including *Methylosinus trichosporium* and those of genus *Methylocystis* (31,38).

Other characteristics that provide fingerprints of the different methanotroph phenotypes include the mole percentage of guanine and cytosine (G + C) in the DNA, major extracted phospholipid fatty acids (PLFAs), and the type of intracytoplasmic membrane (ICM) structure. Generally, the mole percentage G + C is higher in Types II and X than in Type I methanotrophs with reported values between 62 to 67% and 59 to 65%, respectively. Type I methanotrophs, on the other hand, have been reported to contain between 49 to 60 mol% G + C (43,44). Types I and X methanotrophs group similarly in terms of PLFAs, with those containing 16 carbons being the most predominant, whereas Type II methanotrophs have a predominance of 18-carbon PLFAs (45–53). Although C-16 and C-18 PLFAs are in larger percentage in Types I and II methanotrophs, respectively, the specific C-16 and C-18 fatty acids that are most dominant vary among the various genera of each. The ICM structure of Type I and Type X genera has been observed as vesicular disk-shaped bundles stacked throughout the center of the cell, whereas the ICM structure of Type II genera consists of paired membranes that are parallel to the cytoplasmic membrane or extend throughout the cytoplasm.

Methane monooxygenase (MMO) is the first enzyme involved in methanotroph catabolism. In general, type II and type X organisms express two forms of MMO, a soluble or cytoplasmic form (sMMO) and a membrane-associated particulate form (pMMO). Alternatively, Type I organisms, with one exception, express only pMMO. The biochemistry of sMMO and pMMO and the regulation of expression between the two MMOs are central to most studies of methanotrophs and will be presented in detail later. The existence of a complete TCA cycle and associated enzymes also has been used to distinguish between methanotrophic types. With the exception of one Type I methanotroph (54), only Type II methanotrophs have a complete TCA cycle. However, all groups of methanotrophs possess isocitrate dehyrogenase, and their need for NAD^+ versus $NADPH^+$ (or both) is a useful means of separating different bacteria into the types (Table 2; 25). Although all methanotrophs assimilate carbon at the formaldehyde level, Type I strains use the ribulose monophosphate pathway (RuMP) and Type II strains use the serine pathway. Type X methanotrophs possess enzymes for both pathways, 3-hexulose phosphate synthase and hydroxypyruvate reductase, as shown in Table 2. The ability to fix molecular nitrogen (and express nitrogenase) is a characteristic feature of Types II and X methanotrophs, whereas only Type X *M. capsulatus* (Bath) has been shown to express ribulose-bisphosphate carboxylase, the enzyme responsible for catalyzing autotrophic carbon dioxide fixation (25).

Phylogenetic analyses using 16S and 5S rRNA sequence techniques have provided valuable information on the relationships between methanotrophic bacteria

Table 2. Characteristics of Methanotroph Types (6,11,20,25)

Characteristic	Type I	Type II	Type X
Recognized genera	*Methylococcus* *Methylomonas* *Methylobacter* *Methylomicrobium* *Methylocaldum* *Methylospaera*	*Methylosinus* *Methylocystis* *Methylocella*	*Methylococcus*
Cellular Shape	Short rods, some cocci or ellipsoids	Rods, crescent- or pear-shaped	Cocci
Growth:			
• 45 °C	−	−	+
• pH (optimum)	7	7	7
• Resting stages	*Azotobacter*-type cysts	Exospores or "lipid" cysts	*Azotobacter*-type cysts
• Rosette formation	No	Yes	No
G + C content (mole %)	50–55	62.5	62.5
Predominant phospholipid fatty acids	16	18	16
Membrane type:			
• Vesicular disk-shaped bundles	+	−	+
• Paired membranes at periphery	−	+	−
Complete TCA Cycle	−	+	−
Carbon assimilation	RuMP*	Serine	RuMP/Serine
Key Enzymes:			
• Methane monooxygenases	Usually pMMO* only	pMMO and sMMO*	pMMO and sMMO
• 3-Hexulose phosphate synthase	+	−	+
• Hydroxypyruvate reductase	−	+	+
• Nitrogenase	−	+	+
• Ribulose-bisphosphate carboxylase	−	−	+
• Isocitrate dehydrogenase	NAD^{+}*/$NADP^{+}$*	$NADP^{+}$	NAD^{+}

*RuMP = ribulose monophosphate cycle;
pMMO = particulate methane monooxygenase;
sMMO = soluble methane monooxygenase;
NAD^{+} = nicotinamide adenine dinucleotide;
$NADP^{+}$ = nicotinamide adenine dinucleotide phosphate.

and have verified the taxonomic grouping of these bacteria into the three types (16,25,43,44,55–60). These studies have shown that bacteria using the serine pathway for formaldehyde assimilation (including Type II methanotrophs) are grouped into the α-subclass of *Proteobacteria*. Type I methanotrophs are found within the γ-subclass of *Proteobacteria*, and those methylotrophs that use the RuMP pathway for formaldehyde assimilation but do not use methane, are located in the β-subclass. Figure 1 presents the phylogenetic relationship between different representative methanotrophs (16).

BIOCHEMISTRY AND MOLECULAR BIOLOGY OF METHANOTROPHIC BACTERIA

Overview

The biochemistry and molecular biology of methanotrophic bacteria have been presented in detail elsewhere (11,13,15,19,21,22); therefore, only a summary will be presented here. All methanotrophs oxidize methane to methanol catalyzed by MMO (Fig. 2). NADH is required in this first oxidation step and acts as the electron donor when the reaction is catalyzed by sMMO. pMMO uses a higher potential electron donor, cytochrome *c*, resulting

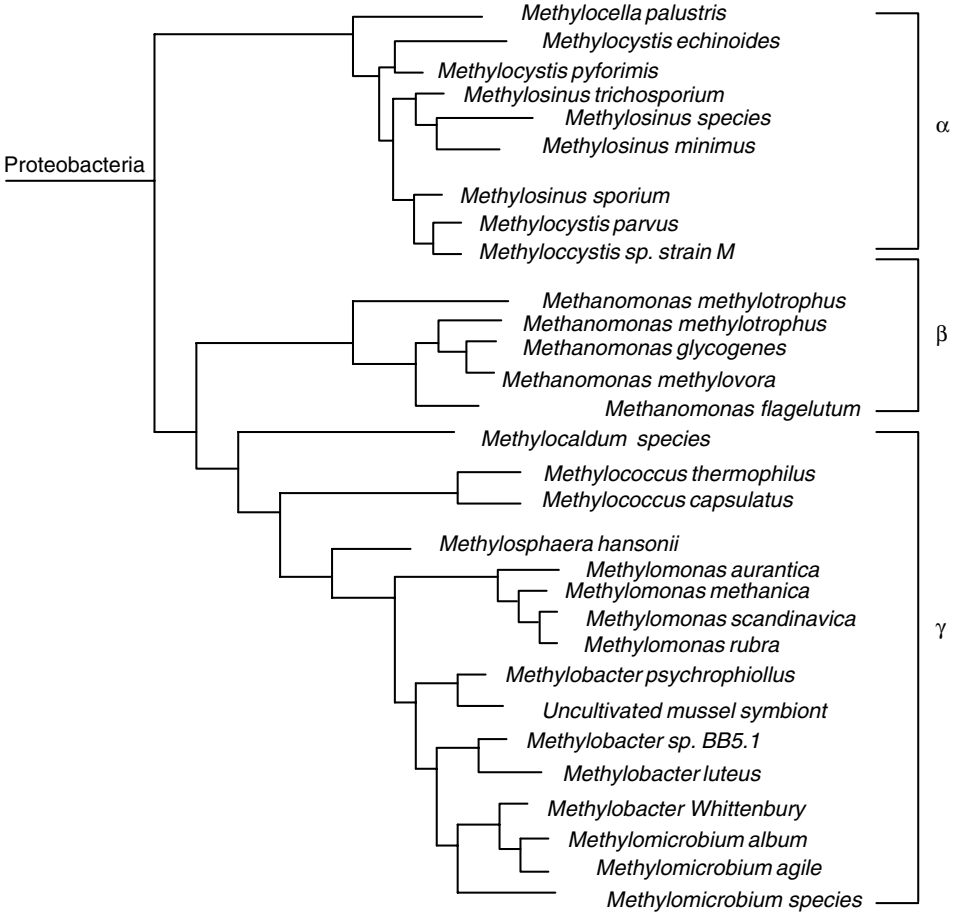

Figure 1. Detailed unrooted phylogenetic tree showing similarity relationship between different types of methanotrophic bacteria with respect to the α-(Type II methanotrophs), β-(nonmethane utilizing methylotrophs employing RuMP pathway), and γ-(type I methanotrophs) subdivisions of the *Proteobacteria* (11,16).

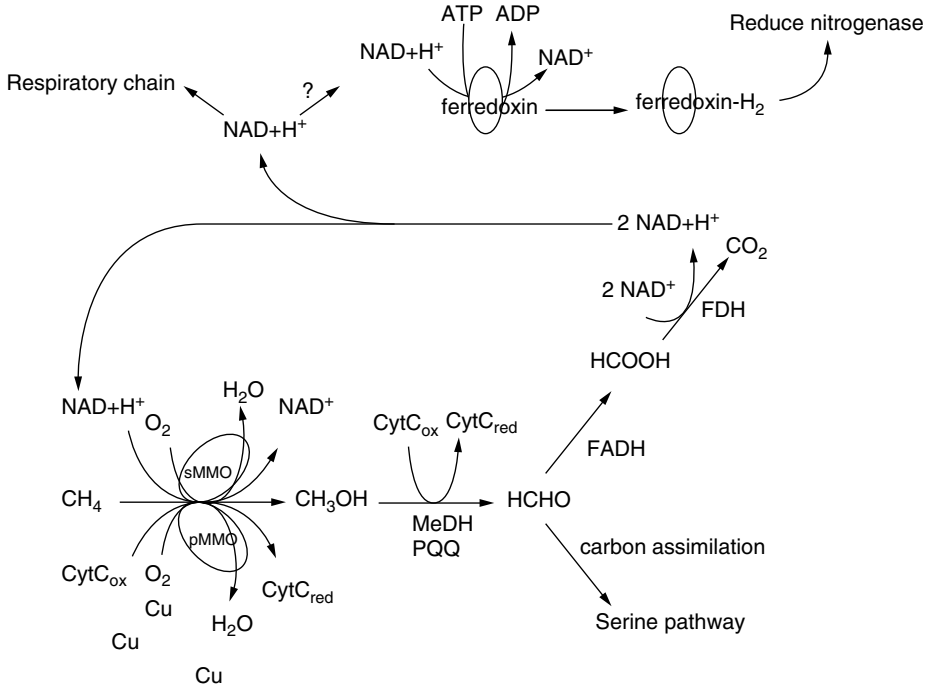

Figure 2. Oxidation of methane to carbon dioxide catalyzed by either pMMO (in the presence of copper) or sMMO (in the absence of copper) in Type II methanotrophs. The oxidation of formaldehyde to carbon dioxide proceeds in two NAD^+-linked steps. One of the NADH formed is invested for the MMO reaction, whereas the other is fed into the respiratory chain or possibly to the nitrogenase system. Carbon assimilation proceeds by the serine pathway and diverges at the level of formaldehyde. Abbreviations: CytC, cytochrome *c*; MDH, methanol dehydrogenase; FADH, formaldehyde dehydrogenase; FDH, formate dehydrogenase; PQQ, pyrrolo-quinoline quinone (11,19,22,63,64).

in higher growth yields as the supply of NADH usually becomes nonlimiting (61,62). Electrons from this first oxidation step are then transferred to the second reaction in which methanol is converted to formaldehyde by a periplasmic methanol dehydrogenase (MDH) along with a novel coenzyme methoxatin, or pyrrolo-quinoline quinone (PQQ) (22,63,64). Cytochrome *c* acts as the electron acceptor as electrons are shuttled from the first reaction by way of the PQQ prosthetic group. Formaldehyde can then either be further oxidized completely to carbon dioxide or diverge from the oxidative pathway to form various intermediates of the metabolic pathway that can subsequently be used to synthesize biomass. This central role of formaldehyde is a common feature of methanotroph metabolism.

In the oxidative pathway, formaldehyde is further oxidized to formate and then to carbon dioxide by formaldehyde dehydrogenase (FdDH) and a NAD^+-dependent formate dehydrogenase (FDH), respectively. The oxidation of formate to carbon dioxide is coupled with the reduction of two NAD^+ molecules that results in the generation of two NADH molecules, in which one of the two is reinvested back into the methane-oxidation reaction. The second NADH molecule is fed into the respiratory chain as a source of reducing power (19,22).

Assimilatory pathways are more diverging with the synthesis of multicarbon compounds from formaldehyde (carbon fixation) proceeding either through the serine-isocitrate lyase pathway (for Type II methanotrophs) or the ribulose monophosphate (RuMP) pathway (for Type I methanotrophs). In the former pathway, 2 moles of formaldehyde and 1 mole of carbon dioxide are used to form 1 mole of acetyl-CoA. In the latter pathway, 3 moles of formaldehyde are used in a complex cycle that ultimately yields pyruvate. Type X methanotrophs appear to possess enzymes from both major pathways.

Many of the aforementioned biochemical pathways are not unique to methanotrophs. A number of methylotrophs that do not use methane employ similar pathways for the generation of reducing power and carbon assimilation. In reality, the unique biochemical trait of methanotrophs is the use of MMO to catalyze the first step in methane oxidation. The goal of this section is to present the current knowledge of properties of sMMO and pMMO and the regulation of the MMO system, to discuss the biochemistry of nitrogen-fixation in methanotrophs, and to briefly review the biochemistry of methanol dehydrogenase because of its relevance in assessing the ecology of methanotrophs in the environment.

Biochemistry of Methane Oxidation

The initial step in methane metabolism, that is, MMO-catalyzed oxidation to methanol, is highly energy-demanding in that two reducing equivalents are required to split the di-oxygen molecule and oxidize methane (19,65). One of oxygen atoms is directly incorporated into methane, whereas the other is reduced to water. Although this initial priming reaction is energetically demanding, it permits the net positive yield of reducing power (NADH) through subsequent reactions in the catabolic pathway (Fig. 2).

As stated previously, two general types of MMO are observed in methanotrophs; Type I methanotrophs express only a pMMO (with one known exception) and Type II organisms and the Type X organism, *M. capsulatus* (Bath), express both a pMMO and a sMMO. The copper-to-cell ratio in the growth environment largely determines whether sMMO or pMMO is expressed in Type II and X methanotrophs (66–69). The regulation of expression of the two MMOs in organisms that express both enzymes is a topic of current intereeview of the biochemist; however, only a superficial understanding of this process exists (15). Current knowledge in MMO expression systems will be presented after a rstry of the sMMO and pMMO.

Properties of sMMO. sMMO is a multicomponent, nonheme iron protein. The enzyme has been highly studied because of its unique biochemistry and its ability to oxidize a large number of environmental pollutants resulting from its broad substrate specificity. The enzyme was first isolated from *M. capsulatus* (Bath) by Colby and Dalton (70). It has subsequently been purified from many other methanotrophs, including from the Type II *M. trichosporium* OB3b (71,72), from *Methylocystis* species M (73), from a bacterium of uncertain taxonomic status of *Methylobacterium* species CRL-26 (74), and, recently, from a Type I strain *Methylomonas methanica* 68–1 (75). All of the purified sMMOs consist of three components: a 245 kDa hydroxylase, containing nonheme iron (component A), a 15.8 kDa regulatory protein (component B), and a 38.4 kDa reductase (component C) (21,71). The genes corresponding to all three of these subunits have been cloned and sequenced from *M. trichosporium* OB3b (76) and *M. capsulatus* (Bath) (77) and have been used for probe construction for sMMO-bearing methanotrophs in natural environments (75,78,79).

The hydroxylase component of sMMO is a dimer of three subunits in an $\alpha_2\beta_2\gamma_2$ arrangement with molecular weights of ~60, 45, and 20 kDa, respectively (15). The active site of sMMO is associated with the dinuclear iron cluster of the hydroxylase subunit and is at a location where oxygen and methane interact to form methanol (71,80). Each of the two $\alpha\beta\gamma$-protomers contains a di-iron cluster, which can exist in three different oxidation states and facilitates the insertion of an oxygen atom into methane through a radical-associated mechanism.

The reductase component of sMMO contains the flavine adenine dinucleotide and a Fe_2S_2 cluster (17). This component transfers electrons from NADH to the active site of the di-iron cluster of the hydroxylase. Component B functions to increase the rate of electron transfer and also to increase the efficiency of coupling substrate oxidation to NADH consumption. Component B also can stop the flow of electrons in the absence of a substrate, which can be hydroxylated (e.g., methane), thus preventing the wasteful oxidation of NADH (81). It is postulated that components B and the reductase subunit are part of a complex regulatory system designed to allow both efficient transfer of electrons and oxygen activation, although simultaneously maintaining a tight coupling of energy used and substrate oxidized (82).

Properties of pMMO. pMMO is not as well characterized as sMMO. pMMO is highly sensitive to oxygen, is easily inactivated on removal from the membranes, and has proven to be difficult to purify and study. Only recently has the enzyme been purified with significant retention of activity observed (83); therefore, less information is available on the pMMO than sMMO. In general, pMMO is a multiple copper-containing enzyme that requires copper for regulation of expression and activity and possibly for coupling to the electron transport system (66,84,85).

The pMMO of *M. capsulatus* (Bath) has three main subunits of ~45, ~27, and 23 kDa (83), with the 45- and 27-subunits probably containing the enzyme-active site. Active pMMO contains 2 iron atoms and 15 copper atoms per mole of enzyme. pMMO also has small copper-binding compounds (CBC) associated with it (86,87). The specific role of the CBC is not known; however, they may play a role in catalysis and enzyme stabilization, act as a copper-sequestering agent associated with enzyme construction and activation, or influence redox conditions around the enzyme (15). The physiological reductant for pMMO is also not known, although cytochromes $b_{559/569}$, c, and c_{553} are possible candidates (15). pMMO has a higher specificity for methane and exhibits higher CH_4-oxidation activities than sMMO (88), thus leading to increased growth yields for organisms expressing pMMO (61,62). pMMO is, therefore, more specific in terms of its ability to oxidize methane, which may partly explain its greater prevalence in nature than sMMO.

Regulation of Expression of the MMO System. Murrell and coworkers (15) recently summarized what is known about the control of sMMO and pMMO expression in Type II and Type X organisms. All evidence suggests that the MMO system is primarily regulated by the copper-to-cell ratio in the growth environment, with low ratios supporting sMMO expression and higher ratios supporting pMMO expression (66). Recent evidence, however, has indicated that oxygen may also play a role in MMO expression and activity, although the exact role of oxygen is unknown (28).

The genes that encode sMMO have been identified and sequenced in various methanotrophs. The genes are all chromosomal and clustered as *mmoX*, *mmoY*, and *mmoZ* for the α-, β-, and γ-hydroxylase subunits, respectively, and *mmoB* and *mmoC* for proteins B and C, respectively (15). An undefined open reading frame, *orfY*, exists between the *mmoY* and *mmoB* (89) (Fig. 3). This gene arrangement appears to be highly conserved between methanotrophs both in terms of amino acid and DNA identities. Active *mmoB* and *mmoC* gene products have been successfully expressed in *Escherichia coli*; however, all attempts to express active hydroxylase subunits have been unsuccessful (90), except in *Methylomicrobium album* BG8 and *Methylocystis parvus* OBBP hosts, which usually possess only a pMMO under low-copper-to-cell ratio growth conditions (91).

Genes associated with pMMO have only recently been cloned and sequenced in one methanotroph, *M. capsulatus* (Bath) (92), although preliminary information on the molecular genetics of pMMO was identified earlier (84).

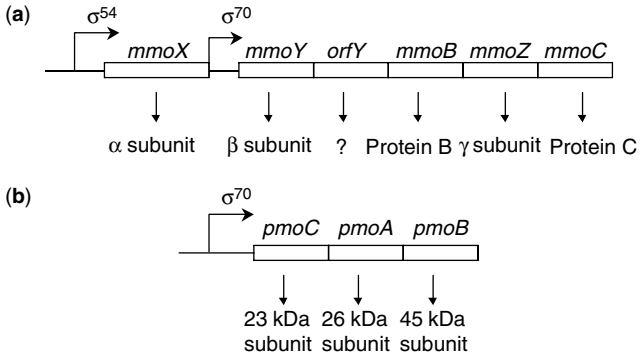

Figure 3. Operon regions for (**a**) sMMO and (**b**) pMMO and their gene products in some methanotrophic bacteria such as *M. capsulatus* (BATH) and *M. trichosporium* OB3b. Under copper-limited conditions, the sMMO genes are expressed from two transcriptional start sites, directed by the two (a σ^{54}-like and σ^{70}) promoters. The product of the open reading *Y* is unknown. Under high copper-to-biomass ratios, the pMMO gene cluster is expressed from a single transcriptional start site directed by σ^{70} (15,84,92).

Semrau and coworkers (84) reported that methanotrophs contained multiple copies of the genes encoding the 45 and 269 kDA subunits (identified as *pmoB1* and *pmoA1*, respectively) and were found to be in the order *pmoA1-pmoB1* on the chromosome. Nguyen and coworkers (85) further showed that the gene encoding the 23 kDa subunit (*pmoC*) was located upstream of *pmoA1*. Stolyar and coworkers (92) showed that the complete gene cluster *pmoCAB* (Fig. 3) was present in *M. capsulatus* (Bath). In fact, two almost identical copies of *pmoCAB* were found in *M. capsulatus* (Bath), and a third separate copy of *pmoC* was also identified. This gene cluster was found to be very similar to the equivalent gene cluster in ammonia-oxidizing bacteria (AOB) that express an ammonia monooxygenase (AMO), suggesting that pMMO and AMO might be evolutionarily linked (93–95). The *pmoCAB* gene arrangement has recently been observed in *M. trichosporium* OB3b and in *Methylocystis* sp. Strain M (96), which suggests that it may be common among other methanotrophs.

Nielsen and coworkers (97) used Northern Blotting and primer extension analysis to show that a full 5.5-kb transcript encoding the entire sMMO operon was expressed only under low-copper growth conditions in *M. capsulatus* (Bath). Subsequent experiments using *M. trichosporium* OB3b provided similar results and showed that the addition of 50 μM copper sulfate fully repressed the expression of the sMMO-related transcript (98). Neilson and coworkers (98) further showed that three major sMMO-related transcripts were observed in *M. trichosporium* OB3b, including *mmoX* only, *mmoY*, *mmoB*, and *mmoZ*, and *mmoY*, *mmoB*, *mmoZ*, *orfY*, and *mmoC*, and they also identified a σ^{54}-like promoter sequence upstream of the *mmoX* gene. Sigma factors (e.g., σ^{70}, σ^{54}, σ^{32}, etc.) are proteins that join with RNA polymerase to allow the enzyme to bind to specific DNA promoter regions. The presence of a σ^{54}-like promoter sequence upstream of *mmoX* gene indicates that the

expression of *mmoX* may be regulated by σ^{54}, a protein that is usually associated with the transcription of nitrogen-regulated genes (discussed later). A similar promoter sequence was found in *Methylocystis* sp. Strain M (89) and in *Methylomonas* sp. KSWIII (99).

A putative σ^{70} promoter sequence has also been identified between *mmoX* and *mmoY* in *M. trichosporium* OB3b, suggesting that sMMO expression may be actually regulated at multiple points. Associated with the repression of sMMO expression and activity after exposure to copper, *pmo* transcripts of 1.2 and 4.0 kDa have been noted in various methanotrophs (15). Evidence suggests that these are transcripts of *pmoCAB* and that they are transcribed from a single start site upstream of *pmoC* initiating at a putative σ^{70} promoter that is negatively regulated under low-copper conditions.

The exact mechanism of the coregulation of sMMO repression and pMMO expression is not yet understood. Various options are being considered, although the presence of σ^{54}-like promoter sequence upstream of the sMMO gene cluster indicates that activator proteins probably play an important role in sMMO repression and pMMO activation in the presence of copper (15). The presence of a σ^{54}-like promoter sequence upstream of the sMMO gene cluster might also explain the observed constitutive nitrogenase expression and activity associated with constitutive sMMO expression in *M. trichosporium* OB3b $sMMO^{C}$ mutants (28).

Nitrogen-Fixation in Methanotrophs

Nitrogen-fixation systems in methanotrophs have not been studied to the extent as MMO systems because early investigations suggested that methanotrophs had a nitrogenase system that was similar to other, well characterized systems (26,77,100,101). Nitrogen-fixation is highlighted because it has been shown that methanotroph ecology is strongly influenced by nitrogen-supply conditions and recent results have suggested that nitrogen fixation in Type II organisms may be coregulated with the MMO systems, and, as such, deserves special attention.

Nitrogen-fixation on all organisms is catalyzed by nitrogenase, a multicomponent enzyme complex. The enzyme catalyzes the reduction of molecular nitrogen (N_2) to ammonia (NH_4^+) in the presence of ATP and an electron source according to the equation (1):

$$N_2 + 10H^+ + 8e^- \longrightarrow 2NH_4^+ + H_2 \qquad (1)$$

This reaction requires the hydrolysis of 16 moles of $MgATP^{-2}$ to $MgADP^-$ and P_i^- (per mole of N_2) making it a very energy-demanding process (102). As a result, organisms must tightly regulate the synthesis of nitrogenase and its subsequent activity to prevent wasteful use of energy when other soluble nitrogen sources are available. Furthermore, because of the extreme sensitivity of nitrogenase to oxygen, N_2 fixation must also be regulated in response to extracellular oxygen levels. Synthesis and activity of nitrogenases in methanotrophs (and in other aerobic diazotrophs) must therefore be carefully regulated in response to the interrelationship between both nitrogen and oxygen. Adding to the complexity of nitrogenase regulation in *M. trichosporium* OB3b, there is evidence that sMMO genes may be expressed from the same promoter that controls nitrogenase expression under low-copper growth conditions (13). Thus, it appears that the regulation of the nitrogenase system in *M. trichosporium* OB3b is complex and might serve as an excellent model for studying the regulation of multiple genes from a single promoter.

Biochemistry of Nitrogen Fixation in Methanotrophs. Nitrogenases from methanotrophs have not been purified to homogeneity (26). However, there is genetic evidence that its protein components are homologous to other characterized nitrogenases. *nifH* gene probes containing universal sequences coding for the structural genes of the Fe protein have been successfully used to screen 13 methanotroph strains. All Type II strains, including *M. trichosporium* OB3b, and the Type X *M. capsulatus* (Bath), were found to contain homologous gene sequences (101) indicating that at least the structural polypeptides of the Fe protein in some methanotrophs are similar to nitrogenases from other diazotrophs. Both strains exhibited the typical sensitivity to oxygen as indicated by the characteristic bell-shaped curves for nitrogenase activity to increasing O_2 tension (26,27,100), although *M. trichosporium* OB3b appears to be more tolerant to oxygen than the Type X strain (100). It seems that *M. trichosporium* OB3b can modify its Fe protein in the presence of elevated O_2 levels, which can permit aerotolerant nitrogen-fixation (28).

Although little structural information is available on methanotroph nitrogenases, some information is available on enzyme function and regulation. For example, in addition to oxygen, fixed nitrogen sources, such as nitrate and ammonia, inhibit nitrogenase expression and activity in methanotrophs so far studied. Both *M. trichosporium* OB3b and *M. capsulatus* (Bath) exhibit the ammonia switch-off response similar to other free-living diazotrophs, although the mechanism of this response appears to differ from other diazotrophs (100,103). Recent results have further shown that *M. trichosporium* OB3b $sMMO^{C}$ mutants also express nitrogenase constitutively, relative to oxygen, whereas fixed nitrogen sources repress nitrogenase in these organisms (28). This indicates that nitrogenase expression and activity might be coupled with sMMO expression and activity (although the basis is unknown); however, the coupling appears to be related to oxygen rather than nitrogen influences.

Most nitrogenases consist of two proteins, namely, a molybdenum-iron (MoFe) protein, an approximately 220-kD protein of subunit structure ($\alpha_2\beta_2$) that contains iron and molybdenum, and an Fe protein, an approximately 64-kD dimer of identical subunits that contains iron. Recently, two Mo-independent nitrogenases have been identified and purified from the *Azotobacter* bacterium, although there is circumstantial evidence that these enzymes are also present in other N_2-fixing organisms. The first of these nitrogenases, often called *V-nitrogenase* or *nitrogenase 2*, contains vanadium instead of molybdenum (104,105), whereas the other nitrogenase, called the *alternative nitrogenase*, or *nitrogenase 3*, contains only trace amounts of either molybdenum or vanadium (106–109). It is

presently unknown whether methanotrophs possess either of these two Mo-independent nitrogenases, although studies are currently under way (28).

Because of the extreme stability of the N_2 molecule resulting from its triple bond, nitrogen fixation is an energy-intensive process. As a result, N_2 fixation requires a continuous supply of two factors in addition to nitrogen and nitrogenase, namely, a source of electrons with low redox potential and ATP. In methanotrophs, there is evidence that the supply of ATP is supplemented by recycling the hydrogen generated during nitrogen fixation in which its oxidation is coupled to ATP synthesis (64). With respect to the supply of electrons, it is suspected that they are supplied by NADH generated from the oxidation of formate, which is coupled to the reduction of nitrogenase through a NADH-ferredoxin reductase (110). This electron transport system appears to be specific for methanotrophs. The supplied electrons are transferred to the electron carrier ferrodoxin, a [4Fe-4S]-containing protein that transfers an electron to the Fe protein of nitrogenase, initiating the nitrogen-fixation process (see Fig. 2). The electron is then passed to the MoFe protein as two molecules of ATP are hydrolyzed, which superreduces the MoFe protein and binds nitrogen. The actual nitrogen reduction occurs on this superreduced MoFe protein in three discrete steps, each involving a pair of electron transfers that reduces nitrogen stepwise to ammonia.

Regulation of Nitrogenase Expression and Activity. The regulation of nitrogenase expression and activity in diazotrophs is very elaborate and involves the regulation of transcription of many linked genes (111). All nitrogenase expression systems studied thus far are controlled by interrelationships between at least oxygen, extracellular fixed nitrogen, and ADP supply levels. In methanotrophs, the role of copper in the regulation of the MMO system, especially in Type II and X organisms, further complicates nitrogenase expression and activity. It is not surprising that copper might impact a nitrogenase expression because copper is frequently associated with antioxidant enzymes, such as superoxide dismutase (SOD), and copper itself has significant antioxidant capabilities (112,113).

All nitrogen-fixing organisms studied thus far control nitrogen fixation at the transcription level of the nitrogen-fixation (*nif*) genes (114). Some regulation also occurs posttranslationally in certain organisms. The genetics of this regulation has been studied extensively in the facultative anaerobe *Klebsiella pneumoniae*. In general, the *nif* gene cluster is subject to regulation through the nitrogen-regulation (*ntr*) system, which involves the products of three genes *ntrA*, *ntrB*, and *ntrC* and, in turn, is regulated by various activators and repressors, such as fixed nitrogen source, oxygen, and ATP-to-ADP ratios. Genetic and molecular analyses of the three nitrogen-regulatory genes (*ntr*A, *ntr*B, and *ntr*C) in methanotrophs by DNA-complementation analysis with *ntr* genes from *K. pneumoniae* has suggested that nitrogen metabolism in methanotrophs is regulated by a similar global *ntr* system as found in most of the other nitrogen-fixing organisms (114). Further, the gene product of the *nifH* gene (the Fe protein) of *Rhodospirillum rubrum* was successfully used to monitor nitrogenase expression in *M. trichosporium* OB3b, suggesting that structural genes in methanotrophs may also be similar to other diazotrophs (28). The product of the gene *ntrA* is a sigma factor (σ^{54}) that recognizes specific *ntr*- and *nif*-promoters that also may recognize promoters responsible for sMMO gene expression under low-copper growth conditions (13,89,98,99). In the presence of a σ^{54}, RNA polymerase interacts with genes containing *ntr*- and *nif*-type promoters, but transcription of these genes requires positive activation by the general nitrogen regulatory protein NtrC (the product of *ntrC*) or by the *nif*-specific activator NifA (the product of *nifA*). The expression of these activating proteins is controlled by various factors, such as the availability of fixed nitrogen (notably NH_4^+) and, in many diazotrophs, by oxygen (115). Kim and Graham (28) provided suggestive data that the uncoupling of the effect of copper on sMMO expression also uncouples the effects of oxygen on nitrogenase expression. This observation may aid in better understanding the central regulation of MMO and nitrogenase expression and the activity in these organisms.

Methanol Dehydrogenase in Methanotrophs

Methanol dehydrogenase (MDH) is the second enzyme in the catabolic pathway of methanotrophic bacteria. Although MDH is not exclusive to methanotrophs, it is highly conserved in methanotrophs and common to almost all methylotrophs, and, as a result, MDH genes have proven useful in molecular ecological applications (116–118). It will only be mentioned briefly because detailed descriptions of MDH biochemistry and molecular biology have been provided elsewhere (12,63,119,120).

MDH is a $\alpha_2\beta_2$ tetramer comprised of large and small subunits of molecular weight, 60 to 67 kDa and 8.5 kDa, respectively (119). It is a quinoprotein with each tetramer containing 2 moles of pyrrolo-quinoline and one mole of calcium; electrons from MDH are transferred to cytochrome c_L, a cytochrome that is specific to the oxidation of methanol in methylotrophs (11). MDH and associated cytochromes are soluble and found in large quantities in the periplasm space of methylotrophs (119). The gene encoding the large subunit and the active site of MDH has been identified as *mxaF* (119) and is highly conserved in methanotrophs (11,15). The regulation and molecular genetics of MDH expression and activity is highly complex and has been reviewed by others (11,12,120,121).

ECOLOGY OF METHANOTROPHIC BACTERIA

Overview

Although methanotrophic bacteria are ubiquitous in nature, the true ecological versatility of these organisms has only recently become apparent. New molecular and other techniques have lead to the discovery of previously unidentified habitats for methanotrophs, including psychrophilic (32,122), thermophilic (35,123,124), (hyper) saline (125,126), acidic (33), and alkaline environments (126–128). These diverse organisms also have been found associated with plant root systems fulfilling a mutualistic

role with the plants analogous to that of rhizobia (129), have been implicated in soil denitrification (130), and are potentially involved in anaerobic CH_4 oxidation in marine systems (131).

The goal of this section is to provide a brief overview of methanotroph ecology, with emphasis to the relative ecological roles of Type I and Type II organisms. Particular attention will also be paid to the results available from the recent advancements in molecular biological monitoring of methanotrophs in the environment.

Classical Methanotroph Ecology

Methanotrophs have been found in almost all environments that contain both oxygen and methane (11). Early studies on methanotroph ecology focused on oxic–anoxic interfacial zones, typically in freshwater and marine systems, and, in most efforts, methanotrophs were successfully enriched from such environments. Unfortunately, many methanotrophs are not readily enriched and grown on laboratory media and, as a result, only few methanotrophs (even in CH_4-rich environments) have been identified using traditional microbiological techniques. This problem was further exacerbated by the fact that even organisms that grew on artificial media did not grow well. Early understanding of methanotroph ecology, therefore, was limited to a few organisms that grew on laboratory media under comparatively rich nutritional conditions, reflecting only a small fraction of methanotrophs actually present in the environment.

Despite these problems, general rules that still largely hold true were developed to define methanotroph selection in the environment. For example, methanotrophs were almost always found at oxic–anoxic interfaces; however, the specific type of methanotroph was dictated by a series of key chemical parameters, including nitrogen speciation and level, the relative levels of oxygen, copper, and methane, and the presence of other one-carbon compounds, such as methanol (11). In laboratory studies, Graham and coworkers (27) showed that a Type II strain *M. trichosporium* OB3b, was competitively successful over the Type I strain *Methylomicrobium album* BG8 when copper, nitrogen, and oxygen levels were low and CH_4 levels were high, whereas *M. album* BG8 was more competitive under the opposite conditions. These results were attributed to the Type II strain's ability to express sMMO and nitrogenase when copper and nitrogen levels were growth-limiting and to the apparent sensitivity of some Type II strains to elevated oxygen levels. Amaral and Knowles (132) confirmed these results using semisolid diffusion columns and showed that Type I strains primarily prevailed where oxygen levels were higher and CH_4 levels lower, and Type II strains prevailed where methane was higher and oxygen was lower. Similar results by others provide the same general picture (133,134); Type I organisms apparently prefer high-oxygen, high-soluble nitrogen, and low-CH_4 environments, whereas Type II strains prevail under the opposite conditions, especially when bioavailable copper levels are also low (11).

Although these general observations are still believed to be correct, the study of methanotroph ecology has been recently revolutionized by the development of new molecular biological tools for studying in situ methanotroph populations (14,16,60,135–137). These new techniques have shown that methanotroph diversity is much broader than was originally believed and that there are more atypical methanotrophs in the environment than was previously realized. For example, a new group of "high-affinity" methanotrophs that effectively grow under atmospheric CH_4 conditions has been identified (116). The identification of this group has changed much of the study of methanotrophs because these methane "scavengers" appear to be ubiquitous in nature and may play the major role in CH_4 oxidation that counterbalances CH_4 accumulation as a greenhouse gas (8,11).

New Techniques for Studying Methanotroph Ecology

The study of methanotroph ecology in situ has expanded on the advent of newly available techniques from molecular biology. Such techniques are particularly useful with methanotrophs because these organisms typically grow poorly on laboratory media, and, therefore, such methods allow the organisms to be studied without the need of subculture techniques. There are two excellent recent reviews on the molecular ecology of methanotrophs (14,15), thus only a summary will be presented here.

Two general strategies for studying methanotroph ecology using molecular techniques have been applied: (*1*) those that rely on polymerase chain reaction (PCR) technology and (*2*) those that directly use phylogenetic or functional gene probes to monitor community conditions. PCR methods are very sensitive and can detect target DNA at very low levels; however, such methods are innately nonquantitative because of the many uncertainties that arise during gene amplification (138). Alternatively, phylogenetic and functional gene probes are quite quantitative, but are somewhat less sensitive. The primary PCR-based protocols that have been used to study methanotroph ecology have included denaturing gradient gel electrophoresis (DGGE) using phylogenetic and functional gene primers, and reverse transcriptase PCR (RT-PCR).

DGGE uses the fact that DNA sequences of similar length, but different composition, migrate differently on gradient gels because of different $\%G + C$ contents. This technique has been used to assess genetic diversity in samples and also to identify major DNA sequences in samples that might be excised and sequenced for probe development and phylogenetic characterization. Alternatively, RT-PCR uses reverse transcriptase to convert mRNA to DNA and then uses PCR to amplify the DNA to determine the genetic message that is in a given sample. In conjunction with the use of appropriate PCR primer sets for the function genes, this method can indicate active gene expression within an environment sample. Both DGGE and RT-PCR can be used to describe broad community characteristics or activities, or they can be very specific, depending on the primers used in PCR amplification.

Phylogenetic and functional gene probes have been used in three general protocols: (*1*) fluorescent in situ

hydridization (FISH), (*2*) small subunit (SSU) rRNA analyses using P^{32}-labeled DNA probes, and (*3*) the tracking of functional genes (e.g., *mxaF*) using PCR primers aimed at those specific genes. FISH is a relatively simple technique that uses the microscopic identification and quantification of specific organisms or groups of organisms by the use of fluorescently-labeled DNA probes that bind to DNA-target sequences in whole cells. At this time, FISH is highly labor-intensive; however, it is the best method available at present for the direct quantification of organisms in environmental samples. ssu rRNA techniques also permit the quantification of organisms; however, this method relies on the extraction of rRNA from the sample and subsequent hydridization of specific DNA probes with the extracted sample rRNA. Quantification is usually performed by autoradiography. Finally, the use of PCR primer sets for functional genes allows the qualitative comparison of the microbial diversity of function in and between the ecosystems. For example, functional genes for sMMO, pMMO, and MDH might be used to compare the potential distribution of organisms containing these three enzymes within a given sample.

Insights into Methanotroph Ecology Using Molecular Techniques

Three major new sets of results have been attained using molecular techniques regarding methanotrophs in the environment, that is, (*1*) a more comprehensive picture of methanotroph biodiversity has been developed, (*2*) many new species have been identified (including many previously unculturable species), and (*3*) new methanotroph habitats have been observed. For example, DGGE has been used to assess diversity of the methanotroph community in landfill soils (136), groundwater impacted by TCE contamination (139), agricultural soils in Norway (135), in the rhizosphere (140), and in soil from rice fields (117). Further, functional gene probes for *pmoA* and *mmoX* and PCR gene amplication has been successfully used to assess methanotroph diversity in freshwater lake sediments (141) and in other environments (118,142–144).

All of these studies showed a greater array of putative methanotroph gene sequences than observed previously, although each separate study presented ancillary information on methanotroph ecology. For example, Wise and coworkers (136) used both molecular and traditional culture-based approaches to assess the influence of pH, air/CH_4/CO_2 level, and media richness on methanotroph community composition in landfill soil cover material. They found that rich CH_4 and nutrient conditions were selected for Type I strains and opposite conditions were selected for Type II strains. Interestingly, results were fairly similar to molecular and traditional detection methods, although the molecular procedures did identify one new phylotype related to the *Methylobacter-Methylomicrobium* group and a new group of related Type II species from the *Methylosinus* and *Methylocystis* genera.

Jensen and coworkers (135) showed that CH_4-enriched organic soil had broader array of methanotroph-associated 16S rRNA gene sequences than observed in sandy soil using DGGE, suggesting that the soil organic content influences the methanotroph diversity. However, Iwamoto and coworkers (139) found that biostimulation by methane of TCE-contaminated soil caused a major change in the phylogenetic community dominance in the soil and observed a shift from putative Type I strains to Type II strains in the system. Auman and coworkers (141) found both Type I and Type II methanotrophs in the top 0.8 cm of lake sediments and showed that sMMO-containing *Methylomonas* strains were more prevalent in the environment than was previously believed. In summary, these examples show that a broad variety of "types" of methanotrophs are present throughout the environment and, in most cases, the different methanotroph types were less systematically present in the environment than previous culture-based methods had indicated.

Recent work by Henckel and coworkers (117,118) is particularly noteworthy because they examined methanotroph community structure, using primers for functional genes and PCR and DGGE, in forest soil and rice fields not significantly enriched with methane (i.e., high-affinity methanotrophs). Henckel and coworkers (117) found that atmospheric CH_4 oxidation occurred only in narrow vertical bands in the soil in winter, whereas CH_4 oxidation was noted in the whole profile in summer (in forest soil). They further observed that total DNA increased with soil depth, but that methanotroph gene sequences were found only in the zones of higher CH_4 oxidation (although the methanotroph community did not change dramatically between summer and winter). Excised and sequenced DNA from parallel DGGE gels showed that the atmospheric CH_4-oxidizing methanotrophs present in these soils were only distantly related to previously identified methanotroph strains.

Henckel and coworkers (118) found similar vertical differences in methanotroph composition in rice fields, but noted that water content significantly impacted methanotroph dominance in the soils. Type I and Type II strains were noted at all depths, although Type II organisms tended to prevail in poorly drained soils. These data indicate that methanotroph community composition is temporarily and spatially dynamic even in soils without major CH_4 enrichment and that such populations are continually shifting on the basis of local variations in habitat conditions. These results also show that there is a pool of methanotrophs in the environment that appear to be quite distinct from previously identified methanotrophs and that they are responsible for CH_4 oxidation in locations other than oxic–anoxic interfaces. The global contribution of this potentially large group of methanotrophs to the carbon cycle is not, as of yet, known (11). However, results indicate that their contribution may be significant, and better defining the numbers, activity, and spatial distribution of these organisms is critical in understanding the balance of methane in the environment and the impact of methane as a greenhouse gas (8).

Recent work of Edwards and coworkers (145), Holmes and coworkers (5), Dunfield and coworkers (116), and Henckel and coworkers (118) provide further confirmation

of high-affinity methanotrophs in the environment. High-affinity methanotrophs have been suspected as important in the environment for many years (8,11,146); however, they have proven very difficult to characterize. This unique group of organisms has very low K_S values for CH_4 oxidation (as low as 10.0 nM), levels that are lower than what has been traditionally considered possible to permit extended survival (8,147,148). Regardless, the biochemistry and genetics of these potentially significant organisms have not been studied because they cannot be readily enriched ex situ because of their unique kinetic properties. As previously noted, evidence from in situ molecular ecological characterization suggests that they may be highly distinct from low-affinity methanotrophs, although the high-affinity organisms do appear to still fall under the classical "type" system of nomenclature. Alternatively, it is possible that other high-affinity methanotrophs have yet to be identified because they do fall within any of the existing primer- and probe-sequence databases.

METHANOTROPHS AND BIOTECHNOLOGY

As discussed earlier in this article, methanotrophs play an essential role in the cycling of carbon and nitrogen in the natural environment. Because of their ubiquity in the environment and of the unique ability of MMO to oxidize methane and a wide range of other chemicals, many have attempted to exploit their catalytic properties for biotechnological applications. Examples of such applications include biodegradation and bioremediation of various hydrocarbons, single-cell protein and polymer production from methane, biotransformations in synthesis pathways, and bioconversion of methane to methanol. In fact, there are numerous patents that address the use of methanotrophs in industrial applications (149–155). Although not intended to be all-inclusive, this section summarizes some of the potential applications of methanotrophic bacteria that have been studied.

Methane is considered a major greenhouse gas and is 26 times more efficient in absorbing and reemitting infrared radiation than carbon dioxide (2,6,11). Because methanotrophs oxidize between 50 and 75% of all methane biologically produced, they naturally play a very important role in our environment. Some studies have focused on optimizing the oxidative capacity of methanotrophs in natural environments as a means of controlling CH_4 release to the atmosphere (such as from landfills) (134,156), and many have focused on determining the conditions for their optimum growth and CH_4 oxidation (157–161).

Use of methanotrophs for in situ and ex situ bioremediation applications for environmental restoration has increased in recent years. Most studies have focused on their use in cometabolizing aliphatic compounds, such as trichloroethylene (TCE), a common contaminant in Resource Conservation and Recovery Act (RCRA) and superfund sites; however, some recent studies have focused on their ability to transform aromatic compounds. A thorough discussion of the benefits of methanotrophic bacteria in remediating TCE-contaminated sites is provided elsewhere in this Encyclopedia (162). Because sMMO has been shown to mineralize more than 90% of TCE (163) and has exhibited a broader substrate range than pMMO (including aromatic compounds), it is desirable to use sMMO-expressing methanotrophs for remediation purposes if possible. For this end, isolation of methanotrophic mutants that constitutively express sMMO, regardless of the copper concentration, has been reported (164). Other studies have focused on the potential of methanotrophs to play an integral role in the degradation of aromatic compounds, including linear alkyl sulfonates, substituted benzenes and biphenyls, by mixed methanotrophic-heterotrophic cultures that are routinely isolated from environmental samples (165–168).

The production of methanol and various alkene epoxides using methanotrophs relating to the use of these microorganisms in industrial applications has been a subject of studies (10,169–171). Large-scale production of methanol has been considered because of its potential to serve as an alternative cleaner-burning fuel, and propene oxide, for example, is a convenient model for gas-solid bioreactor systems and has significant commercial value (172,173). The exploitation of thermophilic methanotrophs is of particular interest in industrial applications. As previously described, CH_4- and methanol-oxidizing bacteria that grow in thermotolerant temperature ranges (45 to 60 °C) and thermophilic ranges (>60 °C) have been isolated (35,123,124). Thermophiles would offer several advantages in biotechnology, including reduced cooling costs, reduced contamination with human pathogens, the possibility of novel biodegradation reactions because of decreased stability of substrates at higher temperatures, and simple recovery of methanol (35).

Despite the earlier examples, the widespread use of methanotrophs in biotechnological applications has not been fully realized. Some reasons for this include the relatively slow growth of these microorganisms, the ability to chemically synthesize methanol relatively inexpensively, and, in the case of bioremediation of substrates more amenable to attack by sMMO, the prevalence of copper concentrations at levels high enough to inhibit sMMO expression by methanotrophs in the natural environment. However, despite these potential drawbacks, the findings reported earlier suggest that these ubiquitous CH_4 oxidizers may play a significant role not only in the natural cycling of carbon and nitrogen in the environment, but also in the cycling of carbon in environmental restoration and industrial applications.

CONCLUSION

Methanotrophic bacteria are ubiquitous in nature, living in any location where air and methane are simultaneously present. They reside in many different habitats and are now being found in locations and performing metabolic functions that were not even considered fifteen years ago. Further, as more novel methanotrophs are identified, particularly thermophiles and high-affinity CH_4 oxidizers, their apparent significance as biotechnological agents should expand further.

It is hoped that this article has provided a brief introduction to classical and emerging topics in methanotroph classification, biochemistry, molecular biology, ecology, and the application of these key organisms in biotechnology. It is also hoped that future efforts, especially related to the role of methanotrophs in the global carbon cycle and greenhouse gas reduction, will be stimulated by this article and further efforts will be expended on this key and environmentally significant group of microorganisms.

METHANOTROPHIC BACTERIA: USE IN BIOREMEDIATION

ROBIN L. BRIGMON
Savannah River Technical Center
Aiken, South Carolina

Specific types of anaerobic microorganisms produce methane in environments in which oxygen is limited. These include swamps, landfills, wetlands, peat bogs, sediments, and the intestinal flora of animals. Methane-oxidizing bacteria (methanotrophs) in turn remove methane from these environments. Therefore, anaerobic sediments are considered to be aerobic sink for methane because of the activities of methanotrophs.

Methanotrophs are a diverse group of bacteria that utilize methane as their sole carbon and energy source (1,2). These bacteria have been isolated from a wide range of environments including soils landfills (3), sediments (4), groundwater (5), salt reservoirs (6), and plant rhizosphere (7).

Methanotrophs were initially classified on the basis of their morphology, type of resting stage, intracytoplasmic membrane structure, and physiological characteristics (8). In recent years 16S rDNA sequence analysis has further clarified these phylogenetic relationships and defined eight genera of methanotrophs, namely, *Methylococcus*. *Methylomonas*, *Methylomicrobium*, *Methylobacter*, *Methylocaldum*, *Methylosphaera*, *Methylocystis*, and *Methylosinus* (9). These genera are divided into two distinct physiological groups. Type I methanotrophs that assimilate formaldehyde that was produced from the oxidation of methane through methanol using the ribulose monophosphate pathway have cellular membranes that are composed of predominantly 16-carbon fatty acids and possesses bundles of intracytoplasmic membranes. Type II methanotrophs utilize the serine pathway for formaldehyde assimilation, have distinct intracytoplasmic membranes arranged around the periphery of the cell, and contain predominantly 18-carbon fatty acids (1). Membranes of the genus *Methylococcus* possess a combination of characteristics of both type I and type II methanotrophs.

Methanotrophs form coherent phylogenetic clusters that share the common physiological characteristics described earlier (9). Type I methanotrophs cluster in the γ-subdivision of the Proteobacteria, whereas type II methanotrophs are grouped within the α-subdivision of the Proteobacteria. The tight phylogenetic clustering of these groups has allowed the design of a range of oligonucleotides, which target a broad range of both

methanotrophs and methylotrophs (1,10,11). A number of 16S ribosomal and gene functional probes are now available for culture-independent detection of methanotrophs and methylotrophs (3).

Several species of methanotrophs that produce methane monooxygenase and participate in the cometabolic degradation of TCE, have been isolated (12). However, soluble methane monooxygenase (sMMO) present in some methanotrophic bacteria has been found to be responsible for oxidizing a wide range of carbon substrates of interest for bioremediation applications (13). No sMMO has been isolated or observed in type I methanotrophs. Moreover, it appears that the sMMO is limited to a few species of type II and type X? methanotrophs. The sMMO has been found, through its nonspecific activity, to affect oxidations, dechlorinations, condensations, and rearrangements of meta-chlorotoluene, phenol, chlorofluorobenzenes, and mono and dichlorobiphenyls via it's nonspecific enzymatic activity. Soluble MMO is believed to be found only in type II and type X methanotrophs during copper-limiting conditions (14). Although membrane and particle-associated MMO has been reported, the rates of chlorinated solvent degradation with these organisms is significantly less than sMMO bacteria (15). These solvents have included halogenated aliphatic compounds such as trichloroethylene (TCE). Methanotrophs can utilize nitrogen as nitrate, ammonia, and molecular nitrogen while demonstrating TCE transformation capacity (16). This activity has been applied in subsurface bioremediation activities with beneficial results. This article concentrates primarily on methanotrophic bacteria applications shown to be effective in chlorinated solvent bioremediation with a focus on TCE.

BACKGROUND

In recent years there has been an increased interest in the use of microorganisms for environmental restoration. The usefulness of microorganisms with a diversity of metabolic activities in wide-ranging applications coupled with advances in the technology has lead to successful demonstrations in the ever-expanding bioremediation field. The application of environmental biotechnology as a successful remediation tool depends on the ability to stimulate or enhance specific activity of indigenous or introduced microorganisms. The challenge has been to enhance the activity of these microorganisms and develop means to bring the contaminant into direct contact with the organisms to achieve optimum bioremediation. Methanotrophic bacteria have a ubiquitous distribution in the environment and the use of natural gas or methane with other nutrients to stimulate their bioremediation activities through methane monooxygenase is a remediation option. These two features allow for a relatively efficient, inexpensive, and safe means to manipulate the environment to accelerate bioremediation. This entry describes the great interest in methanotrophic bacteria in bioremediation.

TCE is a volatile chlorinated organic compound that has been widely used as an organic solvent and degreasing agent and disseminates over large areas in the subsurface at contaminated sites. TCE is the most frequently observed volatile organic compound (VOC) at Resource Conservation and Recovery Act (RCRA) sites (17) and in groundwater (18). TCE is a Voc that is regulated in the United States as an air pollutant under the Clean Air Act Amendments Title III. The U.S. Occupational Safety and Health Administration is setting worker exposure limits for this solvent because of it's toxicity. Dichloroacetate and chloral hydrate are potentially produced in the groundwater in small amounts when TCE is metabolized and can be present in drinking water. Both these compounds have potential health effects because dichloroacetate is an experimental drug used to treat children with lactic acidosis, and chloral hydrate is a sedative (19).

Removing TCE from contaminated groundwater can pose risks while using conventional engineering methods such as vacuum extraction or pump and treat remediation. These risks include transfer of TCE to air through volatilization and handling issues. Because of increasing environmental concerns and federal regulations there is a growing preference for bioremediation applications that reduce risk and produce minimal toxic residuals. Although investigations of the microbial degradation of chlorinated ethenes have been ongoing since the 1950's (20,21), as recently as the 1980's it was believed that TCE could not be successfully biodegraded either aerobically or anaerobically (22). This belief was in part because of the widespread groundwater contamination by TCE. In 1980 alone, California closed 39 public water supply wells in the San Gabriel Valley because of TCE pollution, and New York, New Jersey, and Pennsylvania condemned wells because of the same contaminant (18).

Wilson and Wilson (23) demonstrated that TCE is susceptible to cometabolism by soil communities enriched with natural gas. Fliermans and coworkers (5) and others demonstrated that cultures enriched with methane and propane could cometabolically degrade a wide variety of chlorinated aliphatic hydrocarbons including ethylene, 1,2-cis-dichloroethylene (c-DCE); 1,2-trans-dichloroethylene (t-DCE); and vinyl chloride (VC); toluene, phenol, and cresol. Investigations that utilized methods to stimulate microorganisms in the subsurface vadose zone and groundwater found that both aerobic and anaerobic processes contributed to the removal of TCE as revealed by detection of TCE oxidation and anaerobic transformation products, c-DCE, t-DCE, and VC (24,25). These studies proved that bioremediation provides a powerful means of restoring contaminated aquifers. Mccarty and Semprini (26) concluded from laboratory and field studies that cometabolic transformation of TCE was strongly tied to methane utilization. When methane additions were stopped TCE transformation ceased. Figure 1 outlines the oxidation of methane by methane monooxygenase and the associated cometabolism of trichloroethylene.

It is now well recognized that TCE and other chlorinated aliphatic compounds can be degraded by a diversity of bacteria including methanotrophs (27), selected methanogens (28), and species of *Pseudomonas* (*P. cepacia*, *P. mendocina*, and *P. putida*) capable of also degrading aromatic compounds (29). Ensley (30) has

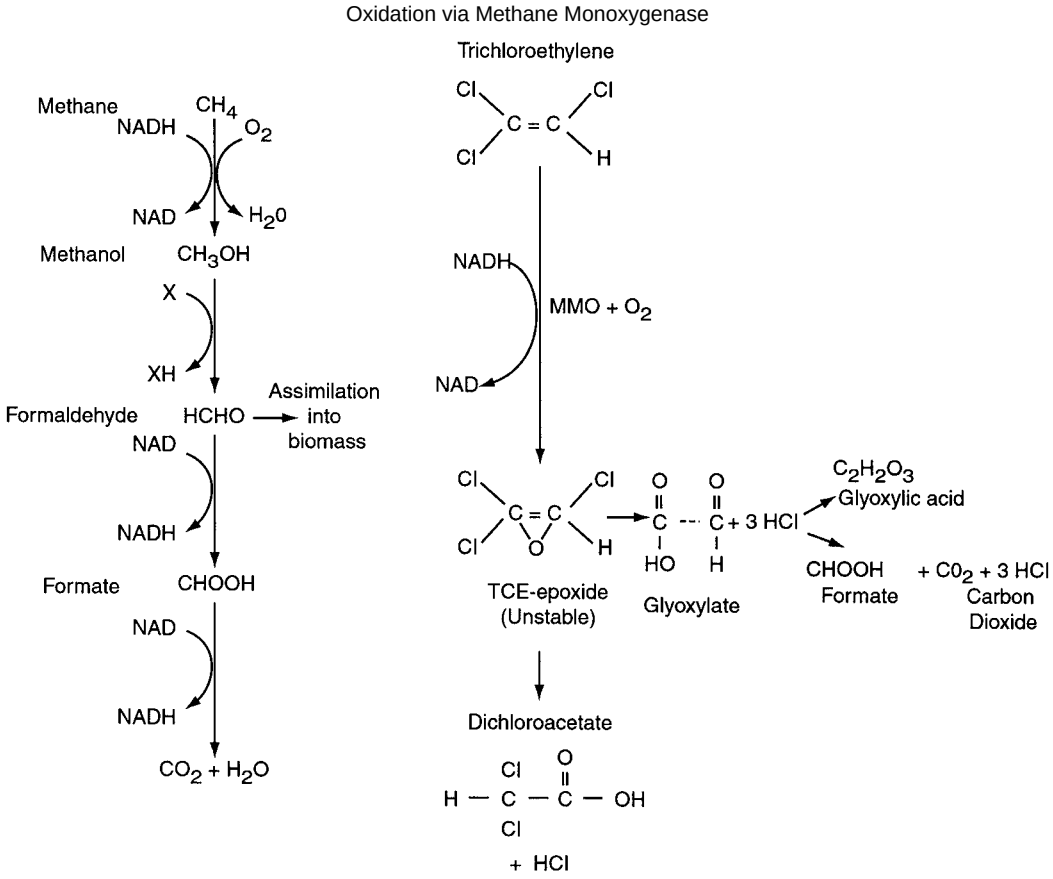

Figure 1. Oxidation of methane by the methane monooxygenase enzyme and the associated cometabolism of trichloroethylene.

demonstrated a linkage between TCE degradation and aromatic metabolism in *P. cepacia* G4, *P. mendocina*, and *P. putida*. Ensign and coworkers, (31) reported that pure cultures of *Xanthobacter* spp. cometabolized TCE with the utilization of propylene as a carbon and energy source presumably using the enzyme alkene monooxygenase. Fliermans and coworkers (5) and Bowman and coworkers (4) have shown that enrichments for methanotrophs in subsurface samples collected from the Savannah River Site in South Carolina stimulated the microbial degradation and complete mineralization of TCE and other chlorinated aliphatic compounds both in the laboratory and in situ. Propane utilizers or propanotrophs that also exhibit nonspecific oxidase activity may also be used for bioremediation of VOCS. Where mixtures of chlorinated aliphatic hydrocarbons including 1,1,1-trichloroethane are present, propane may be the stimulant of choice using air-sparging technology (32). However, methanotrophs are optimum in bioremediation when TCE is the primary contaminant of concern.

An advantage of utilizing methanotrophs for bioremediation is that aerobic conditions do not appear to support the formation of undesirable metabolites, such as c-DCE, t-DCE, or Vc that are partially dechlorinated by-products of anaerobic degradation of TCE. Vinyl chloride, a known animal and human carcinogen, is considered more hazardous than the parent compounds TCE and/or PCE. Methane oxidizers are likely to be found in zones that fluctuate between aerobic and anaerobic conditions such as soils that periodically flood and drain. Enzien and coworkers (33) has suggested that both anaerobic and aerobic populations may both be stimulated to biodegrade TCE in an aquifer under bulk aerobic conditions.

Although there appears to be a diversity of natural microorganisms that degrade TCE, the compound remains the most prevalent organic contaminant in the United States (34). The ubiquity of the TCE contamination suggests that either the environmental conditions do not support biodegradation, or that the correct consortia of microorganisms is not present, or at sufficient cell densities in the ecosystem. Thus, it is important to understand both the biological and the physical parameters associated with biodegradation of TCE. Despite these possible problems, the promise of bioremediation is revealed by the observation mixed methane-grown communities that were once stimulated have been found to metabolize TCE completely to harmless end products with a half-life of less than a day (35).

Although sediment methanotrophic bacteria can be efficient in degrading TCE from contaminated groundwater (4), certain methanotrophs are more efficient at TCE degradation than others (12). It has been suggested that mixed microbial populations are more efficient in TCE degradation than pure culture (36). Field

applications of methanotrophs for removal of TCE from the environment have proven that further studies of these bacteria are needed. Specific areas that need to be explored are associated microbial communities, population dynamics, and potential for biodegradability to decrease or eliminate the contaminant. Thus, there is a need for a better understanding of the microbial ecology of TCE-contaminated subsurface systems for biodegradation applications.

IN SITU BIOREMEDIATION

In situ bioremediation means that the environmental restoration of contaminated sediments are not moved from the site or that groundwater is not pumped and treated at the surface. When an in situ bioremediation technology is employed the relocation and transport of materials may be avoided. This makes in situ bioremediation, where applicable, a highly attractive technology for remediation because contaminants are removed on-site, not simply moved to another location or volatilized (37). In situ bioremediation of chlorinated solvents with methane injection is a site-specific application. This application results in decreased remediation costs, lower contamination risks, shorter restoration time, and increased efficiency, as well as enhanced public and regulatory acceptability. Public relations are enhanced because much of the action occurs with minimum aboveground activity and equipment and bioremediation can be among the least expensive remedial technologies in which its application is feasible.

Bioremediation of chlorinated solvents through stimulation of methanotrophic bacteria has been demonstrated at the Savannah River Site (SRS). The SRS is a 320 square mile facility owned by the U.S. Department of Energy and operated by Westinghouse Savannah River Company. The SRS, located in a rural area along the Savannah River in Aiken and Barnwell counties of South Carolina, has generated nuclear materials for defense, medical, and space applications since the 1950s. During the first 20 years of operation, most of the waste generated at the SRS, including millions of pounds of chlorinated solvents, was handled via burning rubble pits, evaporation ponds, and waste pits resulting in extensive soil, sediment, and groundwater contamination.

The SRS has now completed several successful bioremediation demonstrations on soil and groundwater contaminated with chlorinated ethenes utilizing methanotrophic biostimulation (25,38). The deployment of two projects at SRS designed for field demonstrations of in situ treatment of groundwater contaminated with chlorinated solvents by gaseous nutrient injection have proven the effectiveness of in situ bioremediation.

Demonstration 1

The first demonstration was near the 300-M operations area where fuel and target elements were degreased in processing. An estimated 13 million pounds of solvents were used in this processing from 1952 to 1982. Although evaporation was used to reduce much of the solvents, an estimated two million pounds was released to the M Area Settling Basin (24). These solvent discharges to the M Area settling basin consisted primarily of TCE, perchloroethylene (PCE), and trichloroethane (TCA).

The M area in situ bioremediation demonstration consisted of two horizontal wells for injection and extraction at the process sewer line leaking PCE and TCE (25). Figure 2 illustrates a side view of the 160-ft deep horizontal wells in relation to the surface nutrient injection and extraction systems. Groundwater, extracted air, and sediment samples were taken before, during, and after testing of the system that ran for more than one year. Subsurface gaseous nutrient injection including methane, nitrogen, and phosphorus was found to be an effective in situ bioremediation treatment for TCE-contaminated groundwater at the M Area site of SRS (25). Gene probe analysis demonstrated an increased MMO activity corresponding to significant TCE degradation rates among a high proportion of the indigenous methanotrophic bacteria in the M Area groundwater (4). Species-specific methanotrophic bacteria DNA probes have revealed that perturbations associated with biostimulation resulted in preferential changes in the structure and physiological status of microbial communities (37). Direct evidence of TCE mineralization in this project was demonstrated by increased groundwater chloride concentrations that correlated with severalfold increases in the density of methanotrophic bacteria (39). The rate of TCE biodegradation also correlated with growth of specific species of methanotrophs and nutrient growth factors including injected methane, phosphorus, and nitrogen (38). These increases correlated with methane groundwater concentrations and the pulsed injection regime over the year test period.

The observation that methanotrophic population increases correlated with TCE biodegradation indicated that the zone of influence of gaseous nutrient injection extended at least 60 ft from the injection well in both the horizontal and vertical directions (37). Groundwater monitoring of both bacteria and contaminant concentrations provide information on the efficiency of this technology (25). Application of these methane or air mixtures demonstrated a three to five order of magnitude increase in TCE-degrading methanotrophic bacteria during the methane and nutrient injection (39).

A subsequent remediation project was conducted in the same M Area aquifer to determine the effect of chemical oxidation on subsurface microbiology and cometabolic biodegradation capacity in the same aquifer after treatment with Fenton's reagent (40). The groundwater pH declined from 5 to 2.4 immediately after the Fenton's treatment indicating release of Cl^- ions from TCE/PCE. The pH subsequently rose to a range of 3.4 to 4.0 after 17 months. Limited methanotrophic bacteria growth and TCE degradation were detected in the treated zone (pH 3.4 and TCE 5 $mg\,L^{-1}$) with methane addition. Methane addition to groundwater from the control well without Fenton's Reagent (pH 4.9 and TCE 0.7 $mg\,L^{-1}$) stimulated methanotrophic growth. This was indicated by methane consumption and microbial characterization with fluorescent antibody analysis, phospholipid-based markers, and rDNA probes. Higher TCE concentrations in the Fenton's

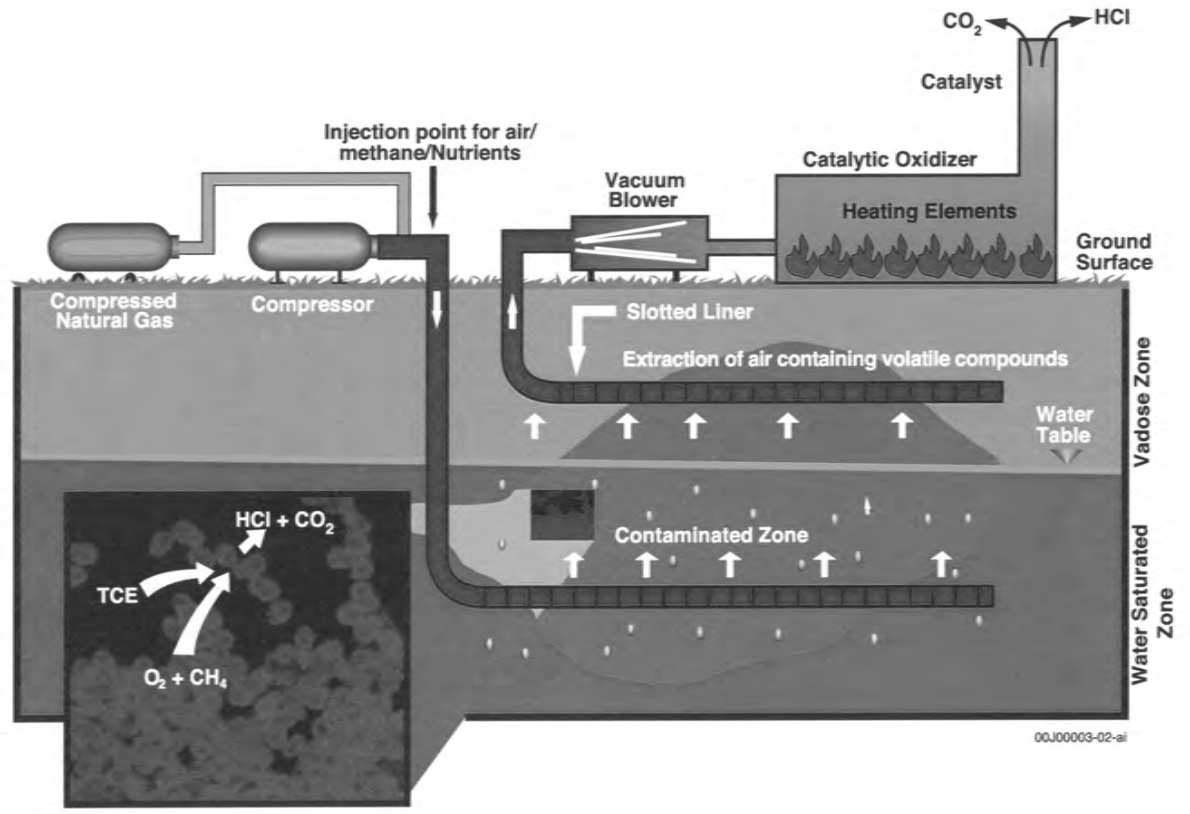

Figure 2. A side view of the horizontal wells in relation to the surface nutrient injection and extraction systems Modified from WSRC, Test Plan for In Situ Bioremediation Demonstration of the Savannah River Integrated Demonstration Project DOE/OTD TTP No.: SR 0566-01 (U), WSRC-RD-91-23, Westinghouse Savannah River Company, Aiken, SC, 1992. See color insert.

Reagent treated zone (16–21 mg L^{-1}) might have inhibited TCE cometabolism. These results also indicate that low groundwater pH resulting from the chemical oxidation process (pH 3.3 vs. 4.9) inhibited TCE biodegradation. Methanotrophic growth and TCE biodegradation may be possible because pH increases both in the treated zone and at the leading edge of the plume if sediments are able to buffer groundwater pH. Treatment with Fenton's Reagent limits the potential for subsequent monitored natural attenuation to occur. However, the Fenton's reagent process could be designed to operate at a higher pH (e.g., $\geq$4.5) and/or lower H_2O_2 concentration to minimize detrimental long-term biological effects, providing an optimum environment to couple advanced oxidation processes with bioremediation technologies.

Demonstration 2

A second demonstration of in situ bioremediation at SRS is at the Non Radioactive Waste Disposal Facility (NRWDF) formerly known as the Sanitary Landfill. The NRWDF began receiving solid waste from construction areas, offices, shops, and cafeterias in 1974. During the course of its operation, the Sanitary Landfill received numerous materials that can leach or generate hazardous compounds, for example, paints, thinners, solvents, batteries, rags, and wipes used with organic solvents. Wastes were cataloged but not segregated within the landfill. As a result, in 1988, recurring evidence of contaminants of concern (COCs) were detected in the groundwater including TCE, PCE, TCA, DCE, VC, and chlorobenzene (CB).

Initially, a treatability study to evaluate the NRWDF bioremediation potential using soil columns was employed to simulate both vadose and groundwater conditions using NRWDF sediment and groundwater (33). The results of the treatability study proved that cometabolic methanotrophic bioremediation of the COCs was possible at the NRWDF. A subsequent in situ optimization test demonstrated that biostimulation by addition of oxygen, nutrients, and methane at two sites within the NRWDF resulted in undetectable levels of contaminants and other organics in both the groundwater and vadose zone (X). Additionally, chloride concentrations in the groundwater at both sites increased significantly as methanotrophic bacteria densities increased, reaching a maximum population in three to four days, whereas contaminant levels decreased.

Figure 3 demonstrates methanotrophic bacteria labeled with direct fluorescent antibodies from NRWDF groundwater concentrated on a 0.2-μm filter (40). The total number of groundwater microorganisms did not change, indicating a selective stimulation of the methanotrophic

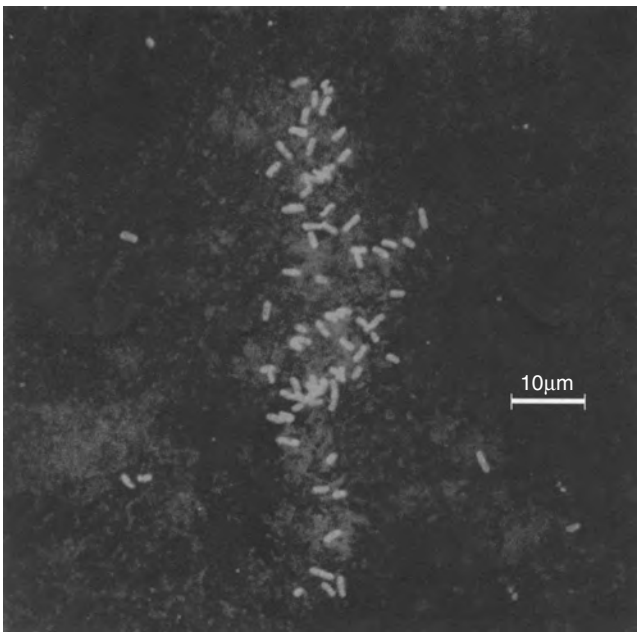

Figure 3. Concentrated groundwater methanotrophic bacteria on 0.2-μm filter labeled with fluorescent monoclonal? antibodies. See color insert.

Figure 4. In situ gaseous nutrient injection system at the Savannah River Site 70-acre nonradioactive waste disposal facility depicting the 400 ft and 600 ft horizontal wells. Insert is gas-nutrient pumping station.

population (40). The loss of contaminants appears to be because of cometabolic biodegradation through biostimulation as loss by volatilization was minimal. This work again clearly demonstrates that one can effectively change the subsurface bacterial population in a relatively short period. A larger scale (400 and 600 ft) set of horizontal wells at the NRWDF site is now being tested with nutrient injection for long-term containment of chlorinated ethenes (Fig. 4). Results to date indicate the spread of the associated TCE plume is being limited by the nutrient injection system.

Similarly, groundwater concentrations, another NRWDF contaminant, have significantly decreased in recent years at the NRWDF with a concomitant increase in chloride ions. Chlorobenzene can undergo microbiological dechlorination and the benzene ring can be converted to catechol, followed by ring fission or oxidation of the side chain. Geochemical data confirm that TCE and CB concentrations are decreasing at a greater rate than would be expected because of NRWDF groundwater transport or dilution.

These demonstrations represent another approach in the development of in situ bioremediation technologies. In both applications, a pulsed application of methane coupled with other gaseous nutrients worked best for methanotroph biostimulation and contaminant degradation. Through the use of the gaseous nutrient injection system (Fig. 4), the NRDWF groundwater COC concentrations are approaching minimal detection limits (5 ppb).

MONITORED NATURAL ATTENUATION

Monitored Natural Attenuation (MNA) is a risk management option that relies on natural biological, chemical, and physical processes to contain the spread of contamination from a source. Containment by MNA relies on sorption, volatilization, dilution, destruction, or biotransformation of contaminants. Comparing rates of contaminant transport to rates of MNA to other methods including groundwater transport models can quantitatively assess the efficiency of this option to prevent contaminant migration in groundwater systems. If groundwater movement is faster and relative to rates of contamination removal, contaminants have the potential to reach points of contact with human or wildlife populations. Conversely, if transport rates are slow relative to removal rates, contaminant migration will be more confined and less likely to reach a point of contact. Evaluating the factors mitigating contaminant transport to predetermined points of contact can assess the efficiency of MNA. Thus, this assessment includes hydrological (rates of groundwater flow), microbiological (rates of biodegradation), and sociopolitical (points of contact) considerations.

The MNA of TCE is associated with anaerobic dechlorination and cometabolism. Under specific anaerobic conditions TCE can be reductively dechlorinated to less chlorinated ethenes including DCE and VC. The presence of these compounds is evidence of TCE intrinsic bioremediation. It has been reported that if the amount of cis-DCE is greater than 80% of the total DCE, which it is in the case of the NRWDF, then it is a biodegradation product of TCE. The MNA of TCE is associated with the accumulation of these daughter products and the increase in chloride ions (39).

Other microbial processes involving methanotrophs may also be of value to bioremediation efforts. For example, denitrification rates in anaerobic environments have been found to be directly dependent on the methanotrophic activity and the percentage of soluble carbon produced during methane oxidation. Any of the three intermediates

(methanol, formaldehyde, or formate) from the methane oxidation (Fig. 1) could be used as electron donors by anaerobes.

A number of MNA investigations involving chlorinated ethene degradation have demonstrated that, although anaerobic dechlorination is occurring, the anaerobic processes alone cannot fully account for the observed contaminant reduction. Sequential anaerobic-aerobic chlorinated ethene degradation field and laboratory studies were carried out at three different remediation sites (39). In all three waste sites, methane generated from associated waste was proven to be stimulating the cometabolism of TCE. Microcosm studies confirmed the aerobic and anaerobic processes that were impacting the distribution and concentration of contaminants at these sites.

Indigenous sources of carbon associated with soils, sediments, and groundwater may be supportive of TCE degradation although certain soils may not support such activities (41). Walton and Anderson (42) demonstrated that TCE-degradation was carried out by indigenous microbial populations in the absence of an added cosubstrate in rhizosphere and nonrhizosphere soil slurries and groundwater samples from a TCE-contaminated site. Although significant differences existed in the rates of TCE cometabolism among methanotrophic microbial communities in these three habitats, similarities existed between the behavior of pure cultures and the indigenous soil microbial populations that cometabolize TCE. Questions regarding the specific populations of microorganisms that are responsible for aerobic and anaerobic degradation of TCE in various habitats still remain.

The growth of vegetation encourages the proliferation of microorganisms in the root zone by providing an environment conducive to microbial growth. The density and diversity of microorganisms in the root zone (rhizosphere) is enhanced when compared with bulk soil. Plants also provide an environment that often leads to increased rates of microbial degradation in the rhizosphere of organic contaminants (42). Enhanced biodegradation rates may be related to nutrient availability as reflected in the increased numbers of microorganisms and/or the increased microbial activity (metabolic or cometabolic) caused by root exudates. In some cases the TCE groundwater contamination is close to surface soils or impacts seeplines where plumes of contaminated groundwater can emerge as a result of geologic and topographical interactions. Significantly higher numbers of methanotrophic bacteria were observed in rhizosphere soils and on roots of *Lespedeza cuneata* (a legume) and *Pinus taeda* (Loblolly Pine). It was previously demonstrated that rhizosphere soils from these two types of plants showed higher rates of ^{14}C-TCE mineralization compared with nonvegetated soils (43). Methanotrophic bacteria activity is observed in organic sediments with aerobic and anaerobic microbial interactions. Seeplines that contain such conditions could be an important mechanism for bioremediation of chlorinated ethenes as a natural area for cometabolism to occur. Plumes of contaminated water are often observed in seeplines discharging to surface streams and rivers. The sediments in these seepline systems often contain highly active microbial communities. Streambeds are another area where contaminated subsurface water interacts with surface water. Complete oxidation of chlorinated ethenes has been observed in organic-rich-stream bed sediments (44). Future work could be focused on in situ microbial distribution and densities, and the role of specific populations including methanotrophs in response to TCE-contaminated groundwater seepage through the rhizosphere, streambeds, and seeplines.

EX SITU: BIOREACTORS

It is evident that significant progress has been made in the application of bioremediation utilizing methanotrophic bacteria. Methanotrophic bacteria have also been used in bioreactors as a means of complete removal of contaminant rather than transferring it from one form to another. Bioremediation with methanotrophic bacteria in bioreactors has been tested with free, immobilized, and attached cells. Studies using methanotrophs for TCE removal have been carried out in bioreactors with bacteria attached to carbon (45), diatomaceous earth (46), glass, and ceramic packing material (47). Both aquatic and air bioreactors utilizing methanotrophic bacteria have been developed to remove TCE.

Because methane is the only nutrient source to the microorganisms, sufficient quantities must be supplied resulting in high flow rates through the bioreactors. Because of the large gas demand relative to the poor solubility of methane and oxygen, this mass transfer can present a design challenge. In addition, pure oxygen and methane can potentially form explosive mixtures, therefore appropriate handling methods are necessary. The medium size or design used should be tailored to the velocity of flow. Bioreactors with methanotrophic bacteria have been successfully maintained with both mixed cultures (17) and pure cultures (36).

As with all microorganisms, maintenance of methanotrophs in a bioreactor or culture requires specific nutrient conditions. Growth factors that can influence methanotrophic activity are methane concentrations, copper concentration, nitrogen source (NO_3, NH_4^+), oxygen supply, pH, temperature, and the origin of the culture or inoculum used. Although methanotrophs have been isolated in culture conditions containing 50% methane (3), optimum conditions for TCE degradation in methanotrophic bioreactors are between 4 and 20% (46). Bioreactors are useful for further physiological studies of methanotrophs and have added to our knowledge of TCE biodegradation.

CONCLUSION

Microbial communities are highly diverse and capable of conducting an extensive range of metabolic activities (37). Irrespective of depth or geologic formation, subsurface microorganisms carry out all the major nutrient (carbon, sulfur, nitrogen, manganese, iron, and phosphorus) cycling. Although each geologic formation appears to have its own microbial structure, sandy formations

that are highly permeable to air or water flow have a higher microbial activity. Considering a generally large subsurface microbiota there is considerable interest for the prospect of degrading hazardous contaminants in situ by stimulating selective bacterial populations (biostimulation) or by the addition of organisms to contaminated sites (bioaugmentation). Stimulation of an indigenous population of methanotrophs by methane is likely to enrich species that are well adapted to their environment, whereas the deliberate addition of more microorganisms into such an environment may be compromised because the introduced organisms are not as likely to be able to compete.

Defining temporal and spatial relationships and population dynamics or interactions of selected microorganisms such as methanotrophs in the natural setting is important for the evaluation of bioremediation potential and its effectiveness. It has become increasingly evident that indigenous microbial systems are able to facilitate the degradation and mineralization of a wealth of compounds that were thought to be biologically recalcitrant twenty years ago. This realization has necessitated technologies whereby defined microbial types can be followed in situ in real time by techniques that are designed to be selective, sensitive, and easily applicable to soils, sediments, and groundwater.

Methanotrophs are physiologically versatile in their ability to exist in a variety of habitats and to live in hostile environments having a wide range of pH, temperature, heavy metal concentrations, oxygen concentrations, barometric pressures, salinity, and radiation. Under these diverse conditions a number of methanotrophs have been isolated that facilitate the degradation of TCE and its daughter products.

Evaluation, characterization, and utilization of microbial communities associated with in situ bioremediation of subsurface and groundwater contamination is a technological necessity for environmental restoration and assessment (48). In the past sixty years both industrial and government nuclear production and waste management facilities have generated a significant quantity of organic wastes. These wastes have found their way into the vadose zones and groundwater resulting in unacceptable environmental impacts. The adaptability and manageability of indigenous microorganisms such as methanotrophs make them ideal for the remediation of hazardous environmental wastes in a diverse range of habitats (49).

Each day, throughout the world, samples are analyzed to determine the number and types of microorganisms present in the environment, and indirectly from the environment to foodstuffs and beverages. Measurements are made to estimate total cells, total viable cells, and specific pathogens or indicator cell types of interest. It has become apparent, however, that many microbes are not responsive to cultivation techniques (1–5). Therefore, conventional enumeration on solid or liquid media may severely underestimate the microbiota of interest. The aim of this article is to present an overview of the principles and the role that flow cytometry (FC) can take in the direct monitoring of microorganisms from various environmental liquids.

FC is now widely used as a means of perceiving, and sometimes also sorting cells (flow cytometric cell sorting — FCCS). It is well suited for the identification of single cells in suspension, ranging from aquatic samples with particulate debris through to aerosols (6,7). Although FC has been recommended several times for environmental microbiology (8–12) and is becoming more common in clinical microbiology (13), it is a grossly underutilized technique owing to the problems encountered with environmental samples and that instruments are largely designed for mammalian cell analysis (14).

Therefore, we begin this article with an introduction to the basics of FC and describe some current microbiological applications. This is followed by an overview of the current state of the art in FC methods used in analytical microbiology, and the most suitable applications of this technology. The remainder of the article outlines the various elements in any FC method, these being *(1)* sample preparation, *(2)* staining, *(3)* instrumentation, and *(4)* data analysis. Finally, predictions regarding future directions in FC are discussed. For general information and free FC software, the reader is also directed to various sites on the Internet (cytometry network sites, *http://nucleus.immunol.washington.edu/ISAC/network_sites.html*; JCSMR FC software, *http://jcsmr.anu.edu.au/facslab/facs.html*; ISAC WWW home page, *http://www.10.uniovi.es/ISAC.html*).

BASICS OF FC

Detailed discussions on FC have been provided previously (15–17) and only a brief outline is provided here. The earliest "modern" flow cytometers were used by the U.S. Army during World War II to detect bacteria and spores (18). These devices incorporated a sheath of filtered air to limit the air sample stream to the central portion of a flow chamber, and the detector was the recently developed photomultiplier tube. The next generation of flow cytometers was built by Kamentsky and coworkers (19), using spectrophotometric techniques to detect and measure nucleic acids and light scattering of unstained cervical cells in a flow stream. At the same time, the first flow cytometer with cell sorting (FCCS) capability was developed by adapting the ink-jet printer principle, using electrostatic deflection of charged droplets (20). Fulwyler's flow cytometer worked by measuring cell volumes obtained by the Coulter orifice principle. However, it was not until the development of an arc lamp-based instrument by Steen's group in 1979 that a flow cytometer with sufficient resolution for bacterial characterization was generally available (21,22) (commercially as the Skatron Argus FC, briefly during the mid-1990s as the Bio-Rad Bryte HS). Nevertheless, while the use of FC has become routine in biomedical applications (the most common area of routine use being in the analysis of blood cells), it is only now emerging from a research-only tool in microbiology (23). Portable flow cytometers specifically designed for microbiology, such as the Microcyte ($33 \times 43 \times 16$ cm and weighing about 15 kg) should

also improve their utility (24), but other modular systems such as the Partec PAS II (Partec GmbH, Munster, Germany) (*http://www.partec.de/indexre.html*) also offer systems for bacterial and yeast applications.

All flow cytometers quantitatively measure the optical characteristics of particles, such as cells, as they are presented, in single file, into a focused light beam. The light source used is either a high-pressure mercury vapor lamp or an assortment of different lasers. Cells can be analyzed at rates of over 100,000 per second as they are carried within a fast flowing air or fluid stream termed the *sheath flow* (Fig. 1(left)).

As particles pass through the light beam three parameters are measured: forward scatter (also called *FSC* or *forward angle light scatter* [FALS]), side scatter (also called *SSC* or *side angle light scatter* [SALS]), and fluorescence (FL). The amount of light scattered forward and at right angles by any particle tends to increase with cell size. In addition, cell refractivity is related to surface properties and internal structure and these also affect FSC and SSC. Natural fluorescence (autofluorescence) is emitted by cellular components, such as flavin nucleotides, pyridine, and photosynthetic pigments. However, most examples of the use of FC for microbial analysis make use of fluorescent dye labels rather than autofluorescence. A typical flow cytometer measures fluorescence in three wavelength ranges. Light of defined wavelengths is channeled to particular detectors; for example, detector FL1 will typically measure green fluorescence, FL2, orange fluorescence, and FL3, red fluorescence (Fig. 1(right)).

The least expensive and simplest flow cytometers are analysis-only instruments; their operating simplicity and reproducibility make them ideal for use in quality control procedures. For more than double the cost of an analysis-only instrument, a flow cytometric cell sorting instrument (FCCS) can be purchased (Fig. 1(right)). The FCCS uses one of two mechanisms to physically collect particles with particular characteristics determined by the operator. The most commonly used mechanism involves the use of a bimorph crystal to vibrate the flow cell. The vibration causes the stream of sheath fluid to form undulations and then break up into droplets. The stream of droplets passes between two deflection plates, which can be positively or negatively charged. Individual droplets can be charged with a negative or positive charge by charging the sheath stream at the nozzle, for the fraction of the second that it takes for a single droplet to form at the end of the sheath stream. This results in a single charged droplet being formed, which then passes between the two charged electrodes. The charged droplet is attracted to either one of the electrodes where it can be collected into a test tube, multiwell plate, or onto a microscope slide. The advantage of this droplet deflection sorting method is that it can operate at very high speed, as fast as 70,000 sorts per second. Also, by charging one droplet with a negative charge and another with a positive charge it is possible to sort two different types of particles simultaneously. The major problem with this type of sorting is that it is very complicated to set up and align the instrument.

The second sorting mechanism is employed by the Becton Dickinson FACScalibur and involves deflecting particles into a side stream by a mechanical arm. After the particles in the sheath stream have passed through the laser, the sheath stream approaches a "Y" shaped intersection. The majority of the sheath fluid and all the particles within the sample travel via the right arm of the "Y." A small amount of the sheath fluid, but no particles within the sample, travels down the left arm of the "Y." A mechanical arm at the "Y" intersection can come out into the stream and deflect particles down the left arm of the "Y." The particles can then be collected into a tube or onto a membrane. The advantage of this sorting mechanism is that it requires no setting up or alignment prior to use. It is very simple to perform and requires little or no experience. However, this sorting mechanism is not suitable for many applications because it is only capable of sorting up to 200

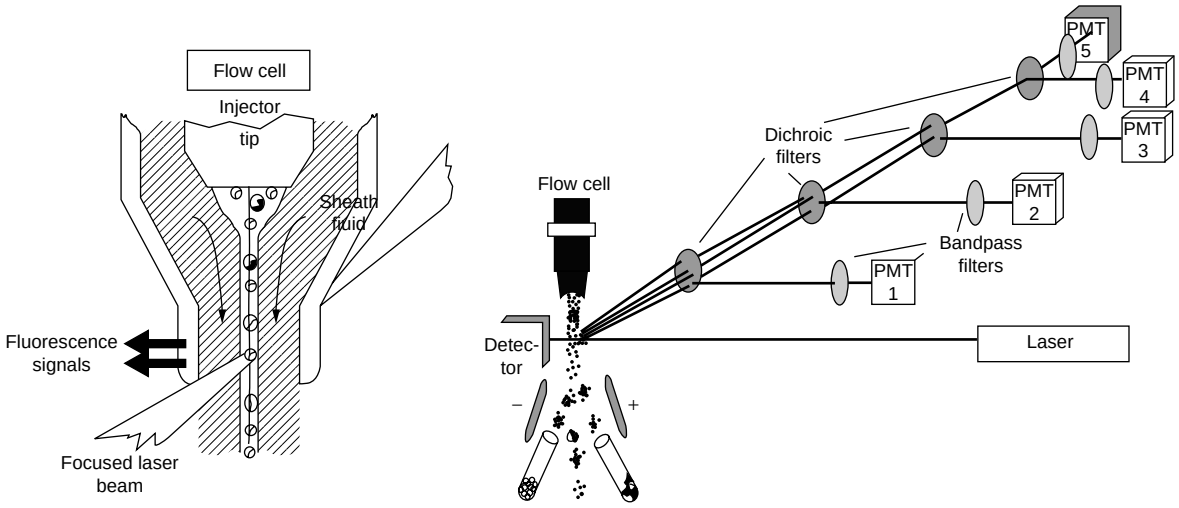

Figure 1. Flow cell illustrating sheath fluid and analysis of light scatter (left). particles per second. A further disadvantage is that the particles are sorted into a continuous stream of fluid rather than in a small droplet. This means that all the fluid is also collected, so particles typically require concentration by either centrifugation or filtration.

The large range of user changeable options on some sorting instruments make them considerably more difficult to operate than analysis-only models. Wavelength-scanning flow cytometers are also being investigated (25), and the so-called solid-state cytometers have recently been marketed for microbiological examination of water and food, where microbes have been collected on slides or membranes. These latter cytometers work by scanning the laser light over the flat surface and recording light scatter and fluorescent signals from cells in a similar way to that used in analyzer flow cytometers. Examples of such instruments include the ChemScan RDI instrument (Chemunex, Maisons Alfort, France) (Fig. 2) and CompuCyte (CompuCyte Corp., Cambridge, Massachusetts, USA).

A range of instruments are available that can detect cellular microorganisms and measure their light scatter and fluorescence properties. Particles that are sufficiently different in measurable properties can be discriminated and, using cell sorting instruments, physically separated from one another. For example, it is possible to differentiate some taxa of microorganisms, such as algae from yeasts from bacteria, simply by measuring the light scatter and autofluorescence of the individual cells (24). However, even with the best resolution available with conventional FC, most microorganisms within any particular phylum would be impossible to tell apart without artificially introducing some difference. For example, the majority of bacterial species, incredibly diverse although they are, appear very similar in terms of their light scatter and autofluorescent properties. To overcome this limitation, labeling techniques are used that discriminate groups

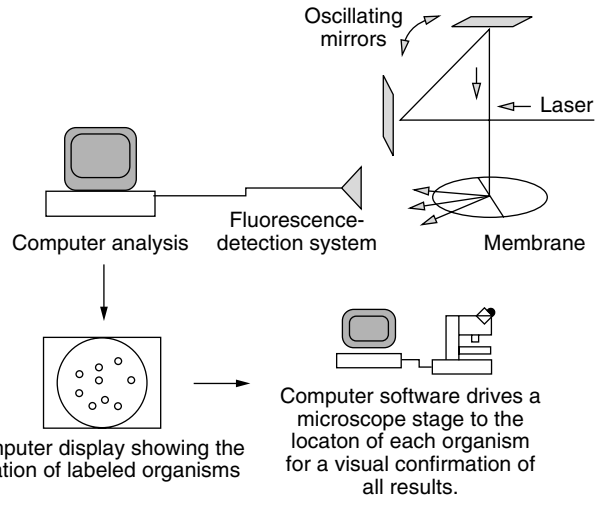

Figure 2. Detection of labeled organisms using the ChemScan RDI instrument. After analysis, the system permits all fluorescent events detected on the membrane to be visually validated by an automated microscope (from Ref. 26).

of microorganisms, typically by making them fluorescent. Various fluorescently labeled antibodies, lectins, and nucleic acid probes or fluorescent dyes are available (27). A considerable range of fluorescent dyes (fluorochromes) are available, for example, ones that bind to specific cell compounds, such as proteins (fluorescein isothiocyanate [FITC]), nucleic acids (propidium iodide [PI]), and lipids (Nile Red); those whose fluorescence depends on cellular physiological parameters (pH, membrane potential, etc.); and those whose fluorescence depends on enzymatic activity (fluorogenic substrates), such as esterases, peroxidases, and peptidases (Table 1) (13). Nonetheless, the most common application of fluorochromes is through their uses when conjugated to antibodies or nucleotide probes to directly detect cell antigens or sequences of DNA or RNA.

Flow cytometers count thousands of cells for each sample and for each cell the amount of forward and side angle light scatter and fluorescence collected by the various detectors is recorded. The actual amount of light (fluorescence or scatter) that is detected is recorded as arbitrary numbers, called *channels*. Channel values range from 0, corresponding to the lowest intensity, up to the highest intensity that can be a number from 64 to 9,999 depending on the setup of the analysis software. The raw data from the flow cytometer could be tabulated, as shown in Table 2.

It is possible to utilize all the data presented, as presented in Table 2, and look at the properties of each cell individually, as one might do when looking down a microscope. For example, in Table 2 the first cell had brighter green fluorescence (FL1) than the second, but that the second cell had brighter red fluorescence than the first and may be a different cell type. The third cell had almost no fluorescence at all and may be different again. With so many thousands of particles to consider however, flow cytometric data is not analyzed in this way, but is plotted in a number of readily interpreted formats. The most common data formats presented are histograms and dot-plots. Histograms show one property, perhaps FL1 intensity, against the number of cells that had a particular intensity for that property. Dot-plots display two properties against one another, for example, SSC against FL1. On a graph of SSC versus FL1, every cell would be shown as one dot, hence the term dot-plot. The limitation of dot-plots is that cells with the same measured optical properties are piled up on top of one another. Three-dimensional isometric plots and contour plots are variations on the normal dot-plot and are used to indicate the number of cells for each optical property coordinate (Fig. 3).

FC can be used to provide multiparametric data for each cell in the sample of interest. Hence, rather than visual comparison of two- or three-dimensional plots, more efficient methods to reduce the dimensionality of the data (such as principal components analysis or supervised multivariate data analysis) allows fewer graphs to be examined, and gives a statistical prediction of the identity of the analyzed particles. In this regard, artificial neural networks may prove to be the most suitable method of data analysis (28).

Table 1. Some of the Fluorescent Molecules Used to Study Microorganisms by FC (13)

Dye	Excitation Wavelength (λ_{max}) (nm)	Emission Wavelength Wavelength (λ_{max}) (nm)	Ligand or Substrate	Applications
TOTO-3	642	660	DNA, RNA	DNA quantification, cell cycle studies
SYTOX Green	504	525	DNA, RNA	Viability, DNA quantification
PI	536	625	DNA, RNA	Viability, DNA quantification, cell cycle studies
Ethidium bromide	510	595	DNA, RNA	DNA quantification, cell cycle studies
Hoechst 33258/33342	340	450	DNA (GC pairs)	Cell cycle studies
SYTO 13	488	509	DNA, RNA	Viability, DNA quantification, cell cycle studies
Mithramycin	425	550	DNA	Cell cycle studies
Pyronine Y	497	563	RNA	RNA quantification
FITC	495	525	Protein	Microbe detection
Texas Red (sulforhodamine isothiocyanate)	580	620	Protein	Microbe detection
Oregon Green isothiocyanate	496	526	Protein	Microbe detection
Indo-1	340	398–485	Ca^{2+}	Ca^{2+} mobilization
Fura-2	340	549	Ca^{2+}	Ca^{2+} mobilization
Fluor-3	469	545	Ca^{2+}	Ca^{2+} mobilization
BCECF	460–510	520–610	pH	Metabolic variations
SNARF-1	510	587–635	pH	Metabolic variations
$DIOC_6(3)$	484	501	Membrane potential	Antibiotic susceptibility, metabolic variations
Oxonol [$DiBAC_4(3)$]	488	525	Membrane potential	Antibiotic susceptibility, metabolic variations
Rhodamine 123	507	529	Membrane potential (mitochondria)	Antibiotic susceptibility, metabolic variations
Fun-1	508	525–590	Yeast vacuolar enzyme activity	Yeast metabolic state
Nile Red	490–550	540–630	Lipids	
Lectins	Depends on fluorochrome conjugated	Depends on fluorochrome conjugated	Membrane oligosaccharides	Cell wall composition, microbe detection
Fluorescently labeled oligonucleotides	Depends on fluorochrome conjugated	Depends on fluorochrome conjugated	Nucleotide sequences	Microbe identification
Calcofluor white	347	436	Chitin and other carbohydrate polymers	Fungal detection
Substrates linked to fluorochromes			Enzyme activities	Metabolic activity
Antibodies labeled with flurochormes			Antigens	Microbe detection

First cell	50	70	921	310	105
Second cell	120	90	191	250	940
Third cell	38	94	2	2	4
⋮	⋮	⋮	⋮	⋮	⋮
*n*th Cell	80	52	690	500	321

APPLICATIONS

Conceptually, there are two approaches used in analytical FC. The most common is population detection and enumeration, in which the clustering of numerous events forms a population. In these circumstances, there may be some overlap between the optical properties of the target population and that of other particles, but by virtue of the shear weight of numbers the presence of the target cell type is perceived. On the other hand, rare or single target cells would either be impossible to discriminate from the background noise or be considered negligible in number.

Therefore, the second conceptual area is the detection of rare events, in which a single event may need to be

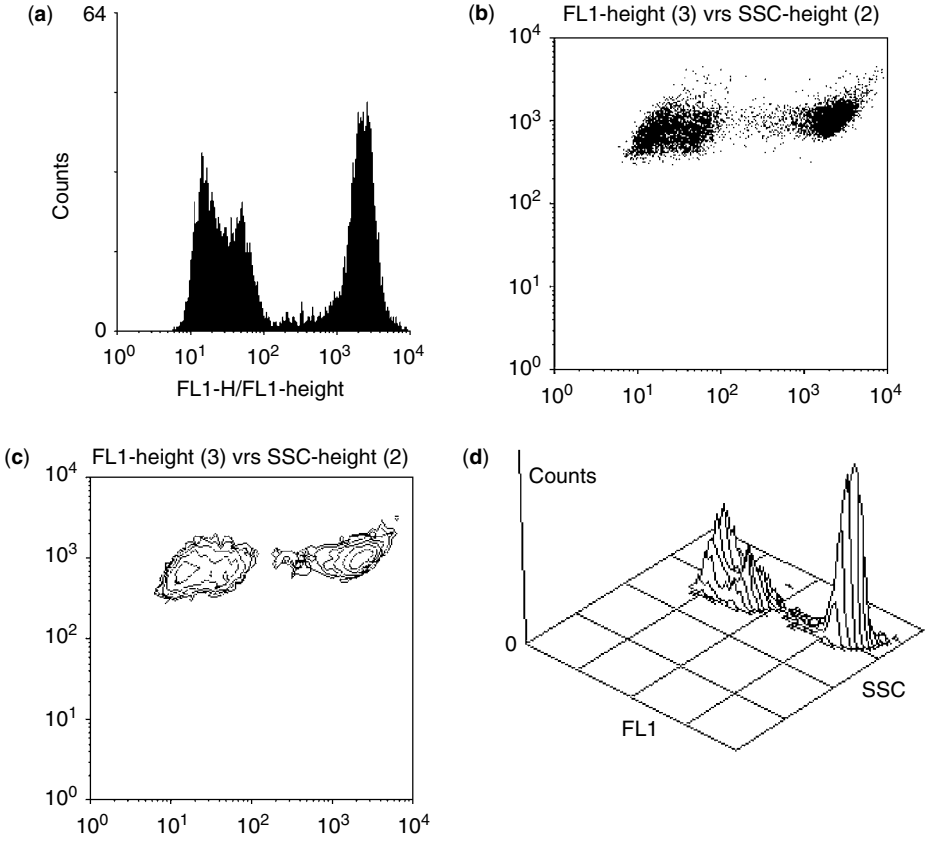

Figure 3. Some common plot types used for flow cytometric data presentation. Panel (**a**) shows a histogram plot for which the *X*-axis shows green fluorescence (FL1) and the *Y*-axis shows the number of cells with a particular fluorescence values (counts). Panels (**b**), (**c**), and (**d**) show a dot-plot, a contour plot, and an isomeric plot, respectively. In these cases, the *X*-axis shows green fluorescence (FL1) and the *Y*-axis shows SSC. Note that for (**b**), the number of cells at each intensity coordinate cannot be determined, whereas this information is given by contours for (**c**) and by a 3D projection for (**d**). Furthermore, the FL1 and SSC axis scales are logarithmic. Such logarithmic scaling is often used to fit cells with very different fluorescent or light scatter properties onto the same plot.

detected and considered to be a positive target (Fig. 4). This requires the target cell type to have optical properties that are very different from any other particle that may be encountered in the samples of interest, a very challenging test for microbiological analysis of complex and highly variable real-world samples.

Simple cytometers can be used to perform total counts of microbial cultures, such as the Chemunex Autosystem (29) or Microcyte (24). There is, however, an advantage in using more complex instruments, such as the Becton Dickinson FACSCalibur or Coulter XL, in that multiparameter analysis permits several measurements to be made simultaneously. For example, Deere and coworkers (30) used a live cell stain, a dead cell stain, and standardized fluorescent counting beads in a three-color assay. As the machine setup can be recorded and reagents combined into a one-tube kit, the three-color assay is as simple to perform as the one-color equivalent but provides additional data.

Total and Viable Counts of Environmental Communities

A first step in the microbial analysis of nonsterile samples is the determination of the total cell count and total viable count of microorganisms present. This gives a measure of the microbial loading and activity (bioburden) of a sample. In assessments of environmental health, determinations of the environmental bioburden provide valuable data. For example, clean waters tend to have lower microbial loadings than those polluted with organic matter. There are many circumstances under which water used in the production, for example, of foodstuffs and pharmaceuticals may not have to be sterile but the bioburden must be within acceptable limits. The effectiveness of routine processes to destroy microorganisms is also assessed by the determination of the bioburden (viz. heterotrophic count in treated waters).

Total Counts. Owing to the nonculturability of most environmental microorganisms, and the labor involved in microscopic techniques, FC is a first choice method for making bioburden determinations in environmental water samples, and staining and analysis methodologies are at an advanced stage. Total counts of waterborne microorganisms have traditionally involved epifluorscence microscopic enumeration of microorganisms supported on

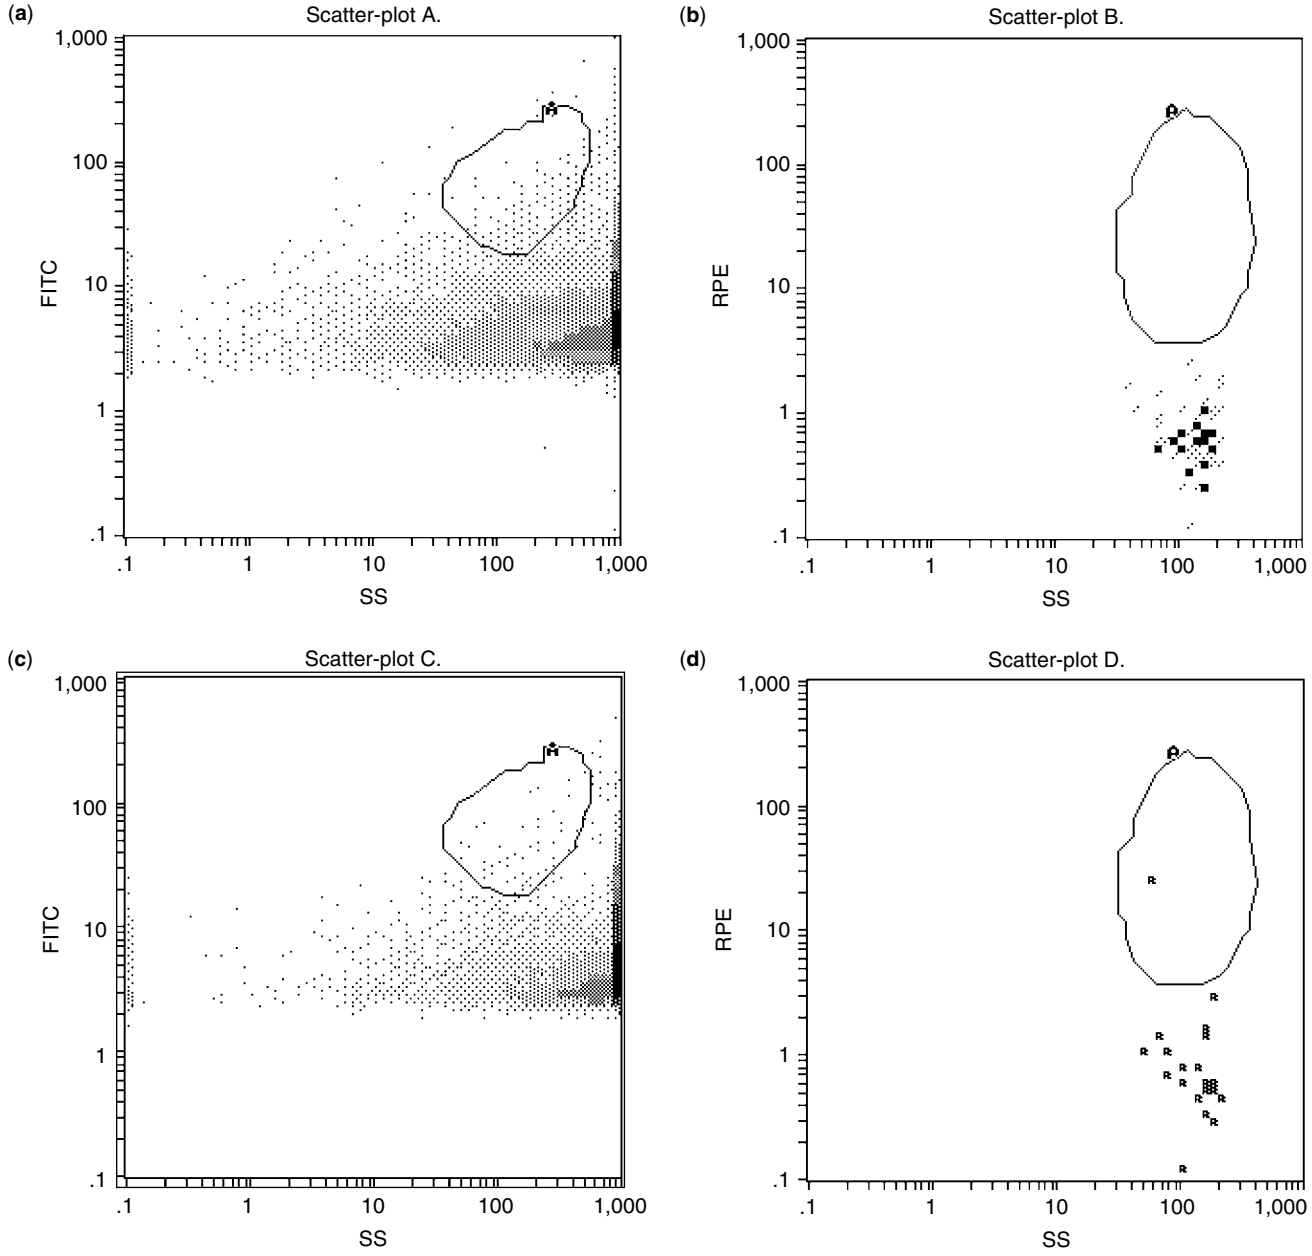

Figure 4. Analysis of river water samples for *D. discoideum* spores. Spores were stained with FITC and PE using two different spore coat mAbs. Axes are Log 90LS (SS) and either Log FL1 (FITC) of Log FL2 (RPE). Scatter plots A and B represent a negative (unseeded) sample. The area in scatter plot B is used to gate scatter plot B. All spores will appear in the area on scatter plot B. Note that there was no spore in this area on scatter plot B. Scatter plots C and D represent the same analysis performed on a similar sample seeded with an estimated single spore. Note the single particle in the area on scatter plot D.

a filter after staining with nucleic acid intercalating dyes, such as acridine orange, DAPI, or Hoescht (31). Various UV excitable dyes have also been used in FC (Table 1). However, the visible excitable nucleic acid stains exhibit significant staining of noncellular particles. Furthermore, the use of DAPI or Hoescht dyes is limited to the handful of microbiology laboratories with access to cytometers configured with UV excitation sources (most use 488 nm lasers). Nonetheless, new generation dyes that have superior nucleic acid specificity compared with acridine orange and are excited by a 488-nm light source have recently become available. For example, Gasol and Del Giorgio (32) have reviewed a range of new SYTO dyes and shown them to give similar results to those obtained with DAPI and direct epifluorscence microscopic counts. Pioneering work by Marie and coworkers (33) involved using the SYTO dyes and many other nucleic acid stains in an attempt to develop methods for the analysis of marine samples. Initial attempts proved unsuccessful because of the delicate biota of these marine samples necessitating

staining directly in the seawater, Hoescht remained the most appropriate dye for this purpose. More recently, 488 nm excitable nucleic acid stains were found to perform adequately in lightly buffered seawater (34). Analysis of both marine samples and pure microbial cultures labeled with the new dye yielded staining patterns, subpopulation distributions and counts that were similar to those obtained after Hoescht staining.

Viable Counts. Rapid bacterial detection and viability measurements have been greatly enhanced by recent advances in the use of fluorescent stains in cytometry. It has previously been shown that four physiological states can be distinguished: reproductively viable, metabolically active, intact, and permeabilized. Previous sorting experiments have shown that not all intact cells readily grow, but some intact cells can grow even when they fail to show metabolic activity, as determined by esterase turnover. To circumvent the limitations imposed by active dye extrusion or cell dormancy on viability measurements used to date (e.g., enzyme activity or cell polarization), a fast triple fluorochrome staining procedure has been developed that takes account of these problems. This allows further cellular characterization of intact cells by active exclusion of ethidium bromide (EB) (metabolically active cells), uptake of EB but exclusion of bis-oxonol (de-energized but with a polarized cell membrane), and uptake of both dyes (depolarized). Permeabilized cells were identified by PI uptake. The method was validated using an electronically programmable single cell sorter (EPICS Elite®) and aged *Salmonella typhimurium* cells. Reproductive viability was determined by sorting single cells to their staining pattern directly onto agar plates. Most polarized cells could be recovered as well as a significant fraction of the depolarized cells, demonstrating that depolarization is a sensitive measure of cell damage but a poor indicator of cell death (35).

There is considerable discussion in the literature on the possible existence of a viable but nonculturable (VBNC) state in many pathogenic and environmental bacteria (36–40) (see Viable but Not Culturable Microorganisms, this Encyclopedia). FC was used directly by Kell and coworkers (38) to investigate, for each cell, attributes, such as apparent cell integrity and the possession of some form of measurable cellular activity and compared to growth on artificial media (culturability). They clearly showed that putative VBNC cells were present, but suggested that most of the reports claiming a return to culturability have failed to exclude the regrowth of a limited number of cells that had never lost culturability. Hence, failure to clearly differentiate between the terms "viability" and "culturability" is fuelling the current debate, and Kell's group along with Barer and Harwood (41) suggest the replacement of the term "VBNC" with expressions that are internally consistent.

An investigation by Domingo and coworkers (42) on the survival of four *Salmonella* strains in river water microcosms included comparisons to standard culturing techniques, direct counts, whole-cell hybridization, scanning electron microscopy, and resuscitation techniques via the direct viable count method and FC. Plate counts of bacteria and in situ hybridization studies suggested a rapid decrease in ribosomal content and viability in filtered and untreated river water (several orders of magnitude within the first week of incubation). In contrast, direct counts remained relatively constant during 45 days in all microcosms. Although the culturable counts of two bacterial strains in filtered water after 31 days represented approximately 0.001% of the total counts, direct viable counts and resuscitation studies with a dilution series suggested that the number of viable bacteria was at least four orders of magnitude higher. Additionally, notable changes in forward scatter and in nucleic acid content were observed by FC only 4 hours after nutrient amendments. However, cells from the resuscitation experiments did not grow on solid media unless cell-free supernatant from viable cultures was added during the resuscitation period. The authors concluded that no immediately culturable *Salmonella* were present, which is similar to the conclusions drawn by others (40).

Total viable bacteria in marine aquaculture have also been determined, using a fluorescein diacetate (FDA) FC method (43). Within a few minutes the difference in the fluorescence scattergram between viable and dead was determined, and with the addition of an antibody, cells of the fish pathogen *Lactococcus garvieae* could be enumerated. One FC assay could be completed within 2 minutes and the total assay time including the preparation of bacterial sample was within 3 hours.

In many circumstances, microbial viability assessment is just as important as the determination of total microbial numbers. However, as is evident from the above discussion, a generally applicable probe for assessing total bacterial viability has not been conclusively identified. One difficulty is that any assessment of viability would require the measurement of some degree of activity and microorganisms with very low levels or in states of dormancy would be very difficult to distinguish from dead ones. Nonetheless, FC in combination with fluorogenic assays of enzyme activity has been shown to be appropriate, and FC can even be employed in difficult media, such as milk (44).

Determinations of Proportions of Major Subpopulations

The discovery of a major genus of marine photosynthetic prokaryotes by FC (45) demonstrated the power of FC for enumerating subpopulations of aquatic microorganisms. Fluorescent emission from endogenous pigments (Chlorophyll-A and phycoerythrin) is used to detect the phototrophs and fluorescent DNA stains are used to determine total microbial numbers. The information is combined with light scatter data to discriminate several ecologically diverse microbial groups. Using bivariate plots, as many as six taxa can be conclusively discriminated and results have demonstrated that the heterotrophic subpopulation had been grossly overestimated in the past owing to their increased culturability (46). More complex statistical techniques discriminated even more taxa; Carr and coworkers (47) used a multivariate approach to group 32 distinct populations of phytoplankton. Neural networks have also been trained to discriminate naturally fluorescent planktonic subpopulations (48). However, although these studies are useful and powerful,

they are ultimately limited by their reliance on discrimination based on inherent optical properties.

A more detailed and rational assessment of the true phylogenetic biodiversity and constitution of environmental samples is extremely difficult to achieve owing to the nonculturability and optical similarity of most microbial species. At present, quantitative direct methods for phylogenetic discrimination of microorganisms can be achieved by hybridizing fluorescent oligonucleotides of defined specificity to the ribosomes in situ within permeabilized whole cells (49,50). For example, FC was used to directly analyze the microbiota of activated sludge (the microbial consortium used to treat most of the sewage and wastewater in the developed world) to quantitatively assess the contributions of different phylogenetic groups to the sludge floc community. Data analysis revealed phylogenetic distributions substantially different from those found using culture based techniques leading to an improved understanding of floc microbiology (51). Similar problems were identified for marine bacterioplankton analyses, where even relatively short-term dilution-culture experiments do not measure in situ growth, but rather growth patterns of a selected enrichment (52). Furthermore, Fuch and coworkers demonstrated that the combination of flow cytometric analysis and sorting combined with fluorescence in situ hybridization (FISH) and degrading gradient gel electrophoresis analysis presented a fairly rapid method of analyzing the taxonomic composition of marine bacterioplankton. The FISH procedure has also being developed as a tool for species level phylogenetic tagging of protozoan pathogens detected in water samples, as the antibodies used are only genus-specific (53–55).

Detection of Specific Cell Types

In the FC detection of individual species or strains of microorganisms, one is often looking for rare events in a background of many nontarget organisms. Prepurification protocols may be possible, but are not preferred, owing to the complexity of the method and potential losses. Hence, key issues discussed next include FC sensitivity and thresholding, both necessary instrument limitations that need to be understood for single event monitoring.

Sensitivity. The detection of low densities of a precisely defined target group of microorganisms is essential for routinely monitoring microbial pathogens and studies of epidemiology and microbial ecology. The specificity of the target group ranges from very general (e.g., wild-type yeasts in a wine production culture), up to strain specific (e.g., *Escherichia coli* serotype 0157 : H7 in meat products). The density of the target microorganisms that it is desirable to detect also varies. For example, for practical monitoring, organisms that have a very high probability of infection per organism, such as the protozoan *Cryptosporidium parvum*, require analysis that can detect one organism per 100 L of water. In comparison, bacterial pathogens, such as *Legionella pneumophila* that have a very low probability of infection per organism, only require analysis that can detect several hundred per milliliter of water. Nonetheless, what these applications have in common is the relative rarity of the target population, typically constituting much less than 0.1% of the microbial community.

Furthermore, to the flow cytometer, the target cells are just another particle and the inherent scattering and fluorescent properties of microbial cells are very similar both to one another and to many noncellular particles. International food and water guidelines often suggest detection limits of one cell in extracts from 25 g of food or concentrates from 100 mL of water, a target cell could be just one of say 10^{11} particles that would be detected above the maximum triggering threshold appropriate for the inherent cellular properties of the target cell type.

Thresholding. A quick calculation reveals that for a flow cytometer to analyze 10^{11} particles at a rate of 10,000 per second (the maximum rate for most cytometers) would require an analysis time of about 4 months! Flow cytometers can, however, analyze samples at rates much greater than 10,000 events per second if the cytometer is set up so that it ignores most of the particles; this is called *thresholding*. The cytometer is set up with a threshold level on one parameter (e.g., forward angle light scatter or a fluorescence detector). Any particles that produce a signal on the threshold parameter below the threshold level are ignored by the cytometer. In most traditional applications of flow cytometry, light scatter is used as the threshold. When attempting to detect a single particle in among 10^{11} other particles with similar light scatter properties this is obviously not appropriate. Therefore, some optical difference must be artificially created between the target and extraneous particles to enable threshold determination. The degree and specificity of this difference is proportional to the threshold level that can be applied and in turn to the speed at which the sample can be analyzed. In almost all applications of flow cytometry to rare cell detection, the optical discriminator used to resolve target from nontarget microorganisms is a fluorescent intensity measurement resulting from a specific fluorescent label. However, it would also be possible to resolve emissions using phase, time, or spectral fingerprint. In practice, the degree of specificity required depends on the desired detection sensitivity. The ultimate sensitivity achievable is the conclusive detection of one microorganism from a large and complex sample, for example, 100 mL water or homogenate of 25 g food.

Detection of Single Cells. The development of a detection method simply involves defining one or more regions, on dot-plots, which enclose all target cells. No events should appear in that region for samples from which that cell type is absent. Furthermore, the number of seeded or naturally occurring target cells present in a sample should equate to the number of events in this region. However, the attainment of such simple methodology and exquisite sensitivity requires a degree of specificity that is very difficult to achieve.

Negative samples often contain interfering particles that will appear within the defined target region. These interfering particles can be either mineral or biological in nature and fluoresce owing to association with the fluorescent label or inherent autofluorescence. Some of the interference may not be from a real particle at all, but

generated by internal electrical noise from the cytometer circuitry that the cytometer mistakes for a particle. Despite these difficulties, detection of single specific microorganisms has been demonstrated. For example, in concentrates prepared from 5 L of turbid water samples Vesey (56) detected the spores of a protozoan slime mould, *Dictyostelium*, at a level of one spore per sample. The organism was labeled with phycoerythrin (PE) and FITC using two monoclonal antibodies that bind to the surface of the spores. The region enclosing stained spores was determined from their light scatter, green fluorescence, and orange fluorescence characteristics. The analysis protocol consisted of enumeration of events within the region representing FITC labeled spores on a dot-plot then gated by the region delineating PE labeled spores (Fig. 4). This level of sensitivity required two highly specific labels and was achieved, without need for sorting and confirmation, using an analysis-only flow cytometer.

Although macromolecular stains, such as nucleic acid intercalating dyes, exhibit excessive nonspecific binding, they are at least partially selective. A number of studies have used this selectivity to help reduce the background count from negative control samples by discriminating dye stained (including cells) from nondye stained particles. For example, using PI, Page and Burns (57) were able to significantly reduce, although not eliminate, background noise. The additional parameter of PI staining was useful when using FC to enumerate flavobacteria introduced into soil. Nonetheless, all methods, including FC, are limited for determining whole-cell numbers in soils and sediments owing to the difficulty of recovering cells bound to particles and aggregates (57).

High Sensitivity Analysis Using Cell Sorting. If a highly specific labeling regime suitable for FC is unavailable, the analysis-only flow cytometer will detect some false-positives and will not conclusively detect rare cell types. Under these circumstances, FC may still be useful in the detection of extremely rare cell types when applied as a means to physically select suspect particles (target cells and false-positives) by sorting. Flow cytometric cell sorting (FCCS) rapidly purifies and concentrates a sample for subsequent analysis using methodologies such as culture, microscopy, or gene probes. For example, Porter and coworkers (58) used FCCS to sort *E. coli* from polluted lake water. Positive events were selectively sorted and subsequently cultured for confirmation and enumeration in the presence of a much-reduced level of competing microorganisms.

During the mid-1990s, water utilities across the globe took to FCCS as part of routine monitoring of water for the presence of cysts and oocysts of the protozoan pathogens *Cryptosporidium* and *Giardia* (59,60). The protocols used could detect one cyst or oocyst in concentrates prepared from 10 to 1,000 L of water, depending on turbidity. Suspect particles were identified by the cytometer, sorted onto slides and enumerated by microscopy. These protozoan pathogens are the most commonly identified cause of waterborne disease in developed countries (61). The cysts and oocysts are robust enough to survive conventional water purification procedures, such as chlorination. This robustness also leads to their prolonged persistence in environmental samples such that they remain viable far longer than the indicator organisms normally used to detect fecal contamination. The probability of infection by very low doses is appreciable. This means that, for practical purposes, any detection method for treated waters would need to be able to find one cyst or oocyst in 10 to 1,000 L of water (62). Of all the methods available, those using flow cytometric sorting are the most effective currently developed (59,63), but methods using less expensive hardware are generally preferred (64).

RAPID METHODS USING FC

FC is probably the method of choice for reliable, rapid, and automatic microbiological analysis. If direct detection is not used, then selective concentration of target-cells, either aids microscopic or molecular analysis. In such a case, FC behaves as an advanced sample preparation method. For detection of specific culturable or nonculturable cells, sensitivities may need to be in the range of one cell per 25 g food or 100 mL water. Emerging microarray technologies (65), are currently less sensitive and require field testing for environmental samples.

Of a range of possible techniques, viability assessment in combination with immunolabeled bacteria with two/three color fluorescence flow cytometric analysis offers excellent activity measurement of specific cell types (66). For example, with the appropriate filter sets on commercial cytometers (Bryte-HS, Bio-Rad, Hercules, CA and FACScan, Becton Dickinson, San Jose, CA), the measurement of separated green (SYBR Green I), orange–red (PI), and far red (RPE-Cy5) fluorescence is possible, allowing the enumeration of viable immunodetected bacteria. Such a technique is quick (<3 hours), and offers numerous possibilities for rapid and precise analyses in sanitary, industrial, and environmental microbiology (43). Rapid methods can also be applied to the detection of human viruses in the environment, with infectious viruses being stained within host cells (11,67) or by detecting changes in the host cell morphology (cytopathic effect), both at an earlier stage than by conventional methods (68,69). Marie and coworkers (70) also describe the use of FC for direct detection of aquatic viruses in the marine environment, and a range of viruses more generally (71).

Sample Preparation for FC

In sample preparation, there are four important issues:

1. *Retention of target cells*, particularly important in quantitative assays, as, unknown losses of target cells will contribute to the analysis yielding an inaccurate, and probably highly variable result. The most common processes that impact on the full retention of target cells are concentration and purification. Commonly used concentration methods, such as centrifugation or filtration, often result in portions of a sample (and therefore target cells contained within the sample) being lost. Also, the forces applied to cells in samples processed these

ways can cause physical damage, which means that they are not recognized as target cells by the flow cytometer, and ultimately are incorrectly omitted from the result. Where concentration and/or purification of a sample is performed as part of a quantitative assay, losses of target cells must be assessed and accounted for accurately.

2. *Size limitation of particles in a sample*, particles contained in a sample analyzed by a flow cytometer must pass wholly through the flow orifice (typically less than 100 μm in diameter), and not disrupt the laminar flow when it does. To avoid the possibility of two particles jamming together in the flow orifice, and thereby blocking the orifice, the maximum size of particle in the sample should be at most half the diameter of the flow orifice. In practice, particles larger than half the diameter of the flow orifice can be analyzed by a flow cytometer; however, blockages do occur frequently the larger the inherent sample particle size becomes. The size of particles contained in a sample can be limited by passing the sample through a mesh filter of specified weave size. However, when processing a sample in this way prior to flow cytometric analysis, care must be taken to ensure that the number of target cells lost from the sample is assessed.
3. *Ensuring a monocellular sample*, as flow cytometers can only analyze discrete entities within a sample. A floc of particles is recorded by the cytometer in the same way as a large particle. This means that the instrument cannot discriminate between a large particle and a clump of particles. If clumps are not dispersed, target cells may not be analyzed by the flow cytometer because they have been part of a clump of particles. Thus, it is important that the particles within a sample are monodispersed prior to flow cytometric analysis, such as by the introduction of surfactant agents (e.g., detergents), or physically (e.g., vigorous vortex or passing through a mesh filter).
4. *Removal of fluorescent staining inhibitors*, which can dramatically affect the performance of immunofluorescent staining methods used to selectively label target particles. This is mostly owing to substances inhibiting the monoclonal antibodies from binding to the target epitopes. These substances can include soluble organic and inorganic compounds (e.g., alcohols or salts). It is for this reason that the suspension fluid of the sample must be compatible with antibodies used to perform the immunofluorescent staining. Replacing the suspension fluid with a suitable buffer can be done by concentrating the sample and re-suspending in a new buffer solution. However, throughout the concentration steps, attention must be given to the guidelines given above for sample preparation in order to preserve the other properties of the sample.

Labeling of Cells for FC

For FC, discrimination of different cell types and particles is generally achieved using fluorescent labels, as described in the previous sections. Fluorescent probes exist for a variety of cellular functions; here, we restrict the discussion to those that reflect cell viability (72). Although the debate as to the efficacy of these probes (i.e., whether they truly reflect viability) is likely to continue as a subject of some controversy, they can be unequivocally validated for particular applications. For example, Porter and coworkers (73), Diaper and Edwards (74), and Deere and coworkers (30) applied this principle to validate a range of dyes as alternatives to colony counts by measuring the culturability of stained and unstained cells after sorting. Assay confidence can be further improved by using combinations of probes that preferentially stain either live cells or dead cells. Even the protein content of cells has been determined using fluorescence and FC (75).

Physiological Labels. To flow cytometrists, the most familiar method of determining viability of leukocytes is the use of dye exclusion by intact membranes. These methods are also applied in microbiological studies to bacteria (76–78) and yeast (30,79). Cells with intact membranes are effectively impermeable to charged dyes, such as PI, EB, and SYTOX. However, if membrane integrity is lost, these dyes can enter and concentrate in association with the nucleic acid within cells, causing permeable cells to become fluorescent. PI is the preferred choice for dye exclusion assays because it has two positive charges making it less permeable than dyes, such as EB or 7-amino-actinomycin D (7AAD) with only one. Emission maxima are green for SYTOX dyes and red for PI, 7AAD, and EB. Problems of nonspecific binding may limit the live/dead discrimination accuracy of dye exclusion methods in highly particulate samples.

Membrane potential studies rely on the presence of an electrochemical transmembrane potential (more negative inside) to preferentially concentrate positively charged dyes, such as rhodamine 123 (Rh123), or exclude negatively charged dyes, such as those from the oxonol group (80–82). Rh123 has been used successfully to determine the viability of pure cultures of bacteria and yeast cells. Staining of dead cells has been investigated using oxonols alone with bacteria (81) or in conjunction with other indicators such as calcofluor white for yeast (82) and protozoa (83), PI for bacteria (80,84), esterase substrates for bacteria (85), or esterase substrates and PI for yeast (30). Rh123 and oxonols are inherently fluorescent, requiring selective concentration within the cell for detection. Whilst this may be acceptable for pure culture applications, nonspecific binding of fluorescent dyes is noted in environments laden with particles (73). In our experience, oxonol is the preferred dye for membrane potential measurements because Rh123 gives comparatively poor discrimination. Both dyes have green emission maxima and are therefore not spectrally compatible in dual stain assays, but can be used in conjunction with dyes such as PI (30).

Many esterified fluorochromes remain nonfluorescent until cleaved by intracellular enzymes, whereupon a fluorescent product is released. Cells only become fluorescent after substrate cleavage by functional cytoplasmic enzymes and product retention by intact membranes.

Therefore, two cellular functions are measured for added assay confidence. Dyes measuring viability using a similar principle are marketed commercially, one for bacterial cells and the other for fungal cells (e.g., Chemunex SA, Paris). The first studies using these types of dye, using FDA, showed poor product retention (86). However, derivatives are now available that have improved retention resulting from additional functional groups. For example, carboxy fluorescein diacetate (CFDA, 27) uses a carboxy group to reduce membrane permeability whilst chloromethyl fluorescein diacetate (CMFDA, 27) includes a chloromethyl moiety that covalently links the esterase substrate to intracellular molecules. A number of these derivatives were investigated using a range of species to monitor the viability of bacterial cultures (74). All were selective to some degree, the most widely applicable being CFDA or ChemChrome B. The validity of these dyes for reflecting true viability during stress has been reported for two bacterial species, *Klebsiella pneumoniae* (74) and *E. coli* (73). Both reports show that during stress incurred by incubation in lake water, the viable count using these fluorescent probes correlated well with the generally accepted standard for viability determination, the direct viable count (DVC, 87). As the DVC measures cell elongation, there is little question that responsive cells are viable. The correlation of the two approaches provided firm evidence that the more rapid fluorescent ester method genuinely reflected viability, despite the stressed cells entering a nonculturable state. These esterase substrates are less susceptible than inherently fluorescent dyes to limitations resulting from nonspecific binding. For example, Porter and coworkers (73) reported that esterase substrates were the dyes of choice to use for assessing total community viability directly in freshwater samples. Their green emission maximum makes them compatible with dyes such as PI.

The electron transport chain of respiring (viable) cells is capable of reducing the membrane permeant, nonfluorescent tetrazolium derivative 5-cyano-2,3-ditolyl tetrazolium chloride (CTC) to a red fluorescent insoluble formazan (88,89). If a cell is sufficiently active, enough precipitate will form for its discrimination from the background. One advantage of this method is that the precipitate may be fixed so as to provide an increased choice of secondary stains. Although this dye has proved useful for pure cultures, it is less generally applicable than esterase substrates for analysis of mixed populations (such as ChemChrome B and V6 dyes, 90) because different cell types require different optimum staining conditions, and abiotic production is also possible.

Enzymatic Labels. Many culture-based methods used specific biochemical assays to identify cell types possessing particular enzymes. For example, the enzyme β-galactosidase is produced by coliforms, where it is involved in fermentation of the sugar — lactose. Flow cytometric assays for β-galactosidase have been described (27) that are applicable to bacterial and yeast cells with active β-galactosidases, either naturally present or transfected. The methods are simple, requiring less than one hour, but specificity must be thoroughly tested in the appropriate sample type because most species of microorganisms in the environment have yet to be biochemically typed and false-positives may result.

Immunological Labeling. Immunological labeling methods are the most familiar to the flow cytometrist. They have demonstrated their utility as specific labels for flow cytometric detection, enumeration, and purification of specific microorganisms. Their scope is limited by the cost of developing specific antibodies. However, once the antibody has been developed production of reagents is inexpensive.

Antibodies must bind epitopes that are always present on, but limited to, the target cell type; if necessary, internal epitopes can be targeted. It is important to realize that epitopes expressed during culture may differ elsewhere, with consequent failure of the detection protocol. For example, during pure culture studies, a sewage isolate of *Ochrobactrum anthropi* bound antibodies during the exponential but not the stationary growth phase (72). It has also been shown that epitopes recognized by antibodies that bind to the surface of *Cryptosporidium* oocysts can be removed by environmental pressures such as water disinfection (91).

Antibodies are large protein molecules and will inevitably bind to contaminating particles present in some samples. These particles may possess the epitope (cross-reactive particles), or associate with antibodies through nonspecific binding. Therefore, the specificity and sensitivity is limited by that of the antibody. For example, antibodies used to detect *Cryptosporidium* are only genus-specific and cross-react with strains that are not harmful to humans (55). Micelles found in milk form globules that bind excessive amounts of antibody leading to very high levels of background staining, reducing sensitivity (44).

Immunofluorescent reagents include either a directly conjugated dye labeled antibody or a labeled secondary antibody that is used to label the primary. Monoclonal antibodies (mAbs) or polyclonal antibodies (pAbs) can be used. For specific detection, direct conjugation is preferable to using indirect secondary staining and mAbs are strongly preferred to pAbs. Furthermore, mAbs of the IgG1 or IgG2 subclass often produce the least nonspecific staining (54). Staining protocols are well understood and require less than 1 hour. However, if suitable antibodies are unavailable, many months or even years may be required for their successful production.

Conjugation of antibodies with fluorochromes is now a routine procedure. Methods are well described for clinical applications (92,93) and many antibody conjugates are commercially available. However, antibody conjugates prepared for an application such as staining clinical samples are often not suitable for staining environmental samples. A small amount of nonspecific binding of an antibody conjugate may go unnoticed when analyzing a stained blood or fecal sample, whereas analysis of an environmental sample stained with the same conjugate is likely to result in the target cells being undetectable as a result of the high background staining. Variation in the binding specificities of antibody conjugates can be due to a number of reasons. The purity of an mAb prior to conjugation with the fluorochrome can

affect its binding specificity (54). Insufficient purification can result in contaminating proteins being conjugated with fluorochrome; these fluorochrome/protein conjugates may bind nonspecifically to particles. The amount of fluorochrome conjugated to a mAb will also effect its binding specificity and brightness after labeling. If too much fluorochrome is conjugated to the mAb, any advantage gained from increased brightness of labeled oocysts may be counterbalanced by an increase in nonspecific binding. Conversely, if too little fluorochrome is conjugated to the mAb, it may not stain target cells with sufficient brightness. Also, the formulation of the mAb conjugate, the working concentration, and the staining procedure recommended by the manufacturer may not be optimum for the analysis of all sample types. Nonspecific binding of antibodies can often be significantly reduced by use of appropriate blocking agents and buffers (94,95).

An alternative to conjugating antibodies with fluorochromes is to conjugate the antibodies to fluorescent beads (96). Suitable beads are commercially available with a wide range of fluorescence excitation and emission properties. The antibody-labeled beads are mixed with a sample to allow the beads to capture the target organism. The target organism can then be labeled with a second specific fluorescent probe that has fluorescence properties that can be distinguished from the bead.

Phylogenetic Labeling. FISH methods, which label specific ribosomal RNA (rRNA) sequences inside intact cells, have been described ("phylogenetic stains"; 97). First, cells are fixed and permeabilized to permit entry of the probe to its target within morphologically preserved cells. Then, conditions of probe binding and washing are selected such that the probe will bind only to its rRNA target sequence. Finally, labeled cells can be visualized by FC. As ribosomes are found in such large numbers within bacterial cells, this naturally amplifies the fluorescent signal. Further, the sequence divergence between the rRNAs of different species has formed the basis of a classification system for microorganisms (98). Portions of rRNA sequences have evolved at different rates and target sequences range from highly conserved (throughout a phylogenetic kingdom) to highly variable (up to strain specific). Information on these sequences, combined with ribosome structural studies, give sufficient information for rational design of selective oligonucleotide probes (see review in Ref. 99). Flow cytometric discrimination of FISH-target bacteria (100) and HIV pro-virus within cell cultures (101) have been described. Wallner and coworkers (10) critically evaluated and optimized protocols for FC and more recently, a modified method was developed for fluorescent labeling of *Cryptosporidium* oocysts (102).

Oligonucleotide probe-conferred fluorescence appears to correlate to cellular rRNA content, which in turn may relate to growth rate, activity, or viability (102–105). In *Cryptosporidium*, FISH has been shown to provide a useful indicator of oocyst viability (102), which antibody labeling methods do not. This is probably owing to the short life of rRNA within nonviable oocysts. Further, FISH techniques can label oocysts with species specificity and so discriminate the species that infects humans (*C. parvum*) from other *Cryptosporidium* species that bind to the genus-specific antibodies used for routine monitoring.

Under conditions of nutrient limitation, such as following pathogen entry into surface or drinking water, however, faecal bacteria undergo a rapid drop in growth rate. The corresponding drop in cellular rRNA content causes hybridization signals to decrease to background levels of fluorescence. It is possible that microorganisms entering into dormant life-cycle phases, such as encystation or sporulation, may similarly undergo some reduction in rRNA levels. For example, we have observed that the fluorescence of oocysts labeled using FISH with FITC conjugated probes is typically more than an order of magnitude less intense than that of oocysts labeled with a FITC conjugated antibody. Therefore, for most species, FISH is limited to the analysis of populations from culture, clinical samples, or environments favoring the target cell type's activity. To date, only modest increases in fluorescent signal-to-background ratio have been achieved using techniques such as multiple probes to different sites on the ribosome (106), enzymatic labeling of probes (107), the use of polynucleotide probes with multiple labels (50,108), and peptide nucleic acid probes (109). A procedure of cell incubation in the presence of a DNA gyrase inhibitor but nutrients (to activate but not allow division of cells, called *probe activated count*, 110) may improve signal strength, but additional signal-to-noise may be necessary for routine FC monitoring of FISH-labeled cells.

Choice of Fluorescent Dye. The choice of fluorochrome used for conjugating reagents used to label microorganisms can have considerable effect on the sensitivity of flow cytometric detection. Different sample types may require different fluorochromes to achieve optimum sensitivity and should be analyzed accordingly. Detection sensitivity is determined by the degree of discrimination of target from nontarget particles. Some nontarget particles will have similar optical properties to labeled target cells owing to nonspecific binding of the fluorescent labels used.

In environmental samples, however, many of the interfering particles are naturally fluorescent (autofluorescent) and include biological debris, algal cells, and inorganic matter. For example, a FITC labeled antibody is used to discriminate *Cryptosporidium* oocysts from other particles. However, particles, such as autofluorescent algae, with similar fluorescence and light scatter characteristics to labeled oocysts are also detected and is one of the reasons that sorting followed by microscopic observation is used to confirm results. A recent study used flow cytometry and fluorimetry to analyze particles present in water to determine the optimum excitation sources and fluorescent labels to use for detection (63). The spectral regions with minimal interference caused by other waterborne particles were identified. The study looked at nine commercially available fluorochromes and four excitation sources covering the range 300 to 700 nm. The longer the Stokes shift (difference in excitation wavelength and emission wavelength) of a fluorochrome, the less the background emission present at its emission peak, and therefore, the more suitable it would be for labeling microorganisms. There was

a trend of decreased autofluorescence intensity at longer excitation wavelengths with two major bands of autofluorescent emission, the shorter beginning at 390, peaking at 440, and ending at 510 nm, and the longer beginning at 640, peaking at 675, and ending at 700 nm. Thus, particles naturally present in water samples would emit detectable autofluorescent noise within these spectral regions. For the detection of microorganisms in water samples, optimum sensitivity would be achieved by avoiding regimes that depend on excitation sources and fluorochromes that require detection in the spectral regions covered by these two autofluorescent bands. In contrast, the emission from waterborne particles was least intense when using an excitation wavelength of between 550 and 610 nm. This implies that the use of fluorochromes excited by wavelengths within this range would be the most appropriate for labeling microorganisms for their detection in water samples. Fluorochromes excited by UV light (351 nm) or red light (633 nm) appeared to be the least useful for labeling microorganisms in both drinking water and untreated water.

There are two main criteria for determining the best fluorochrome for fluorescent labeling of microorganisms in environmental samples. The first is that a labeled microorganism is sufficiently more fluorescent than the autofluorescent particles naturally present in the sample. On the basis of this first criterion, the 488-nm excited FITC fluorochrome is excellent for labeling oocysts in untreated water samples, while the 542-nm excited aminolink carboxymethylindocyanine dye (Cy3), PE, and tetramethylrhodamine B isothiocyanate (TRITC) were the best in drinking water samples (63). The second criterion is that the fluorochrome should not bind to (and cause an increase in the fluorescence of) the particles naturally present in the environmental sample.

The charge and surface hydrophobicity distributions differ between fluorochromes and this will effect the nonspecific binding properties of conjugates. There are reports, however, of cyanine dyes showing excessive binding to monocytes (15). Further advantages of FITC and CY3 are the excitation sources required. The 488-nm lasers are fitted to all conventional cytometers, with the 542 laser required to excite CY3 being the smallest and least expensive of alternatives.

CONCLUSION

The application of FC to environmental microbiology started with the paradigm of the instrument representing a type of automated microscope. The advent of a large array of possible fluorochromes and biochemicals to label target species has now reached a stage where direct analysis FC can be used not only to identify total counts of active cells, but also the presence of low occurrence microbiota within environmentally challenging samples.

As with the advent of other noncultivation techniques in microbiology, FC has both highlighted deficiencies in traditional methods as well as expanded our options for improved analysis of environmental samples. Nevertheless, while FC has taken off in the food and beverage industry, its application to environmental microbiology seems to have been hampered by the cost of instruments. Yet, FC is rapidly becoming a routine methodology in aquatic microbial ecology. The combination of simple to use bench-top flow cytometers and highly fluorescent nucleic acid stains allows fast and easy determination of microbe abundance in lakes and oceans. One of the main advantages of FC over epifluorescence microscopy is the ability to obtain cell-specific measurements in large numbers of cells with limited effort. This characteristic has been used for differentiating photosynthetic from nonphotosynthetic prokaryotes, for measuring bacterial cell size and nucleic acid content, and for estimating the relative activity and physiological state of each cell.

METHODS FOR THE IDENTIFICATION OF MICROBIAL ISOLATES

PENNY S. AMY
University of Nevada
Las Vegas, Nevada

DANA L. HALDEMAN
Community College of Southern Nevada
Las Vegas, Nevada

Isolation and identification of microbial isolates is critically important for industrial microbiology (biotechnology), understanding the ecological role of microorganisms and worldwide microbial diversity, and understanding of disease-causing microbes, both current and emerging. Isolating bacteria involves recreating the natural environment or mimicking it as closely as possible so that isolates change minimally during the process. Fresh-stock cultures should be preserved to provide cells that reflect natural characteristics for future use. Identification methods are currently based on classical techniques that have been used for more than a century, and new genetically based techniques developed over the last two decades. This chapter presents an overview of factors that should be considered when isolating and characterizing microbial isolates.

BACKGROUND

One of the great frustrations of microbiologists is the difficulty associated with naming and classifying microorganisms. Because they are so small, it is difficult to differentiate them by a mere handful of physical or morphotypic characteristics that can be gleaned from colony growth and the shape and arrangement of their cells viewed under a microscope. Therefore, traditional classification schemes have been based on physiological tests, chemical content, shape, color, and so on (1,2). These characteristics may vary because of mutation, genetic plasticity, or environmental influences, resulting in confusion and errors in identification. For example, *Serratia marcescens* produces a pink colony at low growth temperatures and a white colony above 30 °C, owing to inhibition of pigment formation. In this case, taxonomic classification based on colony pigment might be unduly influenced by growth temperature. The lack of a metabolic trait might also serve as the basis for a major taxonomic decision. However, a colony that is incapable of expressing one trait, for example, pigment formation, might merely be a mutant strain and not an unrelated species. In addition, not all isolates of a single species respond in exactly the same manner when tested for metabolic capabilities such as substrate utilization. For example, *Hyphomicrobium*, a stalked bacterium found in aquatic environments, might be classified into species, in part, by a specific trait that appears only in 90% of the isolates, for example, growth on lactate. However, the remaining 10% of the *Hyphomicrobium* isolates would respond differently and taxonomic confusion would result (3).

The identification of microbes has rapidly advanced in the last two decades. This can be evidenced by the change in *Bergey's Manual of Determinative Bacteriology*, the foundational book for bacterial taxonomy and classification. The eighth edition (2) was based primarily on classical testing of physiological or metabolic and structural components of microbes; it consisted of one volume. The newest version of the manual, *Bergey's Manual of Systematic Bacteriology* (4), was expanded and published as a four-volume set based on genetic and metabolic/structural characteristics of microbes. Interest in reclassifying microbes of all kinds took shape with the development of new techniques for classifying bacteria based on molecular systematics. Because of efforts to preserve biological diversity, there has been a resurgence of interest in microbial diversity and systematics as well (5). At the centennial meeting of the American Society for Microbiology held in Chicago, Illinois, in 1999, several symposia were presented on just this topic. One of the most exciting advances resulting from new molecular

techniques is that although it may not be possible to "see" microbes using classical techniques, it is possible to "know" about them through the use of molecular methods, often without even culturing them.

This chapter will concentrate on identifying microbes that have been cultured, although culturing microbes from many environments presents a considerable challenge. Microbiologists report that less than 10% of the microorganisms in natural environments are culturable (6,7). This is probably true in many natural environments; however, in those where sufficient nutrient and a supporting physical factors exist, a higher percentage of viable microbes may be culturable (8). Additionally, some bacteria may be viable but nonculturable (see following section), moribund, dormant, or dead (9), especially in environments that are either geologically isolated or nutrient-limited in some manner (10,11). There is a need for a clear picture of the total biodiversity of natural environments; however, some information can only be gleaned from culturing cells. For example, if one is interested in the physiology of microorganisms, it may be important to grow them for experimental manipulation. If one needs a strain for use in biotechnology or another industrial application (12,13), one needs a culture. If one wants to construct genetic variants of the organism or transfer genetic material between closely related strains, one needs the isolates. Microbial banks needed to preserve the diversity of microbial life will need to be based on isolates; otherwise, they are merely gene banks.

OBTAINING ISOLATES

Many techniques are available for the isolation and purification of microbial isolates (14,15). Direct isolation from the environment is the most common means of isolating bacterial strains. Spread, streak, and pour plates, using agar or other solidifying agents, have the potential for separating cells from a mixed culture into individual colonies (Fig. 1). Before the use of agar for solidifying nutrient mixtures, slices of potato and other fruits and vegetables were used for nutrient and support media (16,17). When solid media are not suitable for microbial isolation, and when enumeration is not necessary, enrichment cultures can be produced by mimicking the natural environment or by providing favorable conditions for the organisms in question. For example, enrichments of iron-rich sediments from southern Nevada gave rise to large numbers of iron-oxidizing thiobacilli (Fig. 2) when enrichment cultures supported by a reduced iron source and acid conditions were provided (18). Another example is enrichment for halophilic bacteria from natural salterns, soil, lakes, or oceans. In this case, an aerobic environment containing a solution of 25% sodium chloride with a rich variety of amino acids and proteins will best select for halophiles. Enrichment and enumeration can be accomplished simultaneously using enrichment most probable number techniques (MPN) (19). The MPN technique involves inoculation of a microbial sample into a series of tubes or wells representing 10-fold dilutions. Positive reactions are used to estimate the "most probable number" of organisms of a specific type in a sample from a statistical table. Recipes for media to support a myriad of microbial types can be found in *The Handbook of Microbiological Media* (20). Enrichment cultures often do not enrich for just a single species or strain. Therefore, further purification must be attempted by direct plating on solid media or multiple transfers resulting in dilution to extinction of unwanted strains.

All decisions about what conditions are of use for growth of isolates should provide for the physiological needs of the microbe in question; these conditions will often mimic the natural environment. Microbial cultures can be incubated in a variety of wavelengths and intensities of light, or darkness, temperature regimes,

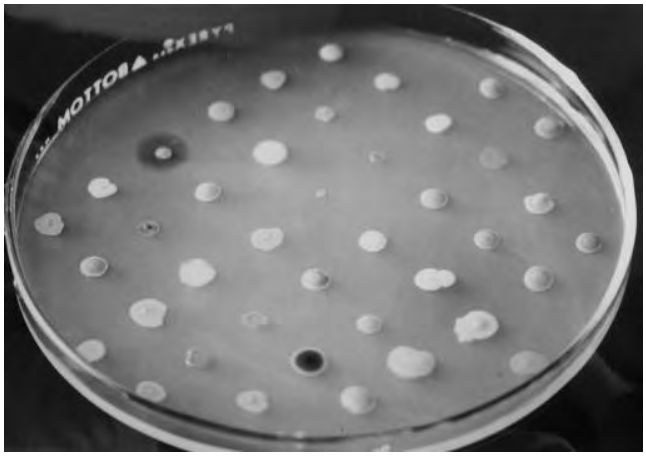

Figure 1. A bacterial garden of subsurface isolates applied to a grid after initial isolation from spread plates. Various colony morphologies and pigment production (e.g., dark colony surrounded by a light ring) can be useful during the identification process. Note: the colony surrounded by a dark ring demonstrates a physiological characteristic, such as agar degradation, that is potentially useful in identification. See color insert.

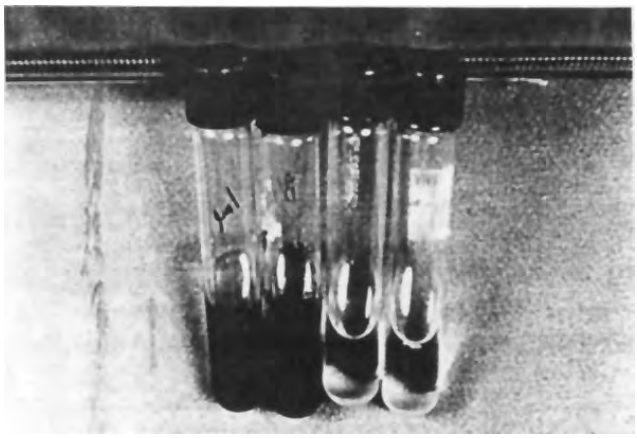

Figure 2. Iron-oxidizing (the two tubes on the left) and sulfate-reducing (the two tubes on the right) bacteria obtained through enrichment from Yucca Mountain, the U.S. proposed high-level nuclear waste repository. Courtesy of Dr. Beth Pitonzo, Characterization of Microbes Implicated in Microbially Influenced Corrosion from the Proposed Yucca Mountain Repository, *Ph.D. dissertation*, University of Nevada, Las Vegas, 1996.

pressures, salinities, and atmospheric conditions. Some cells are strictly aerobic, some are strictly anaerobic, and yet others are microaerophilic, requiring a reduced oxygen level. Cells that are aerobic or oxygen-tolerant can be grown under "room air" conditions. Those with oxygen sensitivity or intolerance require enhanced carbon dioxide incubation or an anaerobic chamber containing oxygen-free gases (Fig. 3). Roll-tubes, Balch pressure tubes, serum vials, and anaerobic/candle jars can also be used to grow anaerobic bacteria (17). Additionally, some microbes may be capable of growth using alternative electron acceptors to oxygen as in the case of nitrate, regardless of the gaseous environment provided; thus these molecules must be added to the growth medium.

Another consideration in obtaining microbial isolates is their interaction with surfaces. Microbes tenaciously stick to particles because of the production of exopolysaccharide (EPS), flagella, fimbrae, and other structures designed for attachment (Fig. 4). Electrostatic forces, hydrogen bonding, and hydrophilic and hydrophobic interactions between cells and surfaces may all play a role in the adhesion of microbes to surfaces (21). If the goal is to remove microbes from surfaces for isolation, such as soil particles, one approach is to interfere with the natural ionic bonding patterns of bacterial cells by shaking them in 0.1% sodium pyrophosphate (22). Centrifugation and blending techniques can also be used to promote the removal of microorganisms from samples and to concentrate biomass for enumeration (23,24). Sonication may separate cells that adhere to one another through biofilm production (25).

Other issues that influence organism isolation include the time of sample analysis and the physiological state of the organisms. Researchers have shown that the microbial communities present in natural samples change during storage (26–28). Immediate analysis of natural samples is critical for culturing some microbes, as faster growing or resuscitated microbes may overgrow those present in

Figure 3. Anaerobic chambers can be used to grow bacteria under defined atmospheric conditions. The gaseous composition can be manipulated to mimic natural environmental conditions. See color insert.

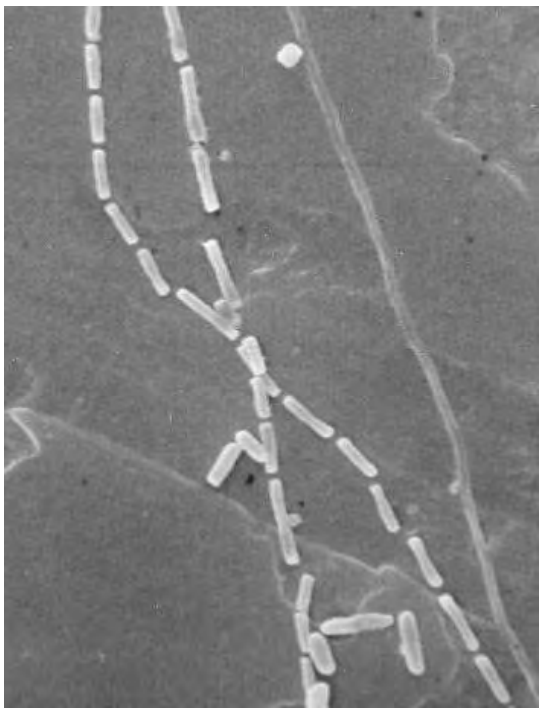

Figure 4. The initial stages of biofilm production on the surface of a polyethylene (plastic) coupon. Individual cells and chains of bacilli are seen attached to the coupon surface in this scanning electron micrograph. Magnification 5,000x. Courtesy of Dr. Gordon Southam.

only low density (29). If cells are injured (30) or viable but nonculturable (VBNC) (31), they may require special resuscitation measures, that is, recovery on a dilute nutrient medium (32) or exposure to distilled water (33). VBNC microbes were first described by Kogure (34) in marine systems where bacteria are nearly all gram-negative and sensitive to the antibiotic nalidixic acid. The resultant nondividing "snakes" were counted and compared to the culturable number from the same sample. The number that could elongate in the presence of nalidixic acid (an inhibitor of division) but could not be cultured were dubbed "viable but nonculturable" or VBNC. Often the previously nonculturable cells are the target of isolation attempts because of their important roles in natural environments. Rita Colwell and her colleagues reported instances where *Vibrio cholerae* and other pathogens have given rise to disease from sources containing VBNC cells (35–37).

Some microbes have not been isolated from natural environments, yet their existence is known because of their activities and they have been observed under the microscope. Techniques are currently emerging to identify these organisms without culturing. These techniques are based on using polymerase chain reaction (PCR) for amplification of indigenous ribosomal DNA (rDNA) (See following section; 38–40). Comparison of cultured isolates and DNA extracted directly from one subsurface rock environment yielded disparate results. The cultured cells were predominately gram-positive species, whereas, the extracted, amplified, cloned, and sequenced rDNA

suggested a community composed predominately of gram-negative bacteria (41).

Once isolates are obtained, it is important that they be maintained as frozen or lyophilized pure cultures. Repeated transfer of natural isolates often leads to loss of characteristics (42–44). Cells can be grown in a nutrient medium and diluted 1 : 1 with 20% sterile glycerol, and can be preserved at −70° to −80 °C. These cultures can be regrown from a few ice-crystal scrapings with a sterile transfer loop or sterile toothpick. Other preservation techniques are described in Gerhardt (15).

APPROACHES TO THE IDENTIFICATION OF ISOLATES

Visual Traits

For some isolates, looking at the colony or the cells under the microscope will lead one to a family or perhaps even a genus designation. However, for many bacteria, for example, the vast number of gram-negative rods, one colony and/or one cell look much like another. In the mid-1800s, not much more than these few observations were available to microbiologists. They extensively stained and described cell shape, cellular arrangement, the presence–absence and cellular location of spores, the presence–absence and types of granules, and motility. Many of these descriptive observations are used in *Bergey's Manual of Systematic Bacteriology* (4). Although this same detail is still available, most microbiologists use more sophisticated techniques when identifying isolates. One important reason to continue to use the older visual methods is that the purity of an isolate needs to be monitored during experimentation or identification. Contaminated cultures are often visible on agar plates if time is taken to observe them carefully. Contamination can also be confirmed using a microscope when the two cultures have different cellular shapes and sizes.

Electron microscopy has provided interesting visual images of bacteria and an ability to visualize cellular projections such as flagella and fimbriae. Cross sections have allowed for confirmation of cell wall structure, capsules, and other layers surrounding cells. Various equipment associated with electron microscopy can also measure the content of structures, for example, crystals, produced by cells (Fig. 5). In addition, special stains can be used to visualize specific structures that may be useful in identification. Much can be learned about individual isolates from microscopy, staining differences, and other visual techniques; however, identification of the organism is not generally possible by these techniques alone.

Physiological/Metabolic Testing

For decades, metabolic testing served, along with visual characterization of isolates as nearly the sole means for bacterial identification. Metabolic capabilities included utilization of various carbon or inorganic substrates, for example, carbohydrates, alcohols, amino acids, ammonium, or sulfate ions, either through aerobic or anaerobic respiratory processes, and enzymatic functions such as catalase and phosphatase. Tables of substrate utilization

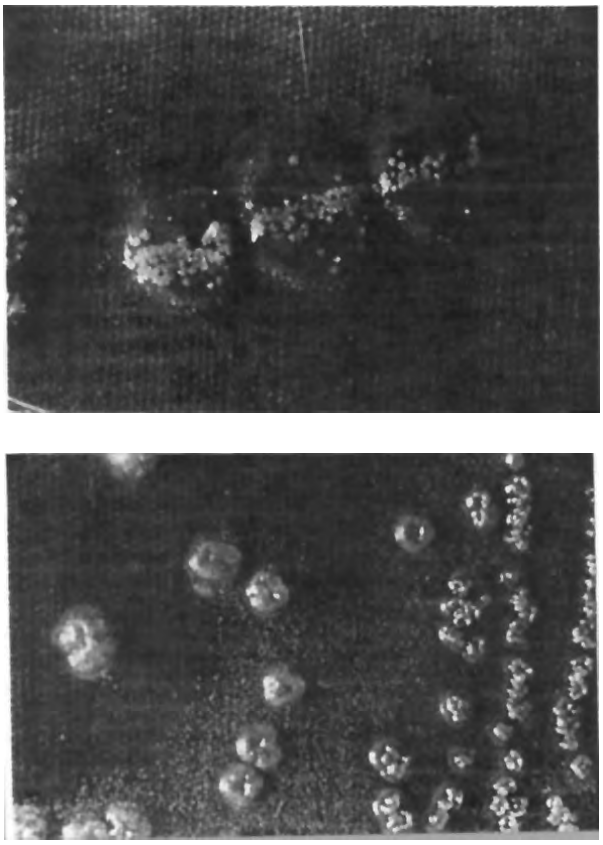

Figure 5. Crystals, visible to the naked eye, were precipitated within the agar matrix (**a**) and/or on the surface of bacterial colonies (**b**) when grown on calcium-containing medium. The ability to precipitate calcium is species or strain-specific. Courtesy of Ms. Mona Khalil.

continue to be an important part of bacterial identification (4). Automated approaches to bacterial identification are based on metabolic characteristics of isolates. These include rapid test strips supplied by API and microtiter plates created for BIOLOG (10) that test for multiple metabolic traits simultaneously. The results are read after incubation of a suspension of a pure culture under specific conditions, and they serve as a means of identifying specific bacterial groups such as enteric bacteria, yeast, anaerobes, and so on. BIOLOG testing is based on a 96-well microtiter plate containing 95 different carbon substrates. Oxidation of the substrate results in the development of a purple color (via a dye complex), the intensity of which is related to the amount of bacterial activity (Fig. 6). One drawback of metabolic techniques is that environmental microorganisms may require a different incubation temperature than clinical isolates. Another drawback for each of these approaches is that a gram stain, or an alternative test to determine cell wall structure (45), is required before the appropriate test strip or microtiter plate can be selected for inoculation. Many environmental microbes are gram variable and thwart attempts at choosing the appropriate metabolic test(s). An example of how important this can be was discovered during characterization of isolates from the subsurface in Rainier Mesa, Nevada

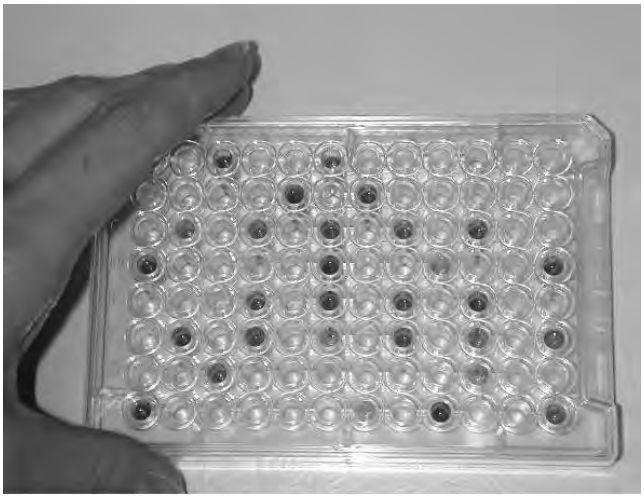

Figure 6. BIOLOG microtiter plates are used to create a metabolic fingerprint useful in the identification of bacterial isolates. Dark-colored wells indicate oxidation of individual carbon substrates. See color insert.

Test Site, Nevada. The isolates appeared to stain gram-negative. Using the API rapid nonfermenting strip, the metabolic profile matched that of *Pasteurella hemolytica*. However, the organisms were actually gram-positive *Arthrobacter* spp. (10). The significance of this error is not just the fact that a strain was mistakenly identified from the environment, but also the implication that pathogenic strains were present when they were not. One advantage to metabolic screening processes such as BIOLOG that contain numerous tests is that even if environmental organisms are not definitively identified, it is possible to develop a tailor-made database within which new isolates can be compared. In fact this may be necessary because most databases created from metabolic systems are based on the identification of isolates of medical importance, but not from natural environments. Additionally, at a general meeting of the American Society for Microbiology held in the year 2000, BIOLOG introduced an automated system utilizing multiple plates that are robotically inoculated, designed primarily for combinatorial analyses.

The importance of other metabolic activities in the identification of specific microbial types are under development but are not yet widely used. RNA provides evidence for metabolic activity and can be used to identify microorganisms in nature, in some cases in situ. The exact placement of these cells in the natural environment may be instructive. Probes can be constructed that target specific mRNA molecules demonstrating which specific cells in soil or biofilms, for example, are metabolically active in situ (46,47).

The presence or absence of resistance markers are traditional characteristics used to profile microbial isolates. Although the information may be interesting and useful in some studies, resistance markers are often located on plasmids and therefore, are in danger of being lost over time (5,48). Additionally, few markers are present in 100% of any one species or strain of bacteria. For example, variable zones of antibiotic and metal inhibition were measured in an investigation to determine diversity within a colony morphotype. Using other criteria, these same organisms were classified as the same species (49).

Although metabolic capabilities have been classical tools for microbial identification, they are not always reliable because of preparation and interpretation of metabolic tests, the fraction of any one species that is positive for a specific activity, and genetic plasticity. For these reasons, the use of metabolic tests to identify organisms have often been replaced by analysis of characteristics that are less variable, such as structural components (chitin, proteins, lipids) or genetic material.

Structural Components

Because some structural components of cells, such as the structure of cell walls, are relatively unchanging, they serve as good characteristics for broad-level identification of microbes. For example, archaebacterial cell walls are not made of peptidoglycan, as are those of eubacteria, rather a complex protein structure and fungal cell walls are composed of chitin. Because of this, suspected archaeal or fungal isolates can be classified into domains without difficulty. Eubacteria can be further classified by the layered structure of their cell walls. One of the first tests conducted on eubacterial isolates is the gram stain. This stain, devised by Christian Gram around the turn of the century, determines placement of bacteria into one of two broad categories based on cell wall structure. Later it was recognized that the gram stain could group cells with many like characteristics together. The principle of the gram stain in identification of bacterial strains is still in use, although an electron micrograph is often used to visualize the cell wall rather than relying on the original staining method.

Lipids are important structural components of microbial cells. Utilizing multiple lipids and components of specific lipids (See SUTTON, NICHOLS chapters), deeper insight into community composition and into metabolic activities can be gained. Although the composition of phospholipids in the cell membrane may change with culturing conditions, under a standardized set of conditions a comparison can be made between microbial isolates. A pioneer in this area, Dr. David C. White laid the foundation for a commercial application that used microbial lipid profiles as identification criteria. Microbial Identification Systems, Inc. (MIDI) uses types and abundances of fatty acid methyl esters (FAME analysis) as an identification tool. FAME profiles are extracted from the cell by saponification, chemically modified (methylated), separated, and identified on a gas chromatograph, or by using gas chromatography/mass spectroscopy. As with metabolic databases, the original database for MIDI was based on pathogenic or medically important isolates and thus was not as useful for environmental microbiology. Over the last decade, isolates from the deep subsurface and from industry have become an important part of the MIDI database. Like BIOLOG, data from the MIDI system can be used to determine the relatedness of isolates even if they are not specifically identified (Fig. 7) (50,51).

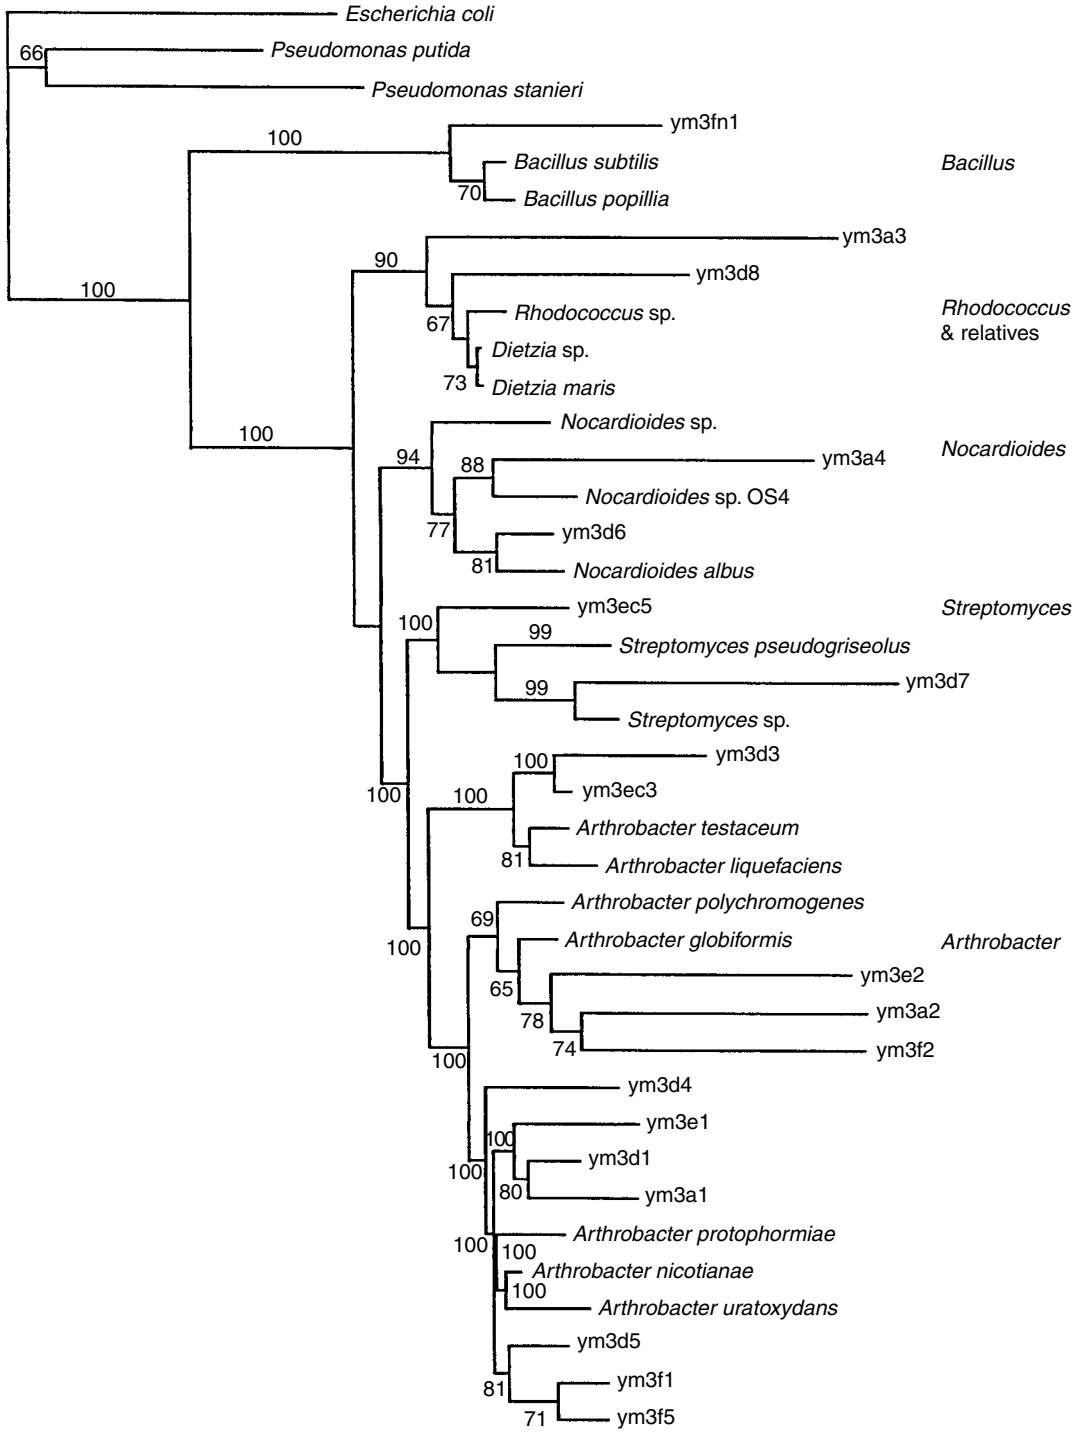

Figure 7. Phylogenetic tree based on MIDI FAME profiles of membrane lipid content. Notice that even unidentified isolates can be clustered near known control organisms. Values represent the percentage of time that the tree would be configured as shown in 100 separate analyses of the data (bootstrapping analysis) (52). Courtesy of Dr. Yingchun Wu, Molecular Analysis of Microbial Diversity Within Yucca Mountain, Ph.D. dissertation, University of Nevada, Las Vegas, 1998.

Other structural components can be used to identify cells by using labeled antibodies against those structures. Antibodies provide for very specific presence–absence and locational information about structures. Although antibodies have commonly been used to detect the presence of specific bacterial types in food and medical applications, they have not commonly been used for environmental isolates or in natural settings. Other structural components of cells, less commonly used for identification, such as flagella, lipopolysaccharide

components, and proteins G and A, and so on are described by others (1,5,15).

Genetic Analysis

By far the most reliable means of identification, and relatedness clustering of isolates, comes from more recent techniques associated with genetic analysis. The eighth edition of *Bergey's Manual of Determinative Bacteriology* (2) was the first edition containing DNA-based identification of bacteria. Individual isolates were described by the traditional means of classification and a percent of the genome accounted for by nucleic acid bases guanosine and cytosine (%G + C). The hypothesis was that cells that were similar would have a similar G + C percentage in their DNA makeup. Therefore, *Escherichia coli* and *Salmonella typhimurium* were expected to have similar G + C percentages because they are closely related. However, a dissimilar genus such as *Arthrobacter* would most likely contain a different G + C percentage. The percentage G + C was determined by a thermal melting curve of purified DNA from the bacterium in question (15). The method worked well for closely related bacteria but the danger that grossly unrelated bacteria might still have similar G + C percentage content was problematic. For example, the G + C percentage content of bacteria ranges from about 25 to about 75%; this range covers the G + C percentage content of all other living things (53). Therefore it is impossible to relate higher organisms to microbes through their G + C percentage content.

A subsequent development that addressed the sequence of nucleotides, not just the G + C content, was that of DNA hybridization. In this method, single-stranded DNA fragments from a microbe of interest were affixed to a filter and then mixed with labeled single-stranded DNA fragments from another bacterium. The strands were allowed to reanneal, and the percentage of DNA homology was determined by the extent to which the label was retained on a filter as double-stranded DNA. The mixed DNA molecules were compared to homologous DNA hybridizations (considered 100% hybridization) (15). This method worked well, but was tedious because many comparisons had to be made and each comparison had to be prepared separately, requiring large amounts of purified DNA.

The next development associated with genetic identification of microbes arose with the discovery of restriction enzymes by researchers at Stanford University. These naturally occurring bacterial enzymes help protect cells from foreign DNA, such as in the case of viral infection. Restriction enzymes cut DNA at sites that are specific for each enzyme. For example, EcoRI, the first restriction enzyme in common use, came from *E. coli* and cut DNA where the following sequence of nucleotides occurs in a strand of DNA:

$$5'\text{G} \downarrow \text{AA TTC } 3'$$

$$3'\text{CTT AA} \uparrow \text{G } 5'$$

Fragments of DNA resulting from restriction enzyme activity could be isolated, separated by gel electrophoresis, and compared to one another. Restriction fragment length polymorphisms (RFLPs) were created by this process and helped compare closely related species to one another without the necessity of harvesting and purifying large amounts of DNA. During electrophoresis, a single gel can hold many samples so that multiple comparisons can be accomplished at one time (14). The process is often repeated using several restriction enzymes to delineate more clearly the differences between microbes. If the entire genome is used, labeled DNA probes to specific areas within the genome may be used for visualization of banding patterns. Alternatively, amplification of small sections of the genome (see PCR in the following section) can provide RFLP banding patterns that can be visualized without probes. Automation of this process, using the Riboprinter by Qualicon, has assisted in epidemiological studies of microorganisms in medical settings and in bioremediation research on fate and transport of microbes.

Currently, the most definitive means of identifying microbial isolates is sequencing the 16S fragment of rDNA from an individual bacterium. Sequencing is conducted on the gene for the 16S RNA fragment of bacterial ribosomes and the 18S RNA fragment of eukaryotic ribosomes. Sequences are compared between isolates to determine their identification (based on extensive databases) and how closely they are related to each other. The historical development of these methods began in the 1980s when Carl Woese of the University of Illinois, Urbana-Champaign, manually sequenced ribosomal fragments of organisms throughout the entire realm of biology. He developed a master "tree of life" that showed how organisms are related to one another throughout all of biology. This Herculean effort gave way to the current scheme of biological inheritance and has revealed so much about the tree of life that classical methods could not address (54). Automation of the sequencing process has provided the ability to rapidly sequence the rDNA of any microbial isolate and compare it to others that have been deposited in sequence databanks (Ribosomal Database Project, RDP, or Genbank). These databases are now available to anyone over the internet and are constantly updated as inputs are made on a daily basis. Because of the revolution in molecular techniques and information technology, the taxonomy of bacterial groups is undergoing rapid evolution. For example, the genus *Pseudomonas*, once included all nonfermentative, gram-negative rods with polar flagella with a percentage G + C that spanned from 58–70 (2). The broad G + C percentage, the large number of species, and the variety of metabolic capabilities suggested that not all these organisms should be confined within a single genus. However, the basis on which to divide them was not clear. Today, this genus has been divided into numerous genera based on the 16S rDNA sequences of these organisms. One entire volume of the 1989 edition of the *Bergey's Manual of Systematic Bacteriology* (4) is based on gram-negative bacteria, many of which were once classified in the genus *Pseudomonas*.

In addition to automated sequencing, another technique has revolutionized taxonomy by allowing the rapid

amplification of minuscule amounts DNA, in some cases as few as 10 cells (55). This process is called polymerase chain reaction (PCR) and can be used both on the DNA of individual isolates or on DNA fragments isolated directly from environmental samples. Before the advent of PCR technology, large volumes of cells had to be grown to extract enough DNA/RNA for sequencing. This process could only be applied to culturable isolates. However, PCR made it possible to understand much more about microbes, even those that could not be cultured. For example, ribosomal DNA fragments have been amplified and sequenced, and were used to determine phylogenetic relationships of the uncultured microbial symbionts of a hydrothermal vent community (56). Short sequences of DNA, called primers, are required for PCR amplification. Specific universal primers have been developed for eubacteria and for archaebacterial groups, as well as other taxonomic groups. These universal primers are based on conserved sequences within the 16S rDNA molecule that abut variable regions in the molecule (14). Because primers are so specific, DNA can even be amplified from fossils (57,58).

Using specific labeled sequences of DNA or RNA as probes, one can determine the presence of a bacterial type (from its DNA) or a metabolic activity (from the presence of mRNA), and locate where in a microbial community that particular bacterial type resides by visualizing those particular labeled bacteria under the microscope. Probes can be radiolabeled or chemically tagged to allow visible or spectrophotometric detection of cells. Recently rDNA probes, domain to strain specific, have become increasingly popular for detection and quantification of specific microbial populations without the necessity of culturing organisms (59–63).

These techniques have taken the process from learning only limited information about culturable isolates to learning quite a lot about even uncultured microbes. With sequences known for many genes, not only can the identity and relatedness of one bacterium to another be rapidly determined, but its metabolic capabilities and structural components can also be discerned without even growing the cells.

Future Considerations

No matter how (relatively) easy it has become to sequence and compare cultured isolates or individual rDNA fragments from uncultured microbes, it is a daunting prospect to consider tabulating all microbial diversity. It is not known how many species or strains there are. However, some have estimated that microbial species alone surpass all other biological diversity (65). Until all species are placed on the microbial branches of the tree of life, one means of relating isolates to one another is through dendrograms, or trees of related microbes. These can be based on 16S rDNA sequences or other group traits, for example, the amino acid sequence of a common enzyme that has been highly conserved throughout bacterial evolution. Examples of conserved molecules might be DNA or RNA polymerase or cytochrome molecules. Trees such as these depict relationships between bacterial isolates and are the current mainstay of taxonomy and systematics research (Fig. 8); they will remain so until the systematics of bacteria is eventually described.

One topic about which little is known is that of how microbes change under varied environmental conditions. Even less is known about how this variability would affect taxonomy. It does not matter what type of bacterial cell is considered, in general, microbes survive a fast or famine existence (66). Organisms as diverse as soil microbes and human pathogens must survive between growth periods and exhibit a plethora of adaptations to meet such challenges. It is clear that organisms cultured in the laboratory (even once) may significantly differ from those in nature. This is no secret to microbiologists. However, bacteria continue to be cultured on media and under conditions unlike those from which the organisms were isolated. Gill Geesey and Bill Costerton revealed one such fundamental difference between nature and the laboratory in their Scientific American article, "How Bacteria Stick" (67). It was observed that the nature of extracellular polymers changed with repeated culture on rich media. Likewise, endolithic isolates from the subsurface have shown exopolysaccharide (EPS) production upon initial culture and lost or repressed the ability within two transfers on even a relatively low nutrient medium. EPS-producing ability, antibiotic production or enhanced corrosion ability was reestablished by contact with crushed rock from their native environment (68,69). In some cases, the same organism may produce different surface components (or different amounts of a surface component), depending on the physiological state of the organism, or the nutrient sources and growth conditions provided the organism (70–72). EPS production is a relatively obvious trait. However, equally dramatic but less obvious changes may occur within organisms when they move from one environment to another. For example, the physiology of *E. coli* in a human lower intestine and in a cold freshwater stream are undoubtedly very different. More is known about *E. coli* than any other living organism; however, it is not known how those two environments affect its activities.

Time is spent on standardizing growth and test conditions while microbes spend their time adapting to a changing environment in ways not yet imagined. Understanding their roles in natural settings will be the challenge of the new century.

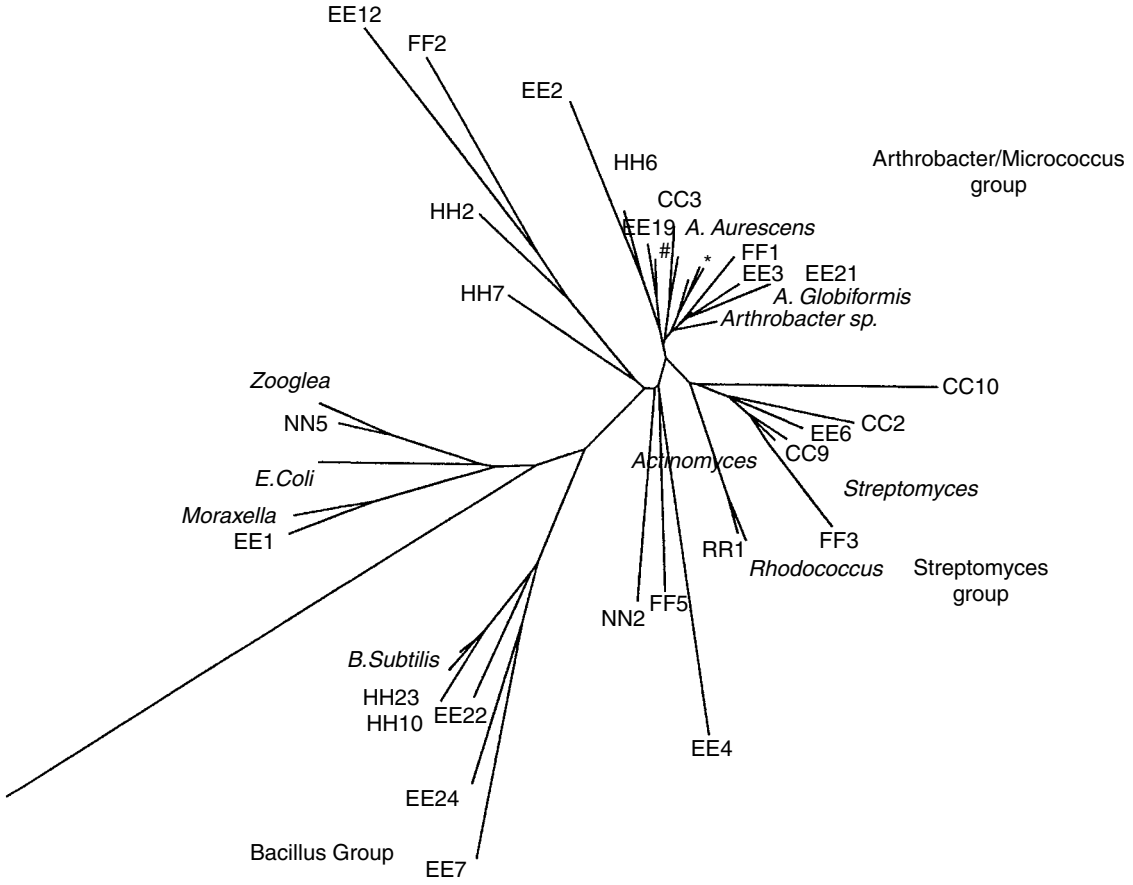

Figure 8. Phylogenetic tree of calcium-precipitating bacteria from paleosols in Eastern Washington state. Most calcium-precipitating bacteria clustered into one of three groups: *Bacillus, Streptomyces*, or *Arthrobacter/Micrococcus*. Note: isolates EE22 and HH6 are nonprecipitating strains. Sequences for the listed genera and/or species were obtained from GenBank or RDP (see text for explanation) and compared to the sequence data from calcium-precipitating isolates designated by letters. # on the figure designates *Micrococcus* sp. and * designates isolates HH1, NN3, and NN4. In time, it may finally be possible to find a basis for a definition of "species" for bacteria and other microbes. This definition has eluded scientists because of the lack of sexual reproduction in bacteria, often the mainstay of a macrobiological species definition. Additionally, much has to be learnt concerning genetic plasticity and gene expression in prokaryotes. Perhaps, with enough information about (bacterial) ribosomal sequences, a formal definition will be proposed. This would allow macro- and microbiologists to better place organisms on the tree of life.

The availability of entire genome sequences from many different organisms marks a new age in biology. This is the first time in history that the entire genetic content of living creatures can be accessed. This is also the first time that one can view a comprehensive and dynamic molecular picture of the living cell under various physiological states using state-of-the-art genomic technologies such as microarrays. The widespread and routine use of genomic technologies will shed light on a wide range of important research questions from how cells grow, differentiate, and evolve to the medical challenges of pathogenesis, antibiotic resistance, and cancer, from agricultural issues of seed breeding and pesticide resistance to the biotechnological challenges of drug discovery and the remediation of environmental contamination.

Microbial genomic information is increasing at an exponential rate. To date, about 40 microbial genomes have been completely sequenced, and at least 100 microbial genomes are currently being sequenced (see TIGR's web site: *www.tigr.org*). The most critical issue in the postgenomics era will be to elucidate the biological function and regulation of sequenced genes. It is expected that developments in microbial functional genomics and associated genomic technologies will have a tremendous impact on environmental microbiology. This article provides a broad description of microarray-based genomic technologies and a review of their applications for monitoring gene expression and for detecting microbial populations within the context of the natural environment. The advantages and disadvantages of the various microarray formats are emphasized here rather than the technical details of the technology.

MICROARRAY BASICS

Concepts, Principles, and History

Microarrays are microscopic arrays of large sets of DNA sequences that have been attached to a solid substrate using automated equipment (1). These arrays are also sometimes referred to as microchips, biochips, DNA chips, or gene chips. To avoid confusion with computer microchips, the term microarrays is preferred.

Microarray assays are based on the hybridization of a single-stranded molecule labeled with a fluorescent tag, or fluorescein, to a complementary molecule attached to a solid support, such as glass. In principle and practice, microarrays are extensions of membrane-based hybridization methods that have been used for decades to detect and characterize nucleic acids in biological samples. In microarray assays, an unknown sample is hybridized to an ordered array of immobilized DNA molecules of known sequence to produce a specific hybridization pattern that can be analyzed or compared to a given standard. The fluorescein-labeled DNA strand in solution is generally called *the target*, whereas the DNA strand immobilized on the microarray surface is referred to as *the probe*. Because the sequence of the immobilized molecule is usually known, it is used to "probe" or investigate the target molecule in solution. However, this terminology is opposite to the convention that originated with Southern blot hybridization, in which the target molecules on the membrane are interrogated by solution-phase probes.

Microarray assays are rooted in early biochemical experiments on solid substrates. In contrast to traditional hybridization assays that utilize flexible membranes (e.g., nitrocellulose) and radioactivity, microarray assays generally utilize nonporous solid surfaces and fluorescent detection. Compared to the macroscopic format of filter-based assays, the miniaturized microarray format represents a fundamental revolution in biological analysis (2). This is primarily due to the use of a nonporous solid surface that allows small amounts of biochemical molecules to be deposited at precise predefined locations on the surface with little diffusion, whereas porous substrates such as nylon allow diffusion of the applied materials and are not amenable to microarray preparation.

The basic principle behind microarrays was first proposed in the late 1980s. Augenlicht and his colleagues provided one of the first descriptions of DNA microarrays for simultaneously monitoring the expression level of thousands of human genes on nitrocellulose with radioactive labeling (3–5). They spotted 4,000 complementary DNA (cDNA) sequences on nitrocellulose and used them to analyze differences in gene expression patterns among different types and stages of colon tumors. At the same time, four groups independently developed the concept of determining a DNA sequence by hybridization to a comprehensive set of oligonucleotides, i.e. sequencing by hybridization or SBH (6–9). Although the concept of SBH is extremely elegant, there are several inherent problems, such as repeated sequences and the imperfect specificity of hybridization, that limit the use of SBH for sequence determination. Therefore, such challenges have motivated most researchers to shift the emphasis to applications that need to be addressed more immediately, such as profiling gene expression.

By the mid-1990s, the reverse dot blot scheme for monitoring genome-wide gene expression was recast by several different groups. Both DNA fragments and synthetic oligonucleotides were arrayed on various substrates, including nylon membranes, plastic, and glass (10,11). All of them depended on sequence-specific hybridization between the arrayed DNA and the labeled nucleic acids from cellular mRNA. Later studies in yeast with both DNA and oligonucleotide microarrays clearly indicated that microarrays are powerful tools for monitoring gene expression (12,13).

Microarray-based genomic technology has greatly benefited from many parallel advances in other fields. Without such advancements, the development of high-density microarrays and the various applications that we see today would not be possible (2,14). First, many genome projects have produced large-scale sequence information

and resources for microarray-based analysis. Second, technical advances have made it possible to fabricate high-density microarrays in a very small area. Finally, recent advances in fluorescent labeling and detection offer significant advantages in speed, data quality, and user safety for microarray-based assays.

Microarray Types and Their Advantages

Types of Microarrays. Microarrays can be divided into two major formats based on the immobilized probe: (*1*) *DNA microarrays* are constructed with DNA fragments typically generated with the polymerase chain reaction [PCR] (11,12,15) and (*2*) *oligonucleotide microarrays* are constructed with short (10- to 40-mer) or longer (up to 75-mer) oligonucleotide sequences that are designed to be complementary to specific coding regions of interest.

DNA microarrays have certain advantages over oligonucleotide microarrays, especially when monitoring gene expression patterns. While oligonucleotide microarrays are limited to array elements of low sequence complexity, the specificity of hybridization for a complex probe is improved with DNA microarrays using DNA fragments substantially longer than oligonucleotides (16). Also, oligonucleotide synthesis requires prior sequence knowledge, but this is not the case for DNA arrays. Nucleic acids of virtually any length, composition, or origin can be arrayed (16). However, oligonucleotide-based microarrays have the advantage of minimizing the potentially confounding effects of occasional cross-hybridization (13), and are uniquely suited for detecting genetic mutations and polymorphisms.

There are two general types of oligonucleotide microarrays based on the strategy used for oligonucleotide immobilization: (*1*) direct parallel synthesis on solid substrates by light-directed or photoactivatable chemistries (17,18) or standard phosphoramidite chemistries (Southern et al., 1994); and (*2*) chemical attachment of premade oligonucleotides to solid supports (8,19–30). Glass surfaces (9,31,32), glass pores (20), polypropylene sheets (33), and gel pads (8,27) have all been used as solid supports for oligonucleotide attachment.

Each strategy for oligonucleotide immobilization has specific advantages and disadvantages (1,34). There are two major advantages of the direct synthesis approach. First, the photoprotected versions of the four DNA bases allow microarrays to be manufactured directly from sequence databases, thereby removing the uncertain and burdensome aspects of sample handling and tracking. Second, the use of synthetic reagents minimizes chip-to-chip variations by ensuring a high degree of precision in each coupling cycle. The photolithographic approach, however, requires the use of photomasks that direct light to specific areas on the array for localized chemical synthesis; these photomasks are very expensive and time-consuming to design and build. Also, the yield and length of synthesized oligonucleotides are subject to wide variation and uncertainty that could lead to unpredictable effects on hybridization across the microarray. For the attachment of presynthesized probes, the concentrations and length of each oligonucleotide on the array can be controlled before immobilization. Standard synthesis chemistry is also well established for many nucleotide derivatives for which no light-inducible monomer equivalents are available. In addition, the post-synthesis approach is less complicated and can be customized according to the needs of the laboratory. However, the critical drawback of the post-synthesis approach continues to be the need for the external synthesis and storage of different oligonucleotides before array fabrication.

The use of polyacrylamide gel pads as an immobilization support for oligonucleotide microarrays offers significant advantages over the use of probes attached to solid supports (35). Three-dimensional immobilization of probes in gel pads may provide higher capacity and a more homogeneous environment than heterophase immobilization on glass, leading to higher sensitivity and faster hybridization kinetics (36). However, like nylon membrane-based supports, gel pads may cause higher background (37).

Advantages of Microarrays. Microarrays offer a number of advantages over conventional nucleic acid–based approaches.

1. *High Throughput and Parallel Analysis*. The attachment surface of nonporous substrates allows thousands of array elements or probes to be uniformly deposited on a very small surface area. As a result, gene expression can be monitored at the genomic level, or many constituents of a microbial community can be simultaneously assessed in a single experiment using the same microarray. This is very important for studying gene expression at the genome-wide level because the large amount of expression data generated from a single microarray experiment can allow researchers to begin to build a comprehensive, integrated view of a cellular system.

2. *High Sensitivity*. High sensitivity can be achieved in probe-target hybridization because microarray hybridization uses a very small volume of probe and the target nucleic acid is restricted to a small area (16,25). This feature enables high sample concentrations and rapid hybridization kinetics.

3. *Differential Display*. Different target samples can be labeled with different fluorescent tags and then hybridized in parallel to the same microarray, allowing the simultaneous analysis of two or more biological samples in a single assay. Multicolor hybridization detection minimizes variations resulting from inconsistent experimental conditions and allows direct and quantitative comparison of target sequence abundance among different biological samples (16,38).

4. *Low Background Signals*. Nonspecific binding to a nonporous surface is very low; as a result, organic and fluorescent compounds that attach to microarrays during fabrication and use can be rapidly removed, resulting in significantly less background than is typically encountered with porous membranes (16).

5. *Real-Time Data Analysis*. Once the microarrays are constructed, hybridization and detection are relatively simple and rapid, allowing real-time data analysis in field-scale heterogeneous environments.

6. *Automation*. Microarray technology is amenable to automation and therefore has the potential of being cost-effective compared to conventional detection methods (16).

Microarray Fabrication

A critical step in using microarrays is the fabrication procedure, which involves attaching or printing the DNA probes on the array (Fig. 1). The microarray format is compatible with many advanced fabrication technologies. The most widely used printing technologies are photolithography, mechanical microspotting, and ink-jet ejection. Each technology has advantages and disadvantages in microarray fabrication (1,2).

In photolithography, oligonucleotides are synthesized in situ on a solid surface in a predefined spatial pattern by using a combination of chemistry and photolithographic methods borrowed from the semiconductor industry (31). Photomasks direct DNA synthesis through the use of light, which serves to activate modified phosphoramidite versions of the four DNA bases for DNA synthesis (31).

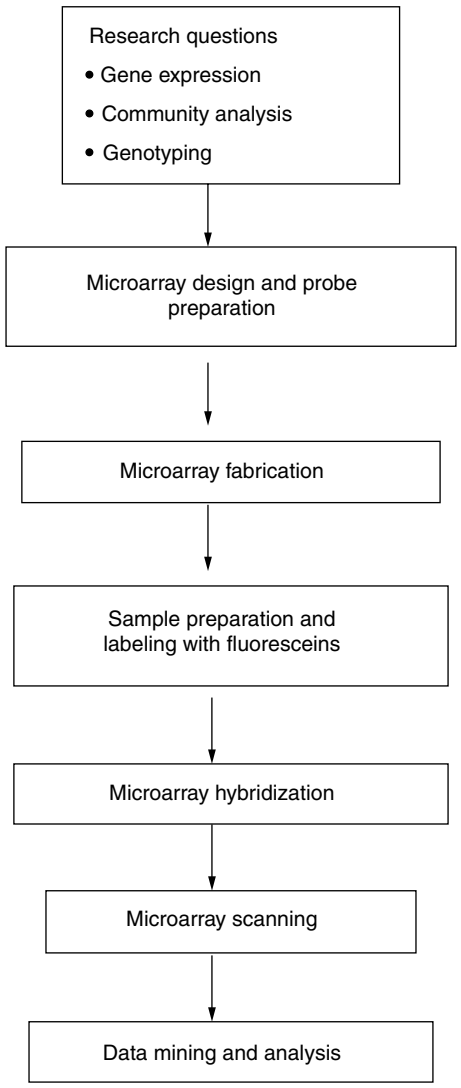

Figure 1. Flowchart of microarray-based experimental approaches.

A single base is added after each coupling step to growing oligonucleotide chains at thousands of defined locations (39). Affymetrix chips currently contain approximately 250,000 oligonucleotides in an area of 1 cm^2. One of the main advantages of this approach is that microarrays of extremely high density can be constructed (38). However, photolithography can only be used with oligonucleotides, not cDNA.

Mechanical microspotting uses an array of pins, tweezers, or capillaries to deliver picoliter volumes of premade biochemical reagents (e.g., oligonucleotides, cDNA, genomic DNA, antibodies, and small molecules) to a solid surface. Printing is accomplished by direct contact with the surface using a computer-controlled robot (14). Currently, more than 1,000 individual cDNA molecules can be deposited in an area of 1 cm^2 (40). The advantages of microspotting are ease of implementation, low cost, and versatility. One disadvantage of this method is that each sample to be arrayed must be prepared, purified, and stored before microarray fabrication. Also, microspotting rarely produces the densities that can be achieved with photolithography.

Ink-jet ejection technologies provide another way to manufacture microarrays. They utilize piezoelectric and other forms of propulsion via a robotic control system to transfer nanoliter volumes of reagents from miniature nozzles to defined locations on a solid substrate without surface contact. Similar to microspotting approaches, ink-jet ejection allows the spotting of virtually any biological molecule of interest, including cDNA, genomic DNA, antibodies, and small molecules. In contrast to microspotting, ink jets have the advantage of avoiding direct surface contact. Ink-jet ejection, however, cannot manufacture microarrays as dense as those prepared by photolithography or microspotting approaches.

All three technologies allow the manufacture of microarrays with sufficient density for genetic mutation detection and gene expression applications. The key considerations in selecting a fabrication technology include microarray density and design, biochemical composition and versatility, reproducibility, throughput, density, and cost. Because of its versatility, affordability, and wide applications, microspotting may become the microarray technology of choice for the basic research laboratory.

Microarray Hybridization and Detection

After constructing the microarrays, the most important issue in microarray-based analysis is the successful performance of target hybridization. Conceptually, microarray hybridization and detection are quite similar to traditional membrane-based hybridization (14). The target DNA or RNA from a biological source is labeled with fluorescent dyes [e.g., Cy3 (green)- or Cy5 (red)-labeled deoxycytidine triphosphate (dCTP)]. The labeled target DNA or RNA is then purified and hybridized with the microarrays. The unbound material is washed away, and the probe-target hybrid on the array is visualized by fluorescence detection with confocal scanning devices or a CCD (charged coupled

device) camera (41). The purity of RNA and DNA is a critical factor in the hybridization process, because cellular proteins, lipids, and carbohydrates can mediate significant nonspecific binding of fluorescently labeled cDNA to glass surfaces.

Fluorescent labeling and detection use fluorescently labeled DNA bases that absorb and emit light at distinct and separable wavelengths. The inherent low level of intrinsic fluorescence of glass and other microarray substrates permits the use of fluorescent labeling and detection schemes that enable a great leap in terms of speed, data quality, and user safety (14). Fluorescence-based assays make it possible to utilize advanced data acquisition technologies such as confocal scanners and CCD cameras.

Generally, a confocal scanner uses laser excitation of a small region of the glass slide ($\sim$100 μm^2), and the entire image of the array is collected by moving the glass slide, the confocal lens, or both across the slide in two directions (41). The fluorescence emitted from the hybridized target molecule is gathered with an objective lens and converted to an electrical signal with a photomultiplier (PMT) or an equivalent detector. The CCD camera exploits many of the same principles as a confocal scanner, but the CCD camera utilizes substantially different excitation and detection technologies (41). One key difference is that the CCD camera-based imaging system often illuminates and detects a large portion of the slide (1 cm^2) and hence does not require moving stages and optics. This reduces cost and simplifies instrument design. However, because the CCD camera does not move the optics or stages, several images need to be captured from different fields of the slide and then combined to represent the entire information on the slide.

Microarray Data Acquisition and Analysis

After the fluorescent signal is converted into digital output by the detection system, the images can be processed by a variety of commercial and free software (42). Signal quantification is usually accomplished by superimposing a grid over a microarray image to specify the target locations, and the likely shape and placement of the hybridization signal is predicted using mathematical methods. Local sampling of the background is generally used to specify a threshold that the true signal must exceed. By using these methods, it is possible to detect weak signals and extract an average density above the background for each array element (43).

Hybridization signals from microarrays should be normalized before comparing data from a single array or among multiple arrays because of differences in labeling efficiencies among fluorescent dyes and other experimental variations (14,44). Basically, two general approaches can be used for data normalization. One is to add a known amount of control RNA or DNA to the samples before labeling. The signal intensity from the controls can be used to normalize the data from a single array among different dyes or multiple arrays. The second approach is to use a set of housekeeping genes that are expressed consistently under certain experimental conditions. The average fluorescent intensity for these housekeeping genes can be used for normalization (44).

On the basis of the spiked controls, the intensity value for each array element can be converted into biologically relevant outputs (e.g., the number of mRNA transcripts per cell, micrograms of DNA per gram of soil). Quantitative gene expression, genotyping, and other outputs can then be correlated with the gene sequences on the microarrays, and higher order relationships, such as coregulation, can be identified using a variety of statistical methods such as cluster analysis, which has been the most widely used statistical technique for analyzing gene expression data (45).

USING MICROARRAYS TO MONITOR GENE EXPRESSION

Using Gene Expression Data to Define Gene Function

Determination of entire genome sequences is only the first step in the complete characterization of an organism. The next step is to elucidate the functions of these sequences and provide physiological and ecological meaning to this information. However, defining the role of each gene in a genome is a daunting task (12,46,47), and understanding how the genome functions as a whole in the complex natural history of living organisms presents an even greater challenge (12).

Both computational and experimental approaches can be used to study gene function and cellular regulatory networks. Sequence homology provides clues about gene function, but homology is not function, and sequence comparison to known genes in public databases has a limited role (46,48,49). One reason is that only 40–60% of the open reading frames (ORFs) in most sequenced microbial genomes have a postulated function (50–56). Even for the most extensively studied microorganism, *Escherichia coli* K-12, 38% of the ORFs have no attributable function (57). Also, the functional assignment of genes by similarity comparison is sometimes misleading or incorrect because of the complicated evolutionary and structure–function relationships among different genes (46). Therefore, experimental analysis must be performed to understand the biological role of a gene product. One of the key experimental approaches to defining gene function and regulation is to identify patterns of gene expression associated with various physiological states.

Gene expression is the process by which messenger RNA (mRNA) and then proteins are synthesized from DNA templates. RNA transcript levels are of great value for studying gene function and regulation for the following reasons (58,59).

1. *Correlation of Gene Expression and Function.* Natural selection dictates that genes expressed in specific cells under specific conditions must contribute to the fitness of the organism. Similar to the phenomena that natural selection has precisely fine-tuned the biochemical properties of gene products, it has also fine-tuned the regulatory networks that control when and where the product is made and in what quantity. Thus, it is believed

that there is a strong connection between gene expression and the function and regulation of the encoded product.

2. *Connection Between Gene Expression and Physiological States*. The set of genes expressed in a cell determine what the cell is made of, how the cell is built, what biochemical and regulatory systems are operative, and what the cell can do. Gene expression patterns can provide information about the dynamic changes in physiological states and functional activities of a cell under different environmental conditions.

3. *Guilt by Association*. It is generally believed that genes that are expressed together may function together. Sets of genes that share similar functions can be grouped on the basis of the similarities in their expression patterns. Also, common regulatory mechanisms can be inferred for genes with similar expression profiles, and conserved regulatory elements can be identified. Thus, based on the expression patterns of known genes, the function of hypothetical proteins can be predicted if such genes are coexpressed with genes of known function.

4. *Importance of Transcriptional Regulation*. While regulation of protein abundance in a cell is by no means achieved solely through the regulation of mRNA, almost all of the differences in cell types or functional states are correlated with changes in the mRNA levels of many genes. Thus, mRNA levels can be used as a measure of gene expression. High-density microarrays containing whole-genome sequence information are powerful and indispensable tools for the analysis of gene expression and regulation. Once one learns the biological consequences of gene expression patterns as a result of the growing knowledge of the functions of individual genes, it should be possible to use microarrays as a "microscope" for visualizing the complex and dynamic nature of living cells (58).

General Approaches to Revealing Differences in Gene Expression

Information about when and where genes are turned on or off under different environmental conditions is fundamental for understanding gene function and regulation. Three comparative approaches have been used for the display of differential gene expression.

1. *Differential Display of mRNA Under Different Physiological Conditions*. Cells of interest are cultured under different physiological conditions, and the differences in mRNA abundance between the test and reference samples are compared using high-density microarrays. This is the most straightforward and widely used approach for identifying patterns in gene expression associated with various physiological states (12,60,61).

2. *Differential Display of Temporal Gene Expression*. Cells of interest are grown under a specific physiological condition and then harvested at different time points during growth. Changes in mRNA levels are revealed using microarrays. Information on the temporal dynamics of gene expression is very useful in understanding when genes are turned on or off and how genes interact with each other.

3. *Comparison of Gene Expression Patterns Between Wild-Type and Mutant Cells*. The expression of genes in response to changing environmental conditions can be very complicated, and oftentimes the expression profiles of many genes are altered as a result. This presents a great challenge to understanding the underlying regulatory mechanisms. The most effective approach to defining the contributions of individual regulatory genes in a complex metabolic process is to use DNA microarrays to identify genes whose expression is affected by mutations in putative regulatory genes (12).

The basic scheme for microarray-based gene expression studies is outlined in Figure 2. In a typical microarray experiment for monitoring gene expression, gene-specific PCR primers are designed based on whole-genome sequence information and synthesized. Gene-specific fragments are then amplified with specific primers, purified, and arrayed on solid substrates. Once the

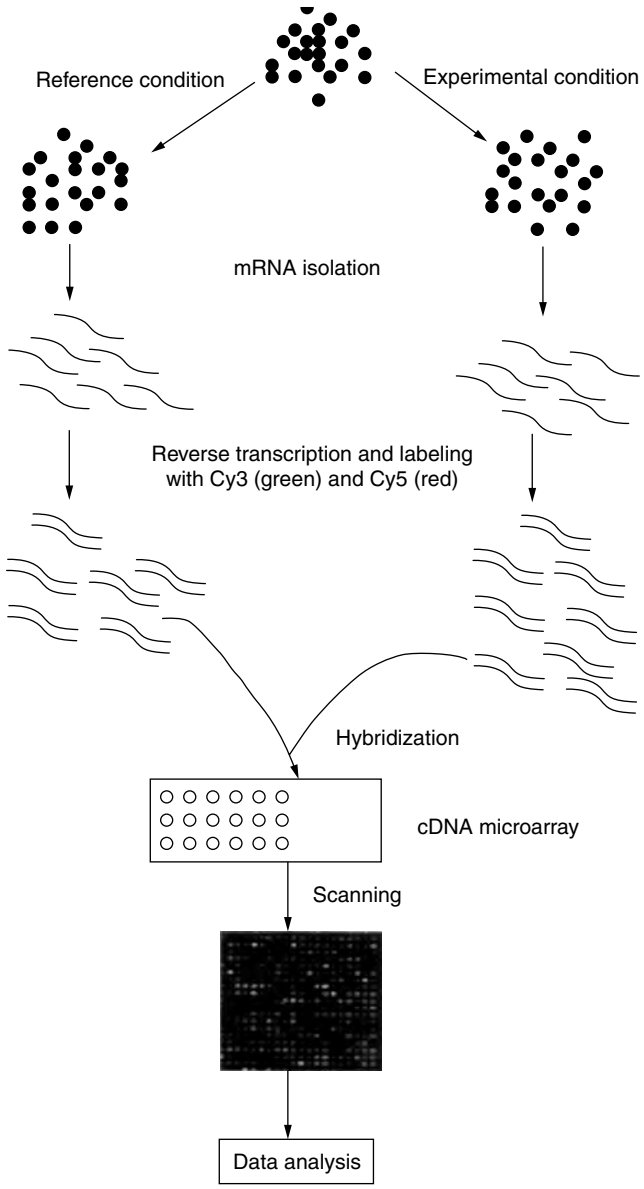

Figure 2. General scheme of microarray experiments for monitoring gene expression. See color insert.

microarrays are ready, total cellular RNA isolated from bacterial cells grown under two different conditions is fluorescently labeled with different dyes (Cy3 or Cy5) via the enzyme reverse transcriptase. The microarray is then simultaneously hybridized with fluorescently tagged cDNA from the test and reference samples. The signal intensity of each fluorescent dye on the array is then measured with a confocal laser-scanning microscope or CCD camera. The quantitative ratio of red (Cy5) to green (Cy3) signal for each spot reflects the relative abundance of that particular gene in the two experimental samples. With appropriate controls, the intensity can be converted into biologically relevant outputs (e.g., the number of transcripts per cell). A series of samples can be compared with each other through separate cohybridizations with a common reference sample, and the data can be analyzed with various statistical methods. A detailed discussion of the technical aspects of microarray experiments for monitoring gene expression can be found in the review by Eisen and Brown (14).

Specificity, Sensitivity, and Quantitation of Microarray-based Detection for Monitoring Gene Expression

Specificity, sensitivity, and quantitation are the three major concerns for any detection technology. Microarrays were initially used to measure gene expression levels in *Arabidopsis thaliana* (11). The microarrays of 48 duplicate cDNA sequences were constructed and simultaneously hybridized with a mixed set of fluorescently labeled probes that also contained cDNA from rat and yeast as negative controls. There was no detectable response from the rat and yeast controls, suggesting that microarray hybridization was very specific. DeRisi and coworkers (12) showed that microarray hybridization could differentiate homologous gene sequences that were less than 75% similar, and oligonucleotide microarrays can, in theory, distinguish single base pair differences among probes (62,63).

The detection limit, or sensitivity, can be evaluated by spiking labeled samples with a known amount of labeled control mRNA. The current detection limit of DNA microarrays used in human genome research allows monitoring of transcripts that represent $1:500{,}000$ (w/w) of the total mRNA. A similar detection limit was obtained using oligonucleotide microarrays (10). Such a detection limit is higher than that obtained with conventional Northern hybridization methods. For yeast, mRNA transcripts present at a level less than one molecule in 100,000 can be detected, which is equivalent to one copy per 20 yeast cells (64). This result suggests that microarray hybridization is very sensitive for detecting gene expression.

The quantitative aspects of microarray hybridization have not been well established. The variability of hybridization signal intensity as a result of variations in array fabrication, labeling, target concentration, and scanning was less than 15% (65). Because of the inherent variations of microarray hybridization and the massive amounts of data that need to be analyzed, genes generally showing a greater than 2-fold change in expression using two-color fluorescence detection were considered to be significantly different in their expression level (66). Comparison of microarray hybridization results with previously known results suggested that microarray hybridization appears to be quantitative enough for detecting differences in gene expression patterns under various conditions (10,12,66). Recently, DNA microarrays were used to measure differences in DNA copy number in breast tumors (67,68). Single-copy deletions or additions can be detected (68), suggesting that microarray-based detection appears to be quantitative.

Using Microarrays to Detect Gene Expression in Microorganisms

Both DNA and oligonucleotide microarrays have been successfully used for detecting differentially expressed genes in yeast (12,13,16,69,70) and bacteria (60,61,71–73). These studies, along with those in plants (11,66) and human cells (10,12,66–68,74–78), convincingly demonstrated that microarrays allow researchers to switch from the very focused view of a single gene or promoter to the global view of a complex regulatory network.

One of the most comprehensive studies demonstrating the feasibility and utility of DNA microarrays for genome-wide exploration of gene expression was carried out with yeast genome sequences (12). In this study, DNA microarrays containing virtually all of the genes of *Saccharomyces cerevisiae* ($\sim 6,000$) were used to study the effect of the diauxic shift from anaerobic to aerobic metabolism under glucose limitation and the concomitant switch to ethanol as a carbon source. By comparing the global view of changes in expression of genes of known functions with their metabolic pathways, DeRisi and coworkers (12) showed the metabolic pathways that were reprogrammed by this shift. The expression patterns of many previously unknown genes were also obtained, and this may provide a clue to their possible functions. In addition, to understand the underlying regulatory mechanisms, microarrays were used to compare the gene expression patterns between wild-type cells and mutants containing deletions in key regulatory genes. DeRisi and coworkers (12) demonstrated that this is a very effective approach to dissecting complicated regulatory networks and defining the functions of individual regulatory genes.

Using microarrays for analyzing gene expression profiles in procaryotic genomes may present some unique challenges because bacterial mRNAs do not have poly A tails, so they cannot be enriched by poly T-based reverse transcription. Because of the low abundance of mRNAs ($\sim$5% of total cellular RNA), rRNA ($\sim$95%) needs to be removed from the total RNA pool to reduce the hybridization background. However, quantitative and reproducible removal of rRNA without losing mRNA is difficult to achieve. Saizieu and coworkers (73) demonstrated that an oligonucleotide microarray containing probes representing approximately 100 genes from both *Haemophilus influenzae* and *Streptococcus pneumoniae* hybridized well with total RNA labeled chemically by a photocoupling reaction using psoralen-biotin. In this study, one to five transcripts per cell were detected, and mRNA quantitation was in good agreement with data from Northern blot analysis. Oligonucleotide microarrays, however, did not work

with total RNA labeled by reverse transcriptase and random priming. Recently, several studies have shown that labeling total RNA by reverse transcription and random labeling in the presence of fluorescent dyes (Cy3-dCTP or Cy5-dCTP) or ^{33}P have worked well with glass-based microarrays for *Mycobacterium tuberculosis* (72) and *Shewanella oneidensis*, and with membrane-based microarrays for *E. coli* (60,61,79). These studies demonstrated the feasibility and utility of microarrays for displaying genome-wide expression patterns in bacteria.

APPLICATIONS OF MICROARRAYS FOR MICROBIAL DETECTION IN NATURAL ENVIRONMENTS

Limitations of Conventional Molecular Methods for Microbial Detection

The detection, characterization, and quantification of microbial population diversity are formidable tasks for microbial ecologists. Traditional culture enrichment techniques for studying microbial communities have proven difficult and ultimately provide an extremely limited view of microbial diversity because the majority of naturally occurring species are not culturable (80). The development and application of nucleic acid–based techniques largely eliminated the reliance on culture-dependent methods, and consequently greatly advanced the detection and characterization of microorganisms in natural habitats (80–82). However, the limitations of conventional nucleic acid–based detection methods prevent them from being readily adapted as high-throughput, cost-effective assessment tools for monitoring microbial communities.

To assess microbial community dynamics and activities in natural environments, microbial detection tools need to be (*1*) simple, rapid, and hence real-time and field-applicable; (*2*) specific and sensitive; (*3*) quantitative; (*4*) capable of high throughput; and (*5*) cost-effective. Although conventional nucleic acid detection approaches [e.g., 16S rRNA gene-based cloning methods, denatured gradient gel electrophoresis (DGGE), terminal restriction fragment length polymorphism (T-RFLP), quantitative PCR, and mass spectrometry–based detection methods] remain vital to studies of microbial communities, they meet these requirements with difficulty. They are slow, labor-intensive, insensitive, nonquantitative, or expensive. Microarray-based technology has the potential of overcoming the limitations of traditional molecular methods for studying microbial community structure.

Advantages and Challenges in Using Microarrays for Environmental Studies

In addition to the advantages previously mentioned, microarray-based technology is well suited for detecting microorganisms in natural environments. Many target functional genes in environments are highly diverse, and it is difficult, sometimes even impossible, to identify conserved regions for designing PCR primers or oligonucleotides. The microarray-based approach does not require such sequence conservation because all of the diverse gene sequences from different populations of the same functional group can be fabricated on arrays and used as probes to monitor their corresponding populations.

In contrast to studies using pure cultures, microarray-based analysis of environmental nucleic acids presents a number of technical challenges. First, in environmental studies, the target and probe sequences are very diverse, and it is not clear whether the performance of microarrays with diverse environmental samples is similar to that with pure culture samples and how sequence divergence affects microarray hybridization. Also, environmental samples are generally contaminated with other substances, such as humic materials, organic contaminants, and metals, which may inhibit DNA hybridization on microarrays. No information is currently available on the performance of microarrays with complex environmental samples. In addition, unlike pure cultures, the biomass in environmental samples is generally low, and consequently, it is not clear whether microarray hybridization is sensitive enough for detecting microorganisms in environmental samples. Finally, it is not certain whether microarray-based detection can be quantitative. Environmental and ecological studies require experimental tools that not only detect the presence or absence of particular groups of microorganisms but also provide quantitative data on their biological activities.

Unlike microarray-based monitoring of gene expression, the application of microarray technology to environmental studies is still new and therefore, limited. It is possible to envision several ways in which microarrays can be applied to advance research in environmental microbiology. The following sections provide a brief description of the various microarray formats that have been used to study microbial populations and some preliminary unpublished data from work conducted primarily in our laboratory.

Functional Gene Arrays (FGAs)

The genes encoding functional enzymes involved in various biogeochemical cycling processes (e.g., carbon, nitrogen, sulfate and metals) are very useful as signatures for monitoring the physiological status and functional activities of microbial populations and communities in natural environments. Microarrays containing functional gene sequence information are referred to as functional gene arrays (FGAs) because they are primarily used for functional analysis of microbial community activities in environments. Similar to the microarrays used for monitoring gene expression, both oligonucleotides and DNA fragments derived from functional genes can be used for fabricating FGAs. Because no data are available for FGAs fabricated with oligonucleotides, the focus is mainly on recent studies using FGAs composed of DNA fragments.

Selection of Gene Probes. FGAs are designed for studying functional gene diversity in environments. To construct FGAs, the gene probes should be carefully defined and selected based on the specific research questions to be addressed. For example, microarrays can consist of gene probes that are involved in various biogeochemical

processes, including nitrification (ammonia monooxygenase, *amoA*), denitrification (nitrite reductases, *nirS* and *nirK*), nitrogen fixation (nitrogenases, *nifH*), sulfite reduction (sulfite reductase, *dsv*A/B), methanogenesis (methyl coenzyme M reductase genes, *mcrA*), methane oxidation (methane monooxygeneases, *mmo*), and plant polymer degradation (cellulases, xylanases, ligin peroxidases).

There are two general approaches for obtaining FGA probes. The first approach is to amplify the desired gene fragment from genomic DNA from pure bacterial cultures with specific primers or from cloned plasmids containing the desired gene insert with vector-specific primers. However, the availability of pure cultures and plasmid clones can be limited. The second approach is to recover the desired gene fragments from natural environments using PCR-based cloning methods (Fig. 3; 83). First, microbial community DNA is extracted and purified from environmental samples using a method described previously (84). The desired genes are then amplified with conserved primers specific to various groups of functional genes and cloned into plasmids, such as TA cloning vectors, which are then transformed into *E. coli* cells. The colonies containing the desired gene inserts are generally identified by PCR using vector-specific primers (83). Unique clones are typically distinguished by differences in digestion patterns generated by two pairs of restriction endonucleases (*Msp*I plus *Rsa*I and *Hha*I plus *Hae*III), followed by DNA sequencing. Finally, the sequences are compared and the clones that show more than 85% similarity can be used as specific probes for FGAs. These two approaches have been used to construct FGAs containing nitrite reductase genes and ammonia monooxygenase genes for monitoring bacteria involved in nitrification and denitrification (85).

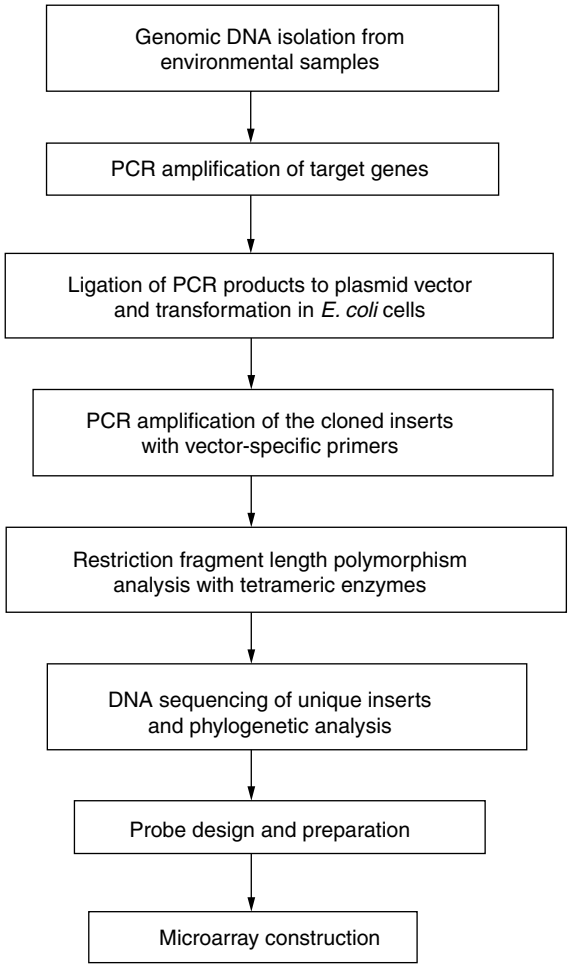

Figure 3. Molecular approach for recovering signature sequences from environmental samples.

Specificity, Sensitivity, and Quantitation. Hybridization specificity is influenced by many factors, such as G + C content, degree of sequence divergence, length, secondary structure of the probe, temperature, and salt concentrations. To determine the specificity of DNA microarray hybridization, functional gene arrays were constructed consisting of heme- and copper-containing nitrite reductase genes (27 *nir*S and 9 *nir*K, respectively), 7 ammonia monooxygenase genes (*amo*A), and 11 methane monooxygenase genes [*pmo*A] (85). 16S rRNA genes and five yeast genes were used as positive and negative controls, respectively. Cross-hybridization among different gene groups was not observed at both low (45 °C) and high (65 °C) stringency. No hybridization was observed with any of the five yeast genes on the array. These results indicate that specific microarray hybridization can be achieved when using DNA extracted from environmental samples.

The detection sensitivity of FGA hybridization was determined using genomic DNA from both pure cultures and soil community samples (Fig. 4). It was found that the arrays have a detection limit, or sensitivity, that was approximately 1 ng for pure genomic DNA and 25 ng for soil community DNA. This level of detection should be sufficient for many studies in microbial ecology. These results suggest that microarray hybridization can be used as a sensitive tool for analyzing microbial community structure in environmental samples.

To evaluate whether microarray hybridization can be used as a quantitative tool, the relationship between target DNA concentration and hybridization signal was examined. A strong linear relationship was observed between signal intensity and target DNA concentration in the range of 1 to 100 ng, suggesting that DNA microarrays can be potentially used as tools for quantitative analysis of environmental samples. Experimental variation between array slides can be reduced to below 15%, which is similar to the results obtained by Bartosiewicz and coworkers (65) in their study on monitoring gene expression. However, sequence divergence has significant effects on hybridization signal intensity (85). The difficult challenge for quantifying the abundance of microbial populations in natural environments is to distinguish differences in hybridization intensity caused by population abundance from those caused by sequence divergence.

Applications. Because functional gene arrays for microbial detection are presently in the development stage, their applications are still being explored. To demonstrate the applicability of DNA microarrays for microbial community analysis, functional gene arrays have been used

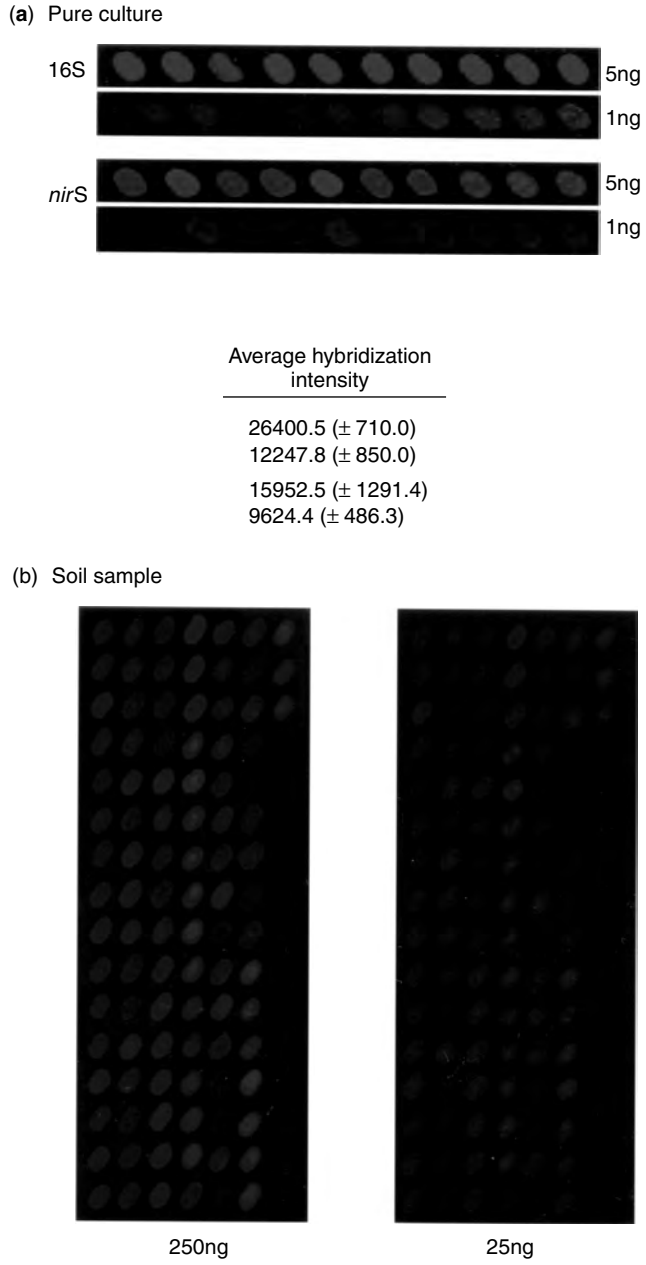

Figure 4. Array hybridization images showing the detection sensitivity with labeled pure genomic DNA and bulk community DNA from soil. (**a**) Genomic DNA from a pure culture of *nir*S-containing *Pseudomonas stutzeri* was labeled with Cy5 using a random primer labeling method. The target DNA was hybridized to nitrogen cycle microarrays at total concentrations of 1 and 5 ng. The average hybridization intensity at each target DNA concentration is presented. (**b**) Genomic DNA from surface soil was labeled with Cy5 as described in (**a**) and hybridized at total concentrations of 25 and 250 ng with the nitrogen cycle microarrays. See color insert.

to analyze the distribution of denitrifying and nitrifying microbial populations in marine sediment and soil samples (85). DNA from two marine sediment samples and four chromium-contaminated surface soil samples was fluorescently labeled using a random primer labeling method and hybridized with FGAs in triplicate. Strong hybridizations were obtained with both marine sediment and soil samples. Although most of the functional gene probes were derived from marine sediment environments, these probes also hybridized well with community DNA from soil samples, suggesting that the types of nitrifier and denitrifier genes on the array are common in both environments. The abundance of *nir*S genes appeared to be higher than that of *nir*K genes in both marine and soil environments. In addition, microarray analysis using labeled genomic DNA demonstrated that *nir*S genes found in pure cultures were dominant in marine sediment environments, whereas *nir*S and *nir*K pure cultures isolated from marine environments were not found in an environmental clone library generated by PCR-based cloning (86), suggesting that the diversity patterns revealed by PCR amplification may not accurately represent the population distribution in these environments.

Phylogenetic Oligonucleotide Arrays (POAs)

Ribosomal RNA genes are powerful molecules for studying phylogenetic relationships among different organisms and for analyzing microbial community structure in natural environments, because these genes exist in all organisms and contain both highly conserved and highly variable regions, which are useful for differentiating microorganisms at different taxonomic levels (e.g., kingdom, phyla, family, genus, species, and strain). Also, rRNA genes have the largest representative database, making them ideal molecules for developing microarray-based detection tools. Oligonucleotide microarrays containing information from rRNA genes are referred to as *phylogenetic oligonucleotide microarrays* (POAs) because such microarrays are used primarily for phylogenetic analysis of microbial community composition and structure.

POAs can be constructed for different phylogenetic taxa and used in community analysis studies. The oligonucleotide probes can be designed in a phylogenetic framework to survey different levels of sequence conservation, from highly conserved sequences giving broad taxonomic groupings to hypervariable sequences giving genus- (and potentially species-) level groupings. Such microarray assays do not require samples of high biomass if PCR or other signal amplification techniques are applied.

Challenges of Phylogenetic Oligonucleotide Arrays. One of the biggest potential problems for microarrays in general is probe accessibility (34). It is not clear how much of the probe is really accessible to hybridization because hybridization on microarrays is not simply a solution-phase reaction in which DNA strands readily associate together. This may depend on target and probe sequences and intrastrand secondary and tertiary structure. Preliminary results suggest that FGAs are less problematic. However, oligonucleotide arrays, especially 16S rRNA-gene-based oligonucleotide microarrays, present more difficult technical challenges.

There are two unique challenges for POAs.

1. *Specificity*. Because the rRNA gene is highly conserved and present in all microorganisms, specific detection with rRNA-targeted oligonucleotide microarrays can

be difficult. First, the probe length and G + C content can significantly impact microarray hybridization (26). Also, probe selection is limited by the sequence differences among the target genes, and cross-hybridization can be a problem for oligonucleotide arrays. In addition, oligonucleotide microarrays typically contain many probes. Ideally, all of the oligonucleotides should have similar or identical melting kinetics, so that all of the probes on an array element can be subjected to the same hybridization conditions at once. This can be difficult to achieve, because the melting temperature depends on the length and composition of the oligonucleotide probe as well as the target 16S rRNA molecules in the samples.

2. *Secondary Structure*. The hybridization of oligonucleotide probes to target nucleic acids possessing stable secondary structure can be particularly challenging because low stringency conditions (i.e., hybridization temperatures between 0 and 30 °C) are required for stable association of a long target nucleic acid with a short immobilized oligonucleotide probe (25,26,87,88). Any stable secondary structure of the target DNA or RNA must be overcome to make complementary sequence regions available for duplex formation. The stable secondary structure of 16S rRNA will have serious effects on hybridization specificity and detection sensitivity.

Applications. Oligonucleotide microarray technology for studies in environmental microbiology has not been rigorously developed. Although gel pad–based oligonucleotide microarrays (26) and the in situ fabricated oligonucleotide microarrays made by Affymetrix (Gary Andersen, personal communication) can be used for monitoring microbial populations, no study, as yet, has shown that microarrays consisting of oligonucleotides attached to glass slides work well in analyzing microbial community structure and function.

In the study by Guschin and coworkers (25), gel-pad oligonucleotide microarrays were constructed with oligonucleotides complementary to 16S rRNA sequences from key genera of nitrifying bacteria. The results showed that specific detection can be achieved with this type of microarray. However, the probe specificity depends on various factors such as probe length. They showed that, as the length of the oligonucleotide probe increases, mismatch discrimination is lost; conversely, as the length of the probe decreases, hybridization signal intensity (i.e., sensitivity) is lost. In addition, they illustrated that hybridization signal variations can be improved by varying probe concentrations and that multiple probe-target populations can be quantified simultaneously using multiple color detection.

Community Genome Arrays (CGAs)

Decades of scientific investigations have led to the isolation of many microorganisms from a variety of natural habitats. However, little or nothing is known about the genomic sequences for the majority of these microorganisms. Such a large collection of pure cultures should be very useful for monitoring microbial community structure and composition in natural environments if microarrays could be developed that did not require prior knowledge of gene sequences. The process of developing community genome arrays (CGAs) or microarrays constructed with whole genomic DNA from many individual pure cultures has commenced. The utility of CGAs depends on sample complexity, hybridization kinetics, and the cultivation of important organisms in the environment to be studied.

Community genome arrays consisting of 54 pure genomic DNAs isolated from different groups of bacteria have been constructed. Both gram-positive and gram-negative bacteria were represented on the array as well as members of the α-, β-, and γ-proteobacterial divisions and various strains of *Pseudomonas stutzeri*. Preliminary results indicated that as little as 50 ng/μl of probe genomic DNA can be clearly detected with fluorescently labeled target genomic DNA, whereas no substantial increase in hybridization signal intensity was observed for arrayed genomic DNA that was greater than 200 ng/μl. Clearly, CGAs can be used to distinguish bacteria at the genus level. Although some of the results suggest that they can also differentiate species of the same genus, more work is required to enhance the specificity of CGAs by evaluating different hybridization parameters, such as temperature. Nevertheless, because they circumvent the need for prior sequence information, genomic DNA microarrays hold considerable promise as a sensitive, specific tool for analyzing the structure and composition of microbial communities in natural environments.

CONCLUSION

Genomics and associated genomic technologies have revolutionized the biological sciences. The availability of whole-genome sequences from numerous bacteria, fungi, plants, and animals will pave the way for functional genomics by providing the information and resources for microarray construction and analysis. Microarrays will be the focal point for functional genomics by allowing the parallel analysis of gene expression profiles, mutations, and genetic polymorphisms. With this technology, it is possible to study the expression of all genes in an organism at once. However, the biggest challenge is how to analyze and interpret the massive amounts of data generated with microarrays.

Environmental microbiology will greatly benefit from the advances in functional genomics and genomic technologies because many microorganisms important to the environment have been completely sequenced or are in the process of being sequenced. It is expected that, in the near future, whole genome microarrays for numerous environmental microorganisms will be constructed and used in functional genomics research to determine patterns of gene expression under various environmental conditions and to identify novel metabolic pathways and regulatory networks. These discoveries at the basic research level will provide invaluable information for environmental studies.

The aim of microbial ecology is to derive the principles capable of explaining microbial community diversity, structure, and function. Such principles can only be

discovered by examining the structure and activities of populations and the properties of individual species (89). However, characterizing the diversity, structure, and function of microbial populations within an environmental context is a great challenge. Various types of microarray-based genomic tools will be very valuable for such a purpose because the interactions between microorganisms and the environment most often occur at the molecular level. With these tools, thousands of different microbial populations in a community can be examined at once and in real time. Although significant progress in applying microarray-based genomic tools to environmental studies has been made recently, these tools are still in the early stages of development. More effort is needed to recover signature sequences from different environments and improve the specificity, sensitivity, and quantitation of microarrays within the context of various environmental samples.

MICROBIAL DEGRADATION OF EXPLOSIVES

JALAL HAWARI
ANNAMARIA HALASZ
Biotechnology Research Institute
Québec, Canada

Explosives are highly energetic chemicals that rapidly release large amounts of energy and gaseous products upon detonation. The history of explosives dates back to the development of black powder long before even the industrial revolution started in Europe. More information on the discovery, use, and development of explosives can be found in a treatise by Linder (1). Explosives can be chemical, mechanical, electrical, or nuclear, but the following discussion covers only the microbial degradation of secondary chemical explosives. Primary explosives (also called initiator explosives) have low energies of activation and are sensitive to low-pressure shock waves or friction. They are used to initiate the detonation of secondary chemical explosives, which are relatively stable, easily manipulated, and make up the bulk of reactive material in most explosive formulations.

Presently some of the most frequently manufactured and used secondary explosives include 2,4,6-trinitrotoluene (TNT), dinitrotoluenes (DNT), 1,3,5-trinitrobenzene (TNB), N,2,4,6-tetranitro-N-methylaniline (tetryl), trinitroglycerine (TNG), nitroguanidine (NQ), ethylene glycol dinitrate (EGDN), nitrocellulose (NC), pentaerythritol tetranitrate (PETN), glycidyl azide polymer (GAP), hexahydro-1,3,5-trinitrio-1,3,5-triazine (RDX), octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX) and 2,4,6,8,10,12-hexanitrohexaaza-isowurtzitane, CL-20 (Fig. 1).

Past and present practices with explosives such as manufacturing, formulations, testing and training, demilitarization, and open burning/open detonation (OB/OD) have lead to severe soil and groundwater contamination (2 to 4). It has been estimated that TNT alone is produced in amounts close to 2 million pounds a year (5) and a

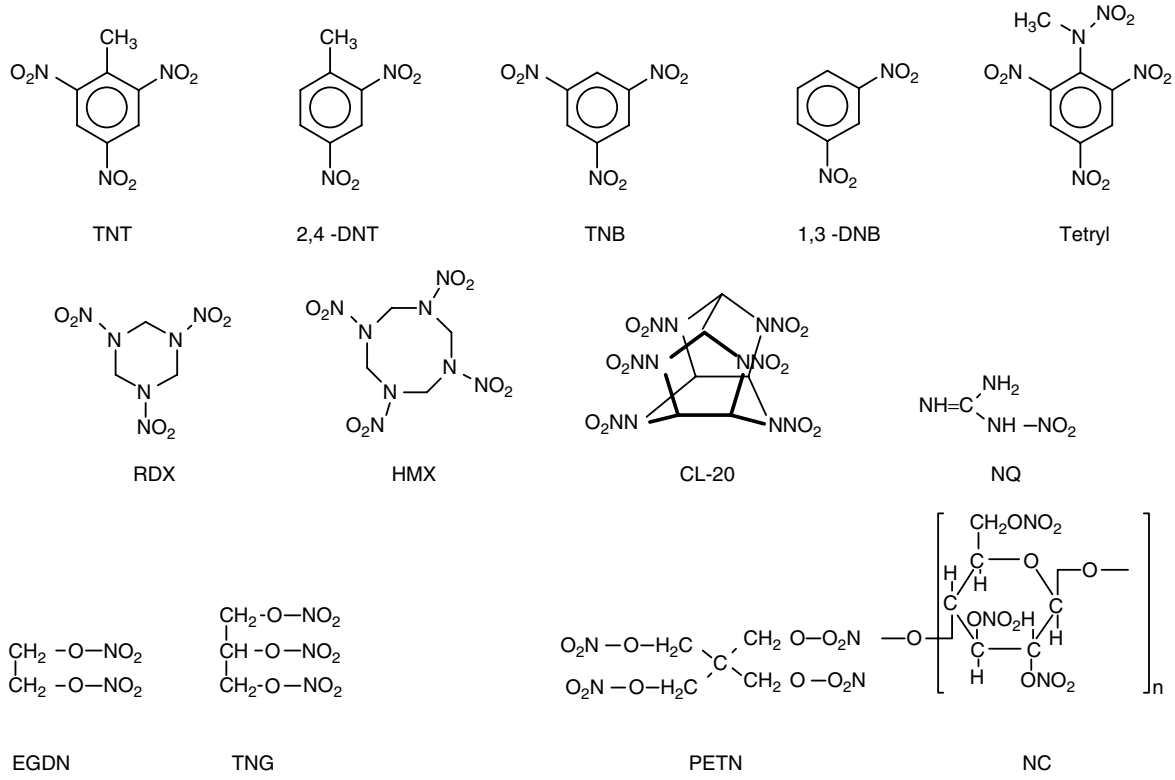

Figure 1. Structures and common names of most commonly used secondary explosives.

single TNT manufacturing plant can generate more than 1.8×10^3 m^3 of wastewater per day (6). During the manufacture of RDX, up to 12 mg/L may be discharged to the environment in process wastewater (7). Presently soil and groundwater contamination by explosives is a worldwide environmental problem that started following intensive military activities in World Wars I and II and the subsequent cold war that lasted until the turn of the century. For example, the widespread contamination of soil and water by explosives in the United States is attributed to activities related to the Second World War and the Korean War (8). Subsequent demilitarization activities caused most of the contamination problem in Germany (9). In Canada, approximately 100 OB/OD and training (air and land force bases) sites are known to be associated with activities involving RDX, HMX, and TNT (10).

Several countries such as United States, Canada, and Germany have initiated programs to determine the level of soil and water contamination by explosives and to develop cost-effective bioremediation technologies to clean their contaminated sites. Other countries whose territories (land and water) have experienced extensive military activities and some of the worst armed conflicts in human memory (First and Second World Wars, Vietnam and Korean wars, wars in the Middle East, conflicts in Africa and the civil wars in East Europe and in the breakaway republics of the former Soviet Union) have no available data on the environmental impact of explosives and the need to decontaminate affected areas.

The physicochemical properties (solubility, octanol/water partition coefficient (k_{ow}) soil/water partition coefficient (k_d), volatility) of some of the most frequently encountered explosives are presented in Table 1 (11–31). Knowledge of the physicochemical properties of explosives can help understand their fate and environmental impact. For example, k_{ow} and k_d values can tell how an explosive interacts with soil and gives an indication of its capacity for subsurface soil migration and groundwater contamination. Groundwater contamination indicates whether explosives and their degradation products leach through subsurface soil to reach the water table and is a useful indicator of the extent of site contamination.

Most energetic chemicals are toxic to aquatic and terrestrial species (32,33). Increased public awareness of the toxicity and risk associated with energetic compounds necessitates the development of cost-effective bioremediation technologies for their removal. The conversion of contaminants to water and gaseous nitrogen or carbon dioxide is called *mineralization*. As far as we are aware, no in situ microbial mineralization–based technologies exist for any explosive, but ex situ bioremediation technologies such as composting (recently reviewed by Burns-Nagel and coworkers (34)) and bioslurry technology (35) have been reported. In almost all reported studies, little to no mineralization is produced, and the fate of the compound and its (bio)transformed products are undetermined. The present document provides an overview of the scope of the contamination problems related to secondary explosives and summarizes relevant key biodegradation studies undertaken under both aerobic and anaerobic conditions to degrade these compounds.

BIODEGRADATION OF EXPLOSIVES

The nitro $-NO_2$ functional groups that define the chemical and energetic properties of explosives also characterize their biochemical and microbial reactivity. For example the frequent observation of reduced amine products during TNT biodegradation is attributed to the presence of highly oxidized $-NO_2$ groups directly attached to the aromatic benzene ring in the parent compound. The π-electrons and the carbon atoms located in the aromatic ring of TNT are shielded from any external attack, particularly electrophilic, by the steric effects caused by the presence of the four functional groups ($3\ -NO_2$ and $1\ -CH_3$) and by the electron withdrawing properties of the nitro groups (10). Consequently, any enzymatic attack on TNT would preferably take place at the external $-NO_2$ functional groups leaving the stable aromatic system intact. As is described later, TNT, under both aerobic and anaerobic conditions, undergoes reduction of the highly electrophilic $-NO_2$ groups to produce the corresponding hydroxylamino derivatives ortho-hydroxylamino-4,6-dinitrotoluene (2-HADNT) and para-hydroxylamino-2,6-dinitrotoluene (4-HADNT). The characteristic functional group $-$NHOH is extremely reactive and can participate in several abiotic and biological reactions such as rearrangement (Bamberger) to produce the corresponding phenolamines ortho-amino-5-hydroxy-4,6-dinitrotoluene, 2-A-5-OH-4,6-DNT, and para -amino-5-hydroxy-2,6-dinitrotoluene, 4-A-5-OH-2,6-DNT (36). Also the $-$NHOH group can undergo further reduction to produce the corresponding amines under both aerobic and anaerobic conditions. Under strictly anaerobic conditions, ADNT (amino-dinitrotoluene) is reduced further to produce the reactive product 2,4,6-triaminotoluene (TAT) (37–41), which can irreversibly bind to soil (38,42).

In the case of the two nonaromatic cyclic nitramines RDX and HMX, which lack the aromatic stability of TNT, it was shown that once an initial successful microbial (or chemical) attack occurs at RDX or HMX, the molecule becomes unstable and undergoes spontaneous decomposition to eventually produce nitrous oxide, formaldehyde, and carbon dioxide (43,44).

General Procedure for Laboratory Test Studies

Contaminated soil (or water) samples can be obtained from either a firing range, a OB/OD, or a manufacturing site and are analyzed for explosives content using a validated method such as the U.S. Environmental Protection Agency's EPA Method #8330 (45). The contaminated soil is then treated with a source of microorganisms (domestic anaerobic sludge, soil indigenous degraders, microbial consortia in manure, or specific isolates) in low volume (50 to 100 ml) serum bottles (microcosms) (Fig. 2; 43,44). Some microcosms are supplemented with either a uniformly labeled [UL-^{14}C] explosive and then fitted with a small test tube containing KOH (0.5 M) to trap liberated carbon dioxide ($^{14}CO_2$). In some cases heavy isotope ^{15}N labeled compounds are used in conjunction with mass spectrometry to confirm the origin of N_2, N_2O, and other N-containing intermediates produced during the biodegradation of explosives such as RDX and

Table 1. Physicochemical Properties of Some of the Most Used Explosives

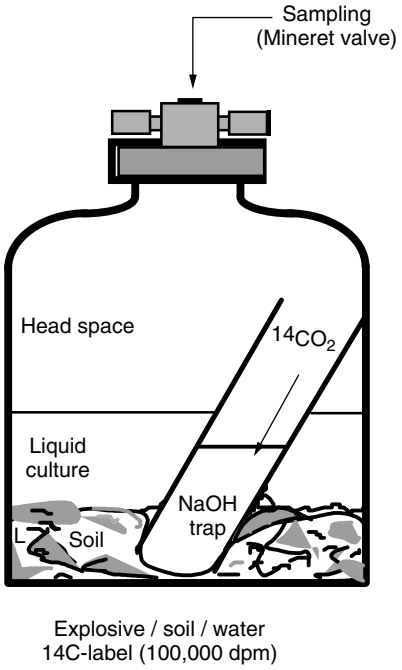

Figure 2. A typical laboratory microcosm used to study the microbial degradation of pollutants. See color insert.

HMX (43,46). Microcosms with the [UL-^{14}C] explosive are sampled for the determination of $^{14}CO_2$ (mineralization) in the KOH trap using a Packard, Tri-Carb 4530 liquid scintillation counter. Microcosms that did not receive ^{14}C-labeled RDX are reserved for the analysis of intermediate degradation products using analytical techniques such as gas chromatography-mass spectrometry (GC-MS), high performance liquid chromatography-UV detection (HPLC-UV) and liquid chromatography-mass spectrometry (LC-MS) (43,44).

Biodegradation of TNT and Other Related Polynitroaromatic Explosives

TNT, which is considered as one of the most widely used explosives, is selected as a model compound to review the microbial degradation of polynitroaromatic energetic chemicals. TNT is a reactive molecule and has been repeatedly reported to biotransform readily to give monoamino-dinitrotoluenes (ADNT) and diamino-mononitrotoluene (DANT) under both aerobic and anaerobic conditions (9,47–49). The resulting amines contain reactive $-NH_2$ functional groups that (bio)transform further to several other products including azo and acetyl derivatives, with little to no mineralization (9,39). In general no significant mineralization has been generated thus far during bacterial treatment of TNT. Fungi can produce relatively high amounts of mineralization (40%) (9) in a liquid culture but no significant mineralization is observed in soil. Tables 2 and 3 (50) summarize the microorganisms (bacteria and fungi) that have been studied for their degradation potential of TNT.

Table 2. Biodegradation of TNT with Bacteria Under Aerobic and Anaerobic Conditions

The addition of a hydride anion (H^-) to the aromatic π-system of TNT can lead to the formation of a Meisenheimer complex that has the potential for mineralization. Vorbeck and coworkers (51) reported the formation of monohydride and dihydride Meisenheimer complexes in the treatment of TNT with *Rhodococcus erythropolis* strain HLPM-1, whereas Lenke and Knackmuss (52) observed a Meisenheimer complex during conversion of picric acid (2,4,6-trinitrophenol) to 2,4-dinitrophenol. In addition, Duque and coworkers (53) reported that denitration of the resulting complex formed from the treatment of TNT with *Pseudomonas* sp. clone A lead to mineralization. Nishino and coworkers (54) showed that 2,4-DNT, a partially denitrated TNT, could mineralize under aerobic conditions using *Burkholderia* sp. An enzymatic denitration process yielding partially or totally denitrated TNT products would thus create a pathway for mineralization if coupled to the process reported by Nishino and coworkers (54).

Biodegradation with Anaerobic Bacteria

There has been extensive reporting on the biodegradation of polynitroaromatic explosives such as TNT under anaerobic conditions. In almost all studies, the initial products are the amine derivatives that biotransform further to other aromatic products without being mineralized. Most reported studies on the anaerobic treatment of TNT have been recently reviewed by Hawari and coworkers (50). Thus far, TNT biodegradation under anaerobic conditions lead to the initial production of 4-amino-2,6-dinitrotoluene (4-ADNT), 2-amino-4,6-dinitrotoluene (2-ADNT), 2,4-diamino-6-nitrotoluene (2,4-DANT), and 2,6-diamino-4-nitrotoluene (2,6-DANT). Reduction of the $-NO_2$ groups in TNT is found to be regioselective and normally favors reduction at the para $-NO_2$ group to produce the corresponding mono- and diamino derivatives 2-ADNT and 2,4-DANT. 2,4,6-Triaminotoluene (TAT) is only observed under strictly anaerobic conditions (Fig. 3; 37,41,55,56). TAT is a very reactive molecule and can undergo several abiotic and biological reactions. The triamine was reported to undergo deamination to produce ammonium ions using a sulfidogenic isolate (41), whereas Funk and coworkers (55) reported the formation of para-cresol from TNT biodegradation. More recently Hawari and coworkers (40) showed that when [$^{13}CH_3$]TNT was treated with the sludge, neither [$^{13}CH_3$]toluene nor [p-$^{13}CH_3$]cresol were detected as TNT metabolites during biodegradation, indicating the absence of denitration or deamination. Table 2 clearly shows that TNT biotransforms effectively without significant mineralization. Figure 3 shows the transformation of TNT to TAT, which accumulates in the system before being transformed to other unidentified products without mineralization.

Biodegradation by Fungi

The interest in using fungi in bioremediation stems from their widespread presence in nature and their ability to produce several extracellular enzymes including lignin peroxidase (LiP), manganese-dependent peroxidase (MnP), and laccase, all capable of degrading several types of chemical bonds. The most recent and comprehensive reports on the biotransformation of TNT with fungi have been recently reviewed by Fritsche and coworkers (9), who described the existence of close to

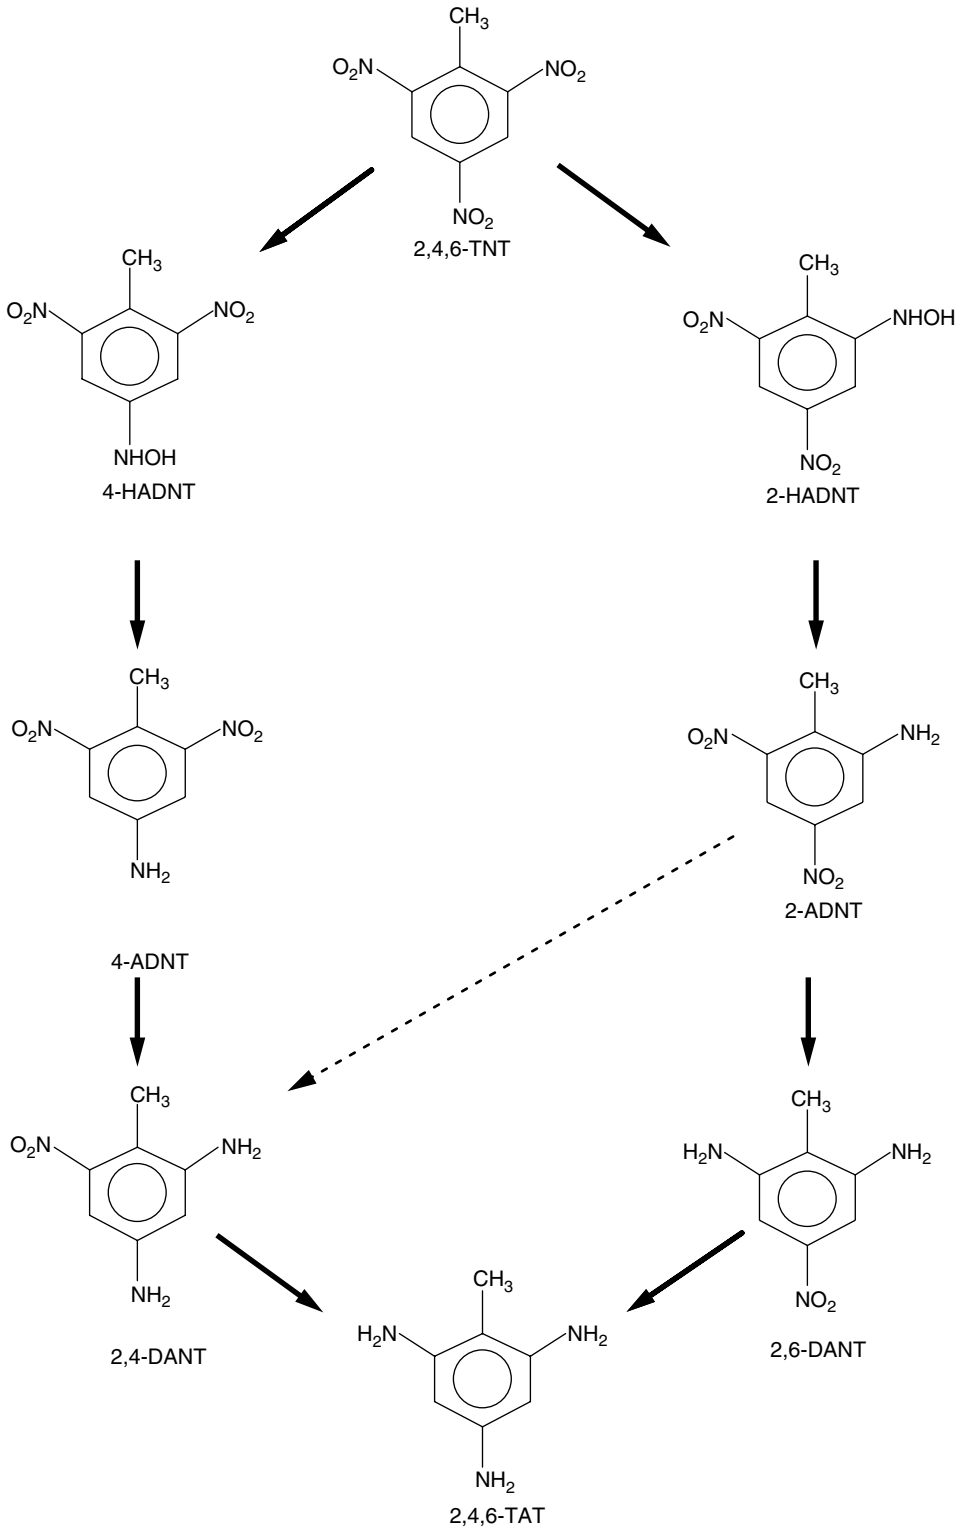

Figure 3. A comprehensive pathway summarizing biotransformation routes of TNT under anaerobic conditions. Constructed from papers that have been recently reviewed in References 37–41,49,50,55,120.

1.5 million different fungal species that colonize a wide range of habitats. Ninety-one fungal strains were tested and most were found capable of biodegrading TNT. In the case of the wood rot fungi, *Phanerochaete chrysosporium*, mineralization of TNT is found to be dependent on the organism's physiological condition being ligninolytic or nonligninolytic (9,46,57). TNT is reported to mineralize under the ligninolytic condition of the fungi, a state identified by the presence of peroxidase enzymes such as lignin peroxidase (LiP) and manganese-dependent

peroxidase (MnP). For example, more than 30% mineralization has been reported for the degradation of TNT with *Phanerochaete chrysosporium* (58) and *Clitocybula dusenii* TMb12 (59) in liquid cultures under ligninolytic conditions. Several other authors (60–62) reported that MnP from basidiomycetous fungi is capable of converting TNT and its reduction products (hydroxylamino- and amino-dinitrotoluenes) to carbon dioxide in relatively high yield.

The initial products from TNT biotransformation with *Phanerochaete chrysosporium* were nitrosotoluene (NsT), ortho-hydroxylamino-4,6-dinitrotoluene (ortho-HADNT), para-hydroxylamino-2,4-dinitrotoluene (para-HADNT) and mono- and diaminonitrotoluenes (ADNT and DANT) (46,63). The initial products NsT, HADNT, ADNT, and DANT were formed under nonligninolytic conditions (no LiP) and biotransformed further to give several other secondary products including azo, azoxy, phenolic, and acylated (acetylated and formylated) derivatives (Fig. 4). Some of the detected azoxy compounds, possibly produced as condensation products between HADNT and NTs, include 4,4′,6,6′-tetranitro-2,2′-azoxytoluene (TN-2,2′-AzoxyT) and 2,2′,6,6′-tetranitro-4,4′-azoxytoluene (TN-4,4′-AzoxyT). The azoxy compounds did not accumulate and they biotransformed to the azo derivatives 4,4′,6,6′-tetranitro-2,2′-azotoluene (TN-2,2′-AzoT) and 2,2′,6,6′-tetranitro-4,4′-azotoluene (TN-4,4′-AzoT), which later reduced to give the hydrazo-derivatives 4,4′,6,6′-tetranitro-2,2′-hydrazotoluene (TN-2,2′-HydrazoT) and 2,2′,6,6′-tetranitro-4,4′-hydrazotoluene (TN-4,4′-HydrazoT), respectively (Fig. 4). In a more recent study, Hawari and coworkers (46) detected nine different acylated products as shown in Figure 4. They included 2-N-acetylamido-4,6-dinitrotoluene, 2-N-AcDNT, and its p-isomer, 4-N-AcDNT, 2-formylamido-4,6-dinitrotoluene, 2-N-FmDNT, and its p-isomer, 4-N-FmDNT, 4-N-acetylamino-2-amino-6-nitrotoluene, 4-N-AcANT, and 4-N-formylamido-2-amino-6-nitrotoluene, 4-N-FmANT, 4-N-acetylhydroxy-2,6-dinitrotoluene, 4-N-AcHDNT, and 4-N-acetoxy-2,6-dinitrotoluene, 4-N-AcoxyDNT, and finally 4-N-acetylamido-2-hydroxylamino-6-nitrotoluene, 4-N-AcOHDNT.

In general, biodegradation of TNT by ligninolytic fungi (*Clitocybula dusenii* TMb12 and *Phanerochaete chrysosporium*) produced higher mineralization amounts than those normally obtained by bacteria (Tables 2 and 3). It has been suggested that the presence of very reactive free radicals, created by an electron transfer process to TNT by either LiP or MnP (9,57,63,64) might enhance the degradation of the aromatic ring. The involvement of highly reactive free radicals in the degradation of TNT by fungi, which can be verified using electron spin resonance spectroscopy (ESR), creates a problem in soil because of the potential quenching of free radicals in soil.

In summary, TNT biotransforms readily under both aerobic and anaerobic conditions with little to no mineralization. Therefore the discovery of new microorganisms capable of mineralizing TNT and other polynitroaromatic explosives such as tetryl or enhancing their irreversible binding (immobilization) to soil is receiving considerable attention from the scientific community. As we will describe later several authors have recently addressed the importance of understanding the mechanisms of interactions between the energetic chemicals and their degradation products with their matrix (soil and biomass) as an alternative soil remediation technology (52,65–67).

Biodegradation of the Heterocyclic Nitramine Explosives RDX, HMX and CL-20

Heterocyclic nitramine explosives such as RDX, HMX, and CL-20 lack the aromatic electronic stability of TNT and its transformed products. Predictably, a successful enzymatic transformation of one of the $N-NO_2$ or the inner C–N bonds of the cyclic nitramine would lead to ring cleavage because the inner C–N bonds in RDX become very weak (<2 Kcal/mole) (68). Recently this hypothesis was tested and proved feasible when RDX produced high amounts of carbon dioxide and nitrous oxide following its treatment with either municipal anaerobic sludge (43,44) or the fungus *Phanerochaete chrysosporium* (69).

Biodegradation Under Anaerobic Conditions

McCormick and coworkers (70) is the first group of workers to describe biodegradation of RDX using microorganisms in anaerobic sludge. They postulated a pathway for the degradation of RDX based on the sequential reduction to hexahydro-1-nitroso-3,5-dinitro-1,3,5-triazine (MNX), hexahydro-1,3-dinitroso-5-nitro-1,3,5-triazine, (DNX), and hexahydro-1,3,5-trinitroso-1,3,5-triazine, (TNX) prior to cleavage to form formaldehyde, methanol, hydrazine, and dimethyl hydrazine. Subsequent reports on the biodegradation of RDX and HMX, reviewed recently by Hawari and coworkers (43), did not provide additional information on the initial and intermediate metabolites and the enzymes associated with their formation. For instance several soil isolates *Providencia rettgeri*, *Citrobacter freundii,* and *Morganella morganii* (71) and consortia from horse manure (72) were found to successfully remove RDX, but apart from the nitroso derivatives (MNX, DNX, and TNX) no other ring cleavage products were reported. Recently, Hawari and coworkers (43,44) reported detailed time course studies for the biodegradation of RDX and HMX by domestic anaerobic sludge and provided evidence for the effective mineralization of both explosives to nitrous oxide (N_2O) and formaldehyde (HCHO), which later biotransforms to carbon dioxide. Using LC/MS, Hawari and coworkers (43,44) provided experimental evidence signifying the formation of two important ring cleavage products, identified as methylene dinitramine, $O_2NNHCH_2NHNO_2$, and traces of dimethanolnitramine, $(HOCH_2)_2NNO_2$ (Fig. 5). Methylenedinitranmine was detected in almost stoichiometric amounts and the suggestion was thus made that RDX underwent ring cleavage via MNX or via a direct attack with a hydroxylase or hydrolase enzyme because neither DNX nor TNX can give methylenedinitramine (Fig. 5). In general, alkyldinitramine and hydroxyalkylnitramines, such as the present $(HOCH_2)_2NNO_2$, are unstable in water and can undergo spontaneous decomposition to eventually produce N_2O. The presence of nitrous

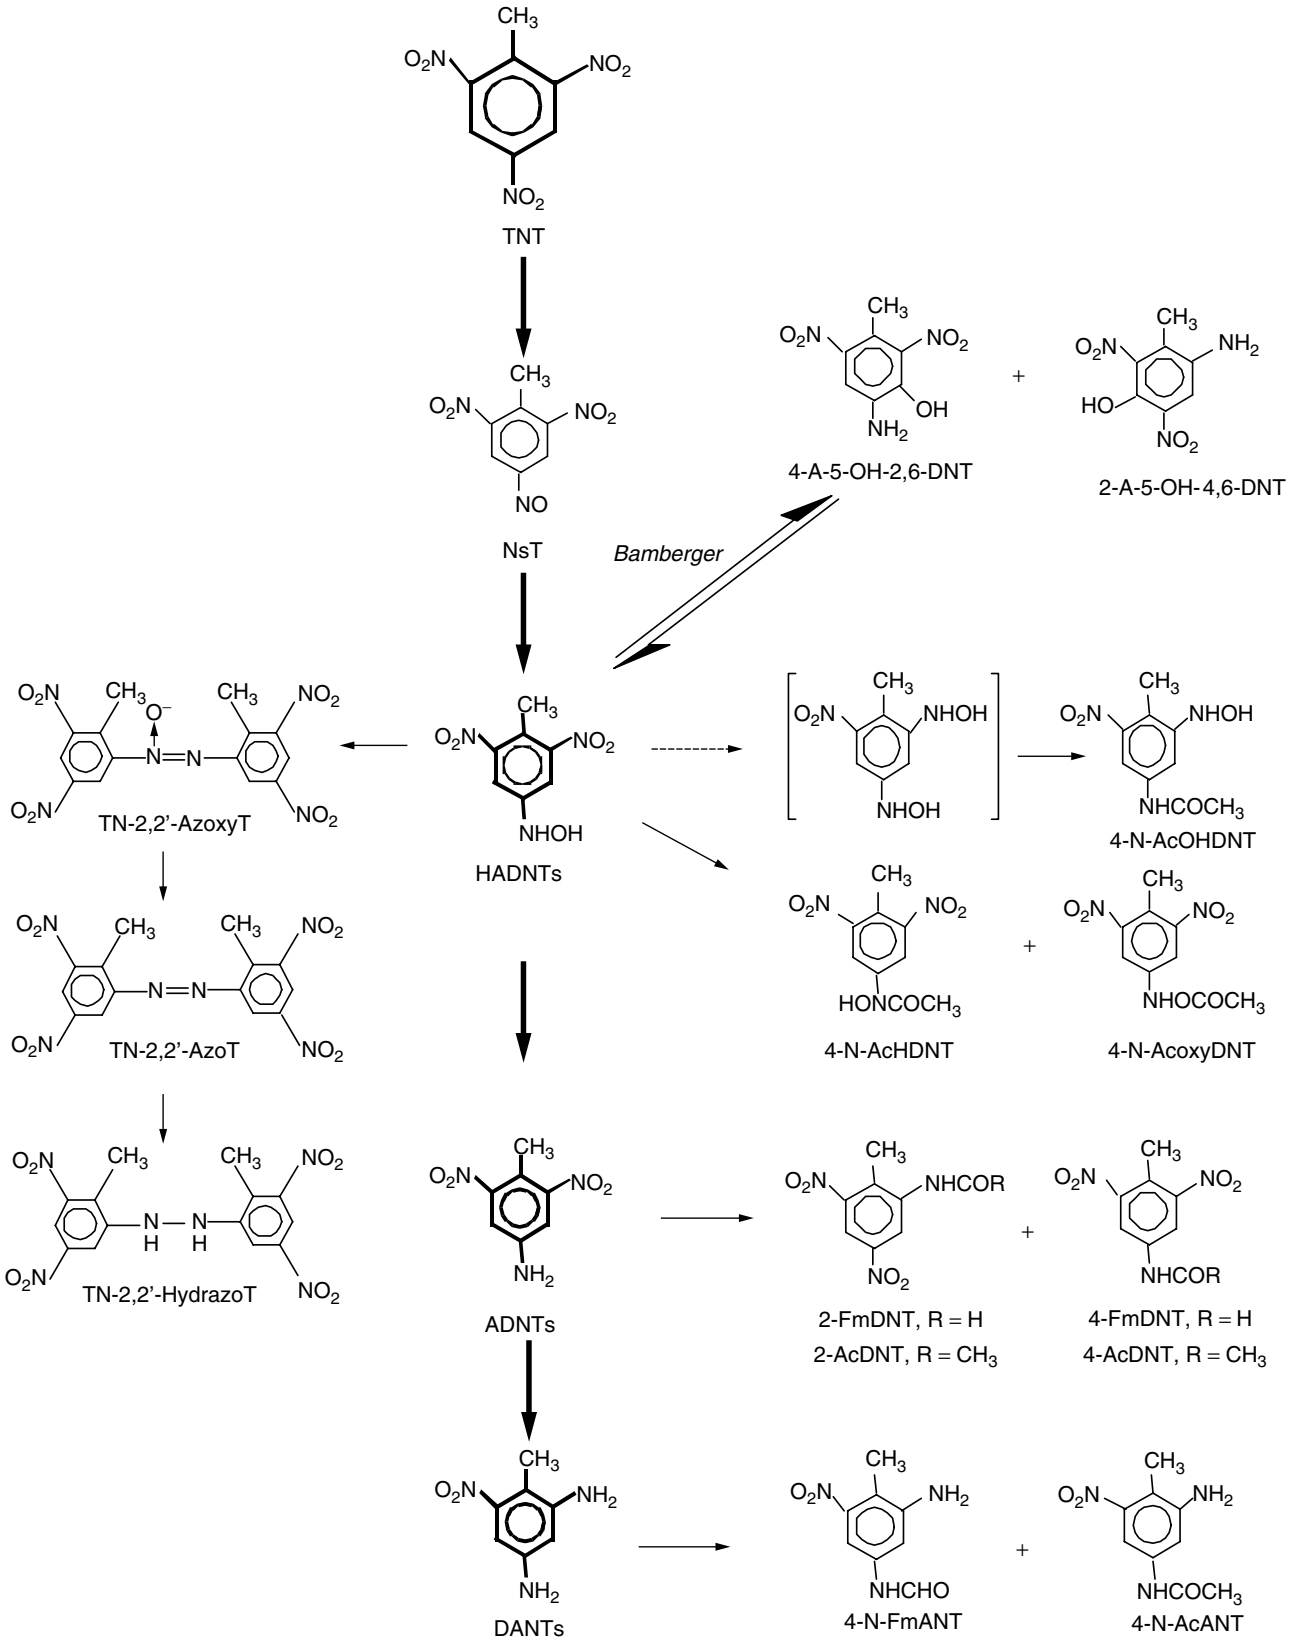

Figure 4. A comprehensive pathway summarizing biotransformation routes of TNT by fungi. Constructed from earlier papers published in the field in References 9,46,57,61,121.

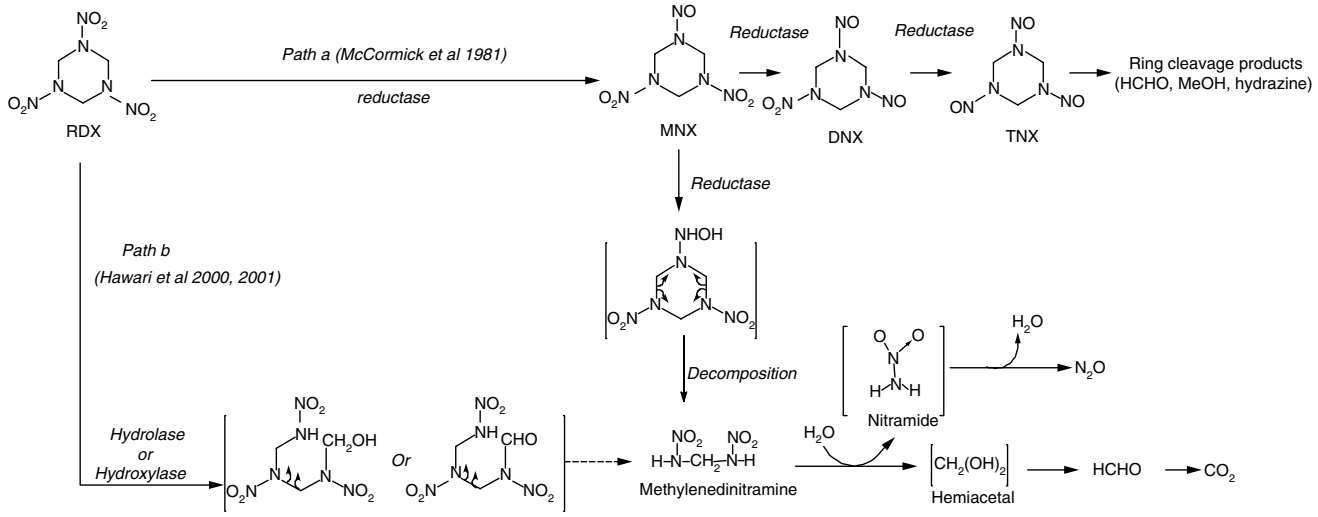

Figure 5. Postulated degradation pathways of RDX with domestic anaerobic sludge in a liquid culture. The observation of methylenedinitramine in stoichiometric amounts might favor ring cleavage as shown in the Figure. Square brackets signify undetected compounds. Modified from J. Hawari et al., *Environ. Sci. Technol.* **35**, 70–75 (2001).

oxide as an RDX metabolite was confirmed by using ring labeled [^{15}N] and the formation of $^{15}N^{14}NO$ detected by mass spectrometry at a mass ion of m/z 45 Da (43).

Interestingly anaerobic degradation of RDX in soil gave the three nitroso derivatives MNX, DNX, and TNX, with preferential accumulation of TNX. The formation of nitroso products from both RDX and HMX is considered to be enzymatic and produced by stepwise 2 electron transfer processes leading to the reduction of $-NO_2$ groups to the corresponding $-NO$ groups (Fig. 5). The resulting nitroso products did not accumulate but the mechanism of their subsequent transformation is not established yet. Degradation initiated by nitroreductases has been suggested as a potential degradation route for cyclic nitramines under anaerobic conditions (73). The authors reported the degradation of RDX by the enterobacterium *Morganella morganii* via the oxygen insensitive Type 1 nitroreductase (a two electron transfer process). No further details on the nature of intermediate products or metabolic pathways were provided. On the other hand, several studies reported the effective biodegradation removal of RDX and HMX in soil bioslurries (74–77), but in most cases no rigorous product analyses or mass balances were given. This information is very important when laboratory data are scaled up for further field application.

Biodegradation Under Aerobic Conditions

Experimental evidence gathered thus far on the aerobic metabolism of RDX and HMX has shown potential for their mineralization (10). Several strains of bacteria including *Stenotrophomonas maltophilia* (78), *Rhodococcus* sp. strain A (79) and *Rhodococcus* sp. strain D22 (80) biodegraded RDX when used as nitrogen source in pure culture. Most of these studies showed the initial formation of nitrite, but no other initial or intermediate metabolites were reported. Binks and coworkers (78) reported the cleavage of RDX with *Stenotrophomonas maltophilia*, but apparently misidentified the degradation products (43). Later Coleman and Duxbury (81) suggested the involvement of cytochrome P-450 in the metabolism of RDX by *Rhodococcus* sp. strain DN22. Recently, Sheremata and coworkers (69) employed the fungal strain *Phanerochaete chrysosporium* to degrade RDX using glycerol as a carbon source and detected the mononitroso derivative (MNX) as the sole RDX intermediate product, which did not accumulate. At the end of the experiment nitrous oxide (60%) and carbon dioxide (55%) were obtained as end- products. Mineralization of RDX (0.028 mg/L) by *Phanerochaete chrysosporium* has been reported earlier by Fernando and Aust (82). Using [^{14}C] RDX the authors reported high levels ($66.6 \pm 4.1\%$) of mineralization in liquid culture. No other metabolites were observed. In summary, despite the recent success in mineralizing cyclic nitramine explosives, the degradative pathways and enzymes involved in the process are unknown and warrant further research in this area.

Biodegradability of CL-20

CL-20 is a newly released energetic chemical whose microbial and environmental behavior is not yet known. However, the energetic chemical is a strained heterocyclic nitramine, which like RDX and HMX contains the $N-NO_2$ functional groups that characterize the chemical and microbial properties of the explosive (83). CL-20 was originally synthesized by Nielsen (84) and later adopted by Thiokol for large-scale production (83). In addition, both RDX and HMX are cyclic oligomers of methylenenitramine, CH_2-N-NO_2, $((CH_2NNO_2)_3$ for RDX and $(CH_2NNO_2)_4$ for HMX), whereas CL-20 is a caged rigid structure that contains the repeating unit

$CH{-}NNO_2$ (27,83). The three energetic chemicals RDX, HMX, and CL-20 are expected to show similar chemical and enzymatic reactions but with different kinetics. Earlier work indicated that initial enzymatic or chemical attack on either RDX or HMX leads to a ring cleavage with the eventual production of N_2O, HCHO, and CO_2 (10). The fact that CL-20 is a heterocyclic nitramine that also contains $CH{-}NNO_2$ and C–N functional groups (83), might indicate that the chemical could degrade by a mechanism similar to that of RDX and HMX (43,44). In fact, it has been reported that the characteristic bond cleavage of $N{-}NO_2$ in both RDX and HMX also occurs in CL-20 (85).

Other Explosives

There has been no extensive reporting on the microbial degradation of other explosives such as PETN, NC, NG, GAP, and CL-20 because the explosive is either a new release (CL-20) to the environment or research is hampered by very poor water solubility or steric effect such as the case with nitrocellulose (NC) (16,86). In the case of GAP, no extensive contamination has been reported in Canada because the explosive is not used by their military. Other explosives such as TNG (very reactive) and PETN are frequently hydrolyzed, water-assisted cleavage of the $-C{-}O{-}NO_2$ bond, to release the nitrite ion with the subsequent formation of a hydroxylated organic (R–OH) product instead.

(BIO)REMEDIATION TECHNOLOGIES

The most recent and important review on the applications and costs of biological treatments of explosives-contaminated soil has been published by Jerger and Woodhull (35). Several field-scale remediation studies have been conducted, but the actual fate of explosives is generally unknown. Table 4 outlines some of the reported bioremediation-based technologies that has been recently reviewed by Jerger and Woodhull (35).

Composting

Composting is a well-known biochemical process frequently used for waste reduction. Because of the presence of a wide diversity of biological activity within the compost, the technique can thus be used to biodegrade pollutants. Several groups of workers have reported the use of composting as laboratory and field-treatment processes for explosives (34,86,87). Composting received a wide public acceptance and the technology is frequently used in Germany and the United States. However, composting usually requires a large volume of organic amendments, making it difficult to trace the fate of the pollutant, particularly TNT and its biotransformed products in the compost. TNT transformed products such as HADNTs and their reduced amino derivatives can bind strongly to biomass or to soil humic material through the formation of amide linkages (–NH–CO–) (immobilization). Several groups of researchers (34,38,65,67) developed diagnostic tools such as NMR spectroscopy and immunoassay kits to determine the environmental fate of the explosive in soil and subsurface soil during composting. More details on the various types of practiced composting technologies including static piles, agitated composting and windrow composting can be found in a recent review written by Burns-Nagel and coworkers (34). These authors described in detail the transformation pathway of TNT under anaerobic/aerobic composting conditions and its eventual fate and environmental impact after composting. Presently composting, particularly windrow composting is accepted in the United States (35,88).

Slurry Phase Process Sabre (Simplot Anaerobic Bioremediation)

This process treats the explosives (RDX, HMX, and TNT) in soil in above ground bioreactors (biocells) under anaerobic conditions (89). In bioslurry technologies, several parameters must be adjusted including temperature, pH, redox potential, soil/water % and the organic source that

Table 4. Comparison of Technologies for the Remediation of Explosives Contaminated Soil (100,000 tones)

Technology	$/Ton	Advantage	Disadvantage
Windrow composting	133	Fast, self-heating, compost as a soil conditioner	Bulking agent and volume, cost for air monitoring (production of ammonia)
WMI TOSS	162	Currently offered as a commercial service	Transportation cost, external heat source,
EarthFax Fungal-based remediation	115	Rapid, extensive explosive reduction	Ambient temperature, inoculum, forced-aeration soil pile,
WR Grace-DRAMEND	130	Smaller final volume, no specialty equipment required	External heat source, limited depth of operation (<18 in.), long treatment time,
Simplot-SABRE bioslurry	125	Proven, treat high concentration, field application	Nature of soil (clay and plant material) Slurry preparation (soil washing), Slurry disposal (slurry dewatering)

Source: Modified from Jerger and Woodhull (35).

serves as a carbon source for the degrading microorganisms. The bioslurry-based technology is licensed by the University of Idaho Research Foundation. Earlier Guiot and coworkers (76) reported that very high concentrations of RDX (24,060 mg/kg) and HMX (7,860 mg/kg) can be effectively removed from contaminated soil in 8 L bioslurry reactors using a cement mixer as a bioreactor. Several other laboratory and field experiments for the treatment of explosives using bioslurry technology have been reported and reviewed by Hawari (10).

Daramend Remediation Technology

The technology is similar to land treatment; however, proprietary amendments are added to the soil to maintain operational cycles under anaerobic, anoxic, and aerobic conditions. The technology has been tested at several U.S. military sites containing soil and sediment contaminated with organic explosives. The technology is patented (U.S. Pat # 5,411,664; 5,480,579 and 5,618,427) and owned by Grace, Mississauga, ON, Canada.

Soil Pile Two-Stage Technology (TOSS)

A two-stage soil (TOSS) process was developed by Waste Management Inc., Cincinnati, OH. In the first stage of the process, the soil is treated with manure or anaerobic sludge in a biopile. The treated soil is then subject to a second treatment using composted wastes under aerobic conditions.

Fungal Treatment in Soil Piles

The technology is developed by EarthFax Engineering, Logan, VT, which is based on the use of extraneous source of fungi with organic amendments to remove explosives from soil. The technology has been tested on soil highly contaminated with TNT and tetryl (35).

Natural Attenuation

The term natural attenuation is a collective terminology that sums up the effect of several natural attenuation processes including transformation (abiotic and biotic) and transport (soil sorption, immobilization, and evaporation) on the environmental fate of pollutants. As the name implies, immobilization is a stabilization process wherein the pollutant and/or its degradation products irreversibly bind to the soil to produce complexes with long-term stability. To be able to understand and enhance immobilization we must first understand the application of the physicochemical properties that determine the binding mechanisms of the energetic chemical to soil (Table 1). For example TNT is relatively soluble in water (145 mg/L) with a soil-water partition coefficient (K_d) >4, whereas RDX and HMX are weakly soluble (45 mg/L and 5 mg/L, respectively) with K_d values around 1. K_d values provide us with quantitative evidence on the mobility and migration of explosives from soil through subsurface soil to cause groundwater contamination. The other physicochemical parameter is the octanol/water partition coefficient, K_{ow}, which indicates the chemical distribution between soil organic matter and water or between soil and plant tissue. Thus K_{ow} values can provide insight on important natural processes such as natural attenuation and phytoremediation. It has been shown that compounds with $1 < K_{ow} < 3$ can transport into the plant tissues.

The ability of TNT to (bio)transform to products that contain reactive amino functional groups ($-NH_2$) capable of binding to soil constituents could have potential remedial applications (natural attenuation) (52,90). The irreversible binding of TAT, a reduced TNT product, to soil and the long-term stability of the resulting complexes are considered important parameters in the enhancement of natural attenuation (41,91,92). Therefore, mechanisms to engineer and enhance the complexation of TNT and its degradation products with soil and improvement of the stability of these complexes would naturally attenuate and stabilize these contaminants in their matrix.

Phytoremediation

The use of plants and their associated microbial populations to remove contaminants from soil and water is an attractive in situ remediation method (93–95) that appears to be more cost-effective (96,97) than existing excavation, incineration, or other physical/chemical extractive methods. The process is also thought to be less disruptive to ecosystems as contaminants are selectively extracted without disruption to matrix organic content or soil microflora. Further insight into market overview of phytoremediation and the International industrial activities in this area can be found in Glass (98).

Terrestrial plants often have specialized microbial environment associated with their roots known as rhizosphere. The rhizosphere can be influenced by the plant through the secretion of nutrients and exudates, compounds that enhance the microbial populations' capacity to degrade a specific contaminant (99). Often the soil microbial population serves to protect the plant from a herbicide or other contaminant. For example, Siciliano and Greer (100) demonstrated the growth of meadow bromegrass (*Bromus erectus* Huds.) associated with a TNT transforming *Pseudomonas* sp. soil microbe on soil containing 46 g/kg TNT. However, more commonly in the case of explosives, the water-soluble contaminant fraction is passively transported in ground water directly into the plant tissue with no immediate transformation. In fact, phytoremediation experiments involving TNT and RDX often make use of constructed wetlands populated by aquatic plants (101–104) or arboreal species with high water demand (105), as the dominant mechanism for the uptake of TNT and RDX appears to be aqueous solubilization and transpirational flux. Furthermore, while TNT and other aromatic explosives are enzymatically modified and sequestered in root tissues (106–109), RDX appears not to be readily transformed and is deposited in leaf tissues following the evaporative loss of water (110). Recently we monitored several indigenous plant species at a Canadian antitank

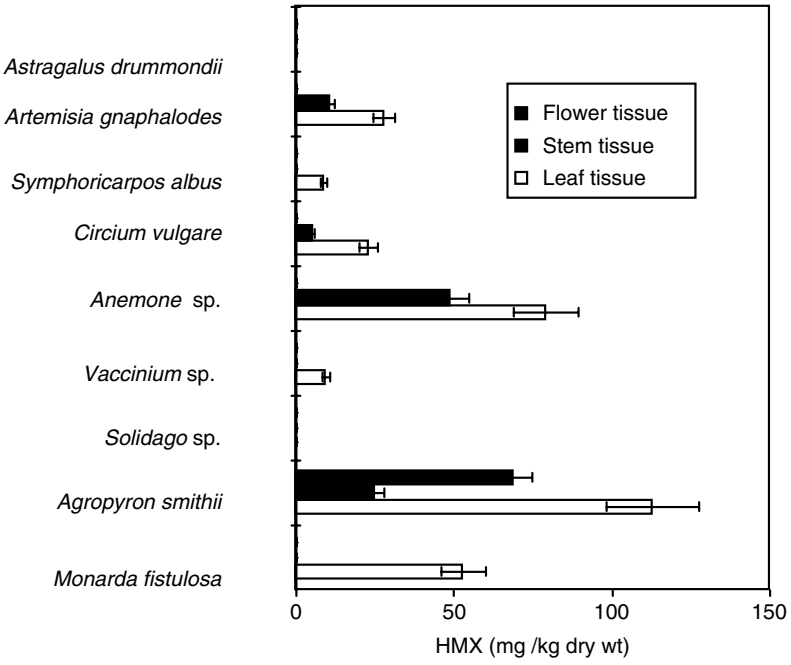

Figure 6. Prairie indigenous plants accumulating HMX in their leaves tissues.

firing range in central Alberta, where the melt-cast explosive Octol (70:30 wt % mix of HMX to TNT) was used and found the accumulation of HMX in the leaves of all tested plants, indicating the potential use of plants as a in situ clean-up option for military-contaminated sites. Rye grass and wheat were found to be the best species to phytoextract HMX from the site, but the heterogeneity of the soil and the lack of uniformity in HMX distribution at the site did not allow the determination of the percentage of HMX removal form the soil. Some of the analyzed plant tissues and their potential to phytoextract the explosive HMX are shown in Figure 6.

In a study involving the uptake of ^{14}C labeled RDX (111) into terrestrial plants gel permeation chromatography fractions with molecular weights of 800 to 1,000 daltons were observed to contain ^{14}C radioactive label. Similarly, in bush bean hydroponic studies involving ^{14}C labeled RDX (112) small quantities of radioactive component began to appear in basic aqueous leaf tissue extracts, which indicated modification of RDX. In both studies no radioactive gaseous products were detected. It is unclear if the labeled products in the studies of Harvey and coworkers (112) and Larson and colleagues (111) were direct conjugates of intact RDX species, or the high molecular weight products resulting from the incorporation of ring fragments or low molecular weight products.

ENVIRONMENTAL AND ECOLOGICAL RISK ASSESSMENT

In addition to their explosive characteristic, energetic chemicals such as RDX, HMX, tetryl, DNT, and TNT are toxic to terrestrial and aquatic species (32,33,113). They are also recalcitrant ($t_{1/2}$ for RDX 1.7 years) (114) and some are classified as carcinogens with adverse effects on the central nervous system (25,115). An ambient water quality criterion for the protection of human health of 105 μg/L has been proposed for ingestion of drinking water (116). The toxic and carcinogenic effects of explosives necessitate their remediation, but their (bio)transformation does not necessarily mean that the technology is working. Because explosives can biotransform to even more dangerous chemicals, a soil remediation technology can be considered successful if both chemical and toxicological indicators confirm that the soil is clean. Integrated chemical and toxicological monitoring methods must thus become available so that valuable information on the initial state of a contaminated site, as well as the fate of these chemicals after remediation can be obtained. Extensive toxicological assays (Ames, acute toxicity and earthworm tests) of composted soil revealed that composting, one of the most widely applied soil remediation technologies, particularly in both United States and Germany, is effective in the reduction of the toxicity of contaminated soil (34,117–119).

SAFETY PROCEDURES

Because of their explosive characteristics, careless handling of sampling procedures can lead to detonation, deflagration, or burning under various stimuli such as friction and electrostatic discharge. Thus, specific safety procedures must be followed while sampling at any explosive-contaminated site, particularly those that have unexploded ordinances (UXOs). It is expected that contaminated sites may contain more than one explosive, and in the case of nitroglycerine (NG), an organic vapor protective respiratory mask should be worn at all times during sampling and sample preparation. Although for other explosives this protective equipment is not needed, explosive powder might be carried away with soil dust. Under these circumstances, a dust mask must

be worn during sampling and sample preparation. Also protective clothing, gloves, and glasses should be worn at all times while working with explosives contaminated materials to avoid dermal contacts and harmful injuries.

CONCLUSION

In general, explosives are labile molecules and once in the environment they can (bio)transform, migrate through subsurface soil to reach groundwater and/or transport to plant tissues. Polynitroaromatic explosives such as TNT biotransforms quite readily under both aerobic and anaerobic conditions to initially produce amines that can react further to give the acyl-, azo-, and azoxy-derivatives with little mineralization. Fungi, however, can mineralize TNT in liquid culture medium (9). No mineralization-based bioremediation technologies are known for TNT or any other explosive and therefore there is a need for the discovery of new and engineered enzymes and microorganisms to promote mineralization of TNT and its biotransformed products. On the other hand the nonaromatic RDX and HMX explosives can biodegrade to produce nitrous oxide and formaldehyde. A potentially useful and emerging cost-effective in situ remediation technology for the clean-up of soils at contaminated military sites is phytoremediation. Another important approach for the management of sites contaminated with explosives is to engineer and create mechanisms to irreversibly bind explosives and their degradation products with soil (humification and immobilization).

ACKNOWLEDGMENT

The authors are grateful to the Defence Research Establishment Valcartier, Quebec, Canada of the Canadian DoD for providing financial help and some of the energetic chemicals while conducting parts of this research. We would also like to thank the U.S. DoD Strategic Environmental Research and Development Program (SERDP #1213) for financial funding of the project on RDX and HMX.

MICROBIAL DEGRADATION OF FUEL OXYGENATES

JOSEPH P. SALANITRO
Shell Oil Company
Houston, Texas

INTRODUCTION AND STATEMENT OF THE PROBLEM

In 1990, the U.S. Environmental Protection Agency promulgated the Clean Air Act Amendments, which, in part, regulated the composition of gasoline motor fuels sold in cities that did not meet the federal ambient air quality standards for carbon monoxide and trophospheric ozone levels (1). The resulting oxygenated fuels and reformulated oxygenated gasoline (RFG) programs required that gasoline contain 2.7 and 2% by weight of oxygen as the oxychemicals methyl *t*-butyl ether (MTBE) or ethanol for reducing tailpipe emissions of carbon monoxide and ozone-forming compounds, respectively. Although other modifications of RFG were being implemented (e.g., reduction in sulfur, olefins, and aromatics content), MTBE was the primary oxygenate used by refiners to comply with the 2 or 2.7 wt.% oxygen (11 or 15% by volume) requirement. Ethanol was also accepted as a fuel blending oxygenate and used in some of the Midwest gasoline markets. MTBE blended RFG was sold in the eastern, western, and southern states. Other branched alkyl ethers and alcohols in addition to MTBE and ethanol have also been used as oxygenates (see Fig. 1) in gasoline blends, but less frequently depending upon hydrocarbon feedstocks and refining operations. For example, MTBE is made from isobutylene and methanol whereas tertiary amyl methyl ether (TAME) is made from isopentylene. Although there were apparent reductions observed in air pollutants in major cities of the United States during the 1990s, a U.S. Geological Survey showed the presence of detectable MTBE in 16.9% of the shallow urban monitoring wells and 3.4% of the rural wells samples (2). In addition, many public well water systems in California have been impacted with MTBE (3). It is now clear that MTBE is present in groundwater from the accidental release of gasoline from the underground storage system at fuel service stations. Gasoline releases from buried tanks or lines can migrate to subsoils and water-soluble compounds like MTBE can disperse into the water table and be transported with the local hydrogeologic flow of groundwater. MTBE is the most water-soluble component of motor fuel and is biodegraded very slowly in subsoils compared to the rapid metabolism of other gasoline organics (alkanes, isoalkanes, and aromatics). MTBE, therefore, has become a groundwater contaminant of concern, which continues to threaten public and private drinking water supplies. The severity of the MTBE groundwater problem has been addressed by an EPA Blue Ribbon Panel (4), which recommended a reduction in the use of the ether, a phase-out, and a replacement by an alternate oxygenate (e.g., ethanol) without compromising air quality standards.

It is widely recognized that aromatic hydrocarbon groundwater plumes (e.g., of benzene, toluene, ethylbenzene, and xylenes; BTEX compounds) from fuel spills are readily biodegraded by microbes associated with most subsoils (5,6). Microbial degradation of these compounds in groundwater is part of the overall intrinsic (natural attenuation) mechanism commonly observed in aquifers and is responsible for the observed reduction or control of groundwater BTEX plumes. In contrast, there is no overwhelming evidence currently that MTBE (or other ether oxygenates) plumes are intrinsically biodegraded (aerobic or anaerobic) in source spill zones or in the soluble portion of plumes. Some of the experimental research underway to address the problem of MTBE biodegradation in cultures, enrichments, and soil, and prospects for enhancing bioremoval mechanisms in aquifers is summarized in what follows.

PROPERTIES OF OXYGENATES

Much of what we know of the biodegradability of gasoline components (especially hydrocarbons) in subsoils and aquifers comes from decades of research on the metabolic capabilities of microbial cultures isolated from soils, sediments, and biosolids (7). The aromatic hydrocarbons and fuel oxygenates given in Table 1 are the most

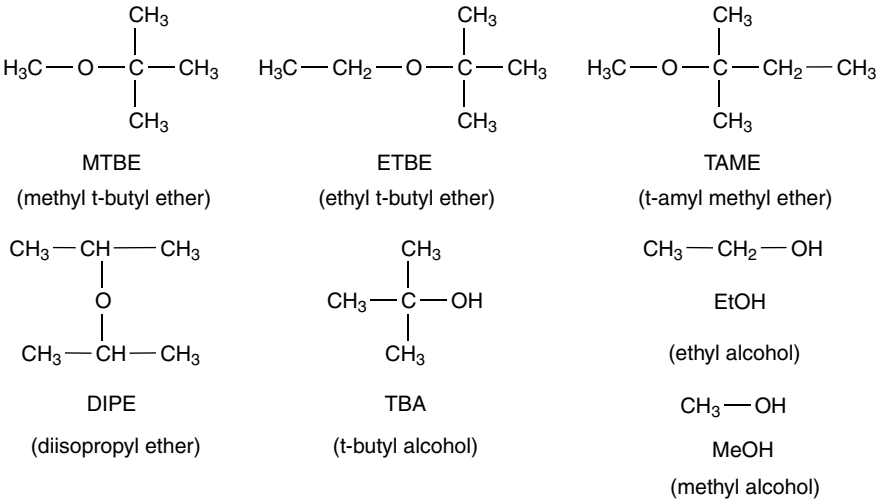

Figure 1. Fuel oxygenates used in gasoline blends.

Table 1. Physicochemical and Biological Properties of Water-Soluble Fuel Hydrocarbons and Oxygenates in Gasoline

Feature[a]	BTEX[b]	MTBE	ETBE	TAME	DIPE	Methanol	Ethanol	TBA

[a] Data on water solubility, log K_{oc}, Henry's law constant, and aquatic toxicity were taken from Ref. 8 unless noted otherwise. Values given are at 20 to 25 °C.
[b] Benzene, toluene, ethylbenzene, and xylenes.
[c] Completely soluble in water.
[d] Relative partitioning of compound between aqueous and organic phases.
[e] Relative partitioning of compound between vapor (air) and aqueous phases.
[f] *Biodegradation:* +, microbial degradation in most soils, sediments, and biosolids usually demonstrated; +/−, biodegradation not always observed or is incomplete. *Bacterial growth:* +, bacterial growth refers to the ability of organisms to produce significant cell mass on the organic compound (e.g., ≥ 0.5 g cells/g compound);−, refers to little or no biomass formed (≪ 0.5 g cells/g compound) through the metabolism.
[g] EC_{50} concentration affecting growth, reproduction, or immobilization of 50% of the test animals unless otherwise indicated for *Daphnia* (48-hour test) and fathead minnow (48- to 96-hour test); aquatic toxicity for aromatic hydrocarbons are from Ref. 9.
[h] LC_{50}, concentration affecting survival of 50% of the test animals (96-hour test).
[i] First and second values are for *Daphnia* and fathead minnow.
[j] Concentration for *Daphnia* is a 24 hour IC_{50}.
[k] Lowest observed effect concentration for *Daphnia* and fathead minnow, respectively, from Ref. 10.
[l] LC_{50} for mysid shrimp and sheepshead minnow, respectively.
[m] Algae and *Daphnia*, respectively.
[n] Fathead minnow.
[o] Various species.
[p] Data from Ref. 11 in wt./wt.% of gasoline; current RFG may contain less than or equal to 1% benzene.
[q] Wt.% by volume for reformulated gasoline containing 2 or 2.7 wt.% of O_2 (first and second value, respectively).
[r] NP, not present. Methanol is not usually added to gasoline but may be present in MTBE — formulated gasoline as a byproduct of MTBE production.
[s] Wt.% by volume as formulated in the gasoline market of the midwestern states of the United States.

water-soluble components of motor fuel and represent the predominant groundwater contaminants detected in monitoring well water samples from accidental gasoline releases at retail sites. Table 1 also is a comparative summary of the physical/chemical (solubility, sorption, and volatility) and biological (biodegradability and aquatic toxicity) features for the most water-soluble components of current formulated gasolines (8). In general, BTEX compounds are the least water-soluble, more volatile (higher Henry's law constant), the most biodegradable, and more toxic to aquatic species. BTEX compounds represent about 20% by weight of the gasoline fraction whereas the dominant oxygenates such as MTBE and ethanol are present at 15 and 10%, respectively. The octanol water partition coefficient (a measure of sorption to soil organic carbon) for BTEX and oxygenates indicates that they have similar but low tendencies to sorb to soils ($\log K_{oc} = 1$ to 2). Henry's law constant, given as a dimensionless value, indicates that the alkyl ethers are at least five times less volatile from aqueous solutions than BTEX. The alcohols, methanol, ethanol, and *t*-butanol (TBA), in contrast, are several orders of magnitude less volatile than BTEX and the ether compounds. BTEX and ethers are more readily analyzed from water samples by gas-liquid and headspace chromatography and purge and trap gas chromatography (P/T GC) and mass spectrometry methods (12). Because of the low volatility of alcohols, samples may need to be analyzed by heated P/T GC.

Some of the main reasons for the persistence of organic chemicals in soil and groundwater, even at low concentrations (μg/L or mg/L), are the (*1*) poor biodegradability by indigenous microbial populations, (*2*) absence of active organisms in soil, (*3*) inability of microbes to grow on the compound and produce actively degrading biomass, and/or (*4*) availability of insufficient concentrations of electron acceptor (e.g., O_2 to promote aerobic degradation). In general, BTEX compounds are rapidly biodegraded by the ubiquitous presence of aerobic hydrocarbon-degraders in most soils. There is now good evidence that this hydrocarbon degradation in aquifers is part of the containment of BTEX plumes under aerobic, and in some cases, anoxic (low oxygen) or anaerobic conditions (5,6,13).

The biodegradation of the fuel ether oxygenates, MTBE, ETBE, TAME, DIPE, and TBA, however, is not always observed in aquifer sediment biodegradation assays.

Studies on the characteristics of isolated cultures and enrichments have indicated that microbes grow poorly (low cell yield) and slowly (long doubling time) on these ethers and TBA. The poor biodegradability property of these oxygenates is, in part, responsible for their persistence in groundwater. The alcohols, methanol and ethanol, are very biodegradable and microbes metabolizing these chemicals are widely distributed in soils, sediments, and biosolids (wastewater activated sludges) (9,10). Ethanol and methanol are readily oxidized to carbon dioxide and methane under aerobic and anaerobic conditions, respectively.

The aquatic toxicities of the aromatic hydrocarbons (BTEX) expressed as EC_{50} (e.g., the concentration affecting 50% of test organisms in growth or survival) to the common aquatic species, *Daphnia*, algae, and fathead minnow are in the range of 15 to 50 mg/L. EC_{50} toxic doses of the alkyl ethers to these same organisms are much higher, usually greater than or equal to $\geq$100 to 2,500 mg/L. Methanol is significantly more toxic (EC_{50}, 2–26 mg/L) than ethanol (EC_{50}, 13,000–16,000 mg/L) or TBA (EC_{50}, 4,430–5,500 mg/L). The aquatic toxicity is critical when assessing the environmental impact of a pure chemical or RFG spill into a water body (river, lake, and stream) and the subsequent effects of eutrophication on survival, growth, and reproduction of affected species.

OBSERVATIONS ON THE MICROBIAL METABOLISM OF MTBE

As indicated previously, MTBE is the predominant oxygenate in the current formulations of gasoline and is a common groundwater contaminant from fuel storage tank spills to subsoils. Research over the last 7 years has focused on assessing the biodegradability of MTBE under aerobic and anaerobic conditions in single or mixed cultures derived from soil and sediment enrichments. Table 2 is a summary of these studies. Under aerobic conditions, three types of bacterial cultures that degrade MTBE have been isolated. Cometabolic cultures of mixed or single species that are able to grow on alkanes (e.g., propane, pentane, hexane) or isoalkanes (e.g., 2-methyl butane and 2-methylpentane) as primary substrates appear to stimulate one or more *monooxygenase* enzymes involved in MTBE metabolism (15–19). However, in some cultures grown on alkanes/isoalkanes, MTBE is cleaved to only TBA (15,16). Metabolic studies with these cultures have shown that uniformly labeled (UL) ^{14}C-MTBE is oxidized 45 to 60% to $^{14}CO_2$, 20% of the label is incorporated into the cells and the remaining 20% is associated with a soluble but less degradable or slowly degrading fraction. Cyclohexane can also serve as a primary substrate in a mixed culture derived by Corcho and coworkers (20), which can degrade MTBE to carbon dioxide.

Several single (pure) cultures have been isolated from soils and biosolids that degrade MTBE but which also grow poorly on the ether. Isolates of gram-positive (*Rhodococcus* and *Arthrobacter*) and gram-negative (*Rubrivivax*, *Hydrogenophaga*, and *Methylobacterium*) bacteria have been obtained from primary mixed cultures that were selected on MTBE (21–24). These organisms grow on many other substrates (e.g., alkanes, alcohols, and sugars) and have the ability to completely or partially degrade MTBE.

Mixed consortia of bacteria, which also degrade MTBE, have been enriched from biosolids obtained from refinery, chemical, and municipal wastewater treatment

Table 2. Microbial Cultures and Enrichments Degrading MTBE

Metabolism	Culture Type[a]	Substrate[b]	Reference
Aerobic	(1) Cometabolic (mixed or single)	Alkanes and/or isoalkanes Cyclohexane	15–19
	(2) Single species	MTBE, other substrates[c]	
	Rhodococcus sp. nov.		21
	Rubrivivax (PM1)[d]		22
	Hydrogenophaga flava		23
	Methylobacterium, *Rhodococcus*, and *Arthrobacter*		24
	(3) Mixed (biosolids and biofilter solids)[e]	MTBE	25–28
	(4) Soil, sediment enrichments[f]	MTBE	30–32
Anaerobic	Soils and sediments	MTBE	
	(a) Methanogenic		34[g], 35[h]
	(b) Iron-reducing		36
	(c) Nitrate-reducing		37

[a] Mixed or single refer to multiple or single species cultures, respectively. Cultures were isolated from soil, biosolids, or obtained from culture collections.
[b] Growth of organisms on MTBE is usually poor compared to most other substrates.
[c] Alcohols, hydrocarbons, or sugars.
[d] A member of the *Leptothrix* group of the β-Proteobacteria subclass.
[e] Activated sludges from refinery or chemical biotreaters or wastewater plants.
[f] Aquifer or surface soils or river sediments.
[g] MTBE transformed to *t*-butyl alcohol only with methane formed from methoxy-carbon of MTBE.
[h] Extent of MTBE degradation not determined; methanogenic conditions produced from other substrates.

plants (25–28). These cultures also do not grow well on MTBE (cell yields are 0.05 to 0.2 g cells/g MTBE) but degrade the ether rapidly with the transient formation of TBA (25). It should be mentioned that the other branched alkyl ethers (ETBE, TAME, and DIPE) occasionally detected in fuels and groundwater are also degraded by these same mixed enrichments (25,26) and single species isolates (15,19). This suggests that there are common ether-cleaving and branched alcohol oxidizing enzyme systems in these cultures.

Laboratory-scale biotreaters of these cultures usually need to be operated with high cell solids retention because of the slow growth and low cell yield on MTBE. Concentrations of MTBE that can be degraded and reported removal rates with these mixed cultures have varied from 5–200 mg/L to 5–70 mg MTBE/g cells/hour, respectively. The presence of other fuel compounds (e.g., BTEX) usually does not affect biotreatment of MTBE in these systems because mixed cultures are not limited in numbers of aromatic hydrocarbon-degraders. A recent study by Deeb and coworkers (29) suggests that 20 mg/L levels of ethylbenzene and xylenes inhibits MTBE degradation in a pure culture of an MTBE degrading organism (*Rubrivivax* PM1). It is not clear, however, that these hydrocarbons would affect MTBE biodegradation in portions of the contaminant plume in which soluble fuel organics and MTBE are present at low concentrations (μg/L to mg/L) and BTEX-degraders are ubiquitous.

Evidence for the apparent aerobic degradation of MTBE by indigenous ether-degrading microbes in aquifer soils (30,31) and streambed sediments has also been shown (32,33). UL-^{14}C-MTBE was degraded to 15 to 65% $^{14}CO_2$ in laboratory microcosms of sediments. Although experiments were done at less than or equal to 1 mg/L MTBE, only 3 of 12 surface or aquifer sediments showed significant mineralization ($\geq$50%) to $^{14}CO_2$. It is not clear whether the ether was degraded beyond TBA in the other site samples in which the amount of $^{14}CO_2$ formed was 5 to 30% of the total isotope used in the experiment.

The degradation of MTBE under the anaerobic conditions of methanogenesis and iron - or nitrate-reduction has recently been reported (34–37). Soil microcosms prepared with anaerobic river sediment that formed methane degraded MTBE to TBA only after several months (34). The degradation of UL-^{14}C-MTBE and ^{14}C-TBA (50 mg/L) was assessed in iron-reducing microcosms containing aquifer material or river sediment from a fuel spill site and amended with Fe^{3+} and humic acid as electron acceptors (35). $^{14}CO_2$ was formed after a long lag period of 250 to 300 days. The maximum percentage of $^{14}CO_2$ formed, however, was 20 to 30% of the labeled MTBE, suggesting that only the methoxyl-carbon of MTBE was mineralized and metabolism terminated at TBA. Similarly, the experiments by Bradley and coworkers (37) on the biodegradation of ^{14}C-MTBE in NO_3-reducing microcosms of stream bed sediments showed that about 20 to 25% of the ether was mineralized to $^{14}CO_2$ indicating that MTBE was only degraded to TBA.

In summary, data on the isolation of mixed and single cultures of naturally occurring bacteria that degrade MTBE indicate that growth on the ether is slow and generates a low cell yield. The single culture strains can grow on other substrates (e.g., alkanes and isoalkanes) which may induce ether and branched alcohol oxygenase-like enzymes that are, in part, responsible for the complete degradation of MTBE to carbon dioxide. Although there is preliminary evidence by some workers that suggest MTBE may be degraded in soils and sediments under induced methanogenic and iron- and nitrate-reducing conditions, it is not certain that the ether has been degraded beyond TBA.

PROPOSED BIODEGRADATION PATHWAY FOR MTBE

A current scheme for the metabolism of MTBE based on our understanding of its degradation by microbial cultures, animal tissues, and chemical oxidation (ultraviolet/air or UV/H_2O_2) mechanisms is given in Figure 2. Studies on UV/H_2O_2 decomposition of MTBE have shown that the major products of hydroxyl radical attack on the ether are TBA, formaldehyde, acetone, acetol (pyruvaldehyde), and methyl acetate; other intermediates include hydroxyacetone, 2-hydroxyisobutyric (HIB), pyruvic, acetic, and formic acids (38,39). Tertiary butyl formate (TBF) has also been proposed as an initial metabolite from the enzymatic attack on the ether in microbial cultures (15,17). The abiotic hydrolysis of TBF is slow ($t_{1/2} = 5$ days) (40) suggesting that the rapid formation of TBA from TBF observed in microbial and rat liver tissues must be enzymatic. TBA is oxidized to acetone and formaldehyde in chemical oxidation reactions but is metabolized by bacteria (15) and mammalian tissue (41–43) to 2-methyl-1,2-propanediol and 2-methyl-2-hydroxy propionic acid (HIB). In one report, however, on the metabolism of TBA by a rat liver P-450 enzyme preparation, the branched alcohol was apparently metabolized directly by a hydroxyl radical oxidation to acetone and formaldehyde (44). For many years, tertiary alcohols like TBA (and tertiary amyl alcohol) were known to be recalcitrant and/or biodegraded slowly in most environmental media (soils and biosolids) containing diverse microbial populations (45,46). The remainder of the MTBE biodegradation pathway for acetone is presumed to occur via the formation of pyruvate, acetate, and then carbon dioxide. In this regard, acetone and isopropanol soil enrichments and isolates derived from these cultures have been shown to metabolize acetone in the sequence: acetone $\rightarrow$ hydroxyacetone $\rightarrow$ pyruvaldehyde $\rightarrow$ pyruvate $\rightarrow$ acetate (47). Pyruvate metabolism to acetate and carbon dioxide is a common biochemical transformation in microbial and animal cells.

PROSPECTS AND CHALLENGES FOR THE BIOREMEDIATION OF FUEL ETHERS

Cleanup goals for MTBE in groundwater supplies vary among states (20–400 μg/L). Much higher concentrations are allowed in groundwater in which drinking water supplies are not at risk (48). MTBE enters aquifers from gasoline spills to the subsoil environment and is transported, in some cases, unattenuated through the local groundwater flow paths because of its high water solubility, low soil sorption, and poor biodegradability. Dissolved

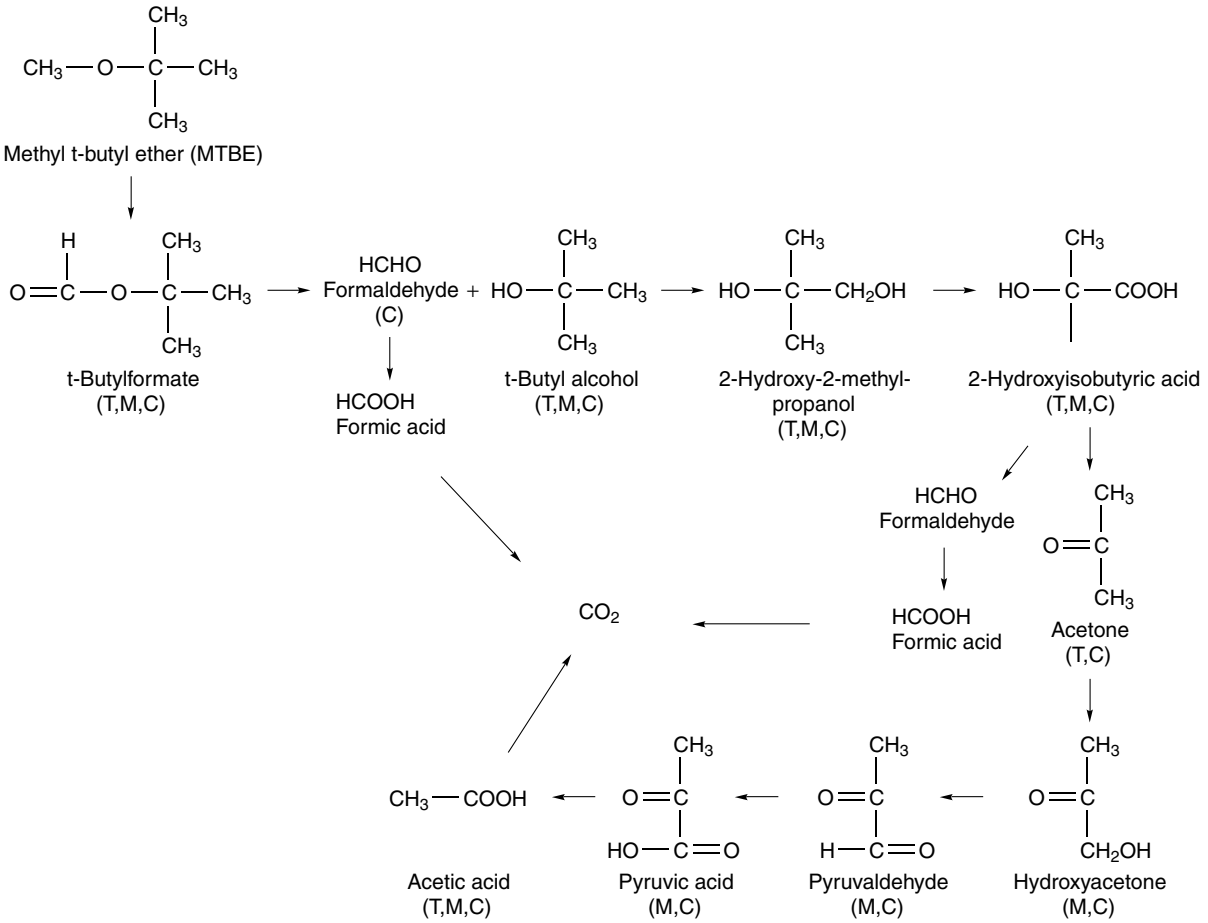

Figure 2. Proposed biodegradation pathway for MTBE. Metabolites shown have been identified from microbes (M), animal tissues (T), or from chemical oxidation (C) experiments.

oxygen concentrations are usually low within the MTBE plume and this also limits microbial metabolism of the ether. In a study to evaluate the potential extent of groundwater contamination by MTBE, researchers have argued that many existing plumes may persist and become even larger and impact more potable supplies owing to uncertainties in vertical and horizontal groundwater transport (49). Unassisted natural attenuation mechanisms and the use of indigenous microbes to biodegrade ethers in groundwater, therefore, may be limited. Engineered in situ MTBE bioremediation systems have been tested in which oxygen and/or cosubstrates (e.g., propane) are sparged into aquifers to stimulate naturally occurring ether-degraders (23,30). In one such field pilot study at the Port Hueneme Naval Base in California, oxygen sparging and the injection of specialized ether-degrading cultures (biobarrier) were used to evaluate the effectiveness of controlling the migration of an MTBE plume (30). In this study, biodegradation of MTBE in the bioaugmented plot occurred faster and was more extensive (no accumulation of TBA) than in comparable plots containing only O_2 or no amendments. Bioaugmentation technology for remediation of aquifers has also been used with other groundwater contaminants such as chlorinated solvents under aerobic- and anaerobic-induced conditions (50,51). This biobarrier concept of nutrient stimulation and/or aquifer seeding of microbial cultures appears to be one tool for controlling the migration of groundwater contaminants. Microbial inoculation of subsoils may be required for compounds like MTBE for which growth on the ether by indigenous microbes is poor and naturally occurring organisms are present in low numbers. However, an understanding of the long-term performance of active groundwater biobarriers will be required for controlling the migration of MTBE plumes. Nutrient limitation, distribution of seed culture, decay of inoculant, reseeding frequency, soil-type effects on activity, and the migration of inoculant are challenges to the long-term stability and function of groundwater biobarriers.

The use of ex situ technologies for treating fuel-contaminated groundwater in bioreactors containing specialized MTBE-degrading cultures has been pilot-tested in laboratory-scale units and biofilters (27,28,30,52). Such studies indicate that these systems are less robust at low pH ($\leq$pH 6.0), low temperature ($<20\,^{\circ}C$), low dissolved oxygen ($\leq$1 to -2 mg/L), and high input MTBE concentrations ($>$150 to -200 mg/L). Also, bioreactors need to be operated under high biomass retention to sustain good removal efficiencies ($\geq$95%). There have been no well-documented field-scale uses of bioreactors for treating

groundwater containing MTBE or other fuel oxygenates. Ex situ biotreatment competes with known "pump and treat" engineering technologies such as air-stripping and activated-carbon adsorption for removing fuel contaminants (ether oxygenates and aromatic hydrocarbons). It should be emphasized that contaminant removal by continuous pumping of groundwater may not be cost-effective for removing high concentrations from source zones. Challenges to the development of efficient ex situ biotreatment technologies for groundwater containing MTBE and other fuel oxygenates will require additional studies to assess reactor size for optimizing and treating various groundwater flow rate scenarios, maximum contaminant concentrations, and efficient biosolids retention.

CONCLUSION

Current knowledge of the biodegradation of the two primary motor fuel oxygenate additives MTBE and ethanol indicates that: (*1*) aerobic MTBE biodegradation (completely to carbon dioxide) can be demonstrated in isolated single and mixed bacterial cultures and enrichments from soils and biosolids, although there have been few reports of partial ether metabolism under anaerobic conditions; (*2*) the metabolism of MTBE in microbes and animal tissues suggests a pathway in which the predominant intermediates are MTBE $\rightarrow$ TBA $\rightarrow$ 2 – hydroxyisobutyrate $\rightarrow$ acetone $\rightarrow$ pyruvate $\rightarrow$ acetate $\rightarrow$ carbon dioxide; and (*3*) ethanol is readily degraded by various microbial populations in soil and sewage biosolids under aerobic and anaerobic conditions. The poor growth of microbial cultures on ether oxygenates remains a biochemical enigma but may explain their recalcitrance (relative to other fuel hydrocarbons) in soil and groundwater systems. In situ biostimulation and bioaugmentation of aquifers and the use of ex situ bioreactors for MTBE remediation will continue to be a challenge for environmental scientists and engineers to make these technologies more robust and reliable.

MICROBIAL FLOCS SUSPENDED BIOFILMS

STEVEN N. LISS
Ryerson University
Toronto, Ontario, Canada

Microorganisms as suspensions within engineered and natural aqueous systems are typically present as flocs. Microbial flocs represent a complex aggregate of microbial cells, bioorganic and inorganic material forming stable associations (1–3). An arbitrary number of 10 cells has been proposed as a minimum requirement for a group of cells to be considered an aggregate or floc (4). The simplest flocs, however, are sedimenting units that can be typically isolated by cascade filtration and ultracentrifugation (5) and are composed of two or more primary particles (e.g., bacterial cell and an inorganic particle) (6).

Floc properties reflect the combined interactions of the physicochemical and microbiological conditions in a given system. As a result of the complexity of the relationships, it is difficult to precisely predict the behaviour and properties of microbial flocs. Nonetheless, floc formation or aggregation can significantly alter the hydrodynamic properties of the constituent particles, and is important to a number of significant environmental processes. This particularly applies to flocculation, settling, and nutrient and contaminant transport properties in biological wastewater treatment and natural aquatic systems (3,7,8). At the gross scale (sizes > 1 μm), the floc is viewed as a structural entity in which emphasis is focused on size, shape, density, porosity, and settling velocity. Although the structure of flocs controls many of their properties including settling and aggregation, structural detail at this resolution yields limited information.

At the fine scale (<1 μm), the importance of the microorganisms and bioorganic material to floc development and properties is well recognized. Visual observations of natural flocs with high-resolution electron-optical microscopy techniques reveal cross-linkages among primary particles by bridges of fibrillar extracellular polymeric substances (EPS or fibrils) (3). EPS are important bridging and stabilizing structures in pelagic associations between microbes and abiotic particles, in activated-sludge flocs and anaerobic granules, and are common components of aquatic systems (freshwater and marine) and sediment (3,6,7,9–11,166).

Understanding the function-structure relationships of microbial flocs is important to microbiologists and engineers. The goal is to be able to solve practical problems more effectively and to provide better information in order to model the ecology and contaminant transport in aquatic environments, and the operation of wastewater systems. This may be achieved as a result of the developments and application of molecular methods used in identifying microorganisms, new methods for examining the microbial community and activities in situ, and novel approaches to examining microbial-floc architecture, including composition, properties, and function relationships.

Figure 1 illustrates and summarizes the complex nature of flocs, that is, factors influencing flocculation and floc properties. The relationship to biofilms is clear but is usually inferred. In many ways, flocs can be defined as biofilm communities as these structures at the microscopic level reveal structural and compositional similarities to fixed films particularly with respect to EPS and its association with either abiotic or biotic surfaces (3,12). Flocs have been described as individual microecosystems with autonomous and interactive physical, chemical, and biological functions or behaviors operating within the floc matrix (2). However, microbial floc are not typically sessile structures. This article focuses on specific aspects of microbial floc structure, bioflocculation, and floc behaviour in the context of a biofilm and as a floating and mobile structure.

ENVIRONMENTAL SIGNIFICANCE OF FLOCS IN NATURAL AND ENGINEERED SYSTEMS

Freshwater Floc

Lacustrine and riverine flocs form flocculated fine-grain sediment found in the benthic regions of freshwater

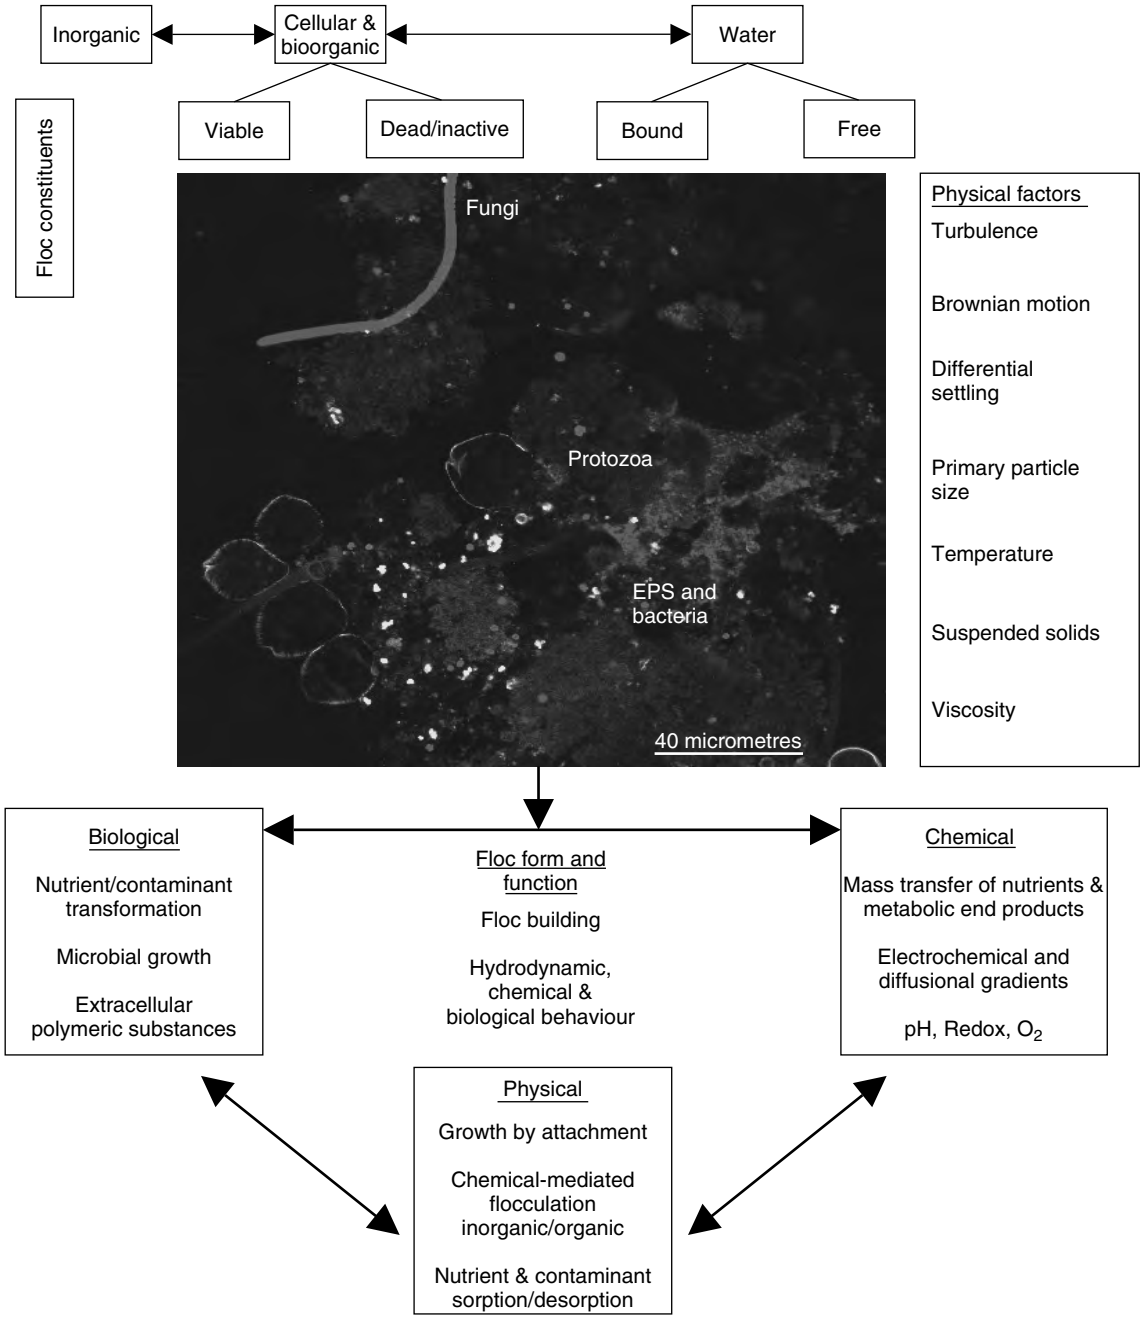

Figure 1. Conceptual description of floc form and function illustrating the physical, chemical, and biological factors influencing microbial floc development (Adapted from I. G. Droppo et al., *Water Air Soil Pollut.* **99**, 43–53 (1997) (2). The microbial floc shown is from activated sludge visualized by scanning confocal laser microscopy following staining with fluorescently labeled lectin stains.

environments (1–3). This sediment is a complex matrix of microbial communities and organic (detritus, cellular debris, and EPS) and inorganic material. It is structurally and functionally dynamic because of multiple interactive processes operating among the various physical, chemical, and biological factors associated with floc properties (1,2,6,8,13). Although flocs can regulate their own environment, they also have the ability to regulate the surrounding water quality by their physical, chemical, and/or biological activity (3,7,8). Microbial flocs in the freshwater fluvial environment can have potentially significant consequences on sediment formation and transport and, consequently, on the fate of contaminants entering this environment.

Aggregation of inorganic particles appears to be primarily associated with biological flocculation (2). Clay surfaces readily sorb nutrients and contaminants on their surfaces and are important sites of microbial colonization in aquatic systems. Ultrastructural studies show that EPS are an important structural component of microbial

flocs with direct association with the inorganic clay particles. The inorganic material typically consists of iron oxyhydroxides, clay minerals (Al/Si), and silicates (5). EPS appears to be the dominant material for the development and stabilization of natural floc (6). This does not exclude electrochemical flocculation completely (Fe,Al/Si,Si), but rather appears to be less significant than biological flocculation within the natural systems observed.

Marine Organic Colloids and Marine Snow

Organic-rich particles produced by microorganisms in marine systems can aggregate often developing into the largest colloids known as *marine snow* (14,15). The most numerous of these consists of bacteria, many of which possess capsules and sheaths composed of EPS. Three principal types of flocs are observed: (*1*) small flocs composed of heteroaggregates of bacteria, EPS, and other colloids, (*2*) disintegrating microzooplankton fecal pellets, and (*3*) marine snow (flocs $>500\ \mu m$). Microbe-mineral associations are not uncommon in marine environments. Mineral ions serve as a nutrient source and a site for colonization. These associations also reflect biogeochemical processes. Flocs enriched in iron and silica are found to be prevalent near deep-sea hydrothermal vents (16).

Marine flocs oscillate through states of disaggregation and aggregation as the EPS matrix degrades or reforms. The composition of the EPS of marine films and flocs has been well-studied (7,9,17,18). The EPS is absorptive and contributes to trophic interactions and biogeochemical processes through the concentration of nutrients and metals in highly oligotrophic environments. Marine snow is represented by diverse structures (15,18,19) and the carbohydrate and protein composition of the floc matrix is highly variable and related to floc structure (18).

Epsiodic blooms of photosynthetic diatoms, cyanobacteria, and flagellates can occur in response to nutrient inputs of carbon (as carbonate) with concomitant limitation of other nutrients such as nitrogen, silicon, or phosphorous (20). Significant excess production of microbial cells and EPS may arise resulting in substantial transformation of environmental conditions when this material begins to biodegrade and oxygen is depleted. The EPS may form dense mats that float and wash up on shores presenting risks to humans depending on the microorganism and causing significant economic loss to regions affected. Aggregation of cells and EPS may result in flocculation and settling to the underlying sediments (21).

Anaerobic Methanogenic Granules

The formation of a dense microbial aggregate, referred to as *granules*, is a prerequisite for the operation of the up-flow anaerobic sludge blanket (UASB) bioreactors. Considerable attention has been given to the granulation process, including the role of EPS, microbial community, and the structure and stability of the granule (see Raskin, Granules (Anaerobic) and Granulation Processes in Biosolids, in this Encyclopedia). Granulation has been observed to occur aerobically under certain conditions in bench-scale sequencing batch reactor (SBR) (22). These granules, similar in size (1 to 3 mm) and stability to anaerobic granules, were composed of bacteria that were attached to a fungal backbone (*Geotrichum* sp.).

Activated Sludge

Considerable attention has been given to the study of activated-sludge flocs (see Kampfer and Wagner, Filamentous Bacteria in Activated Sludge: Current Taxonomic Status and Ecology, Nielsen, Activated Sludge–The Flocs, and Wanner, *Filamentous Bulking in Activated Sludge*: *Control of*, this Encyclopedia). Microbial floc formation and gravity sedimentation of the synthesized biomass in secondary clarifiers of activated-sludge plants are considered to determine the overall efficiency of this secondary wastewater treatment process (23–25). Solid-separation problems, such as microbial bulking and foaming, settling difficulties of microbial flocs, and difficult dewatering of the sediment sludge, however, have plagued the activated-sludge process since its inception (23,26).

Sludge flocs consist of microorganisms, EPS, organic, and/or inorganic colloidal particles (27–30). EPS, salt bridges, a backbone of filamentous bacteria, or a combination of all three account for the integrity and mechanical stability of sludge flocs (31–33). A multitude of factors (e.g., nutrient regime, oxygen, and pH) can affect both the population dynamics and floc structure in a wastewater-treatment system. More emphasis is being placed on the structure and the physicochemical properties of flocs and the suspending medium because these may strongly influence the behaviour (e.g., settling properties) of biomass (34–38). This is not only true for settling properties but may apply to the reduction in biochemical oxygen demand, nutrient removal, sludge dewatering characteristics, and sludge management.

STRUCTURAL AND PHYSICOCHEMICAL PROPERTIES OF FLOC

Microbial flocs are usually not spherical but possess highly irregular shapes characterized by a large range of particle sizes, from single bacterial dimensions (ca. 1 to 3 μm) to large aggregate sizes of more than 1,000 μm (2,11,39). Median shape-factor values range from 0.6 to 0.7 (1.0 = a perfect circle). A bimodal floc-size distribution is often found (11,39,40,167). The percentage by number distributions tend to be positively skewed, whereas the percentage by volume distributions are negatively skewed. Although the majority of the mass is in the larger-size classes, the majority of the particles are smaller. Longest dimensions and widths yield similar distributions of the equivalent spherical diameters with slight variations reflective of the nonspherical shape of flocs. Floc size has significant implications for modeling of contaminant transport because the larger flocs will probably settle down much faster than the finer flocs, which will travel with their associated contaminant much further within the system.

The apparent density of flocs (about 1.03 g/cm^3) is close to the density of water (41,42). Consequently, the small difference in densities between flocs and bulk water leads to low settling velocities. Although a positive

relation between floc size and settling velocity is observed, there is a significant level of variability. Factors that can affect settling rates and impose variability in the results include floc composition, shape, porosity, and water content (2,42–44).

Increasing porosity leads to an increase in water content that forces the density of the floc toward the density of water, thus reducing the settling velocity. Porosity is complex as the definition or identification of pores is highly dependent on the resolving power used for their observation. Pores observed with conventional optical microscopy (e.g., phase or bright field optics) have been assumed to be devoid of materials and appear to be significant open channels for the movement of water through floc as it is settled or transported. These pores, are however, filled with a complex network of cells and EPS (1–3). Calculations of pore water movement that are important for understanding floc settling and contaminant transport that do not consider the internal structure of the pores may be erroneous.

The EPS within the floc matrix may be unattached or loosely attached to the floc surfaces (slime), or tightly bound to the exterior of cell walls (capsules) (3,27,45,46). EPS tend to have a sticky fibrillar nature (particularly the acidic polysaccharides), which may be the main component that gives flocs their strength and psuedoplastic nature (3,6,12). EPS may provide a framework for the floc itself. In activated-sludge flocs, a certain amount of filamentous microorganisms are desirable and thought to be necessary for the formation of larger, denser flocs (backbone theory) (23,33).

The chemical composition of microbial flocs is summarized in Table 1. Accumulation of EPS within the floc matrix probably occurs by metabolic synthesis, cell lysis, and/or adsorption of organic material (e.g., humic substances). The EPS content from metabolic synthesis is strongly related to environmental and microbiological conditions (34,35,47,48). The contribution of cell lysis is often attributed to the physiological status of cells or the EPS-extraction methods employed. The adsorption of organic material (e.g., humics) that contributes to EPS from aquatic systems or wastewater is related to the composition and properties of these organic materials. At present, it is difficult to distinguish the relative importance of the contributions of the three mechanisms to EPS content. The strong correlation between protein and DNA accumulation within the EPS indicates that cell lysis is the primary mechanism (34,35).

Table 1. Chemical Composition of Flocs

Composition	References
Total Mass	49,50
Dry weight 60–90% cellular organic material	
Wet weight 90–98% water	
Extracellular polymeric substances (15–33% of cellular organic material)	30,32,45, 47,51–61
Carbohydrates and acidic polysaccharides (5–40%)	
Protein (20–80%)	
Lipids (13–89%)	
DNA (1–10%)	
Humic substances (0–40%)	
Inorganic salts and particles (10–30%)	
Molecular weight distribution	
500–100,000 daltons (ultrafiltration studies)	56,62
10,000–2,000,000 daltons (chromatographic separation)	57,58,63

Microbial flocs are naturally hydrated because of the presence of large numbers of hydroxyl, carboxyl, and phosphate groups. However, floc surfaces do possess hydrophobic areas (30,64). Side chains in amino acids, the methyl groups in polysaccharides, and the long-chain carbon groups in lipids contribute to the hydrophobic properties of sludge flocs. Flocs are negatively charged under neutral pH conditions. The presence of ionizable groups such as carboxyl, phosphate, and amino groups in the EPS and cell surfaces is responsible for the density of surface charge. The zeta potential of sludge flocs is usually in the range of −10 to −30 mv (55,65,66).

DIFFUSIONAL GRADIENTS IN MICROBIAL FLOC

Ultrastructural studies of microbial flocs indicate a biofilm structure (3). Flocs are essentially biofilms that are turned back on themselves so that the biofilm/substratum interface is internalized as the core of suspended flocs. Large pores within the floc observed by conventional optical microscopy (COM) are not necessarily open channels devoid of structural material, but rather contain a complex matrix of "transparent" EPS (3,18). In sessile biofilms, microbial cells form dense layers of cells, or microcolonies, which are bound to each other by EPS (67–71). However, within these biofilms, there are voids and interstitial spaces between the microcolonies, which form channels and allow transport of material through the matrix. These channels are filled with water and low concentrations of EPS, thereby making the biofilm very absorptive and porous. The microbial floc is more similar to the microcolony within the biofilm. Gradients typically observed in sessile biofilms such as pH, oxygen, redox and substrate concentration may be present within the floc and may support sequential (aerobic/anaerobic) processes. Recent reviews on EPS produced by microorganisms (12,48,72) further supports the notion that the nature and prominence of EPS associated with the floc structure defines the flocs as biofilms.

Transport through porous structures can be attributed to both advection/convection and diffusion. The influence of the bulk-liquid velocity on convection in the voids within sessile biofilms can be interpreted from interfacial transport phenomena (68–71). In a biofilm system, substrate transport involves convection from the bulk liquid to the vicinity of the microcolonies, diffusion through the mass-transfer boundary layer, and finally diffusion through the microcolony to the individual cell (67,68,73). A similar process might be expected to occur in microbial flocs (74,75).

As a result of the high water content of microbial floc, these structures are considered to have a high porosity. The development of porous flocs may be advantageous to microbial communities because substrate removal can

be 60% greater than that for dispersed bacteria (43,76). Flow through the floc pores has been calculated to be up to 100 $\mu m.s^{-1}$. Microbial aggregates would be so porous that these might be permeable to fluid flow within certain shear rates or during gravitational settling. Mass-transfer by diffusion in this situation would be negligible because the flow through the floc is predicted to result in little difference in concentrations of nutrients between the bulk water and within the floc. Li and Ganczarczyk (77) proposed that if there is significant flow through pores, the floc-settling velocity would increase rather than decrease.

Alternatively, flow through flocs could be viewed as being negligible and water could be retained as an integral part of the floc structure owing to EPS having a high water-binding capacity (49,78,79).

Resistance within the floc due to the complex EPS matrix may affect the flux of water in and out of the floc. The EPS, as observed by Liss and coworkers (3), suggests that flocs probably retain a great amount of water as a result of the large surface area it forms and surface water tension. The floc would probably assimilate nutrients and contaminants primarily through diffusional gradients under these conditions.

Where diffusional gradients dominate, the gradients around and inside the flocs would be maintained by a balance between microbial metabolic rates (e.g., uptake, metabolism, end product formation) and diffusion of materials from and to the bulk solution. A floc with an anaerobic/anoxic core and aerobic surface would be consistent with this process. de Beer and coworkers have pioneered the application of biosensors to the investigation of chemical microgradients and activity in biofilms and flocs (79–81). Anoxic microniches have been found to form within aerobic activated sludge, particularly with respect to denitrification and sulfate-reduction. Microsensor measurements revealed that most of the large and bulking flocs examined lacked an anoxic zone and possessed low denitrification and negligible sulfate-reduction activity, although sulfate-reducing bacteria were observed by fluorescence in situ hybridization. Flocs that were reported to be denser, however, were found to contain anoxic zones. It is likely that both advection and diffusion account for nutrient transport through the floc as it does in biofilm.

INTERFACIAL FORCES IN FLOC FORMATION

Forces acting on and between particles include gravitational, hydrodynamic (drag) forces and thermal energy, and interfacial forces. Noncovalent interfacial forces are primarily involved in microbial floc formation. Ionic bonds are also involved in controlling floc formation and its stability. Bos and coworkers (82) have reviewed the physicochemistry of microbial adhesive interactions, particularly as it applies to sessile biofilms.

van der Waals Forces

These forces are attractive forces and depend on the geometry and nature of the interacting bacteria. Typically, energies of van der Waals interactions vary with the inverse sixth power of the particle separation. They contain three terms, namely, permanent dipole–permanent dipole interactions, permanent dipole-induced dipole interactions, and induced dipole-induced dipole interactions. A number of methods have been described for evaluating the values of van der Waals forces among the interacting bacteria (66,83).

Electrostatic Double-Layer Forces

Charged bacteria in an aqueous medium attract oppositely charged ions from the solution leading to the establishment of an electrostatic double layer at the solid–liquid interface (83,84). Electrostatic interactions arise as the electrical double layer of two approaching bacteria overlaps. They are usually repulsive forces and are responsible for the stable dispersion of charged particles. Under neutral pH conditions, bacterial surfaces are negatively charged because of the dissociation of anionic groups associated with the bacterial surface.

Hydrophobic/Hydrophilic Forces

Hydrophobic forces among microbial surfaces depend in large part on the unique properties of the thin layer of water associated with the surfaces and forces at a short distance (<2 nm). Typically, energies of hydrophobic interaction decrease exponentially with the particle-separation distance. They are attractive forces, whereas hydrophilic forces are repulsive. Hydrophobic/hydrophilic forces are of a polar nature and may be two orders of magnitude higher than van der Waals and electrostatic forces (85) at short distances (<2 nm).

Steric Forces

This type of force arises among polymer-coated surfaces. The presence of EPS on sludge surfaces may prevent the approach of flocs, allowing only a loose contact. The situation is even more complicated for charged polymer-coated surfaces. Generally, it is difficult to quantify steric forces in biological systems on account of their complexity (86,87).

MECHANISMS OF FLOC FORMATION

Proposed mechanisms for floc formation emphasize the importance of surface properties in floc interactions. The differences lie where the surface properties is considered to be most important, and how a particular parameter is affected by nutritional and environmental conditions.

Charge Neutralization

On the basis of size and charge properties, aggregation of microorganisms has been described most easily in terms of Derjaguin and Landau (88) and Verwey and Overbeek (89) DLVO theory, which was originally developed to explain the stability of hydrophobic, inorganic colloid suspensions. This theory describes the interaction energies between surfaces and is the sum of van der Waals (attractive) and electrostatic (repulsive) interaction potentials. If cells can get sufficiently close to each other at a distance at which

the van der Waals forces are effective, these flocculate and yield stable structures.

The failure of DLVO theory to explain bioflocculation under certain conditions (29,90) may be related to the complexity of biological systems. The microbial cell surface is not smooth, and hydrophobic/hydrophilic groups and EPS are also found at the cell surface (hydrophobic and steric forces) (91). Therefore, neglecting the hydrophobic/hydrophilic interaction at the surfaces of bacteria, as treated in classic DLVO theory, is probably not reasonable in understanding floc formation and floc strength. Because DLVO theory assumes smooth surfaces on the interacting particles and considers only the van der Waals and electrostatic forces, a consideration of other physical forces, such as hydrophobic interactions, may extend its application [extended DLVO theory (82,85)].

Hydrophobic Interactions

The presence of a shell layer of bound water near the cell surface accounts for hydrophobic/hydrophilic interactions. When two similar surfaces approach each other at a short distance, the bound-water layers surrounding the surfaces will overlap, forming a displacement of the bound-water layer into the bulk water. This leads to a decrease in the free energy (i.e., attraction) in the case of a hydrophobic surface, but to an increase in the free energy (i.e., repulsion) in the case of a hydrophilic surface (92). Any alteration of the cell surface that increases the surface hydrophobicity will enhance the formation of flocs. Increasing experimental evidence indicates that hydrophobic interactions play an important role in bioflocculation (30,34,93–96).

Polymer Bridging

The polymer bridging mechanism has long been used to interpret microbial adhesive interaction (23,32,47,73,82,91,97,98). Floc growth through attachment of single cells or smaller flocs may occur through EPS. EPS constituents including cellulosic polysaccharides and DNA have been described as effective flocculating agents (61,99). Whether the amount or the specific composition of EPS, or both, is crucial to sludge-floc formation has been debated (32,97). The widely held view that the total EPS content is directly related to bioflocculation no longer applies because increasing emphasis is being placed on the type of polymer and its physicochemical properties (34).

Salt Bridging

Both the bacterial surface and EPS provide negatively charged adsorption sites. Inorganic ions, such as divalent cations (Ca^{2+} and Mg^{2+}), have been found to be strongly associated with the chemical structure of flocs and EPS (28,30,31,54,100). Removal of polyvalent cations from the floc matrix by ionic-chelating reactions leads to the disintegration of microbial flocs. Salt bridging agents that lead to EPS–metal complexes are probably needed to bind bacterial surfaces and EPS constituents to maintain floc stability and to increase the structural strength of EPS.

Surface Thermodynamics Approach

The initiation of microbial-floc formation can be interpreted in terms of system-free energy. The basic concept of the thermodynamic model is that the system-free energy is minimized at equilibrium. Consequently, the process of microbial-floc formation will be thermodynamically favored if the process itself causes the system-free energy to decrease. Electrostatic interactions and other specific bindings are ignored. The free energy of the interaction between two identical bacterial cells (B) immersed in a liquid (L) can be described as follows:

$$\Delta G_{\text{flocculation}} = -2\gamma_{\text{BL}}, \tag{1}$$

where $\Delta G_{\text{flocculation}}$ is the free energy of floc formation and γ_{BL} is the interfacial tension for the bacteria–liquid interface. If the total free energy of a system is reduced ($\Delta G_{\text{flocculation}} < 0$) by cell interactions, microbial-floc formation will be thermodynamically favored (101–103).

According to Neumann's equation-of-state, the interfacial tension γ_{BL} is correlated to the surface tension terms of bacterial cells γ_{B} and suspending solution γ_{L} as follows (103,104):

$$\gamma_{\text{BL}} = \frac{(\gamma_{\text{B}} - \gamma_{\text{L}})^2}{(1 - 0.015\gamma_{\text{B}}\gamma_{\text{L}})}. \tag{2}$$

Substituting Equation 2 into Equation 1, the free energy of floc formation can be calculated if the water-contact angle on cell surfaces and water surface tension are known (103).

PHYSIOLOGICAL FACTORS AFFECTING FLOC FORMATION AND PROPERTIES

Significant changes in the internal and surface properties of microbial flocs under various nutrient growth conditions have been observed particularly under nitrogen (N) and phosphorus (P) limitation (31,47,105–107). Generally, N-limited microbial cultures are high in cell polysaccharide and low in cell protein. In P- and N-restricted media, flocs possess large capsules and produce a higher surface charge per unit of dry weight. P limitations have been found to improve metal adsorption capacity of flocs. An increase in the carbon : Phosphorus ratio can result in the production of extracellular polysaccharides (108), and lead to proliferation of filamentous bacteria in sludge flocs (109). Low organic load conditions and a lack of nutrients can cause formation of pinpoint flocs and changes to properties of the flocs including poorer settleability (23,106,165). Short-term nutrient starvation of marine bacteria was found to cause a decrease in cell volume during the starvation period (110).

Other factors that can affect floc properties in engineered and natural systems include agitation, dissolved oxygen (DO) concentration, sludge age, and degradation of the EPS matrix. Agitation may disaggregate flocs and cause surface damage to or disruption of individual cells (90,111,164). Impacts on the metabolic state of floc caused by low DO concentration, anaerobic conditions, or the absence of a suitable electron acceptor may affect

floc stability and result in smaller flocs, which disaggregate (36,109).

Not all microbes aggregate and there is a variation in this ability between strains (4). Among the various bacteria in sludge, some are floc-forming microorganisms that are important in floc formation. They include cellulose (or cellulose-like) producing bacteria such as *Pseudomonas*, *Aerobacter*, *Agrobacterium*, *Azotobacter*, and *Zooglea ramigera* (24,25,98,112). Physiological age of cells is one of the primary factors related to the formation and properties of sludge flocs. Early experimental evidence indicated that large amounts of EPS were accumulated in the endogenous phase, and floc formation depends on the physiological age of cells (32,78,113). EPS is also produced in rapid-growth situations (114–116). Solids retention time (SRT), or sludge age, is a key process variable that can affect microbial growth rates. In general, low SRTs are associated with rapid rates of microbial growth and high rates of sludge production and wastes; high SRTs are related to slow growth and low rates of sludge production. On the basis of kinetic selection principles, a change in the microbial composition with respect to the SRT is expected. A high SRT will favor the accumulation of slow-growing microorganisms, whereas a low SRT enhances the domination of fast-growing microorganisms (117,118).

The SRT is defined as the average residence time of sludge within a bioreactor, whereas the F/M is defined as the ratio of the feed (carbon load) to the microorganisms (biomass concentration) in the bioreactor. These two parameters are not independent, but at steady state are correlated through the following equations:

$$\frac{1}{\mathrm{SRT}} = Y_{\mathrm{yield}}\left(\frac{\mathrm{F}}{\mathrm{M}}\right)E - K_{\mathrm{d}}, \tag{3}$$

$$\frac{\mathrm{F}}{\mathrm{M}} = \frac{S_{\mathrm{o}}Q}{(V\,X)}, \tag{4}$$

where Y_{yield} is the yield coefficient of biomass, E is the COD removal efficiency, K_{d} is the decay coefficient, S_{o} is the influent COD concentration Q is the influent wastewater flow rate, V is the aeration tank volume, and X is the concentration of biomass in the aeration tank. In general, a lower SRT is related to a higher F/M.

The flocculating ability of sludge flocs generally increases with an increase in the SRT (34,114,119–124). Surface charge and hydrophobic interactions are significant determinants in bioflocculation and floc stability, and the type and physical characteristics of EPS are important in biosolid-liquid separations (34,35,38,48,94). This is reflected in observations of floc structure. Flocs at lower SRTs (4 and 9 days) have been observed to be irregular in shape, whereas flocs at higher SRTs (16 and 20 days) had a more spherical, compact structure (125). Flocs at higher SRTs were less hydrated and covered in a dense EPS layer rich in osmiophilic granules indicative of lipidlike material that may account in part for the increased hydrophobicity of these flocs (34). Total EPS content as a sole parameter has limited value in understanding bioflocculation.

There has been considerable attention given to the role of quorum-sensing molecules in biofilm formation and stability (9,12). To date, there is no information on the role of these on microbial aggregation and bioflocculation processes for microbial floc.

METHODS FOR ANALYZING FLOC

The measurement and analytical methods used to study sludge surfaces are important for understanding the effects of physical, chemical, and microbiological conditions on microscopic properties of sludge flocs, and for relating microscopic properties of flocs to their behaviour. Few standard methods with good reproducibility are available, although various physical, chemical, and microbiological measurement and analytical techniques have been developed and used in floc research.

Floc Size and Sample Handling

Flocs are highly irregular in shape, porous, and three-dimensional; therefore, there is really no ideal way to characterize floc sizes. Equivalent spherical diameter (ESD) is the most frequently used term to represent floc size because of its simplicity, and the widely used Stokes' law equation is applied to estimate floc density from the ESD and settling-velocity data. In general, flocs range in size from a few μm to a few *mm* when measured by ESD (13,126). The effective diameter has also been determined as the geometric mean $\sqrt{(d_{\min} * d_{\max})}$ using the maximum ($d_{\max}$) and minimum ($d_{\min}$) dimensions across a two-dimensional floc image (127). Barbusinski and Koscielniak (128) and Li and Ganczarczyk (77) determined an average floc diameter defined as one half of the sum of the longest and shortest dimensions of the flocs to describe floc size. Researchers have also used fractal geometry to describe floc structure (129–133). Many methods and instruments have been developed in the past to measure floc-size distributions of natural and engineered systems. These methods include automated image-analysis systems (11,13), microscopic observations (33), and photographic techniques (28,126). The photographic size measurement, although easy to employ, does not allow measurement of very small flocs. The automated image-analysis systems usually comprise a microscope and a computerized digitizer, which allow for more accurate, reproducible, and fast estimates of floc morphological parameters. The Coulter counter has been used to measure floc size (75,119), but this method is destructive because of its impact on breakage and compression of larger flocs. Other instruments developed include a field-portable laser backscatter particle analyzer (134) and an in situ settling velocity instrument (135). Other less common floc-sizing methods, including filtration, centrifugation, and image-projection techniques (136), usually do not work because of artificial floc breakup or aggregations and are time consuming.

The critical step in floc size measurements is the sample handling and preparation. Considerable efforts have been given to overcome perturbation that may be associated with sampling and specimen preparation. Floc samples are usually collected as bulk suspensions and transported to laboratory for analysis. Subsampling of

flocs in the laboratory is normally done using a pipette. The opening of pipettes used to collect floc samples has to be wide enough (2 to 3 mm) to prevent floc breakage and disaggregation (39). Floc stabilization in low melting point agarose, before any further sample handling, has been found to minimize effects on floc-size distributions (39,137).

Floc Settling Velocity

The most common way to measure floc-settling velocity is by the multiple exposure photographic technique (42,44,126). This technique is effective in measuring floc size and settling velocity, but it lacks the precision in measuring fine flocs. A stereoscopic microscope and a video camera can be used to capture images of settling floc in a column filled with a media similar to the native environment of the samples (6). A small quantity ($\sim$ 1 mL) of floc samples is introduced at the top of the column. A sufficient travel distance is allowed for flocs to reach terminal velocity. Settling images of flocs are then recorded on a VCR as they pass though the focal plane of the microscope. These images are then analyzed using a computer-imaging software for size and settling velocity.

Ganczarczyk and his coworkers have used a power function of the form, $v = AL^n$, and a linear function, $v = A + BL$, to correlate floc-settling velocity (v) with its longest dimension as a characteristic size (L), where A, B, and n are the equation coefficients determined experimentally (42,131,138,139). The power function is considered to be a better way to describe the relationship because the power function predicts that the velocity will be zero when floc size approaches zero, whereas the linear function does not. Measured settling velocities have coefficients lower than that predicted by Stokes' law ($n = 2$). The power law coefficients (n) calculated from the power function generally range from 0.7 to 0.9. Ideally, in measuring floc-settling velocity, the number of flocs measured should be as large as possible and the size range included should be as broad as possible (140). A modified linear model incorporating the floc-settling shape factor has been found to improve the correlation coefficient (R^2) of the linear relationship (138).

Floc Density and Porosity

Density determinations for aggregates are usually on the basis of observations of terminal velocity, although methods based on settling flocs to their isopycnic levels using density-gradient techniques have been used (141–143). This technique, however, does not measure floc size concurrently with its density, thus, a size and density relationship might not be established easily. In addition, the ionic strength of the suspension medium and the nature of the medium itself have to be compatible and nontoxic to the biological flocs.

Stokes' law or modified Stokes' law are commonly used to calculate density from settling-velocity and size measurements (42,44,126,131,139,140,144). Stokes' Law is defined as follows:

$$v = \frac{1}{18}\frac{g \cdot d^2(\rho_f - \rho_w)}{\mu} \tag{5}$$

where v = terminal settling velocity
ρ_f = wet density of particle
ρ_w = density of water (assume settling in water)
g = gravitational constant
μ = viscosity of water (assume settling in water)
d = diameter of particle

Floc porosity from density is calculated as follows:

$$\varepsilon = \frac{\rho_s - \rho_f}{\rho_s - \rho_w} \tag{6}$$

where ρ_s and ρ_f are the dried sludge density (1.34 to 1.69 g/cm^3) and floc density, respectively, and ρ_w is the liquid density. The density calculation is considered to be an approximation because Stokes' law is best applied to spherical particles (139,140).

Variations of the floc-density model have been proposed that take into account the liquid viscosity, settling velocity, pH, and size of the flocs, and making assumptions concerning spherocity, a drag coefficient and the dried-sludge density (44,119,139,140,144). These are based on Stokes' law but there is no universal model. This is simply because these models were developed from their specific conditions such as the type of floc, the type of microorganisms, the hydrodynamic conditions, and the experimental techniques used. Therefore, floc density and porosity must be experimentally determined in all situations.

Extracellular Polymeric Substances

A number of methods have been investigated and applied to separate EPS from sludge flocs. They include physical (centrifugation, sonication, and thermal extraction), chemical (hydroxide addition, acidic stripping, ion exchange, and ethanolic extraction), and combined physicochemical methods (28,32,46,52,145). A more recently developed method involves the use of an ion exchange resin (Dowex resin) for EPS extraction from sludge flocs (45,57) at a low temperature (4 °C). This method yields a higher protein concentration than the widely used thermal extraction–solvent precipitation method, and minimizes lysis of cells at high temperatures.

Hydrophobicity

Techniques for determining hydrophobicity measure the hydrophobic properties of the outer cell surface as a whole or the colonial hydrophobicity of multicellular aggregates (146). Three techniques have been typically used in floc research, namely, microbial adhesion to hydrocarbons (MATH) contact angle measurement (CAM), and salt aggregation test (SAT).

MATH is based on bacterial cells possessing hydrophobic surface characteristics adhering to an oil–water interface, whereas hydrophilic cells do not (147,163). MATH is a simple and general technique for studying cell surface hydrophobicity and has been largely applied to suspensions of pure cultures, but it has also been widely used to measure the hydrophobicity of flocs (86,94,148,170). A limitation of this technique includes cell clumping.

CAM is a useful measurement of hydrophobicity of flocs because the surface-free energy can be estimated from the measurement (66,101,116,149). All measurements involve the preparation of a thin lawn of biomass through the vacuum filtration of a microbial suspension and the determination of sessile drop-contact angles on the lawn of biomass. Axisymmetric drop-shape analysis (ADSA) is an effective technique for determining contact angle measurements of biomass (34,150,151).

SAT is a simple technique in which the order in which cells are aggregated and settled when exposed to salting-out agents (e.g., ammonium sulfate) at increasing concentrations is a measure of their surface hydrophobicity (30,152,169). The most hydrophobic cells are aggregated first at a low salt concentration. The SAT technique has several limitations. Many hydrophobic bacterial cells will clump in the absence of salts. The electrostatic interaction may affect the results of SAT more than other hydrophobic measurement techniques (146).

Surface Charge

Colloidal titration is the most common method for determining the surface-charge density of flocs (34,113) and is routinely applied to determine polymer dosage in biosolids management. An excess amount of positively charged polymer is added to a floc suspension. The excess amount of positively charged polymers is titrated with a negatively charged polymer in the presence of an indicator dye; the surface-charge density of flocs is calculated from this titration. Electrophoretic mobility is particularly valuable because it allows the estimation of the zeta potential. This determination is related to the water chemistry of the suspension solution, and the type, size, and shape of the cells. An accurate measurement is difficult, and requires skill, experience, time, along with the use of specialized apparatus. Other methods include attachment to charge-modified polystyrene and fluorescent probe ion exchange resin, and electrophoretic mobility (153).

Microscopic, Molecular, and Microenvironmental Analysis

Correlative microscopy (CM) is a strategy of using multiple microscopes (3,154) or multipreparatory techniques (3), which collectively enable the microscopist to potentially visualize microbial flocs and their components and identify physicochemical parameters, three-dimensional arrangements of constituents, topography, chemical composition, and forces governing interfacial phenomena. Microscopes include conventional optical microscopy (COM) (1,13,167), scanning confocal laser microscopy (SCLM) (17,1,18,155), two-photon laser scanning microscopy (2P-LSM) (17), atomic force microscopy (AFM) (156–158) and Raman confocal microspectroscopy (159), transmission electron microscopy (TEM) (3,168), and environmental scanning electron microscopy (ESEM) (1,125). Applying CM permits one to detect, assess, and minimize artifacts, which might arise from using only one technique. The use of only one microscopic technique can bias or limit the information acquired because of the artifacts that arise in specific sample preparations and the resolution constraint associated with a particular technique (154,3).

Minimizing perturbations associated with manipulations while preparing material for CM can be achieved through sample stabilization in low melting point agarose (39). The structural integrity of the samples can be maintained through the stabilization, staining, and washing procedures. Nanoplast resin is particularly effective as a stabilization medium because it is a hydrophilic embedding resin, which holds the fibrillar EPS (3). Measurements of the dimensions of colloidal matrix material and their three-dimensional disposition are realistic. Nanoplast has been recently shown to be useful for stabilizing sediment biofilms and the EPS matrix of these structures for observation by SCLM (17). SCLM is a particularly useful technique in bridging the resolution gap between COM and TEM for the study of flocs (125,132,133,160). More detailed description of SCLM is provided by Neu and Lawrence (this publication). SCLM and 2P-LSM can be used in combination with a variety of fluorescent molecular probes to study the spatial distribution of floc constituents and the microenvironment nondestructively (17,18,160).

Molecular tools enabling the amplification, isolation, and sequencing of 16S rRNA genes from environmental samples [e.g., amplified ribosomal DNA restriction analysis (ARDRA), denaturing-gradient gel electrophoresis (DGGE)] are widely used in environmental microbiology to examine complex communities and to establish phylogenetic associations without having to culture individual isolates (161). Whole-cell fluorescent in situ hybridization (FISH) with taxon-specific, rRNA-targeted fluorescent oligonucleotide probes and detection by SCLM permit the in situ exploration of the structural distribution of individual community members (e.g., nitrifying bacteria) in microbial floc (92,79,160). Combining FISH with functionality through microautoradiography and/or differential gene expression (double-probing techniques) may provide a better understanding of processes and factors, that affect the ecology of complex microbial processes in floc associated with engineered systems and natural environments (41).

Information about the in situ activity of bacteria and the microenvironmental conditions within flocs has been possible with the development of microsensor technology (80,81,79). It has been possible to examine diffusional gradients in flocs and the constraints imposed by structure. A variety of electrochemical and fiber-optical microsensors can measure a variety of chemical and physical parameters (NO_3^-, NO_2^-, NH_4^+, CO_2, H_2, H_2S, CH_4, O_2, temperature, and pH) (81). Holding flocs in place in order to insert a microsensor is not trivial compared with a sessile biofilm. A vertical net-jet flow cell has been developed for microenvironmental analysis of flocs by microsensors (74). Flocs are retained above a piece of nylon stocking separating two tubes and an upward flow is applied.

CONCLUSION

Microbial flocs and bioflocculation processes are important to a variety of environmental processes associated with engineered and natural aquatic systems. Morphologically, most flocs are similar with respect to the association of

cellular, bioorganic, and inorganic constituents, although the proportions may vary. EPS contribute significantly to the floc structure and appear to bind the primary particles together. The EPS are arranged differentially within the floc matrix, including the large porous regions as seen by conventional optical microscopy, giving rise to a complex structure. This contributes to an extensive surface area, and owing to the properties of the EPS, a highly absorptive capacity and the ability to retain a considerable amount of water. Advanced optical microscopy and ultrastructural studies reveal a structure indistinguishable from sessile biofilms. Microbial flocs are biofilms, but as suspended structures they are subjected to a range of physical forces and chemical conditions, which may be of less importance in our understanding of sessile biofilms (e.g., settling, porosity, density, colloidal stability). Developments in the methods and techniques in microscopy, molecular biology, and microenvironmental analysis are permitting more detailed examination of microbial flocs. A more detailed and realistic understanding of the internal microenvironment and outward behaviour of flocs will be achieved, as will our ability to better model important environmental processes, such as sediment dynamics and contaminant transport, and better manage engineered systems.

MICROBIAL REMOVAL BY PRETREATMENT, COAGULATION AND ION EXCHANGE

MARK W. LECHEVALLIER
American Water Works Service Company, Inc.
Voorhees, New Jersey

For centuries, the process of providing safe drinking water has relied on the application of the "multiple barrier concept." Hippocrates (460–354 B.C.) writes in *Air, Water and Places* — the first treatise on public hygiene — that "qualities of the waters differ from one another in taste and weight,"... One should "consider the waters which the inhabitants use, whether they be marshy and soft, or hard and running from elevated and rocky situations, and then if saltish and unfit for cooking... for water contributes much to health." (1)

Today, the concept of multiple barriers for water treatment is the cornerstone of sanitary engineering. These barriers are selected to duplicate removal capabilities by succeeding process steps so that sufficient backup system are available to permit continuous operation in the face of normal mechanical failures. Traditionally, the barriers have included:

- source water protection,
- coagulation, flocculation, sedimentation,
- filtration,
- disinfection, and
- protection of the distribution system.

This section deals with the pretreatment and chemical conditioning of water for optimum removal of microbes within the drinking water treatment process. When these processes are combined with disinfection, filtration, and protection of the distribution system; high-quality potable water can be achieved. Alternatively, water source of very high quality may rely only on watershed protection and disinfection. The reader should consult each of these sections to gain a comprehensive view of the microbiology of drinking water treatment.

An example of the benefit of multiple treatment barriers is illustrated by a recent epidemiological study of a karstic groundwater system, in which one well was filtered and chlorinated while the second was only chlorinated (2). A study of antidiarrheal drug sales showed a strong correlation to lapses in chlorination of the well that had disinfection as the only treatment, whereas no effect could be traced to lapses in chlorination of the filtered well. The authors speculated that combination of filtration and chlorination and provided sufficient redundant treatment so that temporary lapses in disinfection did not generate a measurable outcome (2).

PRETREATMENT

Pretreatment can broadly be defined as any process to modify microbial water quality before the treatment plant. Pretreatment options may be compatible with a variety of posttreatment processes ranging in complexity from simple disinfection to membrane processes. Pretreatment can have the advantage of reducing or stabilizing the microbial load to the treatment process.

Roughing Filters

A roughing filter is a coarse media (rock or gravel) filter used to reduce turbidity levels before downstream processes, such as slow sand filtration, diatomaceous earth, or possibly membrane filtration. A review of design variables for roughing filters has been published by the American Water Works Association Research Foundation (AWWARF) (3). Roughing filters typically have a filter box divided into multiple sections containing gravel beds of decreasing size, inlet and outlet structures, and flow control devices. Examples of common configurations are shown in Figure 1.

Roughing filters have achieved peak turbidity removals ranging from 60 to 90%, with higher reductions generally associated with higher turbidity loadings (4,5). Coliform bacteria have been removed to a similar extent. Galvis and coworkers (5) reported pilot studies of various roughing filter configurations (horizontalflow, upflow, and downflow). They achieved 93 to 99.5% reduction in fecal coliform bacteria. When these filters were combined with a dynamic roughing filter (a filter with a thin layer of fine gravel on top of a shallow bed of coarse gravel with a system of underdrains) to pretreat high turbidity events, and subsequent slow sand filtration, fecal coliform removals of 86.3 and 99.8%, respectively, were achieved with an overall combined treatment efficiency of 4.9 to 5.5 log units. In a five-month pilot study of a medium gravel (5.5 mm), horizontal roughing filter in Texas City, Texas, Collins and coworkers (3) reported an average 47% removal of total bacteria measured by epifluorescence microscopy. In the same study, the roughing filter removed

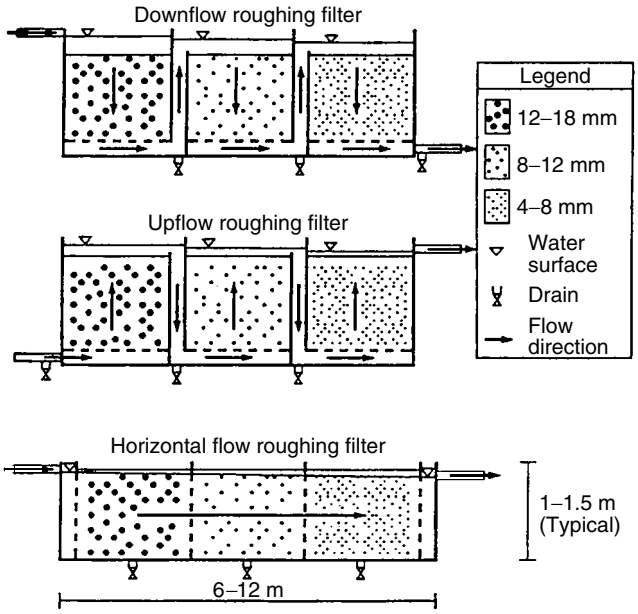

Figure 1. Typical roughing filter configuration loadings (Collins et al. 1994.

37% of the source water algal cells and 53% of the total chlorophyll. The researchers found that the roughing filters performed better for removal of clay particles when the filter was ripened with algal cells. Ahsan and coworkers (4) reported that addition of alum coagulant before a horizontal roughing filter could improve its performance for turbidity, color, organic carbon, head loss, and filter run length.

Microstrainers

Microstrainers are fabrics woven of stainless steel or polyester wires with apertures ranging from 15 to 45 m (usually 3,035 m). Because of the mesh size, microstrainers are useful for removal of algal cells and large protozoa (e.g., *Balantidium coli*), but does not show significant impact on bacteria or viruses. The overall rate of algae removal achieved for microstraining is usually between 40 and 70%, with simultaneous reduction in turbidity of 5 to 20% (6). The performance of microstrainers for specific applications varies depending on the type of algae present. Table 1 summarizes the performance of microstrainers for various types of algae. Although microstrainers can reduce the coagulant demand, it does not reduce smaller species or reproductive forms of algae.

Off-Stream Storage

The effects of off-stream storage are difficult to generalize because important physical, biological, and chemical processes are influenced by hydrological and limnological characteristics of the reservoir. For example, "round" reservoirs and lowland impoundments under strong wind influence can be regarded as homogeneous biotypes because of effective mixing, whereas long-stretched reservoirs whose depth increases with length can be considered as a series of interconnected individual basins (7). Reservoirs created by construction of a dam will have characteristics different from a natural or artificial lake. For the purposes of this discussion, off-stream storage refers to a pumped storage reservoir that feeds directly or indirectly a potable water intake.

Table 1. Performance of Microstainers for Various Algae

Diatoms		
Cyclotella	unicellular	10– 70
Stephanodiscus	unicellular	10–60
Melosira	filamentous	80–90
Synedra	unicellular	40–90
Asterionella	colonial	75–100
Fragilaria	filamentous	85–100
Chlorophyceae		
Chlorella	unicellular	10–50
Scenedesmus	cenobia (4–8 cells)	15–60
Pediastrum	cenobia (4–64 cells)	80–95
Blue-green algae		
Oscillatoria	filamentous	40–50
Anabaena	filamentous	50–70

Note: Adapted from Mouchet and V. Bonnelye, *Aqua* **47**, 125–141, 1998.

Oskam (8) summarized the self-purification processes that improve water quality in off-stream reservoirs (Table 2). The major factors that influence these processes are the degree of compartmentalization, the hydraulic residence time, the shape and flow through the reservoir, and the quality of the source water. In some cases, some of the processes can also degrade water quality. Failure to manage algal growth, control influx of nitrogen or phosphorous or other contaminants, or limit fecal contamination from runoff of surrounding areas or roosting birds can result in poorer quality of the impounded water.

Bernhardt (4) reported an elimination efficiency of coliform bacteria in dammed reservoirs of 8,099 percentage, when residence times were greater than 40 days, and 90–99% reduction of allochthonous bacteria, when retention times exceeded about 100 days. Similarly, reductions of enteroviruses (1.5 logs), Kjeldahl nitrogen (50%), total phosphorus (60%) and ammonium (70%) were reported for a pumped, off-stream reservoir after approximately 100 days retention time (9). Stewart and coworkers in 1997 (10) examined storm events that washed high levels of Giardia cysts (up to 17,000 cysts/100 L) and Cryptosporidium oocysts (up to 42,000 oocysts/100 L) into receiving reservoirs, with only one of 29 reservoir effluent samples, positive. Presumably, the cysts and oocysts were trapped in sediments that settled to the bottom of the reservoir because unattached organisms settle slowly (11). In a study of three Biesbosch reservoirs, storage with long residence times (average 24 weeks) resulted in reductions of 2.3 logs for *Giardia*, 1.4–1.9 logs for *Cryptosporidium*, 2.2 logs for *Escherichia coli*, and 1.7 logs for fecal streptococci (12,13)

Oskam (8) reported that die-off kinetics of microbes could be modeled as first-order reactions dependent on the residence time and short circuiting. For relatively rapid reactions (k-values > 0.05/d), the degree of compartmentalization had a positive effect on water quality. Therefore,

Table 2. Self-purification Processes that Improve Off Stream Reservoir Water Quality

Physical Processes
Equalization of peak concentrations (e.g., chemicals, microbes)
Exchange of oxygen and carbon dioxide with the atmosphere
Evaporation of volatile substances (e.g., solvents)
Settling of suspended solids and adsorbed substances (e.g., turbidity, heavy metals)
Biological Processes
Biodegradation of organic substances
Die-off of fecal bacteria and viruses
Nitrification of ammonium to nitrate
Denitrification of nitrate to nitrogen
Phosphorus elimination by phytoplankton uptake (in pre-reservoirs)
Chemical Processes
Oxidation of divalent iron and manganese
Hydrolysis of polyphosphates and organic esters (e.g., phthalates)
Photolysis of humic substances and polynuclear aromatic hydrocarbons

Note: Adapted from G. Oskam, *Aqua* **44**, 23–29 1995.

it would be better to have a series of three or four smaller reservoirs rather than one large impoundment. With estimated k-values of 0.07/d for removal of *Giardia* and *Cryptosporidium*, and 0.13/d for enteric viruses, compartmentalization in three or four reservoirs would increase the removal effect 15 to 230 times better than that achieved from a single basin (8).

For reservoirs with short retention times (and therefore limited self-purification), management of the raw water pumping schedule can improve water quality by avoiding periods of source water contamination. In a study of the Delaware River (U.S.A.), peak levels of microbial contaminants were associated with turbidity spikes following rainfall events (14). By operating the source water pumps to avoid these peak events, spikes of *Giardia* and *Cryptosporidium* that were 12 to 16 times higher than normal baseline levels could be avoided.

Bank Infiltration

Bank-filtered water is surface water seeping from the bank or bed, or a river or lake to the production wells of a water treatment plant. During the ground passage, water quality changes due to microbial, chemical, and physical processes, and by mixing with groundwater. The process can also be described as *induced infiltration* because the well field pumping lowers the water table causing surface water to flow into the aquifer under a hydraulic gradient. Bank infiltration has been widely used in European countries and is of great interest in many other countries. Variations on the underground passage concept include soil aquifer treatment, injection of surface water for underground passage, and aquifer recharge. Bank infiltration can be accomplished through natural seepage into receiving ponds, shallow vertical or horizontal wells placed in alluvial sand, and gravel deposits adjacent to surface waters, or infiltration galleries.

The advantages of bank infiltration are summarized in Table 3. The efficiency of the underground passage process depends on a number of factors: the quality of the surface water (turbidity, dissolved organic matter, oxygen, ammonia, and nutrients), the composition and porosity of the soil, the residence time of the water in the soil, and temperature. This efficiency can vary over time depending on the difference between the source water (e.g., river stage) and groundwater levels. This difference can influence the degree of groundwater mixing and residence time of the infiltrated surface water.

In the United States, and elsewhere, concern about groundwater under the direct influence of surface water (GWUDI) has caused some confusion on how to regard bank infiltration processes. Clearly, these processes are under the direct influence of surface water. However, the U.S. Surface Water Treatment Rule (USEPA, 1989) (16) ascribes no treatment credit to the infiltration process. Clancy and Stendahl (17) reported that removal of algae and diatoms ranged from 4.8 to 7.2 logs when the quality of the collection well was compared to when the raw water of the Grand River in Ontario, Canada. No *Giardia*

Table 3. Advantages of Bank Infiltration

- A natural pretreatment step requiring little chemical addition
- Reduced turbidity and particles
- Removal of biodegradable compounds
- Reduction of natural organic matter and lower disinfection by-product formation
- Reduction of bacteria, viruses and protozoa
- Equalization of concentration peaks (e.g., spills, temperature, etc.)
- Dilution with groundwater

Note: Adapted from W. Kuhn, International Riverbank Filteration Conference, Louisville, Kentucky.

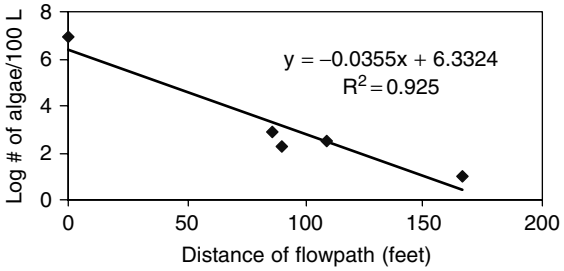

Figure 2. Relationship between algae reduction and theortical flow path. Adapted from Gollnitz et al. 1997 (18).

or *Cryptosporidium* were detected in the collector wells, although they were frequently detected in the river water. A relationship (Fig. 2) between the measured reduction of algae and the theoretical flow path for wells along the Great Miami River at Cincinnati, Ohio demonstrated approximately 1 log reduction for every 28 ft (8.5 m) of separation from the source water (Gollnitz and coworkers 1997) (18). Schijven and Ritveld (1997) (19) measured the removal of male-specific coliphage, entero- and reoviruses at three infiltration sites and compared the measured values to those predicted by a virus transport model. They found 3.1 logs reduction of bacteriophage within 2 m (6.6 ft) and 4.0 logs reduction within 4 m (13.2 ft) of very fine dune sand. Phages were reduced 6.2 logs through river bank infiltration greater than 30 m (98 ft) of sandy soil. In all cases the entero- and reoviruses were eliminated to a value lower than the detection limits (>2.6 to >4.8 logs removals). The virus transport model corresponded reasonably well with the measured results, producing calculated removals ranging from 2.5 to 15 logs. In ongoing studies being conducted by the American Water Works Service Company, Inc. and the Johns Hopkins University, monitoring of three river bank in filtration system along the Wabash (Indiana), Ohio, and Missouri Rivers have shown complete removal of *Clostridium* and bacteriophage indicators (Table 4) and substantial reductions in biodegradable dissolved organic carbon (BDOC) and assimilable organic carbon (AOC), which can stimulate bacterial growth in distribution system pipelines. All these data indicate that bank filtration can be highly effective for removal of microbial contaminants.

COAGULATION/FLOCCULATION/SEDIMENTATION

Coagulation is a process for promoting the interaction of small particles to form larger particles. In practice, coagulation refers to the process of addition of a coagulant and the formation of hydrolysis products, which causes coagulation, particle destabilization, and inter-particle collisions. The physical process of producing inter-particle contacts to form large particles is termed *flocculation*. Sedimentation is a solid-liquid separation process where particles settle under the force of gravity. Excellent reviews of these processes are available (20,21). With respect to coagulation and flocculation, microbes can be considered as particles (e.g., most bacteria and protozoa) or as colloidal organic particles (e.g., viruses).

Conventional

Conventional clarification typically refers to the process of chemical feed, rapid mix, flocculation, and sedimentation (usually in a rectangular basin). The efficiency of the sedimentation process may be enhanced using inclined plates or tubes. Removal of particles is chiefly governed by the particle terminal settling velocity, and the basin surface loading, or overflow rate. In the absence of a chemical coagulant, microbial removals are low because of low sedimentation velocities (11). The addition of coagulants neutralizes (or reduces) the surfaces electrical charge on the microbe and allow colliding particles to contact. Flocculation of these particles results in aggregates with sufficient settling velocities to be removed in the sedimentation basin.

Most studies of microbial removal by conventional clarification are estimated using jar test reactors. In these tests, removal of bacteria (*E. coli* vegetative cells and *Clostridium perfringens* spores) and parasites (Giardia cysts and Cryptosporidium oocysts) typically range between 1–2 logs (Fig. 3) (22). Overall, iron-based coagulants performed slightly better for microbial removal than alum or polyaluminum chloride (PACl); however,

Table 4. Reduction in BDOC, AOC *Clostridium*, and Bacteriophage Levels by Bank Infiltration

Site	Sample	Distance from River (ft)	BDOC (mg/L)	Total AOC (μg/L)	*Clostridium* cfu/100 ml	Bacteriophage

	Well#5	120	0.15	149.5	0.0	0.0	0.0

*Water from this well is not dominated by infiltration.

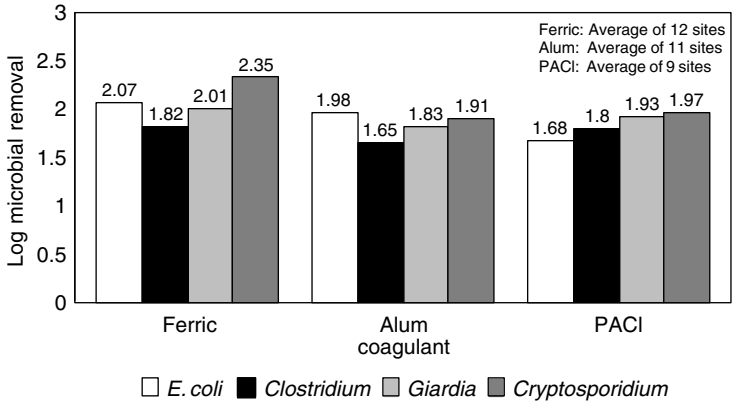

Figure 3. Removal of bacteria and protozoa under optimal coagulation conditions. Adapted from Bell et al. (22).

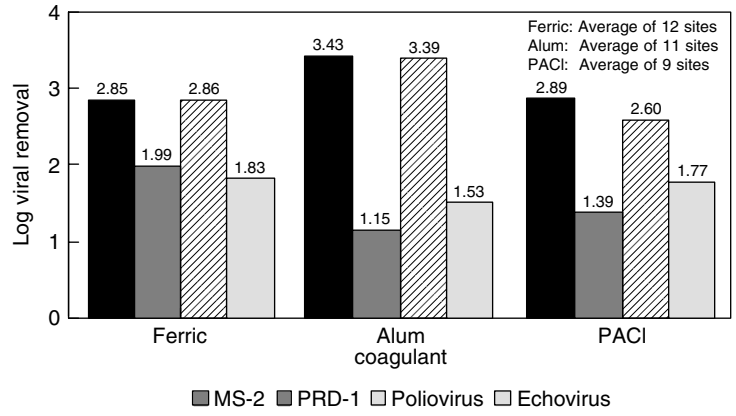

Figure 4. Removal of viruses under optimized coagulation conditions. Adapted from Bett et al. (22).

site-specific water quality conditions caused removal of efficiencies to a greater extent than did the choice of coagulant. Coagulation conditions (dose, pH, temperature, alkalinity, turbidity and the level and type of natural organic matter) impact the efficiency of removal, with slightly better overall microbial reductions under pH conditions (5–6.5) optimum for removal of total organic carbon (22).

Figure 4 shows that different viruses may respond quite differently to coagulation conditions. The bacteriophage MS2 and human enteric Poliovirus had similar removal efficiencies (2.6 to 3.4 logs), whereas the phage PRD-1 and enteric Echovirus were removed at a much lower rate (1.1 to 1.9 logs). Moreover, the differences in virus removal were most pronounced for alum [$Al_2(SO_4)_3$•18 H_2O]. Similar differences in virus adsorption have been observed in granulated gels (23). These results indicate that the performance of coagulation differs for various viruses and caution against extrapolating the data for other untested viruses.

Haas and coworkers (24) reviewed data from four bench-scale or pilot plant studies for coagulation, flocculation, and sedimentation of Cryptosporidium oocysts and chose data where the coagulant type, coagulant dose, pH, temperature, and mixing conditions were described. Using 24 data points, they found that the log removal of oocysts was dependent on coagulant concentration, polymer concentration, and process pH. The model had an excellent fit to the data (R^2 of 0.94). However, when data from other studies were added to the model, the fit of the model decreased. They concluded that additional data are needed, especially where the conditions of coagulation and flocculation are well described (methods of chemical addition, mixing conditions, and time, velocity gradient, etc.).

Performance of full-scale, conventional, clarification processes may be much more variable, depending on the degree of optimization. In an international report summarizing the performance of treatment plants from various countries, Gimble and Clasen (1998) (25) indicated that average microbial removals for coagulation and sedimentation ranged between 27 to 74% for viruses, 32 to 87% for bacteria (total coliforms or fecal streptococci), and 0 to 94% for algae. Low protozoan levels and limitations of the analytical methodology, limit full-scale data for *Giardia* and *Cryptosporidium* (26). Research has emphasized the need for an optimum coagulation dose as the most important factor to ensure good removals of cysts and oocysts by sedimentation and filtration (27–30). Impaired flocculation was one of the factors in the 1987 outbreak of cryptosporidiosis in Carrollton, GA (28). In a study of eight water filtration plants, Hendricks and coworkers in 1988 (31) concluded:

> ... without proper chemical pretreatment Giardia cysts will pass the filtration process. Lack of chemical coagulation or improper coagulation was the single most important factor in the design or operation of those rapid rate filtration plants where Giardia cysts were found in finished water ... with

proper chemical coagulation, the finished water should be free of Giardia cysts, have few microscopic particles, and have turbidity levels less than 0.1 NTU

Other factors that can influence the efficiency of the clarification include: variable plant flow rates, improper dose, poor process control with little monitoring, shear of formed floc, inappropriate mixing of chemicals, poor mixing and flocculation, and inadequate sludge removal (32). In addition to metallic coagulants (e.g., alum or ferric), polymeric coagulation or filter aids, or both, may be necessary to produce low turbidity levels (<0.1 NTU), especially for high-rate filtration (>4 gpm/sq ft or >10 m/h). Preoxidation with chlorine or ozone has been shown to improve particle removal by sedimentation and filtration (33,34). In some cases, current treatment plants are being designed with intermediate ozonation specifically to aid in particle removal by sedimentation and filtration (35).

Coagulation and sedimentation can be effective for removal of algal cells, and in most cases researchers have reported that coagulation conditions do not cause the release of algal toxins, provided oxidants are not added (36). Removal of algal toxins directly by coagulation and sedimentation has resulted in low removal levels, ranging from 0 to 49%, although addition of powdered activated carbon to the clarification process increased removals to 90% or better, depending on the carbon dose, type of carbon, toxin level, and organic matrix (36). A natural coagulant derived from shrimp shells (termed *chitosan*) was shown to be effective (>90% reduction) for removal of the algae *Chlorella* and *Scenedesmus quadricuda* at neutral to alkaline pH conditions and chitosan doses greater than 10 mg/L (37).

High Rate Clarification

Beginning in the 1930s, and increasing in usage in the 1970s and 1980s, were application of technologies to achieve high-rate clarification. Floc-blanket sedimentation or more generically, solids contact clarification, enhances particle removal by increasing particle concentration in a fluidized blanket so that flocculation and the rate of sedimentation is increased. Ballasted-floc systems combine coagulation with sand, clay, or carbon to increase the particle sedimentation rate. Adsorption or contact clarification is a process in which coagulated water is passed through a bed material where particles attach to previously adsorbed material. Because all these processes occur in smaller basins with higher surface loading rates than conventional clarifiers they can be generically termed as *high-rate clarification*.

When properly operated, high rate clarifiers can be as, or more, effective than conventional basins for removal of microbes. The choice of an appropriate blanket polymer is important for optimum operation (20). Bell and coworkers in 1998 (38) reported turbidity removals of 98% for Superpulsator® clarification (raw water turbidity 20–50 NTU, settled water 0.6 to 0.75 NTU), 89% for Accelator® clarification (raw water turbidity 4–10 NTU, settled water 0.5 to 0.9 NTU) and 61% for circular floc-blanket purification unit clarification (raw water turbidity 1.2–16 NTU, settled water average 0.97 NTU). Baudin and Laîné (39) evaluated three full-scale treatment plants and found complete removal (>2 to 2.8 logs) of *Giardia* and *Cryptosporidium* by pulsator clarifiers. The units produced between 1.0 and 2.7 logs of turbidity removal. Other investigators (40) have reported similar efficiencies for floc-blanket clarifiers. A combination of preozonation and Superpulsator® clarification reportedly improved clarification of *Giardia* and *Cryptosporidium*-sized particles from approximately 1.5 to 2.5 logs removal (41). Pilot plant studies of the sand ballasted-floc (actiflo system) showed effective removal of turbidity and particle counts (42). In addition, microscopic particulate analysis of raw and settled water showed average algae removal of 3.9 logs and 4.5 logs removal of diatoms (42). Floc formed on magnetic particles can be rapidly removed by using magnets within the sedimentation process (43–45). The particles can be collected and regenerated for reuse.

Dissolved Air Flotation

In dissolved air flotation (DAF), bubbles are produced by the reduction in pressure of a water stream saturated with air and the bubbles attach to floc particles causing the agglomerate to float to the surface where the material is skimmed off (20). DAF is most applicable to waters with heavy algal blooms or contains low turbidity, low alkalinity, and highly colored water. These waters are difficult to treat by sedimentation because the floc produced has a low settling velocity.

The effectiveness of DAF for treating algal-laden, humic colored, water is illustrated by the comments of Kiuru (46) a Finish researcher, who indicated that only DAF treatment plants have been built in his country since the mid-1960s. A 1.8 log removal of the algae *Aphanizomenon* and *Microcystis* was achieved by pilot-scale DAF. Similar results (1.4 to 2.0 log removals) have been obtained in full-scale studies (6). The effectiveness of DAF for treatment of algae also results in good removal of cell-associated toxins (6).

Plummer and coworkers (47) reported that depending on the coagulant dose DAF achieved between 2 and 2.6 logs removal of Cryptosporidium oocysts when conventional sedimentation resulted in 0.6 to 0.8 log removal. The performance of DAF for oocyst removal depended on the pH, coagulant dose, flocculation time, and recycle ratio. Other researchers have confirmed the effectiveness of DAF for oocyst removal, particularly when polyelectrolyte coagulant aids were added to help stabilize the floc (40).

Lime Softening

Precipitative lime softening is a process in which the pH of the treated water is increased (usually through the addition of lime or soda ash) to precipitate excessive concentrations of calcium and magnesium. Reduction of calcium can be achieved at pH values typically between 9.5 and 10.5 although removal of magnesium hardness requires pH levels between 10.5 and 11.5. This distinction is important because the pH of lime softening can inactivate many microbes at the higher end (10–11),

but may have less impact at more moderate levels (9.5). In precipitative lime softening, the calcium carbonate and magnesium hydroxide precipitates are removed in a settling basin before the water is filtered. Therefore, the microbial impact of lime softening can be a combination of inactivation by elevated pH and removal by settling.

Logsdon and coworkers performed a comprehensive evaluation of the effects of lime softening on the removal and disinfection efficiency of *Giardia*, viruses, and coliform bacteria (48). Coliform bacteria in river water (spiked with raw sewage) were inactivated 0.1 log at pH 9.5, 1.0 log at 10.5 and between 0.8 to 3.0 logs when exposed to a pH of 11.5 for six hours at 2–8 °C. Bacteriophage MS2 was sensitive to lime softening conditions, demonstrating more than 4 logs inactivation in the pH range of 11–11.5 within two hours. Hepatitis A virus showed a 99.8% reduction when exposed to pH 10.5 for six hours. Poliovirus was the most resistant virus tested, requiring exposure to pH levels of 11 for six hours before showing 2.5 logs inactivation. Reductions were less than 1 log when exposed for six hours to pH levels less than 11. The viability *Giardia muris* cysts (measured by excystation) were not significantly affected by exposure to pH 11.5 for six hours. *Cryptosporidium* viability (measured using dye exclusion) was not affected by exposure to pH 9 for five hours (49).

When the microbial removal by sedimentation is added to the microbial inactivation because of exposure to elevated pH levels, jar tests of precipitative lime softening at pH 11.5 resulted in 4 logs treatment of viruses and bacteria and 2 logs treatment of *Giardia* and *Cryptosporidium* (22). Limited full-scale data suggests that 2 logs removal can be achieved through sedimentation by precipitative lime softening (48).

In-Line Coagulation

For high-quality source waters (e.g., those waters where turbidity and other contaminant levels are low), coagulation may be performed within the raw water pipeline before direct filtration. In this case, coagulants are added directly to the pipeline, typically before an in-line static mixer, and a basin for sedimentation is not used. This method of in-line coagulation permits particle destabilization (charge neutralization) necessary for proper particle removal by filtration, but microbial removal by sedimentation does not take place.

ION EXCHANGE

Ion exchange is a treatment process in which a solid phase presaturant ion is exchanged for an unwanted water ion. The process is used for water softening (removal of calcium and magnesium), treatment of some radionucleides (radium and barium), and various contaminants (nitrate, arsenate, chromate, selenate, dissolved organic carbon). The effectiveness of the process depends on the background water quality, competing ions, and total dissolved solids. Although some ion exchange systems can be effective for adsorbing viruses and bacteria (50) they are not generally considered a microbial treatment barrier because the organisms can be released from the resin by competing ions. Therefore, breakthrough of the system is possible. Alternatively, ion exchange resins may become colonized by bacteria whose growth can contaminate treated effluents (51,52). Backflushing and other rinsing procedures, even regeneration, will not remove all of the attached microbes. Impregnation of the resin with silver suppresses bacterial growth only until a silver-tolerant population develops. Disinfection of ion exchange resins using 0.01% peracetic acid (one hour contact time) has been suggested (51).

MICROBIAL STARVATION SURVIVAL IN SUBSURFACE ENVIRONMENTS

THOMAS L. KIEFT
New Mexico Institute of Mining and Technology
Socorro, New Mexico

Abundant research findings in the 1980s and 1990s firmly established the existence of diverse microorganisms in a variety of subsurface environments (1–5). Subsurface habitats include sediments and rocks, and they range from shallow subsoils to rocks lying at depths greater than 3 km below land surface. The depth limit of the biosphere has not been determined; but if we assume that temperature constrains the distribution of microorganisms with depth and that the upper temperature limit for life is approximately 110 °C, then the biosphere extends to average depths of 4 and 6 km into the oceanic and terrestrial crust, respectively (6). Calculations of this type have led several investigators to conclude that the total subsurface microbial biomass outweighs all other forms of life on Earth (6–8). Microorganisms in the subsurface represent a diversity of phylogenetic types as well as a diversity of metabolic capabilities (9,10). The diversity of

metabolic types no doubt reflects the range of energy sources in the subsurface. Although microorganisms, primarily prokaryotes, abound in the deep subsurface, theirs is not an easy life. Energy sources and other nutrients are almost never present in sufficient quantities to support rapid reproduction. Nutrient fluxes are among the slowest in the entire biosphere, and thus rates of microbial activity are infinitesimally slow (6,10,11). Most subsurface microorganisms are subject to extreme long-term nutrient stress and may remain viable in a relatively inactive, starved, quiescent state for intervals that can be measured most appropriately on a geologic timescale. Deep, isolated subsurface environments may be among the most extreme on Earth, and the ancient microorganisms that persist under these extreme conditions may possess unique adaptations for long-term survival.

This article addresses energy sources available in the subsurface and the responses of subsurface microorganisms to the generally low, or even nonexistent, nutrient fluxes in deep subsurface terrestrial environments, with emphasis on the persistence of microbial populations for thousands to millions of years. There is a large body of literature, including many excellent reviews, on starvation survival of microorganisms in other environments, especially the open ocean (12–18). This information is not reviewed here, except as it relates to survival in the deep subsurface. Starvation of subsurface microbes has received considerably less attention and so correspondingly less is known about starvation capabilities and responses of subsurface microorganisms. Other recent reviews on this or related topics include those of Amy (19), Kieft and Phelps (10), Kieft (20), and Morita (17).

ENERGY SOURCES IN THE SUBSURFACE

Organic and inorganic energy sources support microbial growth and activity in subsurface environments. Organic energy sources can be photosynthetically generated organic matter transported from the surface by groundwater flow or organic matter that has been sequestered at the time of geological deposition. For example, in the coastal plain aquifer sediments of the southeastern United States, most of the microbial activity is based on catabolism of low concentrations of dissolved organic carbon (<0.5 mg/L in the Middendorf aquifer) that is transported from the recharge zone via groundwater flow; however, there are also localized residual organic carbon deposits in the form of lignite (21). Where the energy sources are primarily surface-derived organic matter that is transported through an aquifer, it is possible to estimate rates of microbial activity based on changes in aquifer chemistry along a flow path. Biogeochemical models of this type have estimated microbial activities in groundwater aquifers to be orders of magnitude slower than in nearly all surface environments (10,11,22). Phelps and coworkers (22) estimated generation times of hundreds to thousands of years for microorganisms in the coastal plain aquifers of South Carolina. Although this seems like a relatively slow-paced life, it is probably faster than in many other subsurface environments. Rates of groundwater flow and, consequently, rates of nutrient flux are even slower in aquitards, tight rock formations, and in thick, unsaturated (vadose) zones in arid and semiarid environments. Extremely sluggish rates of metabolism in some fine-grained sediments can be inferred when viable microorganisms are detected along with significant quantities of organic carbon that have persisted since the time of geological deposition, for example, in 6- to 8-million-year–old lacustrine sediments (23), in 90- to 93-million-year–old shale (24,25), and in 230-million-year–old shale (26). Extremely slow rates of metabolism in thick vadose zones of arid regions can be inferred from slow rates of groundwater recharge, slow diffusion of nutrients through thin, discontinuous water films, and persistence of entrained organic carbon (27–29). These relatively static, vadose zone environments may be the most nutritionally extreme in the entire biosphere, and indigenous microorganisms may be the ultimate microbial survivors.

Not all subsurface life is dependent upon photosynthetically generated organic matter; inorganic energy sources can also be significant in the subsurface. Reduced, inorganic sources of energy (e.g., H_2, H_2S, Fe^{2+}) may be products of anaerobic microbial metabolism or they may be generated by purely geochemical processes. Fredrickson and coworkers (30) were among the first to demonstrate chemolithotrophic activity in the subsurface, with the finding of nitrifying, sulfur-oxidizing, and hydrogen-oxidizing bacteria in Atlantic coastal plain sediments. Since then, a number of subsurface environments have been shown to harbor chemolithotrophs. Microorganisms capable of oxidizing hydrogen may be especially important in the subsurface. Several thermophilic, hydrogen-oxidizing, metal-reducing bacteria have been isolated from deep, hot environments (31–33). These may be of particular evolutionary interest, as hydrogen oxidation coupled to metal reduction occurs in many thermophilic microorganisms that represent deep branches of the phylogenetic tree, and this form of respiratory metabolism has been posited to be that of the last common ancestor of all organisms (34). Entire subsurface ecosystems may exist that depend on geochemically derived sources of hydrogen for primary sources of energy and that are therefore independent of photosynthesis for electron donor or electron acceptor (7,35–37). Stevens and McKinley (35) presented evidence of chemolithoautotrophic ecosystems in deep basalt aquifers in which hydrogen-oxidizing methanogens are the primary producers. The hydrogen can be generated geochemically through basalt weathering (35,38). Pedersen (36,37) has proposed a similar mechanism supporting life in a deep, fractured granite subsurface environment in Sweden. Hydrogen can also be generated by radiolysis, that is, splitting of water by ionizing radiation; such radiolytically produced hydrogen has been hypothesized to serve as electron donor for microorganisms in deep environments with sufficient radiation flux (26,39). Regardless of the source, inorganic energy in forms such as H_2 is probably made available in only sparing amounts and chemolithotrophs in these environments probably lead just as impecunious an existence as their heterotrophic counterparts.

Although exogenous energy sources may not be adequate to support frequent cell divisions in most subsurface environments, they may be utilized at a slow rate to fuel cell maintenance and repair. Morita (17) recently made a case for H_2 as the universal energy source that enables long-term survival of microorganisms in otherwise energy-poor environments. Morita's case for H_2 is built on the following points: its ubiquity in the biosphere, its ability to penetrate membranes, its low energy of activation, its ability to dissociate into protons and electrons in the presence of Fe(II), and the widespread phylogenetic distribution of hydrogenases in microorganisms. Low-level consumption of H_2 could provide sufficient energy for cellular repair of damage to macromolecules, including racemization of amino acids in proteins and depurination of nucleic acids. In the absence of exogenous energy sources such as H_2, it is hard to imagine that endogenous metabolism of storage products could be sufficient to maintain essential macromolecules for thousands to millions of years.

THE NATURE OF STARVED SUBSURFACE MICROORGANISMS

The majority of microorganisms in subsurface environments are prokaryotic and most of these appear to be bacteria (9), although the Archaea are also represented, especially methanogens in deep, anaerobic environments (35,40,41). Surprisingly, spore-forming bacteria do not comprise a significant component of most subsurface communities, even in those with negligible energy inputs. A possible explanation for this is that spores are incapable of repairing the unavoidable, accumulated damage to nucleic acids by ionizing radiation (42). Vegetative cells, on the other hand, are capable of at least some metabolic activity to support repair mechanisms and/or occasional DNA replication and cell division. Successful cell division effectively "resets the clock" on accumulation of DNA damage. Therefore, endospores dominate only in subsurface environments of more recent origin. As an example, endospore formers were found to be common among relatively shallow Siberian permafrost buried for 5,000 to 8,000 years, whereas they were rare in deeper, older (1.8 to 3.0×10^6-year–old) permafrost (43). Spores of actinomycetes and fungi may be rare in deep, ancient subsurface environments for the same reason.

Thus, most microorganisms in the subsurface are vegetative forms that lack obvious morpholological adaptation for resisting environmental challenges such as nutrient deprivation. In the absence of sufficient nutrient flux to support active metabolism, they exist as dormant cells. The term "somnicells" has been coined for these quiescent bacterial forms (44,45). Many of them are nonculturable, perhaps in a viable but nonculturable state, and so they remain hidden from traditional culture techniques in a state that is variously termed *cryptobiosis* or *anabiosis* (45). Clearly, there exists a broad spectrum of physiological states of microorganisms. Live, rapidly multiplying cells occupy one end of the spectrum; at the other extreme are cells whose membranes are no longer intact, that are incapable of substrate uptake and metabolism, and that are thus truly dead. Within that spectrum, one can envision cells that have one or more characteristics of life, for example, the ability to take up and metabolize substrates, cellular maintenance and repair, and so on, without undergoing cell division. A majority of deep subsurface microbes may exist in a state somewhere in the middle of the spectrum, that is, slowly metabolizing exogenous or endogenous energy sources, but rarely if ever dividing.

Further evidence for the starved state of subsurface bacteria lies in the fact that they exist in situ predominantly as extremely small, spherical cells, that is, "dwarfs" or "ultramicrobacteria" (20). The same holds true for surface soils, where dwarf cells make up the bulk of the biomass. As in soils, these dwarf forms probably represent a combination of potentially normal-sized bacteria that have miniaturized in response to nutrient deprivation as well as intrinsically small cells, that is, dwarf bacteria that do not grow into larger cells even when resuscitated by introduction of nutrients. Small size generally denotes a Spartan lifestyle. Intrinsically small cells are likely oligotrophs with high surface to volume ratios that favor high substrate uptake capacity relative to the low maintenance requirements of a small cell. However, stable dwarf bacteria that are capable of rapid growth have been isolated from a surface soil (46).

The dwarfing response in starved bacteria has been well documented in bacteria isolated from a variety of environments, including the subsurface (20,47–50). Starved cells undergo rapid diminution in cell size during the initial stages of response to starvation and thereafter the cell size stabilizes. In many bacterial types, the decrease in cell size begins with reductive division, also known as fragmentation, which is cell division without cytoplasmic growth (50). After two to three rounds of reductive division, size reduction continues as individual cells metabolize endogenous substrates. Whereas initial rates of endogenous metabolism may be rapid to provide energy for synthesis of new proteins, replication of DNA, and so on, long-term starvation survival requires a slow, frugal use of endogenous substrates at a rate that is just enough to support cellular maintenance. Dwarfing in marine *Vibrio* strains has been shown to be a response specifically to carbon starvation and is not triggered by nitrogen or phosphorus starvation alone (51). This may hold true for other genera and other environments. The lower size limit for dwarf cells has not been firmly established, but theoretical considerations as well as empirical data suggest a minimum cell volume of $0.004\ \mu m^3$, corresponding to a 0.2-μm–diameter coccus (20). Reports of considerably smaller sized "nannobacteria" in geological materials (52) are likely artifacts or possibly fragments of microbial cells. Likewise, the putative "nanofossils" in Martian meteorite ALH84001 (53) are unlikely to be fossils of microorganisms as they are known on Earth.

Starvation survival is of no selective advantage if cells are unable to respond when an energy-rich substrate finally becomes available. Starved bacteria have been shown to have a high affinity for energy-rich substrates (16,54). Substrate uptake requires an energized

cell membrane, that is, an active proton pump (or sodium pump in marine bacteria) coupled to electron transport to maintain a pool of high-energy compounds, for example, adenosine triphosphate (ATP) (45,55). Starving cells maintain a minimal concentration of ATP and may even increase their ATP content as starvation proceeds (56). Adenylate energy charge (AEC) is a measure of the physiological status of cells. AEC = ([ATP] + 1/2[ADP])/([ATP] + [ADP] + [AMP]). High values (>0.8) are thought to indicate active metabolism; intermediate values (0.4 to 0.8) indicate resting cells, and low values (<0.4) indicate dead or moribund cells. Kieft and Rosacker (57) measured AECs that ranged from 0.23 to 0.76 in deep southeastern coastal plain sediments. Each of these values likely represents an assemblage of microorganisms that vary in their levels of metabolic activity. The highest AEC value occurred in the sediment that had the highest number of culturable bacteria. AEC values were correlated with laboratory-measured respiration rates. Response time following addition of an energy-rich substrate is another measure of the physiological status of microorganisms. Kieft and coworkers (58) measured lag times for glucose mineralization that increased with depth and sediment age in a series of vadose zone sediments. This is similar to the laboratory findings of Amy and Morita (59), who found that the lag time for growth of a marine *Vibrio* was directly related to the length of time of starvation.

As in most other natural environments, the total numbers of cells (counted by microscopy or estimated from chemical analyses) are orders of magnitude greater than the numbers that can be cultivated. Culturability percentage ranges from an anomalously high 90% in highly conductive, Atlantic coastal plain aquifers (60) to more typical values of 0.01 to 0.0001% in a variety of other subsurface environments (27,29,58,61). Reasons for nonculturability are varied. Many cells are likely not cultured by currently available methods simply because we fail to understand their nutritional needs. Other cells may be injured, moribund, or actually dead. Dead cells may outnumber live cells in many subsurface environments. One measure of this is the relative amounts of membrane phospholipid fatty acids (PLFAs) and diglyceride fatty acids (DGFAs) (62). DGFAs are thought to be generated from PLFAs by the action of phospholipases immediately following cell death. Kieft and coworkers (58) measured ratios of DGFA to PLFA that increased with depth in a vadose zone, from approximately 0.001 in near-surface sediments to greater than 10 in deep sediments that have been buried for 10^4 to 10^6 years. Since there is ample evidence that subsurface microorganisms are capable of altering the chemistry of their environments (given sufficient time), it is clear that a significant proportion is viable and metabolically active, albeit at glacially slow rates. These may be in a starvation-induced, viable, but nonculturable state (44), and/or in a viable but as yet uncultured state (63). Since they resist cultivation, they can only be characterized by indirect approaches using molecular techniques (e.g., extraction, cloning and sequencing of DNA, or probing with oligonucleotide probes) or chemical analyses (e.g., PLFA profiling).

Finally, if one can generalize about diverse organisms occupying a wide range of habitats and perhaps comprising the majority of the Earth's biomass, the typical subsurface microorganism exists in situ as a relatively inactive, non-spore-forming, vegetative bacterium that is severely nutritionally challenged. Its starvation diet is directly related to its diminutive size and apparent nonculturability. Prolonged starvation stress selects for organisms that can maintain cellular integrity by slow endogenous metabolism of intracellular substrates and/or metabolism of meager exogenous substrates, possibly including H_2. Despite prolonged nutrient deprivation, it remains energetically poised for action should energy-rich nutrients appear.

LABORATORY STUDIES OF MICROBIAL SURVIVAL

Most of what we know about adaptations to starvation stress is based on laboratory incubation experiments. The traditional approach is to cultivate a pure culture of microorganisms in a rich nutrient medium, wash and resuspend the cells in a nonnutrient buffer solution, and then monitor characteristics such as culturability, cell morphology, and cellular physiology over time. This approach has been used to good advantage to investigate starvation responses of gram-negative marine heterotrophic bacteria (48,49,56,59,63,64,65). Experiments of this type have demonstrated various patterns of decline in culturability, in some cases preceded by a brief period of cell division without growth, that is, fragmentation (50). Cell volumes of these marine bacteria diminish during the early stages of starvation survival (49). Chemical composition of the cells changes as they convert to endogenous metabolism. Cell lipids, carbohydrates, and storage products (e.g., poly-β-hydroxyalkonoates) are consumed first, followed by a slow metabolism of cellular proteins and RNA. Starvation-specific proteins make their appearance with the onset of starvation stress (59,66,67). Some of these may be DNA-binding proteins that confer long-term stability (68). Starvation stress also results in changes in membrane lipid composition, as indicated by the appearance of stress signatures in the profiles of membrane PLFAs (48,62,69). Adaptations for starvation stress survival also confer cross-protection against other environmental insults, as well (68,70), for example, osmotic shock (71,72) and high temperature (72–74). The molecular mechanisms involved during induction of starvation survival are becoming understood in increasing detail for organisms such as *Escherichia coli* and marine vibrios (68,75–77). The low molecular weight compounds cyclic adenosine monophosphate and ppGpp appear to be important in intracellular signaling of starvation stress (68). The heat shock protein and molecular chaperone DnaK appears to play a central role. Mutant *E. coli* lacking *dnaK* failed to undergo reductive cell division when challenged by carbon starvation (74). DnaK mediates levels of the sigma factor RpoS, which in turn regulates expression of various starvation response genes (72). It remains to be seen whether the same molecular mechanisms are responsible for long-term starvation survival in subsurface bacteria. Microbial genome studies will likely

add to our knowledge in this area as they are expanded to include subsurface microbes.

This laboratory incubation approach to starvation studies has also been applied to soil microorganisms. Gram-positive, non-spore-forming soil bacteria of the genus *Arthrobacter* have been shown to be exceedingly starvation resistant. Early studies by Boylen and Ensign (78,79) showed that *Arthrobacter crystallopoites* could survive extended periods of starvation through a slow, sparing metabolism of endogenous substrates, including a glycogen-like polyglucose. Boylen and Ensign (78) found that 100% of cells remained viable after a 30-day incubation in nonnutrient buffer and that they decreased their rates of endogenous metabolism 80-fold during the first 2 days. In an experiment combining starvation and desiccation stress, Boylen (80) found 50% viability after 6 months in air-dried soil and that endogenous metabolism was slowed to a rate at which it could be projected that 50% of cellular carbon would remain after 12 years. However, as impressive as this is, it still does not compare to persistence on a geologic timescale in buried rocks and sediments.

Only a few subsurface bacteria have been tested for their starvation survival responses using laboratory incubation methods. Amy and coworkers (47) tested six strains isolated from volcanic tuff at the Nevada Test Site by suspending them in nonnutrient artificial pore water for 100 days and found patterns of response similar to those found in marine bacteria, that is, a rapid initial decline in culturable cells followed by a near–steady-state survival of a constant number of cells. Five of the six strains increased the number of culturable cells during the first two days of starvation, evidently by fragmentation. All six strains declined in cell volume during the early stages of starvation.

Kieft and coworkers (69) tested a *Pseudomonas aureofasciens* and an *Arthrobacter protophormiae*, each isolated from a subsurface sediment, for responses to nutrient deprivation in a porous medium, silica sand. The *Pseudomonas* altered its membrane lipid PLFA profiles in patterns that were similar to other gram-negative bacteria undergoing stress. The *Arthrobacter* showed no change in PLFAs when challenged by nutrient stress. In a longer-term study, Kieft and coworkers (48) tested the starvation-survival capabilities of subsurface *Pseudomonas* and *Arthrobacter* strains and compared them to those of closely related strains of bacteria isolated from surface environments. Phylogenetic relatedness was evidenced by similarity in 16S ribosomal RNA gene sequences. Starvation was carried out in two different sediments. One was a fluvial silt and other was a similar silt that had undergone soil development and was subsequently buried, forming a paleosol. Sediments were incubated under two different moisture conditions: one saturated with water and the other unsaturated to mimic conditions in vadose zone sediments. All strains survived for over a year in all treatments. Interestingly, there were no significant differences in viability percentage (quantified by plate counts) between the surface and the subsurface strains. However, the *Arthrobacter* strains survived better than the *Pseudomonas* strains under all conditions, as might be expected, given the well-documented starvation-survival characteristics of Arthrobacters. Survival was better in the paleosol than in the silt that did not undergo soil development. Survival may have been enhanced in the paleosol by the presence of residual soil organic matter as an exogenous substrate. Greater survival in the paleosol is also consistent with the observation of higher numbers of microorganisms in paleosols than in other buried sediments (27,81). Survival was better in saturated sediments than in unsaturated sediments, which is also consistent with field observations. Although vadose zone environments are generally relatively moist (matric water potentials greater than, i.e., less negative than, −0.1 MPa), the thin discontinuous water films of unsaturated sediments severely limit the flow of nutrients and the mobility of microorganisms (27,29). Thus, microorganisms in unsaturated, vadose zone sediments have even less access to exogenous substrates than in saturated sediments. Cells of both genera miniaturized during the early stages of incubation, as is typical of starved bacteria from all environments. Both the surface and surface *Pseudomonas* showed membrane PLFA profiles that are typical of nutrient-stressed gram-negative bacteria: increased ratios of saturated to unsaturated fatty acids, increased ratios of *trans* to *cis* monoenoic fatty acids, and increased ratios of cyclopropyl fatty acids to their monoenoic precursors. Again, the subsurface isolate reacted in a similar manner to the surface isolate. The surface and subsurface *Arthrobacter* strains demonstrated no discernible changes in membrane lipid PLFAs, as observed previously in the short-term starvation experiment (69).

The general conclusion from these experiments is that subsurface isolates are adapted for surviving long periods without exogenous nutrients, but perhaps not any more so than isolates from aquatic or soil environments. However, these laboratory incubation experiments have two severe limitations: one is that they are limited to culturable microbes whereas the majority of subsurface microorganisms are not culturable by currently available methods. The second obvious shortcoming is that laboratory incubations are relatively short, generally no more than a year or two (or a funding period) whereas microbes may be sequestered in the subsurface with limited nutrient availability for thousands of years or more. To truly grasp the concept of microorganisms remaining viable with little or no nutrient input for thousands to millions of years, one has to consider microorganisms in their natural geologic setting.

FIELD-BASED STUDIES OF MICROBIAL SURVIVAL

Two explanations can account for the presence of microorganisms in the subsurface. One is that they have survived since the time of geological deposition and the other is that they have been transported with groundwater more recently than geologic deposition. Depending on the environment, one or both of these explanations may be valid. The survival explanation is of greatest interest here. In many subsurface settings, the transport of microbes may be precluded by physical

conditions. Cemented sediments or crystalline rocks may lack fractures or pores of sufficient size to allow passage of microbes. Fine-grained sediments may preclude transport in a similar fashion (23,24). Thick unsaturated zones in arid regions may have insufficient rates of groundwater recharge to allow microbial penetration to any significant depth. By determining the time of geological deposition (or time of the last previous sterilizing event by heating) and the groundwater age, one can constrain estimates of the time since microorganisms were introduced into an environment. In subsurface strata with very old pore waters (thousands of years or more), it can be concluded that the inhabitant microorganisms have remained sequestered for at least as long as the age of the groundwater. If there is not a residual supply of organic carbon or other energy sources to these microbes, then it is likely that they have undergone few cell divisions in the subsurface and that any living cells that can be detected have maintained their viability as individual cells for exceedingly long periods of time.

There is a growing number of examples of apparently ancient microorganisms that have been resuscitated in culture from microenvironments that have been sealed against the influx of modern microorganisms for thousands and even millions of years (82–84). The finding of viable *Bacillus* endospores in the gut of an insect sealed in amber for 25 to 40 million years, by Cano and Borucki (85), is an especially striking case. The subsurface offers cases of ancient microbes that have been entombed for thousands to millions of years; however, the evidence for true sequestration from outside influences (immigration and/or nutrient transport) is generally more equivocal than it is for ancient amber.

Kieft and coworkers (58) quantified sediment ages, pore water ages, and microorganisms in a series of buried sediments at two sites in the Channeled Scablands of eastern Washington State. The sediments are aeolian loess sediments ranging in age from modern to approximately 1 million years. The sediment series constitutes a chronosequence in that age since time of geologic deposition is the main variable. Each of the sediments underwent some degree of soil development while at the surface before being buried by subsequent layers of very similar sediments. The pore water ages in the deepest, oldest sediments were estimated by the chloride mass balance method to be 1,200 years at one site and 3,000 years at the other. Microbial abundance (measured by microscopic counts, plate counts, and total PLFAs) declined with depth and sediment age in a pattern that was similar to patterns of microbial survival in laboratory starvation experiments, that is, rapid decline in the early stages of the experiment (represented here by shallow sediments of recent origin) and much slower decline in the later stages (represented by deeper, older sediments). Culturability percentage declined with depth. Microbial activities (radiolabeled glucose uptake and mineralization, β-glucosidase activity) showed similar patterns. PLFA profiles indicated the presence of several different types of microorganisms even in very deep sediments. PLFA signatures representative of gram negatives (e.g., *Pseudomonas*), gram positives (e.g., *Arthrobacter*), actinomycetes, and microeukaryotes were present even in sediments greater than 500,000-years old, with pore water age greater than 1,000 years. These data demonstrate the persistence of a diversity of microorganisms for a minimum of 1,000 years and probably much longer. Transport of microbes into the deep sediments cannot be ruled out, but the slow rates of groundwater recharge and the fact that microbes are usually transported more slowly than water in porous media suggest that microbes have persisted for much longer than 1,000 years. Likewise, the nutrient fluxes are extremely slow, and thus it is probable that these populations have undergone very few cell divisions.

Similar studies were carried out by Balkwill and coworkers (86) and Brockman and coworkers (28) in other low-recharge vadose zone sediments in eastern Washington State. Balkwill found evidence of a diversity of bacteria, including gram negatives and gram positives, in sediments with pore water ages of 15,000 and 30,000 years. Brockman and coworkers (28) isolated spore-forming and non-spore-forming bacteria from 4-million-year-old unsaturated sediments that have had only minimal groundwater recharge (~15 μm/year) since Pleistocene flooding about 13,000 years ago. Given the low recharge rates and negligible nutrient fluxes, these vadose zone bacteria appear to have survived starvation for 10^4 to 10^6 years.

Studies of volcanic tuff at the Nevada Test Site have revealed diverse bacteria, apparently existing within pores or fractures in the rock matrix (87–89). The environment here consists of unsaturated tuff, some of it highly welded by heating. Recharge rates are extremely slow and the depth to the water table is hundreds of meters. Microbes in some of these unsaturated strata are thought to have been trapped in minute pores within the rock matrix for at least 250,000 years (19).

SPECIAL CASES

Bacteria in Ancient Salt Deposits

Halophilic archaea and bacteria have been isolated from large deposits of NaCl evaporite (halite) from the Permian (225 to 270 million years before present) and Triassic (195 to 225 million years before present) Periods (90–94). Modern salt beds typically contain viable archaea; and it has been shown that archaea can become trapped within brine inclusions as halite crystallizes during evaporation, that various species of haloarchaea can survive within fluid inclusions for up to 6 months, and that these halophiles can then be resuscitated when the salt crystals are dissolved in a suitable growth medium (95). Fluid inclusions can comprise as much as 1% of the volume of halite deposits (96), and so they could conceivably harbor a significant number of cells. The question then is whether the microorganisms isolated from ancient salt beds have survived within fluid inclusions or whether they are more modern cells that exist on the surfaces of salt crystals or within fractures or pores in the salt beds. Comparisons of 16S ribosomal DNA (rDNA) sequences from modern isolates

with those from Triassic and Permian salt bed isolates do not show significant differences (97). Fredrickson and coworkers (96) concluded from rates of amino acid racemization and DNA breakdown that cells likely could not survive and that macromolecules would not remain from the Permian or Triassic Periods. Moreover, they were unsuccessful at cultivating halophiles or amplifying haloarchaeal 16S rDNA from 200-million-year-old salt crystals after disinfecting crystal surfaces and then dissolving the crystals; when the same techniques were applied to modern salt beds as a control, viable cultures and archaeal rDNA were produced. Vreeland and coworkers (94) reported cultivating a *Bacillus* isolate from the interior of a 250-million-year-old Permian primary halite crystal collected from the Salado Formation at 569 m depth in the Waste Isolation Pilot Project in New Mexico. The crystal is thought not to have undergone recrystallization since deposition, suggesting survival of an individual cell, presumably as an endospore, for 250 million years. This is an extraordinary finding that appears to contradict standard ideas regarding the long-term stability of macromolecules and the limits of microbial starvation survival. It may be that low water activity and/or protective proteins allow the persistence of microorganisms in halite. It remains to be seen whether more isolates will be recovered from such ancient halite. Fluid inclusions in other minerals, for example, silica, could also be sources of ancient microorganisms (98).

Bacteria in Frozen Environments

Permafrost soils in Arctic and Antarctic environments are another fascinating source of ancient bacteria that have persisted over a geologic timescale through limited reproduction or by surviving as individual cells for millions of years (see PERMAFROST, this Encyclopedia). Permafrost soils typically have extremely stable subzero temperatures, and so microbes in these habitats are not subjected to freeze-thaw stress (99). Microbial abundance in permafrost soils is often surprisingly high, 10^7 to 10^8 total cells/g dry weight, even in soils that have been buried for 3 million years and that are thought to have remained permanently frozen (100–102). The percentages of culturable cells can also be high, typically 0.1 to 10% in permafrost soils of Siberia (101,102). Fewer Antarctic permafrost microbes can be cultured: 0.001 to 0.01%, possibly because of the colder temperatures (−20 to −27 °C) (103). A diversity of microorganisms, most of them psychrophilic or psychrotolerant bacteria, has been isolated from buried permafrost soils, including aerobic heterotrophs, nitrifiers, denitrifiers, iron reducers, and sulfate reducers (43,102–104). Viability percentage and diversity generally decline with age of the permafrost (43). Even though the bulk of Siberian permafrost soil is permanently frozen at −10 to −15 °C, a significant proportion of the water (2 to 7%) exists in thin films of supercooled liquid (100), and this liquid water is thought to provide a protective habitat for microorganisms. Solidly frozen ice samples generally have few viable microbes, probably because of the irreversible damage caused by intracellular ice crystals (105). Thick cell walls, gelatinous capsules, and intracellular compatible solutes may also contribute to survival (105). The degree of metabolic activity in the permafrost bacteria is unknown. Certainly the temperature severely limits the rates, but the liquid water may provide nutrients at a rate sufficient to support occasional cell replications. The high percentages of culturable cells also suggest active metabolism. The deep cold biosphere deserves further study.

Survival of Potential Pathogens in Groundwater

Survival of pathogens in groundwater can be considered to be a special case in the context of this article because they are not naturally occurring in the subsurface and their survival in groundwater for even a short period is of interest from a public health standpoint. The topic of survival and transport of pathogenic microorganisms has been reviewed elsewhere (106–109), and so it is given only a cursory treatment here. Types of pathogens that can occur in groundwater include enteric bacteria (e.g., *Campylobacter jejuni*, *E. coli*, *Salmonella* spp., *Shigella* spp., and *Vibrio* spp.), protists (e.g., *Entamoeba hystolytica*, *Cryptosporidium parvum*), and viruses (e.g., hepatitis A, coxsackievirus, poliovirus). Sources of contamination can be treated or untreated wastewater that is introduced into the subsurface by infiltration, via leach fields from domestic septic systems, and by artificial recharge of groundwater (106,108,109). Animal wastes can also be a source of groundwater contamination (110). Factors controlling survival of pathogens in groundwater are the physical and chemical characteristics of an aquifer, the presence of competing or predatory microorganisms, and the characteristics of the pathogen itself. Survival is generally prolonged by lower temperatures. High concentrations of dissolved organic carbon in groundwater may enhance survival. Survival is generally longer in sterile groundwater than in the presence of natural groundwater communities (111,112). Most enteric pathogens are poorly adapted for growth and survival outside human and animal gastrointestinal tracts, and so they generally survive for only a few days to a few months in groundwater environments (109). Enteric bacterial pathogens in groundwater are frequently the same species as (or close relatives of) many of the ones that have been tested in laboratory incubation studies, and thus many of their physiological characteristics, including adaptations for starvation survival, are relatively well understood. Many have already been shown to enter a viable but nonculturable state when incubated in surface waters, including *C. jejuni*, *E. coli*, *Salmonella* spp., *Shigella*, spp., and *Vibrio* spp. (113,114), and the same is undoubtedly true when they occur in groundwater aquifers. Viruses may remain infective in the subsurface for longer than pathogenic bacteria, especially when they are protected from inactivation by sorption to aquifer solids.

CONCLUSION

There is now a substantial body of evidence that microorganisms are able to persist in the subsurface under energetically challenging conditions for thousands to millions of years, and that many of them do so as vegetative

cells lacking any obvious features favoring survival. How they do it is still largely unknown. An open question is whether subsurface microorganisms have evolved unique adaptations for long-term survival, whether selective pressures in the subsurface have generated unusually effective versions of starvation survival adaptations that also occur in surface microbes, or whether subsurface microorganisms have exactly the same starvation survival characteristics as their surface counterparts. Of course, each of these possibilities may be embodied in various subsurface microorganisms. This is related to the larger question of whether subsurface microbial populations and communities are unique to the subsurface or whether they can also be found in surface habitats. Amy (19) made a case for the uniqueness of subsurface microbial communities, based on their patterns of substrate utilization. At least some microbes in the subsurface are slowly metabolizing and slowly reproducing, as evidenced by changes in groundwater chemistry along a flow path, and thus they undergo natural selection in subsurface habitats. Given sufficient time, they should evince this evolutionary separation in their phenotypes (e.g., in adaptations to nutrient deprivation) and in their genotypes (e.g., in the sequences of "molecular clocks" such as 16S rDNA). However, 16S rDNA sequences may not change rapidly enough to demonstrate separation of subsurface microorganisms from surface populations. Also, gene flow between the surface and subsurface habitats is not permanently stanched; microbes enter and leave the subsurface via groundwater flow, tectonic activity, and so on (115). Thus, more information is still needed to determine the extent to which subsurface microorganisms are adapted specifically to life in the subsurface, including unique adaptations for long-term survival. Related to this, we need a better understanding of the in situ physiological status of microbes in deep subsurface environments, including any molecular structural features that may favor extreme long-term stability of DNA and other macromolecules. More data on the environment will also help. Continuing geochemical characterization of subsurface habitats is expanding our understanding of the energy sources that are available to support long-term survival and activities of subsurface microorganisms.

Prior to 1970, microorganisms were thought to be an insignificant biotic component below the root zone. However, the past quarter century has seen considerable research focused on the characterization of subsurface microorganisms in sediments and groundwater using a variety of microbiological and biochemical measurements. Research has been conducted to gain a better understanding of the types of microbial communities existing in the subsurface, their abundance, their activities, and their potential for in situ biostimulation or ex situ biotechnological applications. These investigations will continue to provide information with respect to use of the subsurface for acquiring drinking water and for waste disposal practices.

This article will focus primarily on sites along the Atlantic Coastal Plain (ACP) where the microbiology of the sediments has been investigated extensively. Descriptions of methodologies used to characterize microbial abundance, spatial and temporal variability, diversity, transport of microbial populations through the subsurface, and the metabolic and degradative capabilities of microbial communities will be presented.

SITES

The majority of sites discussed in this article are located along the United States Atlantic coast: Savannah River Site (SRS), South Carolina; Dover Air Force Base (AFB), Delaware; Cape Cod, Massachusetts; and Oyster, Abbott's Pit, and Taylorsville Basin, Virginia (Fig. 1). These sites share common features of interlaid sands, silts, and clay lenses. Other sites also representative of unconsolidated sediments are included in this article though they are not located on the ACP.

In 1986, a series of boreholes were drilled as part of the Department of Energy's (DOE) interdisciplinary Subsurface Science Program for long-term microbiological and geochemical studies. Three boreholes were drilled to a depth of 200–300 m below land surface (bls) at DOE's SRS in 1986 (1), and a fourth borehole near Allendale, South Carolina, was drilled to approximately 437 m in 1988. The subsurface geology in this region consists of about 400 m of unconsolidated sands, clayey sands, and sandy clays of Tertiary and Cretaceous ages, which overlie a basement of dense metamorphic rock, igneous intrusives, or consolidated sedimentary rock. A more detailed account of the geochemistry described below can be found in reference 2. Sediments at depths greater than 30 m bls were saturated. Major confining clays of regional extent typically contained greater than 20% clay and had low hydraulic conductivity ($k < 0.1$ mm/sec) and low permeability ($k(\mathrm{D}) < 0.1$) and were found within the Ellenton, Pee Dee, and Middendorf formations. Nonconfining layers contained mostly sands with hydraulic conductivity ($k > 100$ mm/sec) and higher permeabilities ($k(\mathrm{D}) > 10$). Sediments from the confining layers exhibited higher total organic carbon (TOC) concentrations (2 to 3.5 mg/kg) than did highly permeable aquifer sediments (0.1 to 0.6 mg TOC/kg sediment). Nitrogen (nitrate and/or ammonia), sulfate, iron, and sodium concentrations were typically greater than 10 mg/L in the pore water. Phosphate concentrations were less than 10 mg/L in pore water extracted from sandy sediments or in pumped groundwater. The dissolved oxygen content of the groundwater was generally between 0 and 5 mg/L. Redox potentials were greater than 250 mV for shallow sediments, whereas deeper and downgradient sediments exhibited lower redox potentials, indicating anaerobic environments. For example, the Cape Fear formation at 463 m bls had a redox potential of 150 mV.

The Cape Cod site is the United States Geological Survey's Toxic Substance Hydrology Program Research Site. Treated sewage effluent from Otis AFB has been

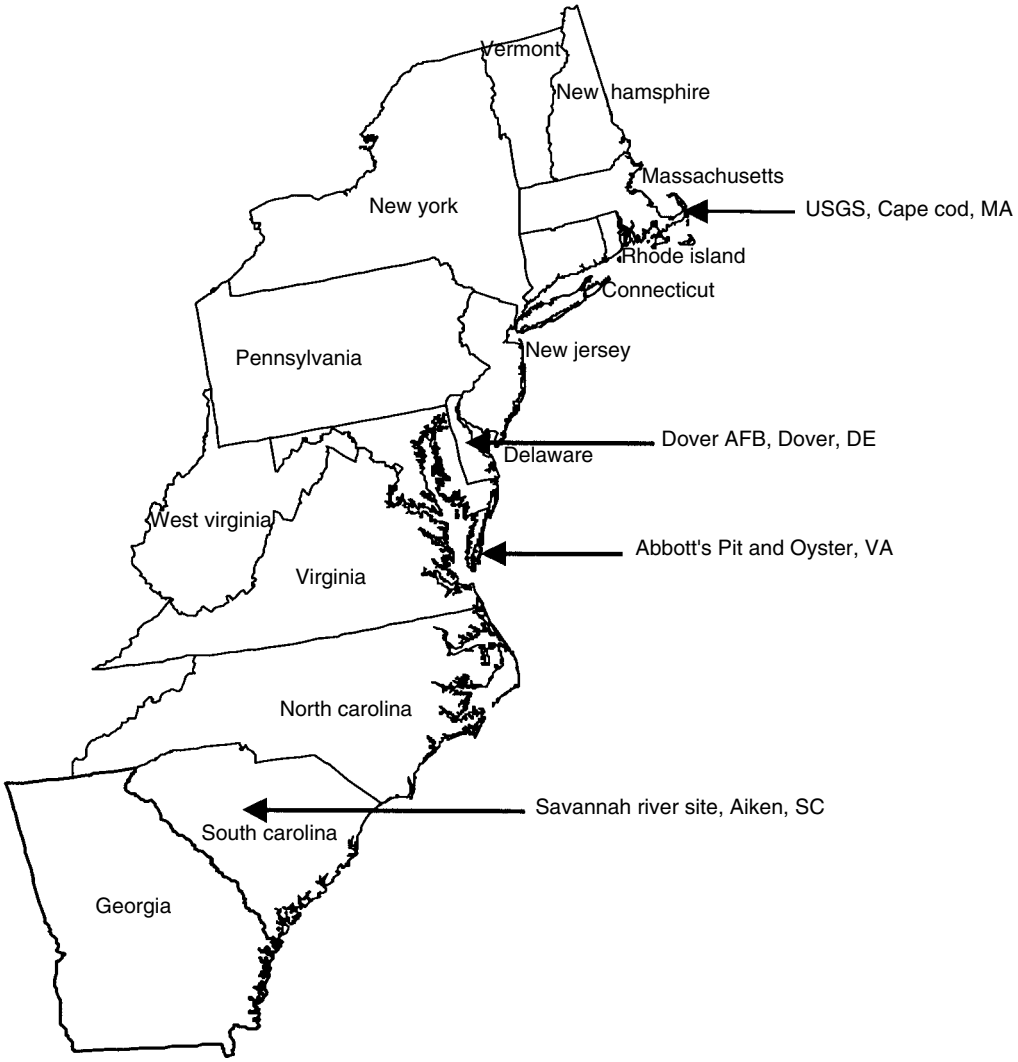

Figure 1. Map of Atlantic coastal states with the location of primary field sites. Additional work is described from other sites within and outside of this region.

disposed onto rapid-infiltration sand, resulting in a 5-km-long plume of organic contamination within the shallow unconfined sand and gravel aquifer (3). The groundwater flows southward toward Nantucket Sound. The plume is characterized by elevated temperature, specific conductivity, and dissolved organic carbon (up to 18 °C, 450 msec/cm, 4 mg/L) relative to uncontaminated zones of the aquifer (10 °C, <80 msec/cm, <1 mg/L) (4). Hydraulic conductivity is ~ 0.1 cm/s (5). Average porosity and mean grain size are 0.35 and ~ 0.59 mm, respectively (6).

The Delmarva Peninsula is the location for the Oyster and Abbott's Pit, Virginia, and Dover, Delaware, sites. The sediment at these sites (Oyster, Abbott's Pit, and Dover AFB) is predominantly shallow marine shoreface sediments deposited in the subtidal zone. The surficial aquifer is 24 to 30 m thick and the water table ranges in depth from 1 to 6 m bls. The pristine sediments at Abbott's Pit consist of medium- to fine-grained sands. The water table is typically at 3.75 m bls with fluctuations of a meter (7,8). Oyster has a shallow water table (1.5 to 2.2 m bls) and a narrow variation in grain size (0.12 to 0.25 mm) below the soil zone. Some sites at Dover AFB are contaminated with low levels of chloroethenes and petroleum hydrocarbons (9,10). The sediment texture at Dover AFB is more varied than at Abbott's Pit and ranges from coarse sand to clay. The water table varied from 3 m bls in the southeast portion of the base to 6 m bls in the northwest portion of the base (7,8).

The sites at Oyster are fields currently operated for agricultural operations and receive periodic fertilization (ammonia, phosphate). Ammonia is quickly converted to nitrate and has been detected in the groundwater. Phosphate has not been detected in the groundwater. At Oyster there are two distinct zones: an aerobic zone and an anaerobic zone (11). The aerobic zone has dissolved oxygen at greater than 1 mg/L, which is consistent with the regional groundwater. The anaerobic zone is located near an area of buried vegetable waste and the dissolved oxygen is less than 1 mg/L. Differences were noted in the geochemistry between the aerobic and anaerobic sites. The aerobic zone exhibited concentrations of 40 to 50 mg/L nitrate, less than 0.01 mg/L dissolved iron,

undetectable amounts of ammonia, and 18 to 40 mg/L carbonate (alkalinity). Conversely, the anaerobic zone exhibited concentrations of 0 to 1 mg/L nitrate, 10 to 40 mg/L dissolved iron, 0.4 to 2.4 mg/L ammonia, and 150 to 380 mg/L carbonate.

Dover AFB sediments generally exhibited concentrations of 5 to 15 mg/kg phosphorus, 1 mg/kg nitrate, 6 to 20 mg/kg sulfur, 13 to 31 mg/kg iron, and combustible organic matter of less than 0.1% (K. Deweerd, personal communication). Shallow groundwater wells typically showed dissolved oxygen at greater than 1 mg/L, dissolved iron at 0 to 2 mg/L, sulfate at 20 to 50 mg/L, and sporadic presence of both aliphatic and chlorinated hydrocarbons and methane. Deeper groundwater wells typically showed dissolved iron at 0 to 3 mg/L and sulfate at less than 10 mg/L, sporadic detection of aliphatic hydrocarbons and methane, and consistent detection of chlorinated hydrocarbons. Dissolved oxygen varied from greater than 1 mg/L in regions of little or no contamination to less than 1 mg/L in regions of higher contamination. In both the shallow and deep groundwaters, ammonia and phosphate concentrations were generally below detection limits (12).

SAMPLING THE SUBSURFACE

Sampling of subsurface sediments, rocks, and groundwaters for microbiological and geochemical analyses requires specialized technologies and equipment for sample collection. Different lithologies of sediments may also require different approaches (13, the author wants the article by W. T. Griffin in this Encyclopedia to be cited here). For example, methods appropriate for collecting cores from consolidated sediments may not retain samples of unconsolidated sediments such as "flowing" sands. When core sampling is prohibitive (i.e., costly with depth) then it may be necessary to rely on groundwater samples. Although the composition of the microbial community and activity of the groundwater samples may be vastly different from their host sediment, groundwater sampling is commonly used for routine monitoring, such as in situ bioremediation (14,15). An effect of groundwater sampling is smearing of local heterogeneities across a sediment column, thus representing a larger picture than would a sample from a discrete sediment interval. On the other hand, discriminating trends over time may be difficult to observe in less-frequent sediment coring regiments. Consequently, groundwater monitoring may prove advantageous over temporal and regional scales. In addition, the development of multilevel sampling provides a means to sample discrete groundwater intervals.

An overwhelming concern when examining subsurface environments is chemical and biological contamination of samples either by extraneous sediments or by the smearing of circulating drilling fluids during the coring, retrieval, and processing stages. Because of this it is important to employ tracers to detect and quantify the extent of bacterial and drilling fluid contamination. A variety of microbiological, chemical, and physical tracers have been used to evaluate biological or chemical contamination of subsurface samples (16, insert ref to an article in this Encyclopedia by W. T. Griffin here)

Another major concern and source of contamination occurs during sample processing, transport, and storage prior to sample analysis. Sample processing is typically conducted under an inert atmosphere minimizing biogeochemical alternations (17). Samples are generally stored under inert conditions and cooled during transport with all analyses initiated as soon as possible after core retrieval or within 72 hours. By understanding the limitations and shortcomings of subsurface exploration technologies and by employing rigorous procedures for sample recovery, QA/QC, and processing, representative subsurface samples of defensible quality can be obtained.

METHODS FOR COMMUNITY ANALYSIS

Quantification of microbial populations may be assessed by direct microscopy techniques. Acridine orange direct counts (AODC) provide a total estimate of microbial abundance, whereas INT [2-(*r*-iodophenyl)-3-(*r*-nitrophenyl)-5-phenyl tetrazolium chloride], LIVE/DEAD *Bac* Light, and nalidixic acid direct counts provide an estimate of the viable cell count (18). Fluorescent antibody direct counts provide an estimate of specific populations (e.g., nitrogen-transforming bacteria). Microbial assessment usually includes classical methods for the enrichment and isolation of bacterial strains. The most commonly used methods include counts of colony forming units (CFU) on solid media (plate counts) and determination of the most probable number (MPN) using replicate dilution series, which may employ selective and/or differential media to grow and enumerate bacteria, fungi, and protozoa (19–22). Whereas it is accepted that these cultivation methods underestimate in situ populations by one to three orders of magnitude, these methods can provide useful indications of the predominance or significance of specific microbial populations. The inability to recover specific populations in culture does not preclude their presence. Likewise, the presence of populations representing a high percentage of the total culturable microorganisms is not evidence of relative importance. For example, the presence of greater than 105 cell/g of obligate anaerobes (sulfate reducers, methanogens, and acetogens) in a sediment sample in which 107 aerobic heterotrophs/g were detected provides evidence that anaerobic processes may well be important.

It is well established that cultivation of microorganisms represents only 0.1 to 10% of the total microbial community. Methods for determining microbial biomass and community structure, which do not require cultivation, include phospholipid fatty acid (PLFA) and nucleic acid techniques that quantify cellular macromolecules (e.g., lipids or DNA). As these markers are typically decomposed soon after cell death they can be used to estimate viable microbial biomass and diversity (23). In the case of PLFAs, the phosphate is cleaved from the phospholipid molecule upon cell death producing diglyceride fatty acids (DGFA) (24). Therefore, the PLFA provides an estimate of recently viable cells, whereas the DGFA provides a measure of dead cellular residue. PLFA also provides an assessment of the nutritional and physiological status of the microbial community. Whereas both PLFA and nucleic acid techniques can estimate overall community

structure and detect changes and shifts in community composition, nucleic acids can target individual members of the community or a specific gene of interest.

Metabolic or respiratory capacities may be assessed to determine microbial community activity by analyzing the utilization and formation of metabolic intermediates (e.g., the conversion of nitrate to nitrite during denitrification). For example, rainwater entering the subsurface contains significant dissolved oxygen. The removal of dissolved oxygen from groundwater indicates altered physiological parameters and biogeochemical activity. Metabolic pathways are often assayed using radiolabeled electron donors or acceptors. One method of assessing the metabolic activity would be to supply ^{14}C-acetate as the carbon source and analyze for the respiratory end products of ^{14}C-carbon dioxide, ^{14}C-methane, or for the incorporation of ^{14}C-acetate into cellular components (e.g., total lipids) (25–27, Kicks and Fredrickson, 1989). Another method uses the Biolog^{TM} system for screening 95 different substrates simultaneously in a multiwell system containing an indicator dye that changes color upon utilization of the substrate. This method provides a community-level physiology profile (CLPP) (28,29). These metabolic methods can also be applied for the detection of contaminant degradation capabilities (e.g., BTEX, trichloroethylene [TCE]) (15,26,30).

These microbial assessment methods are based on laboratory experiments using retrieved sediment or groundwater samples. It is important to note that these retrieved samples are subjected to the redistribution of nutrients during sample collection and sample processing and the stimulation of microbial activity during sample storage and shipment (31–33). These disturbance artifacts may result in the overestimation of in situ microbial activities (2).

In addition to microbial assessment methods, various techniques are used to characterize sediment and groundwater chemistry (e.g., nitrate, pH, TOC, dissolved oxygen) for the purpose of determining electron donors, acceptors, and end products, type and age of sediment, age of groundwater, and groundwater flow regimes (34,35). Sediment physical parameters (e.g., particle size, water content, porosity) are investigated because they may impact the localized chemistry and microbial activity as well as constrain biogeochemical activity on regional scales.

Presence, Abundance, and Diversity of Microorganisms in Atlantic Coastal Plain Sediments

Direct and Viable Counts

At the SRS, the highest AODC values were observed in surface soils (10^8 cells/g) and decreased with depth to $\sim 10^6$ to 10^7 cells/g (22,36). Sandy aquifer formations had the highest AODC counts, whereas clayey interbed layers had the lowest counts (22). Viable counts (10^3 to 10^7 cells/g) were lower than the direct counts (36). Sandy sediment samples contained the highest viable counts (10^5 to 10^8 cells/g) as compared to the confining clayey layer ($<10^3$ cells/g) (19,22).

The highest viable counts were observed with dilute media; yet 10 to 50% of the bacteria could grow rapidly on nutrient-rich media, suggesting high metabolic flexibility. In the shallow sediments at Oyster, Virginia, the viable counts at the surface were 10^6 to 10^7 cells/g and declined to 10^4 cells/g at 1 m to less than 10 cells/g below 6 m depth (7). Similar results were seen at Long Island, New York, where 10^6 to 10^7 cells/g AODC counts were demonstrated for both shallow (1.5 to 5 m) and deep (10 to 18 m) sediments (27). Microbial communities of sediments from various sites at Dover AFB were estimated using MPN, PLFA (37), and DNA methods (10). Biomass estimates for subsurface sediments were 10^3 to 10^7 cells/g by MPN, 10^6 to 10^7 cells/g by PLFA, and 10^7 cells/g by 16S DNA methods, whereas surface sediments exhibited 10^7 to 10^8 cells/g for all methods. In shallower vadose zone sediments (at depths of 1.7 to 2.0 m) at Dover AFB, the viable counts were 10^2 to 10^5 cells/g (38,39). When groundwater and adjacent sediment were investigated, the groundwater samples generally exhibited direct and viable counts that were one to three orders of magnitude less than the sediment samples (36). Furthermore, the difference between the viable and direct counts for sediments or groundwater was two to three orders of magnitude.

Diversity may be judged based on colony morphology. Balkwill (19) showed that typically 11 to 62 distinct colony types were seen on enumeration plates for aerobic facultative heterotrophs. Furthermore, the diversity did not decrease with depth. However, the diversity varied extensively between geological formations. Similar results were demonstrated by Shanker and coworkers (40). Diversity based upon colony morphology was dependent on the degree of nutrient added to the medium. Subsurface samples were observed to have higher viable counts on diluted nutrient medium, yet colony morphology was difficult to distinguish. On nutrient-rich medium, colony morphology, colony size, shape, and pigmentation provided an estimate of greater diversity than the dilute nutrient medium (19,41). In Figure 2, the advantages of both nutrient-rich and diluted media for estimating viable counts and diversity are demonstrated. Species richness was also highest with nutrient-rich medium (41).

MPN and Enrichments

Several other microbial trophic groups besides the abundant aerobic heterotrophic communities exist in the ACP sediments, making for physiologically diverse microbial communities. In the same sediment sample, it is not unusual to detect aerobic heterotrophs, facultative heterotrophs, and obligate anaerobes, likely reflecting localized niches (21,31,42).

Methylotrophs (C-1 compound utilizers) have been observed in low populations (10^2 cells/g or less) for both SRS and Dover AFB sediments (15,37). These microorganisms were of particular interest for their potential to degrade TCE (43). At both SRS and Dover AFB, cometabolic bioremediation demonstrations utilized the addition of methane to stimulate methylotrophic populations to increase up to five orders of magnitude (15,38,39,44).

Nitrifiers, sulfur-oxidizers, and hydrogen-oxidizers were cultured from ACP sediments in South Carolina (20). Denitrifiers were detected by Francis and coworkers (42)

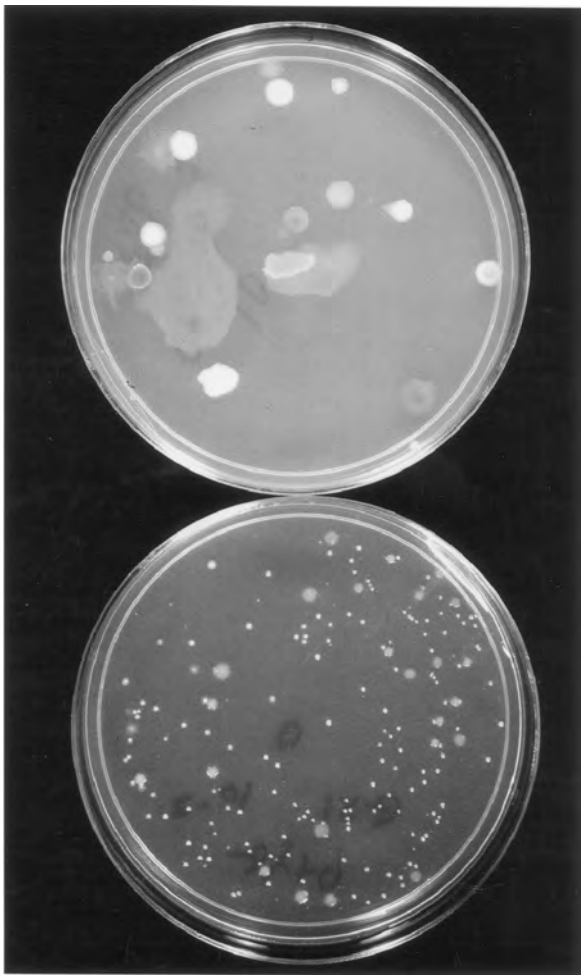

Figure 2. Colony-forming units on a dilute medium (left plate) and a nutrient-rich medium (right plate) for an SRS sandy sediment. For the same plating dilution of the sample, the dilute medium provides higher total numbers and the nutrient-rich medium provides more diversity.

and iron reducers were isolated by Lovley and coworkers (45). Based on geochemical data, the potential for iron reduction coupled to organic matter oxidation in ACP sediments was observed by Murphy and coworkers (35). Furthermore, Murphy and coworkers demonstrated that ferric oxide coatings were found in the sediments in which iron reduction was indicated by microbial enrichments. Sulfate-reducing bacteria were found in sediments having low redox potential and a sufficient concentration of sulfate. These bacteria were found in deep aquifers (21,34), in the distal portion of aquifer flow paths (35), and in subsurface areas of high organic matter concentrations, for example, organic contaminants, such as BTEX (46,47), and organic carbon deposits, such as lignite (35).

Other forms of naturally occurring organic carbon, such as simple organic acids, have been found in the ACP sediments. Jones and coworkers (21) detected short-chain organic acid accumulations (e.g., acetate) in microcosms derived from South Carolina coastal plain sediments, and Murphy and coworkers (35) detected acetic, formic, and oxalic acid near lignite particles within the Middendorf aquifer in South Carolina. It is the presence of these fermentation products (hydrogen, organic acids) that supports the anaerobic microbial activities found in ACP sediments. Furthermore the abilities of these resident microorganisms to produce carbon dioxide, change nitrogen, sulfur, and iron species, excrete volatile fatty acids, generate methane, and degrade chlorinated ethenes, petroleum, and polyaromatic hydrocarbons have impacts on water quality.

Eukaryotic microorganisms (protozoa, algae, lower fungi) may be important in groundwater aquifer communities, given their potential impact as heterotrophic feeders. Amoebae and flagellates were observed at concentrations of generally 10^1 to 10^2 cells/g in shallow SRS aquifer samples containing high bacterial viable counts, though ciliates were not detected. In addition, a variety of green algae, phytoflagellates, diatoms, and a few cyanobacteria were found. Fungi were widespread across the 30-m depth in SRS borehole profiles and usually ranged from 1 to 50 propagules/g (22). In pristine aquifers at the Cape Cod site, these eukaryotic microorganisms are usually present at concentrations of less than 10^2 cells/g dry weight aquifer material. The aquifer is dominated by small flagellates but amoebae and ciliates are occasionally present (48). In organically polluted aquifers at the Cape Cod site, where bacterial abundance was increased because of the pollution, the protist concentrations increased several orders of magnitude (3).

Microorganisms with unexpected or unique properties have been isolated from ACP sediments. Subsurface microorganisms have been shown to exhibit increased resistance to UV radiation (49) and tolerance to higher levels of hydrogen peroxide (50). Some microorganisms isolated from great depths (2,500 to 3,000 m) can grow at elevated temperatures (50 to 60 °C), for example, *Bacillus infernus* (51), and reduce iron under thermophilic conditions (52).

Microbial Community Profiles

Microbial community structure and metabolic potential have been investigated using the broad spectrum method of the API or Biolog™ technology. The latter method allows for high number of substrate utilization tests at the same time on one sediment sample. Substrate compounds have been expanded to test recalcitrant or toxic chemicals. Upon oxidation of the substrate by the microorganisms in the sample, the tetrazolium dye is reduced, producing a detectable color response. Aerobic chemoheterotrophs isolated from ACP sediments exhibited diverse metabolic capabilities where all but two of the API carbon sources were utilized by 40% of the isolates and three of the carbon sources were utilized by 75% of the isolates (53). Surface versus subsurface isolates exhibited different utilization responses.

Common names for this method when applied to the mixed communities of environmental samples are CLPP (28) and ecofunctional enzymes (29). ACP sediments showed a preference to utilize amino acids over carbohydrates and selected individual compounds, such as acetate as sole carbon sources (7,28,29). At the

Oyster, Virginia site, the aerobic utilization of carbon sources decreased significantly with depth. The surface samples exhibited the largest values for substrate utilization and the next highest values were seen at sample depths that coincided with the water table (7). Fliermans and coworkers (29) used the ecofunctional enzymes to distinguish the physiological patterns of the various microbial communities during groundwater remediation of TCE at SRS. Differences in function of microbial communities were observed among the bioventing treatments of 1 and 4% methane injections, pulsed injections of air, methane, and nutrients. The microbial communities in the groundwater changed their activity against certain substrates during the changes in remediation process. Community differences were also seen between and among the sampling wells and the demonstration site. With Taylorsville Basin samples, the CLPP community profiles were used to distinguish among surface soils, aquifer waters, drilling muds, and sediment cores. Similar results for distinguishing phenotypic changes in microbial communities between drilling operations and cores were obtained by PLFA analysis (28). Make-up waters showed PLFA patterns typical of gram-negative bacteria. The drilling mud had a combination of monounsaturated and terminally branched saturated fatty acids. The types and percentages of the terminally branched saturated fatty acids have been shown to be indicative of gram-negative obligate anaerobes, for example, sulfate-reducing bacteria. In addition, the PLFA results provided estimates for microbial biomass values, which ranged from 124 pmol PLFA/g in drilling muds to 7 to 13 pmol PLFA/g for outer and inner parings of the cores.

Metabolic and Degradative Activities

Potential rates of microbial activity are measured in laboratory microcosms. Sediment or groundwater material is placed in a closed container (with or without additional substrate amendments) and incubated under controlled conditions; disappearance of reactant and/or appearance of a product is measured. Typically, sterile or poisoned controls are used to distinguish between biotic and abiotic processes. The types of metabolic or degradative activity examined may include production of carbon dioxide (Kieft et al., 1991, 54,55), incorporation of acetate into lipids (56), thymidine incorporation into DNA (56), reduction of sulfate (40), formation of methane (21), or disappearance of the recalcitrant or toxic compounds (26). Denitrification activity has been quantified in ACP sediments using the acetylene-blocking technique, analyzing the production of N_2O, and quantifying nitrate disappearance (42). Madson and Bollag (57) measured the disappearance of glucose and indole under both aerobic and anaerobic conditions. Under anaerobic conditions, the disappearance of lactate, formate, acetate, phenol, and benzoate was measured, and potential rates of acetogenesis and methanogenesis were determined (21). These other activities of microorganisms in the subsurface, including denitrification, sulfate reduction, and methanogenesis, are covered in greater detail by Kieft and Phelps (58).

The use of radiotracers is potentially useful for measuring microbial activity, thanks to the high degree of specificity and sensitivity. By labeling a particular compound, with ^{14}C, ^{3}H, or ^{35}S, one can measure the rate of transformation of that substrate as well as the rate of the end product formation. As compared with aquatic or terrestrial environments, radiotracer experiments for subsurface environments may take incubation times of hours rather than minutes. It is important to note that the rates measured by these methods should be considered potential rates and not actually in situ rates. Thus, they are useful for comparing relative activities among subsurface samples. The potential for ACP subsurface microorganisms to degrade a diverse array of compounds has been demonstrated through microcosm studies testing a variety of ^{14}C-labeled organic compounds for degradation or transformation. Most CO_2 production assays have utilized either ^{14}C-glucose or ^{14}C-acetate and analyze for $^{14}CO_2$ (27,54,57,59,60).

Aerobic CO_2 production rates for ACP sediments were estimated at 80,50 to 70, and 0.6 to 4.9 nmol/g/day for surface, sandy aquifer, and clayey sediments, respectively (40). Anaerobic CO_2 production rates (mmol CO_2 per liter per year) in ACP sediments were estimated at 2.4×10^{-1}to9.0×10^{-3} for the shallower Black Creek and Middendorf Aquifers and at less than 10^{-5} for the Cape Fear aquifer (61). However, geochemical estimates of these in situ activities indicate metabolic rates of 10^{-4} to 10^{-6} mmol CO_2/L/year (2,61). Thus, the radiotracer laboratory microcosm studies overestimated microbial in situ activity by a factor 10^3 to 10^6. Alternatively, the differences in these microcosm studies may indicate that water, nutrient availability, and redox condition may have a dominant effect on the microbial activities. For example, CO_2 production rates in a jet fuel–contaminated aquifer were stimulated with the addition of nitrate (26); without the nitrate addition the production rate was negligible. Some of the more recalcitrant or toxic compounds tested include chlorobenzene, *r*-chlorophenol, BTEX, and trichlorobenzene (15,25,26,43,55).

Physical and Chemical Factors Limiting Microbial Abundance and Activities

Variability in measured microbial activities within many subsurface samples is, in part, caused by differences in water availability, hydrologic flow, sediment structure, and the associated biomass. In ACP sediments, population density had a moderate positive correlation (0.4 to 0.6) with sand content and a moderate negative correlation with clay content (22). This was also supported by Phelps and coworkers (17,31) who showed the effects of particle size and moisture content on the abundance of aerobic heterotrophs and on microbial activity, as measured by acetate incorporation into lipids. The trend is: at less than 20% clay content, lower abundance and lower activity were observed than with sandy samples. Samples containing greater than 70% sands had similar microbial abundances, but activities were much lower in samples that were at less than 70% saturation. In general, sandy samples had lower activity responses under conditions of low water content, low permeability, and low hydraulic conductivity as compared to the sands with higher values for these three parameters (17,31). Thus, these parameters of silts and

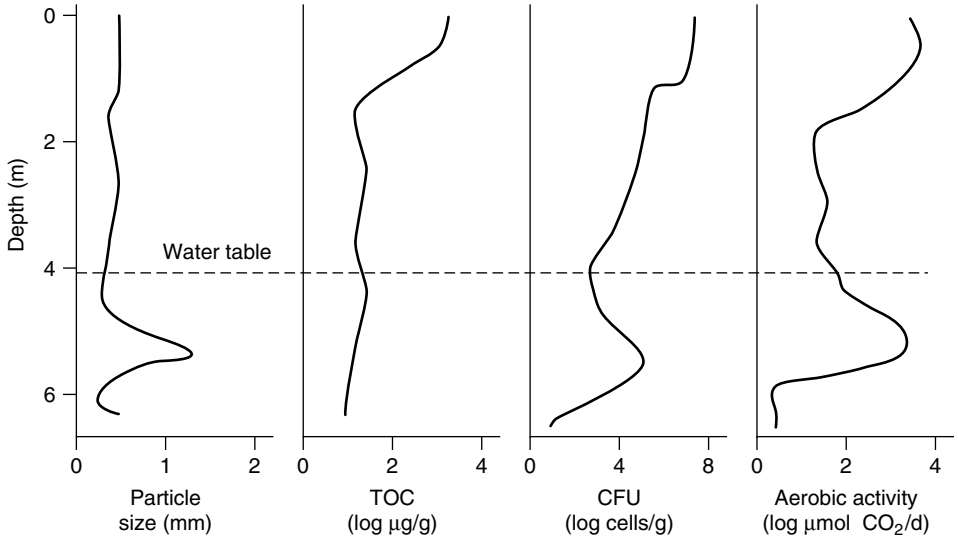

Figure 3. Schematic representation of changes in physical, chemical, and microbial parameters with depth.

clays may limit the flux of water and the flow of aqueous nutrients. Figure 3 shows a schematic representation of the changes in microbial abundance and activity to the changes in particle size and total organic carbon of ACP sediments across a vertical profile. Near the surface organic carbon, microbial abundance and activity are elevated. These parameters decrease with depth until the depth profile intercepts the water table and a responding increase in microbial activity is observed. A second change is shown when a zone of sediment containing larger particle size is met, which may allow for better flux of nutrients through the sediment. The subsequent microbial changes were observed as increases in both abundance and activity measures.

Nutrients may be limiting in the subsurface environment and this poses challenges for bioremediation of contaminated sites. In laboratory microcosm studies, the nutrients are mixed and redistributed, making them available to resident microorganisms. Similarly, in a field demonstration for TCE bioremediation at the SRS, vacuum extraction or air sparging caused a stimulation of subsurface microbial populations and activities (14,15). It was hypothesized that air sparging at 200 scfm or vacuum extraction would redistribute nutrients and/or toxicants, resulting in the increase of microbial populations and TCE degradation. However the total microbial community abundance did not increase (15,38,39).

Laboratory microcosms studies investigated potential limiting nutrients. Previous research on nutrient-limiting conditions in ACP sediments investigated combinations of nutrients under aerobic and anaerobic conditions. The effects of N (sodium nitrate), P (sodium phosphate), S (sodium sulfate), C (glucose), trace minerals, and water on the incorporation of ^{3}H-acetate into membrane cellular lipids of ACP sediments showed that each addition caused stimulation in at least some samples (31). Based on the degree of stimulation, nitrogen and phosphorus were found to be limiting for the ACP sediments. For the SRS bioremediation demonstration, ammonia, nitrous oxide, orthophosphate and triethylphosphate (TEP) were tested for potential field application by using microcosms containing site groundwater. Based on the greater stimulatory responses of TEP and nitrous oxide in the microcosm studies, they were chosen as supplements for the field operation (62). Furthermore, they had an additional advantage of being readily dispensed as a gas.

Investigators at the WSRS Integrated Demonstration of TCE bioremediation (14,15,38,39) decided to inject gaseous nitrous oxide and TEP along with the addition of methane with the intent of stimulating subsurface microbial activities, including the biodegradation for TCE. Within six weeks, TCE degrader populations increased and they were evidenced in greater numbers upon enrichment. Modeling, toxicant concentrations in groundwater, and chloride chemistry substantiated the observation that nitrous oxide and TEP stimulated subsurface microbial populations resulting in increased toxicant degradation. The results indicated that less than 0.1% of added TEP was likely incorporated into biomass and that the stimulated microbial activities were still less than micromolar levels per year, with less than 1% of total in situ microbial activity directed toward the cometabolic degradation of TCE and related chlorinated toxicants. Importantly, the laboratory and field experiments developed fundamental conceptual tools for assessing, predicting, and visualizing subsurface microbial activities that were capable of being stimulated and directed toward toxicant bioremediation (14,38,39). Furthermore, the observation from this applied bioremediation project was consistent with the conceptual understanding of subsurface microbial ecology of the Atlantic coastal plains.

Presence Abundance and Diversity Detected by Molecular Methods

Nucleic acid methods are only now coming into use for characterization of microbial communities and have had limited application in ACP sediments (10,63). In the past, specific microorganisms and populations have been monitored using techniques that rely on selective enumeration media and fluorescent antibody labeling.

These methods have been applied at sites on the Delmarva Peninsula (64). However, such methods are very limited in their application to the characterization of natural microbial communities because of the inability to cultivate the vast majority of microorganisms on standard microbiological media. The application of nucleic acid hybridization techniques to environmental microbiology has provided a new opportunity to investigate and quantify overall microbial community structure, detect changes and shifts in population composition, as well as target specific microbial groups and individual members of the community (e.g., 16S ribosomal RNA [rRNA]). Moreover, the use of labeled DNA probes, specific for a gene(s) of interest (e.g., genes responsible for degradative ability), can be used to characterize and monitor microbial activity.

Microbial Community Composition and Diversity

In ACP sediments, the primary published community information comes from comparative techniques such as denaturing gradient gel electrophoresis (DGGE) and randomly amplified polymorphic DNA (RAPD) techniques to analyze 16S ribosomal DNA (rDNA). In these techniques, nucleic acids (DNA and RNA) are extracted from environmental (sediment) samples, either by mechanical separation of microorganisms from soils (i.e., cell fractionation; 65,66) or through direct isolation of DNA (67). Differences in chemical and physical characteristics of sediments may require optimization of these procedures (68). To date, the majority of molecular studies fingerprinting microbial community structure and diversity in sediments and groundwater have used 16S rRNA as the molecular marker. The 16S rDNA fragments, obtained by reverse transcription of rRNA (69) or enzymatic (polymerase chain reaction [PCR]) amplification of DNA (69), are subsequently cloned and can be sequenced or subjected to restriction endonuclease digestions to generate restriction fragment length polymorphism (RFLP) patterns of microbial diversity. DGGE separates PCR-amplified 16S rDNA fragments according to sequence differences (reviewed in 70). The number of DGGE bands is presumed to correspond to the number of predominant members in the microbial community and this technique can detect shifts in community structure. DGGE bands can be hybridized with specific probes and excised to obtain DNA sequence information. Another PCR-based diagnostic method, RAPD, uses short oligonucleotide primers of an arbitrary sequence to fingerprint microbial community diversity (11).

Interpretable patterns have been obtained using the DGGE and RAPD techniques on ACP samples. DGGE has been used to monitor shifts in soil microbial community structure during natural attenuation and enhanced bioremediation during a controlled oil spill in Delaware plain sediment (71). Sequence analyses of DGGE bands indicated that oil treatment promoted growth of the alpha *Proteobacteria* subgroup and members of the *Flexibacter-Cytophaga-Bacteroides* phylum. Franklin and coworkers (11) employed RAPD to determine aerobic and anaerobic community diversity from a shallow ACP aquifer. Although RAPD cannot provide information on specific microbial taxa, genetically distinct microbial consortia were detected in the aerobic and anaerobic aquifer regions, and spatial and temporal differences were observed that were correlated with changes in groundwater chemistry.

Zhou and coworkers (72) cloned and partially sequenced eubacterial rRNA genes to examine the composition of a tundra soil community. Whereas no dominant RFLP patterns were detected, the majority of the clones belonging to the alpha and delta subdivisions of the *Proteobacteria* displayed considerable phylogenetic diversity. A similar molecular approach has been applied recently to characterize microbial community composition and diversity in low–carbon-saturated subsurface, surface, and vadose soils from the Delmarva Peninsula (73). Subsurface sediments from various sites in the ACP appear to have similar gross phylogenetic compositions (44,73,74, Zhou, personal communication). The *Proteobacteria* appeared to dominate both contaminated (Dover AFB) and uncontaminated subsurface sites (Abbott's Pit), representing over 80% of the clones. The gamma subdivision of the *Proteobacteria* represented the highest percentage of 16S clones examined. The alpha and beta subdivision of the *Proteobacteria* followed as the next most abundant group. However, the relative proportions of these varied among samples and sites. The next most prevalent, representing less than 10% of the clones, were the gram-positives, *Fibrobacter*, other groups, and unknown groups represented the remaining 10% of the clones.

A few specific types of bacteria appeared in the dominant groups at both the contaminated and uncontaminated sites. Many of the gamma subdivision 16S sequences were closely related to *Pseudomonas* and typically the closest matches were to species such as *stuzeri*, *mendocina*, and *putida*. There were also sequences related to *Acinetobacter*. In the alpha subdivision of the *Proteobacteria*, sequences closely related (up to 100% similarity) to strains of *Agrobacterium tumefaciens* consistently appeared, along with an occasional sequence related to *Sphingomonas*. There was a more diverse collection of beta subdivision-like sequences found that included *Rhodoferax*, *Azoarcus*, *Rastonia*, and *Burkholderia*. The most frequent gram-positive–like sequences (up to 95.5% similarity) were to related *Bacillus* spp.

Comparisons of the ACP results to those using similar approaches in cloning and sequencing of 16S rRNA indicates interesting patterns that may be related to water content and redox. Additional sampling at many more sites is needed before generalities can be made with confidence. However, it appears that the ACP communities and those from an arid paleosol differ to a much greater degree than do communities from spatially distinct areas of the ACP (e.g., Abbott's Pit and Dover AFB). Three of the most commonly occurring sequences (*Pseudomonas*, *Bacillus*, and *Burkholderia*) found from a study of deep (188 m bls) paleosols at an arid site (75) were also found in the ACP sites. However, many of the common clones from the arid site, including *Micrococcus*, *Clavibacter*, *Nocardioides*, *Comanonas*, and *Erythomicrobium* were not readily detected in the ACP sites examined (44,73,74, Zhou, personal communication). Interestingly, sequences recovered from Carolina Bay (a shallow freshwater pond)

sediments from under 18 cm of standing water at an ACP site in South Carolina (76) have many common features with the Abbott's Pit and Dover AFB subsurface sediment samples. Alpha, beta, and delta *Proteobacteria* sequences were common in both sets of samples. Also, *Fibrobacter* sequences were observed in both. Some of the major differences (e.g., the presence of green nonsulfur bacteria in the Carolina Bay samples) are probably related to anaerobic photosynthetic processes that would not be expected in the ACP subsurface sediments. The greater importance of anaerobic processes probably also accounts for many of the differences between sequences from the ACP sediments and sequences recovered from contaminated samples from Michigan (Dojka et al., 1997). Again, the similarities were the frequent occurrence of sequences related to alpha, beta, and gamma subdivisions of the *Proteobacteria*. The redox environment (with zones of methanogenesis, sulfate-reduction, and iron reduction) at the Michigan site is probably reflected in the occurrence of sequences related to the green nonsulfur bacteria, the Archaea, and *Syntrophus*.

Catabolic Gene Probes

Techniques that target specific components of the microbial community have been more broadly applied to ACP samples. Molecular-based approaches (i.e., DNA-DNA hybridization) have been applied for site assessment and characterization of specific microbial populations, changes in microbial community structure, and abundance of catabolic genotypes in contaminated subsurface sediments (10). A growing list of gene probes, specific for catabolic genes that encode the enzymatic ability to degrade many environmental contaminants (Table 1), are available as molecular diagnostic tools to monitor subsurface microbial responses. Gene probes have been effectively used in monitoring bioremediation in ACP sediment and groundwater.

Gene probes to monitor *tod*, *smmo*, and *mdh* (see Table 1) abundance were used to assess microbial community responses to injections of air, methane, and nutrients in saturated and unsaturated sediments during the integrated in situ demonstration at SRS. *Tod* genotype frequency exhibited a slight increase with air injection and a decrease upon methane and nutrient treatments (10). Whereas low biomass, poor DNA recovery, and coextracted contaminants precluded quantitative measurements, the *smmo* genotype increased with air injections and decreased with methane injections. The *mdh* gene frequency decreased upon air treatment, whereas methane and nutrient treatments corresponded with increased *mdh* genotypes. These results supported the changes observed in methylotrophic populations as determined by PLFA and MPN techniques (15,38,39,77). Gene probes (*smmo*, *mdh*, *tod*, *nahA*, *nahH*, and *codh*) were also used to characterize the intrinsic and accelerated anaerobic bioremediation of chlorinated solvents at the Dover AFB, Delaware, site. The overall trend observed was an increase in gene frequency in contaminated areas relative to uncontaminated control samples. Recently, a suite of gene probes (*alkB*, *nahA*, *nahH*, *todC1C2*, and *xylA*) were used to monitor indigenous subsurface aquifer sediment microbial community responses to hydrocarbon contamination at Columbus AFB, Mississippi (78). Significant increases in each of the catabolic genotypes were observed during the course of study and reflected shifts in microbial community structure associated with the hydrocarbon exposure and migration in groundwater.

Plasmid Incidence

The presence of extrachromosomal elements in bacteria in ACP sediments has been documented (79), but the data are sparse. Plasmids are autonomously replicating extrachromosomal elements ranging in size from a few kilobases to greater than 500 kb. The occurrence of plasmids has been well documented among Bacteria and Archaea or eubacteria and archaebacteria (80). The presence of such accessory elements typically confers a novel or advantageous trait to the host cell. Examples of some typical plasmid-encoded traits include protection from UV light damage, resistance to heavy metals, proliferation in the presence of antibiotics, and catabolism of xenobiotic compounds. Catabolic plasmids are widespread in nature (reviewed in 81) and plasmids have been reported to increase in frequency in contaminated environments (82).

Contaminated environments may increase plasmid frequency but the data are ambiguous. For example, in ACP samples Fredrickson and coworkers (79) reported conflicting data on plasmid occurrence in deep subsurface sediment bacteria isolated from SRS. A greater frequency of plasmid-containing bacteria was observed in uncontaminated deeper sediments relative to surface soil and upper aquifer sites. A whole-plasmid gene probe assay

Table 1. Examples of Catabolic Gene Probes Used to Monitor Microbial Activity

Gene Probe	Relevant Characteristic	Reference
AlkB	Alkane hydroxylase	Kok and coworkers (1989)
Codh	Carbon monoxide dehydrogenase	Jablonski and Ferry (1992)
NahA	Naphthalene dioxygenase	Simon and coworkers (1993)
NahH	Catechol-2,3-dioxygenase	Ghosal and coworkers (1987)
Mdh	Methanol dehydrogenase	Machlin and Hanson (1988)
Smmo	Soluble methane monooxygenase	Wackett and Gibson (1989)
todC1C2	Toluene dioxygenase	Zylstra and Gibson (1989)
XylA	Xylene monooxygenase	Suzuki and coworkers (1991)

indicated homology between numerous subsurface plasmids and the catabolic plasmid TOL in bacteria from both uncontaminated and putatively contaminated samples at this SRS site. However, Ogunseitan and coworkers (83) reported a greater than fourfold increase in plasmid frequency in bacteria isolated from pristine shallow aquifer materials relative to hydrocarbon-contaminated sites.

Spatial Distribution

The spatial distribution and the scale of microbial variability in the subsurface has been the subject of discussion and attention in the literature that focuses at the grain size level (84) and above (85). The measurement and description of spatial variability can be confusing, especially because there is no consensus on the methods for doing so. Numbers of samples, sampling intervals, site complexity, and the presence of contaminants vary considerably among studies. However, microbial heterogeneity and variability can be important in bioremediation (86). Investigators have found striking differences in activity that appear to be related to toxicity of and enrichment by contaminants in ACP sediments (87). However, if we examine the published evidence on uncontaminated sites, there are some general observations that can be made. It appears that, at the smallest scale of variability (e.g., grain to grain), samples from the ACP appear to be small (e.g., references). However, at scales of above 20 cm there can be considerable variability (8).

The majority of studies of spacial variability in the ACP have occurred at a limited number of sites, including the Abbott's Pit and Oyster sites (8,11,88) on the Delmarva Peninsula. As described elsewhere in this article, these sites are predominantly shoreface deposits (sands laid down just off shore of beaches). Thus, they are relatively uniform with low clay contents. Our conclusions on spatial variability may not hold for other types of sediments, particularly those containing clay lenses. In those sites, the geology and arrangement of the clays may play an important role in the spatial variability. Also, much of the high-density sampling that allows for appropriate evaluation of spatial variability has been done in the vertical dimension (7,53). This is likely because of the significantly reduced costs associated with intense vertical sampling from the same bore hole compared to sampling from excavations to depths or multiple boreholes at close intervals.

There are several methods that have been used to examine small-scale variability, and some of these have been applied to ACP sediments. The first method is direct microscopic examination or other imaging of spatial distribution at the grain scale (84,89). The second is the measurement of microbial properties using a variety of sample sizes (90). A third method that has apparently not been applied to ACP sediments is the characterization of communities on fractionated soil samples (91). Complicating all these methods is the potential for density-dependant factors to influence the measurement of microbial communities in sediments (90). Zhang and coworkers (8) found that sample size in the range of 0.1 to 100 g had no significant effect on CFU counts at the Oyster site. This contrasts with similar measurements at an arid subsurface site (less than 15 μm recharge/year) with generally low activity and biomass (92), where many of the smaller samples had no detectable activity. At those low activity sites larger sample sizes were required to sample the apparently rare patches of activity. However, they found that at similar sites with significantly higher recharge (e.g., 25 cm/year) the situation was more similar to those observed at the ACP sites, with patchness not effecting the measurement in the 0.1 to 100 g sample range. In a series of samples taken at close intervals for CFU counts at the Oyster site, Zhang and coworkers (7) found that the variability in these sediments at the centimeter scale was generally less than that reported in other studies (18). The ratio of the maximum/minimum CFU counts for samples 3–5 cm apart was 10 or less in eight of nine instances and never reached the factor of 220 seen by Beloin and coworkers (18). These CFU results were largely confirmed later at the Abbott's Pit site (8) and were similar for microbial activity (e.g., acetate incorporation). However, in samples near the water table the bacterial environment can change rapidly, and these changes may increase close interval variability (8).

Methods describing the spatial distribution and scale of microbial variability above the grain size level are still being developed, and one promising technique, geostatistics, has been borrowed from geology. Although not commonly applied in microbiology, geostatistical and other spatial analysis techniques are clearly useful in analysis of subsurface microbiological data. Their application gives us insight into the spatial distribution in ACP sediments. Geostatistical techniques are largely unfamiliar to microbial ecologists, except for some of those who deal with (surface) soil- and plant-associated microbial communities (93–95). However, the advantages of these techniques in analysis of spatial distribution of bacteria have been addressed (92). These spatial analysis techniques are now being applied at a variety of scales in many biological applications ranging from within cell spatial distribution (96) to epidemiology (97).

Conventional statistical techniques assume that the properties within a sampling unit are spatially uncorrelated. This implies that the sample mean is the best estimate of a property at any location within the sampling unit. Clearly in a functioning ecological system the assumption of uncorrelated samples is often violated as communities interact. Under the hypothesis that subsurface properties exhibit some spatial autocorrelation, conventional techniques (e.g., linear regression) that ignore spatial correlation will yield poorer results in estimating subsurface properties at unsampled locations than do geostatistical techniques.

Geostatistics provides a tool for incorporating the spatial autocorrelation between samples into the estimation of subsurface properties at unsampled locations. Central to most geostatistical methods is the construction and analysis of variograms. Variograms traditionally describe the correlation between a subsurface characteristic, such as hydraulic conductivity, as a function of the distance and direction separating measurements of the characteristic. However, we can apply this to a microbial property

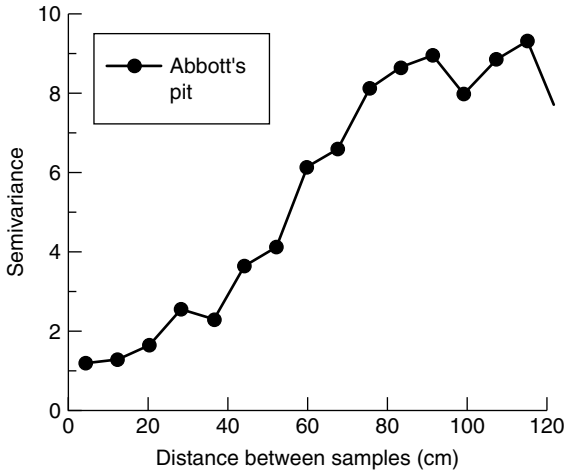

Figure 4. Evaluation of the scale of variability of CFU at the Abbott's Pit site. Comparatively low variability is present at 20 cm and below.

such as CFU (Fig. 4; 98). Analysis of the variogram provides important insights into the magnitude, direction, and scale of spatial autocorrelation.

The spatial distribution of subsurface microbial activity and community structure is hypothesized to be controlled by water transport, nutrient delivery, and the redox environment of the porous media. These latter variables, in turn, are likely dependent on the physical and chemical properties of the subsurface media. Therefore, the spatial structure of subsurface microbial communities should be strongly dependent on the spatial structure of key physical and chemical properties of the subsurface media. Geostatistical techniques offer approaches to testing these dependencies.

As indicated by geostatistics, the variability of CFU distribution with depth (41,98) at these sites increases rapidly at distances over 20 cm (Fig. 5) Thus, the distribution of CFU in closely spaced samples (e.g., 0 to 20 cm) is strongly correlated. This implies that predictions of CFU counts at closely spaced intervals

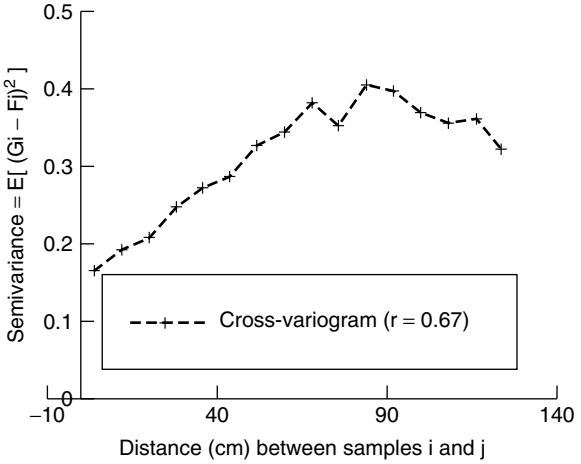

Figure 5. Variogram plot for CFU and microbial activity. Again there is considerably less variability at 20 cm and below.

from adjacent samples are relatively robust. However, at greater distances from a sample, the "representativeness" of the sampled location for the unsampled location becomes very poor. Thus, as in the ACP data presented in Figure 5, samples taken at intervals of 1 m in a vertical direction are likely to miss important features of the bacterial distribution. These can be seen in data from Zhang and coworkers (8) where a sample interval of 1 m in the ACP sediments could have missed a 1,000-fold increase in CFU and a significant increase in bacterial activity associated with a defined layer in a relatively uniform geological setting. One meter sampling spacing is not uncommon in subsurface microbiology (99), and it may be appropriate in some environments. However, it is apparent that closer sampling is desired for these ACP sediments.

The spatial relationships among variables can also be described using geostatistics (Fig. 6), and these relationships can be important in improving predictive ability and potentially in reducing sampling costs. For example, CFU counts have been found to be spatially correlated with microbial activity in these ACP samples (Fig. S2). The microbial activity (data not shown) varied over similar spatial scales as the CFU counts (Fig. S1). Thus, there was a reasonable cross correlation between the activity and the CFU data. This allows for better use of the CFU data in predicting activity in unsampled locations or better use of the activity data in predicting CFU in unsampled locations. This improvement in predictive ability can be important when there is a large cost difference among analysis for different variables, particularly when doing spatial analysis, such as geostatistics, that commonly requires a large number of samples (92). In those cases, identification of a good "proxy" variable can save time and effort and improve with little degradation (loss) in prediction of the other variable. This can be very important when applying some of the more costly and time consuming molecular methods described above (nucleic acid and PLFA methods).

There has been limited examination of horizontal heterogeneity with respect to microbial community structure in ACP sediments. For example, in a PLFA analysis (data not shown) of vadose zone microbial communities at Dover AFB, three samples taken within the 1.7- to 2.0-m interval from each borehole clustered together (Fig. 7). Boreholes C and E were the closest of those used in the analysis, at 30 m apart, and the community similarity was greatest between these two sites (they clustered together). The most divergent community was from borehole F, which was 40 m from E and 60 m from H but also had a higher clay content (data not shown). Thus, at the same sampling depths, there was stronger spatial discrimination among communities at the tens of meter scale than was evident within a borehole. This is important as it gives confidence that differences in communities seen at the tens of meters scale are not random fluctuations (if this were so we might expect the replicates from different boreholes to cluster).

At the Oyster, Virginia site, a study of the microbial community in groundwater indicated that there could be significant well to well differences in the microbial communities over fairly short distances (11) and over

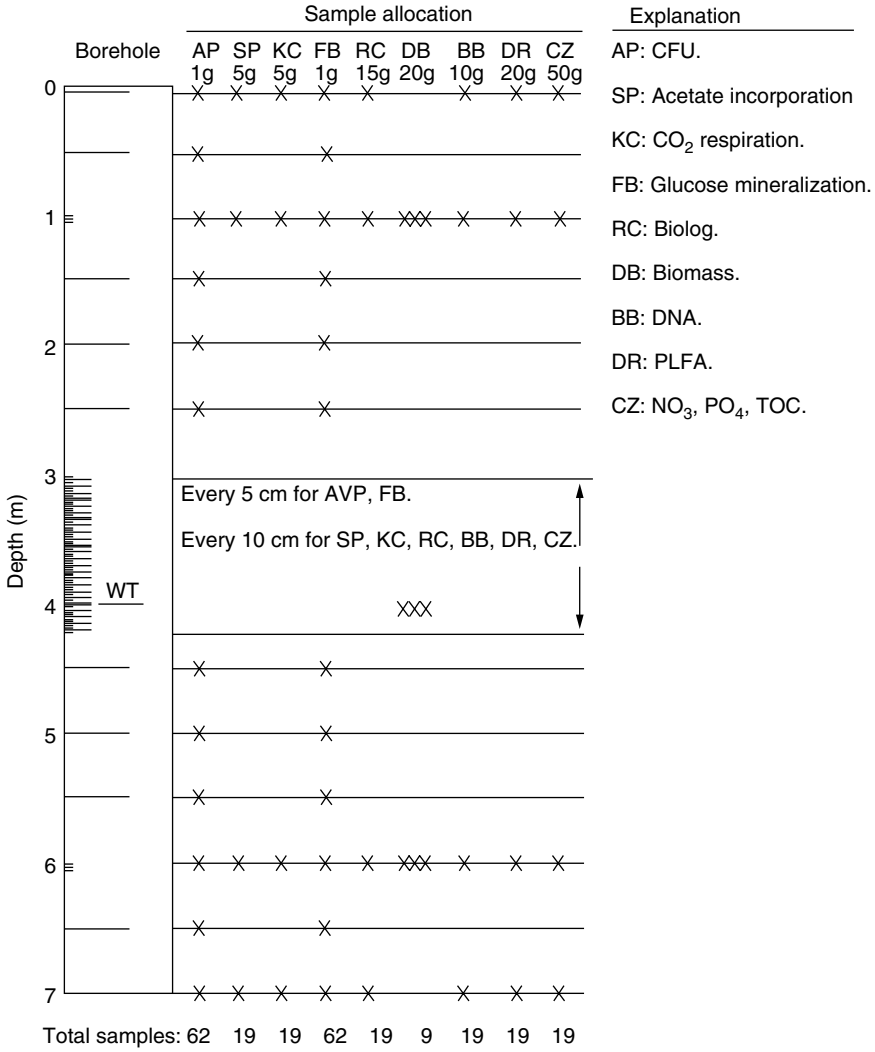

Figure 6. Field sampling plan for microbial and physical parameter analyses that could be used in geostatistical analysis of the data.

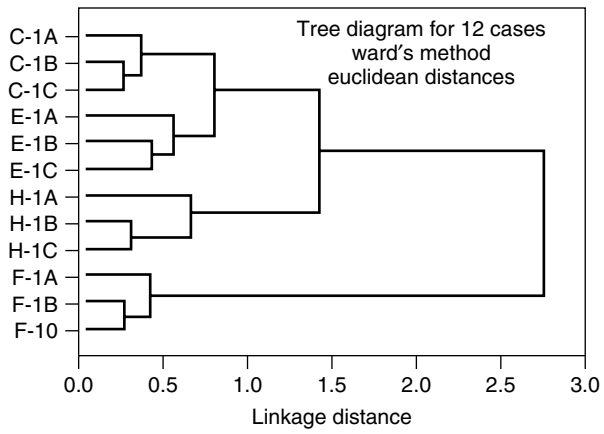

Figure 7. Hierarchical cluster analysis of PLFA microbial community profiles of triplicate vadose zone samples from each of four boreholes (C,E,H, and F).

time. These differences appeared to be related to redox gradients (anaerobic and aerobic zones) and shifts in the spatial location of the gradients over time. Groundwater chemistry apparently exerted considerable control of the community structure in these samples. The researchers concluded that there is considerable potential for variance in microbial community structure at scales of 10 to 100 cm, well within the spacing of wells at field sites. This would put the potential for horizontal heterogeneity where there are strong geochemical gradients in the groundwater at these ACP sites within the same scale as that for the vertical heterogeneity.

Bacteria Transport

To those unfamiliar with bacterial transport in the subsurface, the surprising aspect of bacterial transport in ACP sediments is the general lack of transport and high retention of microorganisms in sandy sediments with groundwater flow rates on the order of 20 m/year (8). For example, in a bacterial transport experiment at the Oyster Virginia site, bacteria were tracked 4 m from the injection point (100). However, it appeared that the majority of the biomass injected was retained within the first 0.5 μm of flow from the injection point. Similar results have been observed in similar sediments at Cape Cod (101). The Cape Cod site also is a largely sandy

site, with only 10% of the particulate mass falling below a grain size of 0.21 mm. Typically, peak breakthrough concentrations of bacteria sampled 6 m downgradient from the injection point were less than 10% of the peak bromide breakthrough concentrations (101). Numerous laboratory studies using sand from ACP sites have confirmed the large degree of retention of bacteria during transport though these porous sand (101). Thus, although water flows quite freely though these porous sediments, bacterial transport is very limited. Bacteria can only be transported long distances in very small numbers as the high degree of retention indicates.

The potential for bacterial transport in sediments can increase with increasing physical heterogeneity (102,103) where there is connected pore space (104), with reductions in geochemical interactions. In the Cape Cod study, there was one layer sampled where the peak bacterial concentrations reached 25% of the bromide concentration (101). The significant difference in retention of the bacteria in different sand layers points out the large degree of variability that can occur over 1 m vertical distances in these sediments. The presence of iron minerals can also contribute to absorption of the bacteria (105) and the ACP sediments typically contain iron-coated quartz (8, Parsons and Swift, 1995). Thus, heterogeneity in both physical and geochemical properties can be important in transport.

Heterogeneity in seemingly uniform ACP sediments has also been implicated as causing large differences in bacterial transport in the vadose zone (106,107). In laboratory experiments using intact blocks of ACP sediments from the Oyster site consisting of greater than 99% sand, flow and bacterial transport were extremely heterogeneous. Only 6 to 16% of the defined vertical regions in the block produced flow when simulated rainfall was applied to the surface of the block. Vertical regions producing the fastest water flow did not produce the highest peak bacterial concentrations. The effects on bacterial transport appeared to be related to soil particle size rather than to porosity. Bacteria were trapped in layers of the block containing smaller sand particles.

The high degree of attenuation of bacteria during transport in these sediments indicates that growth may be a key in the long distance transport of bacteria (108). Thus, although there are documented differences in bacterial properties related to attenuation even within a single strain (109,110) other bacterial properties related to growth and survival may also play a role in long distance transport.

CONCLUSION

The microbial communities in ACP subsurface environments are quite diverse. Microbial trophic groups commonly observed in these environments include aerobic heterotrophs, methylotrophs, nitrifiers and denitrifiers, sulfur or iron-oxidizers, anaerobic heterotrophs, sulfur or iron-reducers, methanogens, fungi, and protozoa. These microbial populations vary depending of the physical and chemical composition of their immediate environment, thus providing for the heterogeneity seen in the subsurface microbial communities. By their presence in the subsurface sediments and groundwater, these microorganisms can impact water quality by producing carbon dioxide, changing nitrogen, sulfur and iron species, producing methane, excreting volatile fatty acids and degrading chlorinated ethenes, petroleum, and polyaromatic hydrocarbons. The rate of impact may be limited by physical and chemical factors that limit microbial metabolism and growth; yet manipulations of the environmental conditions (i.e., oxygen and carbon addition) may alter microbial growth and metabolism to the advantage of reducing contamination in the subsurface environments.

MICROBIOLOGY OF CRETACEOUS SHALES AND SANDSTONES OF THE SOUTHWESTERN UNITED STATES

LEE R. KRUMHOLZ
The University of Oklahoma
Norman, Oklahoma

GEOLOGICAL BACKGROUND

Cretaceous rock formations of the southwestern United States originated as marine sediments deposited between 66 and 100 Ma (Ma = million years before present) (1). At that time, a large sea covered the western United States and often extended from Montana south into Mexico. The size of the sea depended on the worldwide fluctuations in sea levels. The series of advances and retreats in water levels resulted in the formation of extremely productive shallow marine and coastal ecosystems that contained considerable levels of plants, algae, and bacteria in addition to marine sediments. The influences of decomposition, burial, temperature, pressure, and chemical reactions worked in concert to convert the decaying plants, algae, and microorganisms to petroleum, coal, and organic carbon-rich shales.

In certain locations, the rapid changes in water levels created an intertonguing of sands and clays of relatively shallow thickness (to tens of meters) (2). Sands were deposited in shallow waters and finer grained silts, and muds at greater depths. Where the water was deep for longer periods, thicker shales were formed. Coastal systems associated with this sea exhibited fluvial (deposited in rivers) as well as deltaic formations, especially as the sea began to retreat during the late Cretaceous period. Through microbial, geochemical, and hydrological activities, sediments subsequently became cemented with quartz overgrowths as well as calcite, gypsum, and pyrite minerals. The biodegradation of organic materials and subsequent release of carbonate into solution resulted in precipitation with soluble calcium to form calcite. Reduction of sulfate to sulfide and the subsequent reaction of sulfide with Fe(II) formed pyrite. The net result was the hardening of sand into sandstones and of mud and silt into shales.

In the studies discussed within this review, shale and sandstones obtained as cores from the San Juan Basin (Cerro Negro), were originally deposited at alternating shallow intervals as described (3,4). The sandstone members from Paguate, Cubero, and Lower Oak Canyon formations represent near-shore (shore-face or near-shore-bar) depositional environments, whereas the shale members from Whitewater Arroyo, Clay Mesa, and Upper Oak Canyon represent adjacent, but deeper and less-energetic, near-shore ("toe-of-slope") environments (Fig. 1).

During the late Cretaceous period, as seas receded, fluvial sediments were often deposited. These tend to have similar characteristics to the earlier mentioned alternating intervals, except that rock are of freshwater origin and therefore, pore water concentrations of NaCl and sulfate are lower.

SULFATE AS ELECTRON ACCEPTOR

An important characteristic of sediments of marine origin is the abundance of sulfur oxidized in the form of sulfate or reduced in the form of sulfide minerals like pyrite (FeS_2). The importance of sulfate in marine and other environments is evident when one considers the microbial component. Groundwater flow is relatively slow in the vertical plane as a result of the confining nature of shale and clay formations. Consequently, in order that surface water enters the more permeable aquifers, organic-rich shales must often be traversed. The introduction of biodegradable organic compounds into the surface waters as they move down from the surface, often results in depletion of dissolved oxygen (present at only 250 μM at saturation) as microorganisms respire within the sediments. When oxygen is no longer available to act as respiratory electron acceptor, sulfate will be used by sulfate-reducing bacteria (if it is present). The presence of sulfate allows for the biodegradation of organic materials, including petroleum components (see review

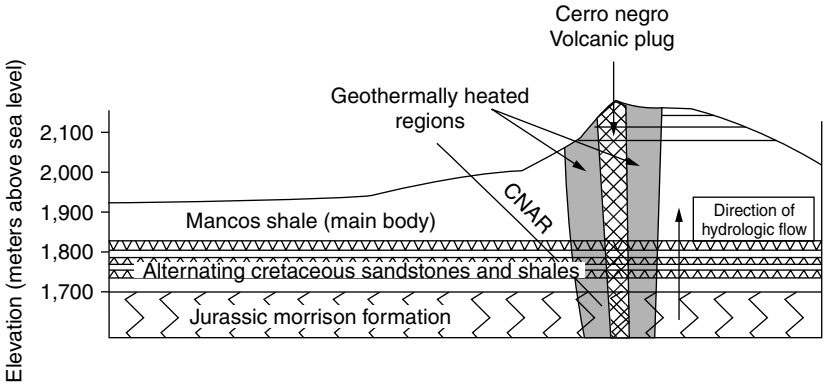

Figure 1. Diagram showing the geology of the drilling site in the San Juan Basin. CNAR represents the actual angled borehole from which cores were obtained. Alternating sandstones and shale formations are named in the text. Regions adjacent to the volcanic plug were sterilized at approximately 3.4 Ma (14).

on petroleum biodegradation (5)) that would be degraded slowly or not at all in its absence. It should be noted that the rate of biodegradation of the organic compounds would be considerably faster if oxygen were acting as the primary respiratory electron acceptor rather than sulfate. The equation below describes the degradation of organic materials by sulfate-reducing microbial communities.

$$\text{Buried organic material} + SO_4^{2-} \longrightarrow HCO_3^- + HS^-$$

Following the release of dissolved sulfide, it frequently reacts with iron to form pyrite as described in the following series of reactions:

$$Fe^{2+} + HS^- \longrightarrow FeS + H+$$
$$FeS + HS^- + H^+ \longrightarrow FeS_2 + 2H$$

If the sulfate is completely consumed at a particular organic-rich location, the only remaining respiratory electron acceptor will be bicarbonate. Bicarbonate is usually abundant in subsurface systems and its reduction by microorganisms with consequent methane production is commonly observed in organic-rich subsurface systems including petroleum-bearing sediments (6). Methane produced through methanogenesis as a result of the biodegradation of organic compounds is an important component of certain natural gas deposits.

THE SAN JUAN BASIN

Through a United States Department of Energy (DOE) sponsored project, the microbiology of the interfingered cretaceous sandstones and shales of the San Juan Basin was studied. These formations were drilled in the latter months of 1994, in a large effort that involved investigators from several universities and DOE's national laboratories. The drilling operation brought rock cores to the surface that were six centimeters in diameter. The cores were immediately placed in an anaerobic glove box to minimize air exposure of potentially oxygen-sensitive microorganisms and to prevent oxidation of reduced chemical species. The cores were then fractured into five to fifteen centimeter lengths before shipping them on ice to investigators.

Much of the core material was from sediments that are below the water table. Groundwater sampled early in the study was found to be devoid of oxygen, to contain low levels of reduced iron [Fe(II)], and was rich in sulfate and sulfide (2). A hypothesis was proposed, suggesting that sulfate reduction would be the most likely respiratory process for microorganisms living within this subsurface environment. To test the possibility of sulfate reduction in the subsurface rock cores, a technique involving silver foil was employed in which sheets of silver foil (7×7 cm), along with a solution containing radiolabeled sulfate, are placed on intact core faces and incubated for about six weeks (7). During incubation, labeled sulfide formed by the reduction of sulfate reacted immediately with the silver and became fixed. At the end of the incubation, the foil was removed and excess sulfate washed off leaving the labeled product attached to the foil as silver sulfide. The foils were then subjected to autoradiographic imaging to determine the location of sulfate-reducing activity within the cores (Fig. 2).

Although some cores showed no activity, the majority exhibited some activity that was localized within small patchy areas on the core face (Fig. 2). The most interesting results came when the total counts on each foil were determined and plotted as a function of depth. Several cores had activity that was extremely high, 200- to 1,000-fold greater than the others. These samples were found near sandstone–shale interfaces within the sandstone and below the interface (7). Examination of the organic carbon content of the rock samples suggested a hypothesis as to why activity was highest in these particular zones. When total organic carbon concentrations were plotted as a function of depth, the highest levels of organic carbon were also observed at these interfaces in the shale. In fact, the steepest gradients of organic carbon exist across the same interfaces in which the greatest level of sulfate-reducing activity exists. Along with these laboratory studies, multilevel sampling of well waters showed a decreased $\delta^{13}C$ for dissolved inorganic carbon and highest levels of dissolved sulfide within sandstones near shale sandstone interfaces (8). These results suggest that organic matter trapped in shales during deposition diffuses across the sandstone shale interfaces from the shales, and supports the existence of discrete microbial communities at and near these sandstone shale interfaces within the adjacent sandstones

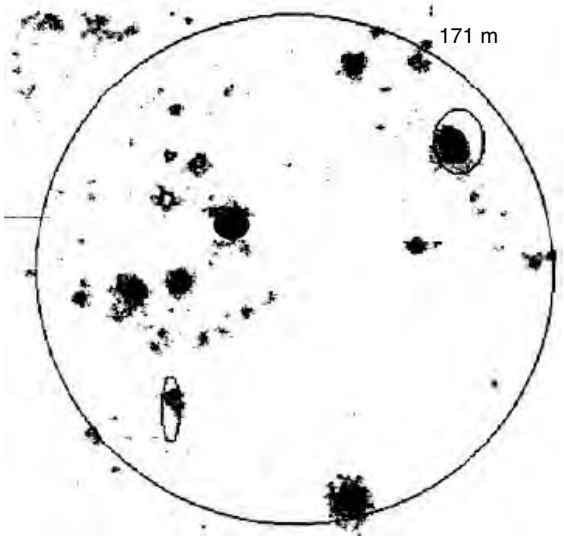

Figure 2. Autoradiographic analysis of sulfate-reduction activity on the freshly exposed face of a rock core obtained from 171 m depth of the Cerro Negro, N.M., exploratory drilling site. The image shows the localization of sulfate-reducing activity on a two-dimensional scale. This core shows the patchy distribution of microbial activity. The interior of the black circle represents the contact area of the cylindrical core with the foil. The level of radioactivity at that location on the foils is represented by darkness with some enhancement to improve contrast. Small circles represent points of reference and not necessarily microbial activity (7).

(Fig. 3). These microbial communities are apparently growing on organic matter laid down approximately 90 million years ago.

Experiments were designed, in which ground rock material was used to test the hypothesis that carbon-rich shales with low permeability supply nutrients for microbial communities living in higher permeability adjacent sandstones. To avoid contamination from the exterior of the core, cores were fractured and, with the aid of a sterile masonry drill bit, samples were ground from the center of the core. In these experiments, ground shales and sandstones were combined to determine the influence of shale organic matter on sulfate reduction as well as acetogenesis within these samples. When ground rock was incubated over time, sandstones carried out sulfate reduction and this activity was increased when ground shales were added to the incubations. Additionally, acetate was produced and this production was proportional to the shale addition. On the other hand, the shale did not reduce sulfate or produce any acetate when incubated separately. Therefore, it appeared that shales provide the energy needed to stimulate microbial activity within the sandstone. These results suggest that complex organic matter bound in shales can diffuse across sandstone shale boundaries (Fig. 3). This organic matter in turn, provides a source of nutrients and energy for heterotrophic bacteria living in a discrete microbial community within the sandstone at the sand–shale interface. Products of these microorganisms provide the reducing equivalents needed for sulfate reduction and possibly for acetogenesis. This model illustrates a novel mechanism for the long-term survival of microbial communities in the subsurface.

In another detailed study of these rocks, Fredrickson and colleagues (2) have shown that the distribution of pore throat diameters varied dramatically between shales and sandstones. The vast majority of shale pore throats were smaller than any known culturable bacteria (about 1–100 nm). In contrast, pore throats for sandstones were sometimes as large as 10 to 20 μm, which would likely allow transport of most known bacteria. A variety of techniques including acetate mineralization rates, sulfate-reduction rate, and culturable bacterial numbers, again showed that microbial numbers and microbial activity were far smaller in shales than in nearby sandstones. A rational hypothesis based on these data is that growth and metabolism of shale bound organisms is limited by slow diffusion of nutrients and/or by the microbes inability to easily migrate through the narrow pores.

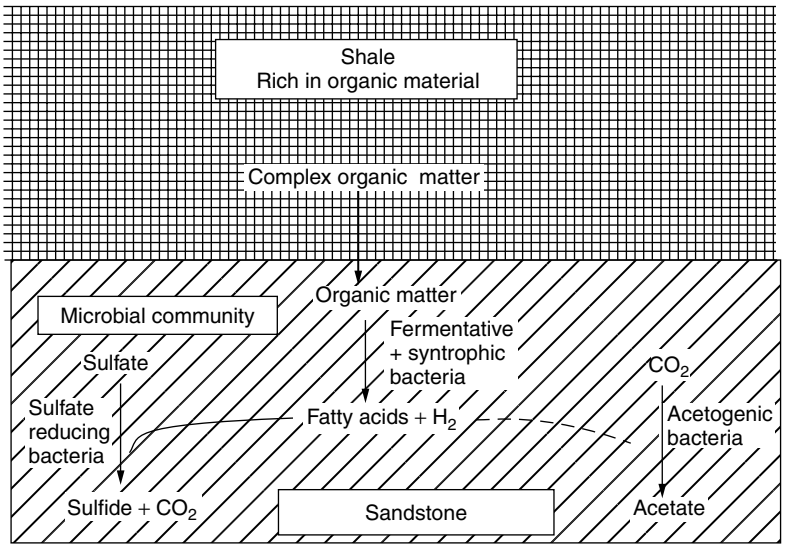

Figure 3. Drawing of the microbial processes postulated to occur near the interfaces of Cretaceous sandstones and shales (27).

The idea of ancient organic matter fueling microbial growth has been previously postulated for microorganisms living near oil deposits. Microorganisms appear to grow by catabolizing components of the buried petroleum. In recent years, several research groups have isolated microorganisms from both marine and continental oil reservoirs (9–11). Additional geochemical or geophysical characteristics, of these subsurface locations apparently limit the biodegradation process so that petroleum remains.

ISOLATION OF PURE CULTURES FROM THE SAN JUAN BASIN

A mineral medium was inoculated with a sandstone groundwater mixture and these were incubated with H_2 as electron donor and sulfate as electron acceptor (12). Under these conditions, both sulfide and acetate were produced and two pure cultures of organisms were isolated from these enrichment cultures. The hydrogen-utilizing sulfate-reducing bacterium was named *Desulfomicrobium hypogeium* and the autotrophic acetogen was named *Acetobacterium psammolithicum*. The two organisms were typical of members of their genera with the ability to use hydrogen as electron donor.

As H_2 is a critical intermediate in the biodegradation of complex organic compounds, it is important to understand which group of organisms is responsible for its consumption. Experiments were designed to examine competition between the two organisms to elucidate which was the dominant process for H_2 consumption; sulfate-reduction or acetogenesis. Studies which determined the lowest H_2 concentration utilizable for growth showed that the sulfate-reducer was capable of drawing H_2 concentration much lower than the acetogen. This in turn indicated that under the conditions tested, and likely under subsurface conditions that typically exhibit threshold H_2 concentrations, the sulfate-reducer is presumably responsible for the majority of H_2 consumption. In competition experiments in which both organisms were grown together in the presence of H_2, the sulfate-reducing culture was able to prevail over the acetogen, thereby indicating once again that sulfate reduction was likely to be the most important process for H_2 consumption.

ORIGINS OF MICROORGANISMS IN THE SUBSURFACE

Experiments at the San Juan Basin and Piceance Basin (see following section) were originally designed to test the following hypotheses. (*1*) Bacteria present today are descendents of organisms originally deposited within sediments. (*2*) Bacteria have migrated from the surface or other locations to subsurface sediments. This question was tested using samples obtained at the Cerro Negro site in the San Juan Basin where a volcanic neck protruded through the buried cretaceous sediments about 3.39 Ma (13), thereby sterilizing the sediments near the neck (Fig. 1). It was proposed that if hypothesis A was correct, then sediments adjacent to the volcanic intrusion would be currently sterile. In contrast, organisms would be discovered in this sterilized zone if existing organisms migrated to the sterilized sediments from the surface or from nearby sediments during the last 3.4 million years. To obtain samples from the sterilized region, an angled borehole was directed at the volcanic neck and samples collected throughout the drilled interval. Fission track analysis undertaken at the same time determined the temperature of rock during the volcanic intrusion to have reached a maximum of 210 to 320 °C (14). Hydrologic flow models of groundwater near the site suggested a generally vertical flow at this location from the underlying Triassic Chinle formation upward through the cretaceous sediments, indicating the possible transport of microorganisms from underlying sediments (14) (Fig. 1). The rock cores from the sterilized region were shown to contain active microorganisms based on phospholipid fatty acid (PLFA) analysis and microbial activity studies (2). It appears that rock colonization likely occurs continuously as microorganisms are transported in groundwater.

PICEANCE BASIN, COLORADO

Microbial analysis was carried out on rock cores from late cretaceous and tertiary sediments of the Piceance basin in western Colorado. The sediments were deposited during 73 to 35 Ma in a fluvial environment deeply buried between 35 and 5 Ma, with temperatures peaking between 120 and 145 °C (6,15) during this time. The result was interbedded sandstones, shales, and coal deposits. During the last five million years, temperatures have cooled, with current temperatures ranging from 43 to 85 °C for the sampled regions. Cretaceous sediments sampled in the lower part of the interval have current in situ temperatures of 81 °C for the 1,996-m depth interval and 85 °C for the 2,091 to 2,096-m interval. The harvested sediments were incubated at 65 °C, in microbiological media designed for the cultivation of a variety of different physiological groups of bacteria. Among the range of microbial types in which cultivation was attempted, both Fe(III) and Mn(IV) reducing (respiring) bacteria grew from the Cretaceous sandstones (16,17). Sulfate-reducing activities were detected in some of the core material (unpublished data, L. R. Krumholz and J. M. Suflita); however, it is likely that Fe(III) reduction and methanogenesis are also important respiratory processes in the sandstones. Positive enrichment cultures, plus the fact that the rock at the 1,996-m depth interval contained PLFA (microbial membrane components) at levels above the detection limit, suggest that the upper interval of these late cretaceous sandstones and coal material contain active metal-reducing microbial communities.

Energy Sources for These Communities

Cretaceous sediments in the Piceance Basin are important sources of fuel as they are rich in both methane and coal (6). Methane and hydrocarbons have recently been shown to be oxidized by methanogenic Archaea in a process coupled to the reduction of sulfate (18,19), although

this has not been demonstrated with pure cultures. It seems probable that methane and coal-derived organic compounds are the major energy sources for existing microbial communities in deep cretaceous sandstones from the Piceance Basin.

ORIGINS OF MICROORGANISMS

Sediments from the upper Cretaceous layer appear to be inhabited by metal-reducing organisms; however, the depth interval obtained from a somewhat more hydrologically isolated region a few hundred meters below did not yield detectable organisms (16). A similarity with the Cerro Negro site in the San Juan Basin is that both of these regions had been previously subjected to sterilizing temperatures and have now cooled to temperatures capable of supporting life. Only the upper region from the Piceance basin appeared to have an associated microbial community, suggesting that the lower, hydrologically isolated region has not been recolonized. The mechanism for colonization of the upper region is almost certainly via transport of microorganisms from nearby formations or from the surface.

Muds are typically used during drilling operations to lubricate drill bits and remove rock cuttings from boreholes. Thermophilic (60 °C) incubations of drilling mud from the described earlier operation produced Fe(III)-reducing enrichment cultures (17). The enrichment cultures coupled the oxidation of H_2 as well as a variety of low molecular weight organic acids to the reduction of amorphous Fe(III) oxide. Magnetite and siderite ($FeCO_3$) were the reduced products of iron reduction (20). The temperature range for the enrichment cultures was 45 to 75 °C. These enrichment cultures have been studied and the individual components have been characterized phylogenetically (17). The major components of the Fe(III)-reducing enrichment cultures from this site and enrichments obtained from Triassic Age Taylorsville Basin in Virginia represent a unique lineage of iron-reducing bacteria. The fact that these clones are very deeply branched within the phylogenetic tree of life has allowed the authors of the work to suggest that thermophilic iron reduction may have evolved early as a form of microbial respiration. The isolation of thermophilic bacteria capable of producing magnetic rock in ancient sediments also points to the possible biogenic origin of magnetic rock formations during these or earlier time periods.

RELATED STUDIES

Although the goal of this review is to discuss the microbiology of Cretaceous shales and sandstones of the southwestern United States, two additional analogous microbial ecosystems must also be mentioned. One occurs within the alternating cretaceous sand and clay layers of the Atlantic coastal plain where low levels of sulfate reduction have been observed in clays and much higher levels in adjacent sandy sedimentary layers (21). The apparent lack of sulfate-reduction activity in clays has resulted in a buildup of fermentation products within clays (22,23). The diffusion of microbial fermentation products across a sand-clay boundary apparently provides the organic electron donors needed for sulfate reduction in adjacent sand formations, in the same way that organic materials from shales fuel sulfate reduction in adjacent sandstones within the Cretaceous sediments of the San Juan Basin.

The other is a relatively well-characterized site in the Texas coastal plain represented by late Cretaceous and Eocene (~45 Ma) sediments. The aquifers studied were deposited in fluvial and/or deltaic environments (24–26). Eocene sediments are composed of sands and silts with interbedded clays and lignites. Lignite is a remnant of ancient plant material. Using the silver foil technique outlined earlier, and a direct measurement of sulfate reducing activity (26), it has been shown that sandy regions have sulfate-reducing activity, which clay regions do not have. The most active sulfate-reducing zones lie directly adjacent to clay and lignite deposits. Products from the fermentation of organic matter within the lignite-clay deposit appear to provide the energy for sulfate-reducing microbial communities that live at these lignite sand interfaces. These sulfate-reducing microbial communities, present in discrete regions can only be evaluated if the heterogeneity is examined at the centimeter scale in core material. Microbial activity occurs as a result of the diffusion of organic compounds originally trapped in clay and lignite into adjacent more permeable sand regions. Once in the sand, microorganisms are capable of growing on these organic compounds. This geochemical process could likely sustain these microbial communities over long periods of time.

CONCLUSION

Studies on cretaceous rock have illustrated the adaptability of subsurface microorganisms and their ability to grow in different environments. Subsurface bacteria will consume buried organic materials trapped in sediments over millions of years. Long-term growth of microorganisms in organic-rich subsurface formations appears to rely on a rich source of organic material trapped in a shale, lignite, or clay, which on their own suppress microbial activity. As the organic compounds migrate out of these rich materials into permeable sandy sediments, they appear to be degraded by the resident microorganisms. This process could maintain microbial communities over long periods of time.

Deeply buried organic-rich subsurface sediments are usually anoxic and the resident microflora rely on electron acceptors including sulfate and bicarbonate, resulting in the formation of sulfide minerals or biogenic methane.

Colonization of subsurface formations occurs during and following burial of those sediments. It seems likely that the microflora of subsurface formations is constantly in flux, with microorganisms migrating in groundwater from one location to another. Those microorganisms that are most efficient and/or adaptable will likely be the ones to prosper at any given location.

Acknowledgments
Our research on the subsurface has been supported by the U.S. DOE, Subsurface Science Program and more recently, the DOE NABIR program. I thank Dr. Cecelia Brown for editorial assistance and Tom Dewers for helpful suggestions.

Economic wealth in today's world continues to depend on subsurface environments that provide societies with fossil fuels for energy to sustain industrial activities. During the twentieth century, geologic understanding of these subterranean realms has increased considerably and yet, we have only recently discovered that microbial communities exist in these oil- and natural gas-bearing deep terrestrial and marine sedimentary formations. For a thorough comprehension of the factors that contribute to the accessibility, quality, and origin of these natural resources, we are compelled to learn more about the life that coexists with this organic energy. Hydrogen sulfide in crude oils from sedimentary strata has corrosive and toxic effects, and this gas may be biogenic. Furthermore, because of the relatively well-defined geology of these environments and the chance for occasional access by drilling, microbiologists are attracted to opportunities to conduct discovery science in which they can learn more about these unusual communities. Knowing the geologic context of these austere habitats allows microbiologists to place conditional constraints on the presence of living cells in these deep-earth locations and test hypotheses related to such relevant issues as microbial transport through confined spaces in porous media or colonization of geologically sterilized strata. Through these studies we learn more about the edges of the biosphere in places where life was, if acknowledged to exist, not thought to be of great importance. The questions now frequently considered by microbiologists are "how deep? how hot?" (1). We are also led to consider the likelihood that microscopic life has been sustained under related conditions on other celestial bodies.

This article will consider the microbiological characteristics of deep sedimentary environments and identify common themes among the microorganisms that exist therein. Firm microbiological information for these habitats is still difficult to come by, largely because of the infrequent and expensive nature of well-designed and carefully conducted sampling opportunities. Any research

in this field, however, has the potential to illuminate our limited understanding of who is there, how they got there, and what they are doing there.

DEEP SEDIMENTARY BASINS CONTAINING MICROORGANISMS

The earliest study that considered the presence of microorganisms in deep sedimentary strata was conducted by Bastin and coworkers (2), who noted evidence of sulfate-reducing bacteria in oil reservoir fluids. More recently, a variety of microorganisms have been cultured from oil wells around the world (3). Research that has focused on the microbiology of subsurface environments since the 1980s has seen marked attention to the methods of sample collection and, therefore, an increased level of confidence that microbial communities are indigenous to deep-earth systems (4). The findings of several of these recent studies with regard to deep sedimentary rock environments in which microorganisms have been detected are detailed. The investigation of the Piceance Basin in western Colorado is highlighted because it combines various approaches to evaluate present and past conditions of this extreme microbial environment. Specifically, determinations were made for: (*1*) thermal histories by fluid inclusion microthermometry and vitrinite reflectance, (*2*) hydrologic patterns by isotope geochemistry, (*3*) pore throat dimension by mercury porosimetry, and (*4*) microbial colonization rates by numerical simulation of groundwater flow. By linking these methods, the presence of microorganisms in the subsurface and the nature of their existence can be more easily explained.

PICEANCE BASIN

One of the sedimentary basins of importance to gas production in the United States is the Piceance Basin in western Colorado. By some estimates, this coal-bearing basin contains more methane (84 trillion cubic feet) than any other coal bed resource in continental United States (5). These resources are contained within low-permeability strata of Cretaceous age and oil shales of Tertiary age. The gas- and coal-bearing formations in the Piceance Basin have been extensively surveyed for their gas and coal resources, yielding considerable information related to the geologic and hydrologic history of the subsurface. In 1994, this information was used by the U.S. Department of Energy's Subsurface Science Program to guide investigations of microbial communities in the deep strata (6). Selection of this site was based on the following criteria: (*1*) the sedimentary basin is hydraulically tight, so deep strata have minimal communication with near-surface microorganisms through transport in groundwater; (*2*) the basin has a well-characterized tectono-thermal history; and (*3*) the strata contain abundant trapped natural gas compartments that could potentially harbor microorganisms. The focus of this study was to determine how geologic parameters constrain the presence of microorganisms in deep sedimentary strata, specifically the degree to which geologically sterilized formations were subsequently colonized and the factors that might prevent or retard this colonization.

Geologic Setting

The Piceance Creek Basin is located on the Colorado Plateau in western Colorado (Fig. 1). The sedimentary rocks within the basin are composed predominantly of shale and sandstone (Fig. 2) deposited in marine, coastal, and nonmarine environments during the Late Cretaceous to Early Tertiary [about 73 to 35 million years ago (Ma)] (7). The maximum formation temperatures were achieved at 35 Ma. The uplift of the Colorado Plateau started as early as the Early Eocene (8). Apatite fission track analyses indicated that the last phase of erosion started about 9 (9) or 5 Ma (10). Since then, erosion has removed 1 to 1.5 km of strata along the Colorado River valley. The Piceance Creek Basin contains large volumes of natural gas within sandstone bodies intercalated with shale. Natural gas production and testing data indicated that the rock formations, although fracture-bearing, are hydraulically tight, with reservoir permeabilities that are typically tens of microDarcies (μD) and rarely reach tens of milliDarcies (mD) (11).

Core Description and Analysis

Mud and gas log analyses collected during the drilling of the deep gas-exploration well, 1M18 (Fig. 1), indicated that a sharp transition from low to high gas concentrations occurred in the sandstone bodies within the upper Mesaverde Group. Three coring intervals (above, within, and below this transition) were targeted for sampling and to capture shale/sandstone interfaces in which microbial activity was anticipated to be the highest.

By piggybacking the drilling of deep wells for gas resource development, cores were collected from rocks as deep as 2,096 m below land surface. Considerable care was used in obtaining, handling, and processing these cores before microbiological characterization (4,13). This involved the use of tracers to assure core quality, paring of contaminated core sections away from sections that were used for microbiological study, the shipping of blind controls and blanks, and overnight shipping of samples to microbiologists. Chemical and physical tracer measurements and phospholipid fatty acid (PLFA) analyses of the cores and the drilling mud identified core subsamples with little or no chemical or microbial contamination (6).

Two cores of sandstone and shale and one core of sandstone were obtained with a gel coring device (Baker Hughes, Houston, TX, U.S.A.) during the drilling of a gas-exploration well at the 1M18/1M8 site (Fig. 1). The coring depth intervals were 856 to 862 m (Core 1), 1,996 to 1,996.7 m (Core 2), and 2,090 to 2,096 m (Core 3) below land surface, mbls, (Fig. 2). Core 1 was obtained from the fluvial G-sandstone of the Wasatch Formation (Lower Tertiary). Cores 2 and 3 were obtained from the fluvial interval of the Mesaverde Group (Upper Cretaceous). Gas analyses performed on the drilling muds during the coring verified the transition from low to high methane concentrations between Cores 2 and 3 (14).

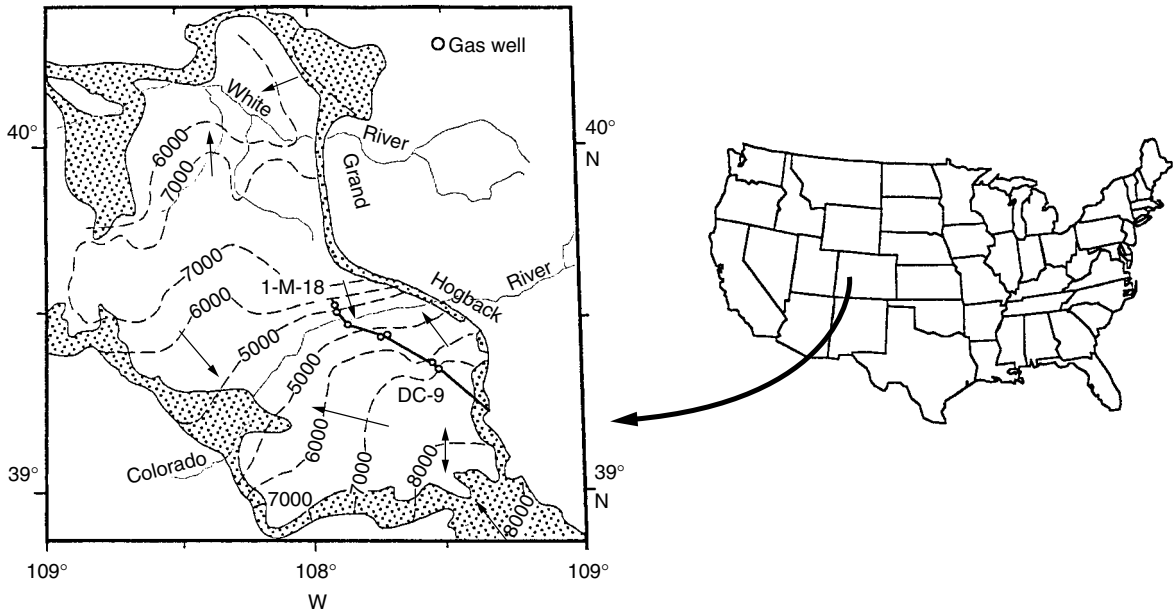

Figure 1. Groundwater flow direction (arrows) and potentiometric surface (contours in feet) in the Mesaverde group (simplified from G. W. Freethey, B. A. Kimball, D. E. Wilberg, and J. W. Hood, *General Hydrogeology of the Aquifers of Mesozoic Age*, Upper Colorado River Basin, U.S. Geological Survey, Reston, Virginia, 1988). The line connecting gas production wells is the location of the cross section shown in Figure 2.

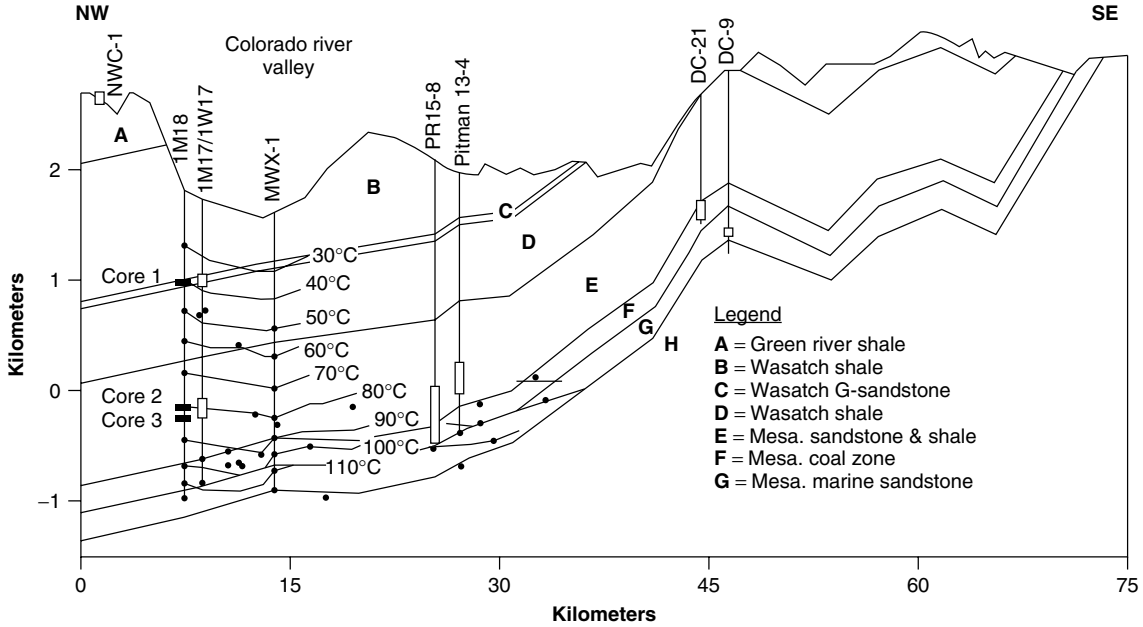

Figure 2. A NW-SE cross section along the maximum hydraulic gradient. The 1M18/1M8 is the microbial coring site. Also shown are the main stratigraphic units, locations, and depth intervals (open boxes) for the sampled wells and springs, and present-day isothermal contours interpolated from temperature logs and corrected bottom-hole temperature measurements (solid dots).

The present-day formation temperatures at the depths of Cores 1,2, and 3 were measured by logging three months after drilling was completed and were found to be 42, 81, and 85 °C, respectively. The maximum natural gas concentrations at the three coring intervals were 2.6×10^3, 2.1×10^4, and 8.8×10^5 ppm in order of increasing depth.

Core 1, consisting of sandstone and shale, had been pervasively cemented by quartz, calcite, pyrite, and various clay minerals, with gas porosities from 1.3 to 12.2%, permeabilities from 0.001 to 0.62 mD, and a maximum pore throat diameter of 0.5 μm, as measured by Hg injection porosimetry. Two nearly vertical natural

fractures with apertures on the order of millimeters were encountered within Core 1. Core 2 had gas porosities from 5 to 7% and permeabilities from 0.007 to 2.3 mD. Petrographic observations revealed large (up to 1 mm) connected pores that were partially filled with quartz, albite, illite, and chlorite cements. The pores in Core 2 were up to 1 mm in diameter, with a maximum pore throat diameter of 3.0 μm. Core 2 intersected a vertical, natural fracture. Core 3 was composed entirely of very homogeneous sandstone with gas porosities from 5.6 to 7.5% and permeabilities from 0.02 to 0.5 mD, and a maximum pore throat diameter of 2.0 μm. No fractures were encountered in this core. Generally, the cores were of low porosity, low permeability, and narrow pore throats as a result of diagenetic cementation.

Investigators used a battery of approaches to determine microbial biomass and different physiological types of microorganisms. Cores were scrutinized for culturable anaerobic bacteria, including Fe(III)- and Mn(IV)-reducing bacteria, fermenters, sulfate-reducers, nitrate-reducers, and methanogens. Ester-linked phospholipid fatty acid (PLFA) and selected enzyme and physiological activities were assayed as well. Acridine orange direct counts were generally at or below the limits of detection for this method, making this approach of limited use in estimating biomass.

Low but measurable microbial biomass was detected, however, by total PLFA analyses and by enrichments for anaerobic bacteria in the core obtained from 856 to 862 mbls (6). This core yielded anaerobic, thermophilic (growth up to 75 °C) Fe(III)-reducers and fermenters. A single positive enrichment and lower PLFA values were evident in samples from the core obtained from 1,996 to 1,997 mbls. Methanogens and sulfate-reducers were not detected in any of the samples, nor were bacteria that could grow with methane and any added electron acceptors. As with many deep subsurface samples that are low in biomass, attempts at direct extraction and amplification of microbial DNA from the samples were unsuccessful. However, 16S rRNA genes could be cloned from products of polymerase chain reaction (PCR) amplification of DNA extracted from a positive Fe(III)-reducing enrichment that resulted from incubation of core material from 858 mbls. The bacteria in this enrichment were related to bacteria in the genus *Desulfotomaculum*, characterized as gram-positive, spore-forming sulfate-reducing bacteria.

Geothermal History

The thermal history at the drilling site was reconstructed on the basis of fluid inclusions microthermometry (15) and vitrinite reflectance data (16; Fig. 3). Vapor-liquid inclusions (5 μm in diameter) found in crystalline quartz and calcite cements of the two natural fractures in Core 1 yielded homogenization temperatures from 75 to 125 °C (average, 95 °C), indicating that fluid at least this hot once migrated through the natural fractures. The salinity of the fluid was close to that of freshwater. Crystalline quartz filling the fracture in Core 2 contained vapor/liquid fluid inclusions that homogenized between 138 and 155 °C. The salinity was close to that of freshwater. The pressure correction for these homogenization temperatures was less than 5 °C on the basis of the maximum burial of the formations (<3 km).

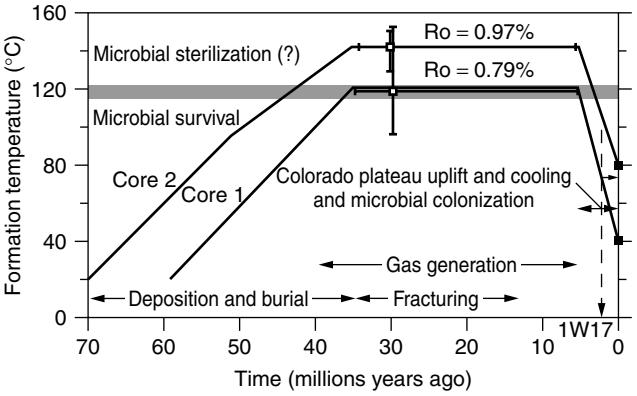

Figure 3. Geothermal history of cores 1 and 2. The solid circles with error bars are fluid inclusion data from fracture-filling minerals. The solid squares are data from borehole logging. The maximum temperature plateaus are based on vitrinite reflectance data.

The average vitrinite reflectance of centimeter-sized coal fragments in Core 1 was 0.79%. The average vitrinite reflectance value of carbonaceous shale from Core 2 was 0.97% (Fig. 3). The vitrinite reflectance values of three drill cuttings of the coal zone of the Mesaverde Group were determined to be 1, 1.67, and 1.77% at depths of 2,231, 2,677, and 2,753 mbls, respectively. Theoretical vitrinite reflectance profiles were derived with the model of Sweeney and Burnham (17) and were based on the burial history (7). The best match between the predicted profile and the five data points was obtained by assuming a geothermal gradient of 50 °C/km from 35 to 5 Ma and 35 °C/km during other times. The present-day geothermal gradient is around 35 °C/km. A higher paleo-geothermal gradient of 58 °C/km was estimated for a much deeper well drilled some 30 km to the southeast of the 1M18/1M8 site (10). At a geothermal gradient of 50 °C/km, the maximum geothermal temperature (T_{max}) for Core 1 was about 120 °C, assuming an average surface temperature of 20 °C. A T_{max} of 125 °C was calculated with the equation of Barker and Pawlewicz (18). The T_{max} of Cores 2 and 3 were calculated to be 140 to 145 °C and 145 to 150 °C, respectively.

The fluid inclusion homogenization temperatures and the vitrinite reflectance derived T_{max} are similar within error and indicate that the paleotemperatures of these formations almost certainly rendered these rocks lifeless within the constraints of our current understanding of life at high temperature. As recently as 5 Ma, through uplift and erosion by the Colorado River and a decline in the geothermal gradient, the formations cooled to present-day temperatures, which are more permissible for microbial colonization and survival. This suggests that the presence or absence of microorganisms in Cores 1 and 2 would be dictated by past thermal regimes that sterilized the formations at depth, the present thermal regimes that are comparatively permissible in terms of microbial survival, and by the microbial migration into these deep rock formations through the movement of groundwater.

Stable Isotopes of Formation Water

The chemical and isotopic compositions of water samples collected from wells producing from the Mesaverde Group and Wasatch Formation and from springs in the overlying Green River Formation (see Fig. 2 for sample locations) place constraints on the paleohydrology of these formations. The modern meteoric water, obtained from a shallow spring (NWC-1 in Fig. 2) on the high plateau above the Colorado River valley, is characterized by a $\delta^{18}O$ of -16.9% and a δD of -122%. In contrast, the $\delta^{18}O$ and δD of the deeper Mesaverde Group and Wasatch Formation waters were much heavier than the modern meteoric water. The water sample from Pitman 13–4, a Mesaverde Formation well, had a $\delta^{18}O$ value of -4.0% SMOW and a δD value of -47% (Fig. 4). The water from Mesaverde well, DC-9, had a $\delta^{18}O$ of -3.4% (its δD was not determined), whereas water from an adjacent but shallower (Fig. 2b) Mesaverde well, DC-21 (Fig. 2), had a lighter $\delta^{18}O$ value of -15.9%, relative to DC-9 and a δD of -109%. The 1W17 well producing water and gas from the Wasatch G-sandstone yielded a $\delta^{18}O$ value of -6.6% and a δD value of -58%. One other Wasatch Formation water sample from well 3W17 had isotope ratios of -10.6% for the $\delta^{18}O$ and -82% for the δD, both lighter than those for 1W17. The Wasatch and Mesaverde isotopic analyses yield a linear trend with a slope lower than the global mean meteoric water line (dashed line in Fig. 4), which is a relationship that is found in many intracratonic basins (19). These trends result from a variety of processes including H isotopic exchange between groundwater and hydrocarbon gases and O isotopic exchange between groundwater and diagenetic carbonates. The amount of exchange increases as the age of the groundwater increases. The trend may also be formed by mixing of meteoric water and a diagenetically altered groundwater of nonspecific age and isotopic composition at least as heavy as that of Pitman 13–4. In both instances, the intersection of this trend with the global meteoric water line yields the $\delta^{18}O$ and δD of meteoric recharge, which in turn reflects mainly the latitude and altitude of precipitation (20). This trend intersects the GMWL at a $\delta^{18}O$ of -13% and a δD of -100%, values that are distinctly heavier than the present-day precipitation or spring water. The North American plate has remained at the same latitude since at least the Cretaceous, but the altitude of the surface may have changed during the main uplift phase of the Colorado Plateau. The groundwater recharged before the uplift of the Colorado Plateau would have been isotopically much heavier than that of either modern recharge or of the intersection of the Mesaverde-Wasatch trend with the GMWL (arrow in Fig. 4). This suggests that the recharge age of the Mesaverde-Wasatch water occurred during the uplift of the Colorado Plateau and while the paleotemperatures of those formations were falling below the T_{max}. An alternative explanation is that the trend represents diagenetic modification of or a mixing line with modern precipitation (lower dashed line in Fig. 4), but that it has been displaced upward by 15% by isotopic exchange with hydrocarbon gases or hydrogen sulfide. The ^{36}Cl isotopic analyses of 1W17 (not shown) suggest a subsurface residence time of 1.6 Ma, which would

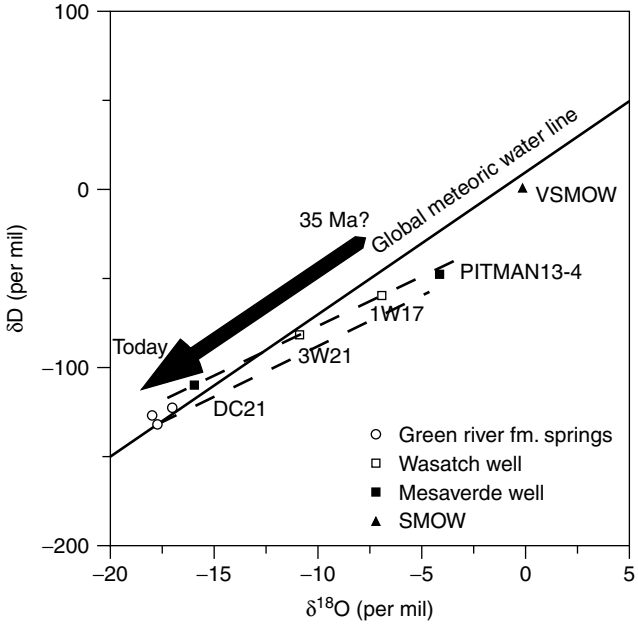

Figure 4. $\delta^{18}O$ and δD of water samples collected from springs and wells. The upper dashed line is the mixing line formed by data and the lower dashed line is the same trend displaced downward and anchored to present-day precipitation. VSMOW is Vienna Standard Mean Ocean Water. GMWL, the Global Meteoric Water Line, from [H. Craig, Science 133, 1,702–1,703 (1961)]. The arrow delineates the hypothetical migration of the isotopic composition of precipitation in western Colorado from 35 Ma since the beginning of uplift.

support the former explanation. The total dissolved solids of the Mesaverde Group water increases from about 0.8% at the DC-21 site to 2.8% at the 1M17 site, preventing accurate ^{36}Cl age determinations. When the age of 1W17 is compared with the thermal history (Fig. 3), it indicates that the temperature of the Wasatch G-sandstone was 75 °C, whereas that of the Mesaverde Group sandstone was greater than 100 °C. This indicates that the Wasatch was certainly habitable at the time the formation water was at the surface. To understand how rapidly the groundwater moved into the Wasatch strata requires more detailed modeling of the paleohydrology.

Numerical Simulation of Groundwater Flow

Groundwater flow and heat transport within a two-dimensional domain were simulated by using a finite element code (22; Fig. 5; Table 1). The cross section was discretized into 23 rows and 75 columns. The groundwater flow and heat transport in the basin were assumed to have reached steady states. The groundwater table was assumed to coincide with the upper boundary of the model domain because of the numerous streams on the surface. The surface temperature was set to 10 °C. The measured heat flux within the basin was set at 65 mW/m^2 (8) and assumed to be uniform on the bottom. Other boundaries were no-flow boundaries and nonconductive to heat. The permeabilities used in the model (Table 1) were within the range of measured permeabilities from well production and testing (11). The modeled temperatures were within

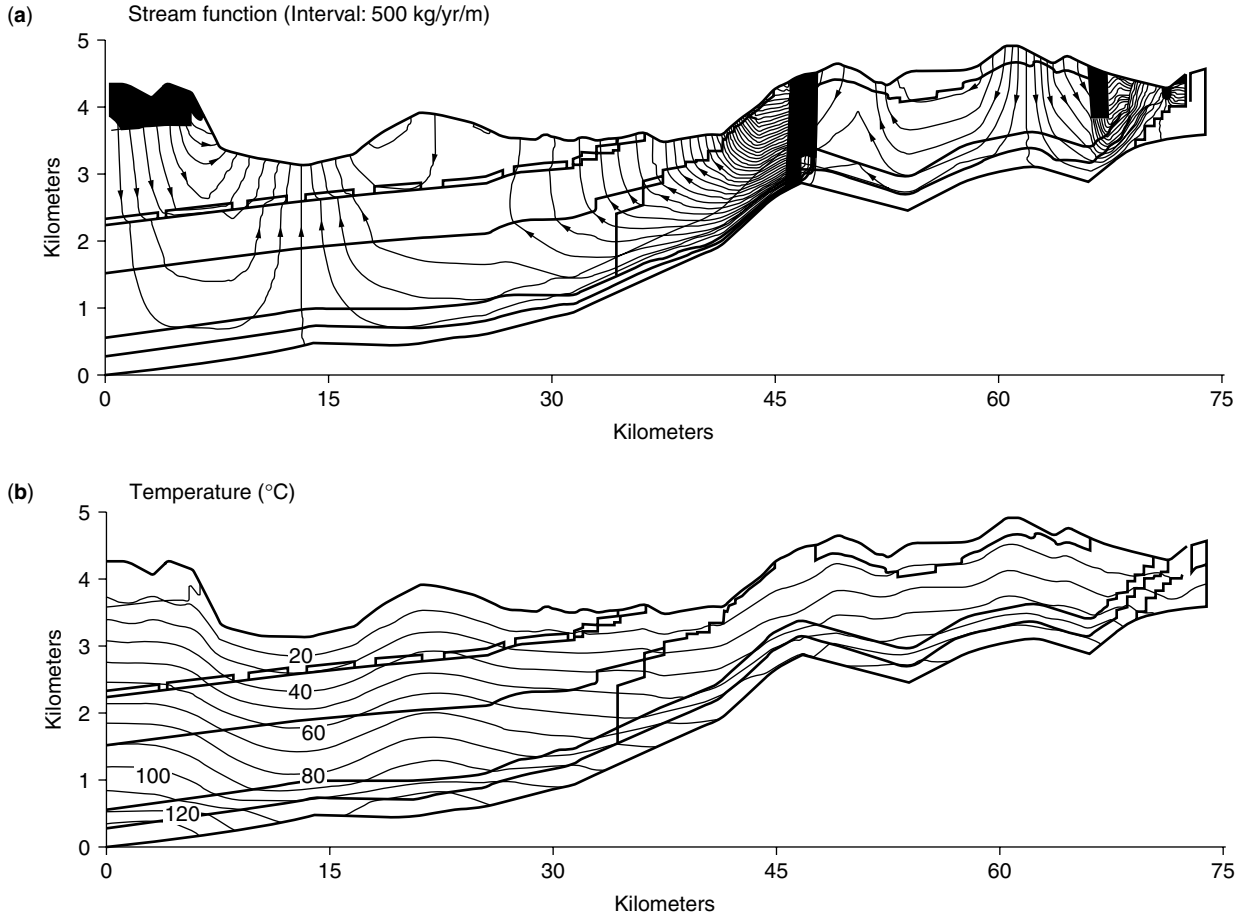

Figure 5. Numerical modeling results: (**a**) stream function and (**b**) temperature. See text for explanation.

Table 1. Material Properties used in Simulation

Rock Unit	1	2	3	4	5	6	7	8	9
Kx (m/yr)	10	0.01	0.5	0.01	0.05	0.1	0.05	0.1	0.1
Kx/Kz	1.0	0.001	1.0	0.001	0.5	1.0	0.5	1.0	0.5
ϕ (%)	0.20	0.10	0.10	0.10	0.10	0.10	0.10	0.15	0.10
λ (W/°C-m)	2.0	2.0	2.5	2.0	2.5	2.5	1.0	1.0	3.0

Note: Kx, Kz = horizontal and vertical hydraulic conductivity; λ = bulk thermal conductivity of the solid; ϕ = porosity.

5 °C of most corrected bottom-hole temperatures (compare Fig. 2 with Fig. 5b). The model correctly predicted that both the Wasatch Formation and Mesaverde Group are under hydrostatic pressure at the 1M18 site but are overpressured at the MWX-1 site. Simulated overall flow directions in the Mesaverde Group were consistent with those inferred from the potentiometric map constructed from drill stem tests of natural gas wells (compare Fig. 1 with Fig. 5a).

The model indicates that groundwater recharged on the plateau above the Colorado River valley can infiltrate vertically downward into the Wasatch Formation. The average linear velocity is 0.003 to 0.008 m/yr in the upper Wasatch Formation and 0.05 to 0.1 m/yr in the G-sandstone. Using the simulated average linear velocity and the flow path indicated by the stream function (Fig. 5a), the travel time of a particle from the oil-rich Green River shale to the G-sandstone is about 0.5 million years, neglecting the effect of diffusion, dispersion, and adsorption. The total groundwater flux into the Upper Wasatch Formation and the G-sandstone is about 3,000 kg/yr per meter of width of cross section. With this flux, several million years would be required to completely flush the Upper Wasatch Formation with fresh and isotopically light meteoric water. Thus, the simulated groundwater flux is consistent with the stable isotope ratios and ^{36}Cl data for the formation water in the Wasatch G-sandstone.

The average linear velocity is about 0.003 to 0.009 m/yr within the lower Wasatch and Mesaverde Group near the 1M18 site. The calculated particle travel time by advection alone is about 1.2 million years from the Green River Formation to the sampling depths of Cores 2 and 3. The smaller topographic relief at the beginning of the uplift and erosion could increase the travel times.

Piceance Basin Summary

Although low microbial biomass and infrequent culturable cells were the rule in samples from the Piceance Basin, indeed at the limits of detection in many cases, the microbiological characteristics of the samples were generally comparable to other deep sediment materials in being sparsely colonized by microorganisms (23). This paucity of microbial life is a common theme for investigations of cores from pristine deep strata and often contrasts with the results of studies that characterize microorganisms in aquifer or formation waters obtained through an existing well. Probably most deep strata are lightly colonized by hardy survivors of subsurface conditions although this may change once a well is drilled, bringing with it the changed conditions, including a flux of fluids surrounding the well installation.

That the bacteria found in these formations frequently exhibit metabolic flexibility has been demonstrated in the past (24,25) and may not be surprising given the need to exercise a range of metabolic strategies in order to survive. More difficult to understand would be the manner in which such organisms alter their metabolic approaches when they are probably so constrained by available energy. For example, a microorganism known to reduce both manganese and iron as terminal electron acceptors appears to have different terminal reductases depending on the metal being reduced (26). Whether both reductases would be maintained ready to function in cells surviving hostile subsurface conditions in which they may be deprived of electron donors is uncertain. The energy required for the conversion from one metabolic strategy to another would seem daunting to a cell existing under such circumstances. Hydrogen has been proposed as a subsistence energy source for subsurface microorganisms in which the primary objective of the cells is survival and not growth (27). Research studying the energy required for cell maintenance or physiological adaptation is hampered by the geologic timescales under which these cells must survive, and laboratory studies have not focused much attention on this point.

Two hypotheses can account for the presence of bacteria in the two uppermost cores: (*1*) the bacteria represent members of microbial communities that were entrapped during burial of the sandstone strata and survived the maximum paleotemperature of 120 to 145 °C for about 30 million years and (*2*) the maximum paleotemperature experienced by all three cores eradicated microbial communities entrapped during burial (Fig. 3) and bacteria infiltrated the strata during uplift and cooling of the formations over the last five million years.

The generally accepted upper temperature limit for the survival of bacterial vegetative cells and spores is 120 °C (28). Hedrick and coworkers (29) reported the presence of significant concentrations of ether lipids and phospholipid fatty acids in hydrothermal vent flanges exposed to fluid temperatures of 350 °C. This observation suggests that, within these environments, eubacterial survival at temperatures greater than 120 °C may be possible. If such hyperthermophilic bacterial survivors were present in Cores 1, 2, and 3, they should have been detected in the PLFA analyses of Core 3. The PLFA analyses are consistent with the lack of any positive microbial enrichments at incubation temperatures as high as 85 °C and suggest that bacteria did not survive the thermal history experienced by Core 3.

The hydraulically tight structure of the sandstone may have added to the demise of in situ microbial communities by limiting the supply of soluble nutrients required by the bacteria to maintain the cell and macromolecular integrity under the depravations of extreme heat. The high methane concentrations in the stratum sampled by Core 3 (14) suggest that fluid exchange was much more limited than in the strata sampled by Cores 1 and 2. This interpretation is consistent with the observed presence of fractures in Cores 1 and 2 and the absence of fractures in Core 3. If the sandstone that comprised Core 3 held pressurized gas, the entry of water and microorganisms would have been prevented. Column experiments indicate that gases in porous media form a relative permeability seal that prevents flow of water past the free gas (30,31).

Isotopic analyses of the formation of water and numerical simulations of the fluid flow indicate that meteoric water has penetrated these formations, particularly the sandstone bodies sampled by Cores 1 and 2, within the last few million years during which formation temperatures gradually dropped into the permissible range for microbial colonization. Numerical simulation yielded a water molecule travel time from 0.5 to 1.2 million years from the surface to the sampling depths. However, microbial travel time could be longer, given the small pore throats in the sandstone, if the microbial adhesion to the mineral surfaces was low and the closely spaced fractures acted as the main pathways for microbial transport during the uplift and cooling phase of the basin (Fig. 3).

Accordingly, sandstone proximal to fractures in Core 1 and 2 could be colonized, whereas small pore throats of the encompassing shales would impede colonization of the sandstone in Core 3, unless it was near the fractures. The overpressured nature of the sandstone compartment sampled by Core 3 indicates that gas transport is impeded, which certainly implies that it is impervious to microbial infiltration. Because the microorganisms cultured from these formations do not exhibit growth at temperatures greater than 75 °C, they more likely represent immigrants rather than survivors.

MICROBIOLOGY OF OTHER DEEP SEDIMENTARY STRATA

Taylorsville Basin

The Taylorsville Basin underlying Virginia, U.S.A., is another deep sedimentary basin where the microbiology has been studied through the analysis of cores. The basin is a Late Triassic-Early Jurassic synrift basin

that formed on the eastern edge of North America (32). The Mesozoic sandstone and shale of the basin are overlain by Coastal Plain sediments of the Miocene age (to 5 Ma) (33). The Coastal Plain sediments are relatively permeable and receive considerable recharge; however, the low-permeability Triassic strata are hydrologically more isolated and thus, more likely harbor microbial cells that have been removed from surface contact for long periods. This feature, along with infrequent drilling activity in the deeper, older strata made the Taylorsville Basin a target for studies of ancient subsurface bacteria. As with the Piceance Basin coring efforts, the degree of contamination as a result of the coring was minimized and quantified (34,35).

Several studies verified the presence of unique microorganisms in the strata of the Taylorsville Basin and one of these has been highlighted in the literature. *Bacillus infernus* was obtained from a rotary sidewall core sample taken from 2,799 mbls in the Taylorsville Basin (36). This microorganism exhibits several attributes that suggest that it is designed to survive under subsurface conditions. Like many others isolated from subsurface strata, it is metabolically versatile (24). Although it is strictly anaerobic, it can use a number of diverse electron acceptors, including Fe(III), MnO_2, trimethylamine oxide, and nitrate. Cells of *B. infernus* can ferment glucose or oxidize formate or lactate coupled to the reduction of oxidized iron or manganese. It is thermophilic, growing at temperatures up to 61 °C and halotolerant with strains growing at up to 2.1 M Na^+. The cells are able to survive starvation for at least 52 days at 50 °C. This survival capability, along with its placement in the genus *Bacillus*, suggests that the organism can form endospores, although they have not been observed. Phylogenetically, its affiliation as a species within *Bacillus* is quite interesting because no other strictly anaerobic species of *Bacillus* had been described.

Other microorganisms from the Taylorsville Basin include new species of the genus *Desulfotomaculum* (37). In contrast to *B. infernus*, these bacteria are nonmotile, endospore-forming, sulfate-reducing bacteria that do not use metals as terminal electron acceptors. Liu and coworkers (25) described thermophilic Fe(III)-reducing bacteria that were obtained from the Taylorsville Basin (and from the Piceance Basin). They too, are unique from *B. infernus*, based on the 16S rDNA phylogenies, and this study represents the first consideration of the importance of thermophilic metal reducers in the context of early earth history. Evidence of the wide phylogenetic distribution of iron reducers, these subsurface organisms constituting a new lineage apart from the mesophilic iron reducers, suggests an early evolution of the iron-respiring trait and subsequent conservation of the trait through the diverging lineages of the Bacteria (38). That these microorganisms were recovered from geographically and geologically isolated, ancient sedimentary basins and that they maintain the capability to reduce iron further suggests that this phenotypic attribute extends back at least to the Mesozoic (25).

Tseng and coworkers (15) attempted to constrain the mechanisms by which these microorganisms could exist in the subsurface of the Taylorsville Basin. To assess the likelihood of long-term microbial survival in place or transport into the Mesozoic strata, this group refined models of the thermal and burial history of the basin by characterizing aqueous and gaseous fluid inclusions and evaluating fission track data from materials derived deep in the basin boreholes. Their data suggest that at the time of maximum basin burial (ca. 200 Ma), temperatures at the microbial sampling depths probably exceeded 160 °C for several million years. Although we cannot verify that microorganisms did not survive these conditions, microbial biomass would be significantly reduced during this period of high temperatures in the basin. Furthermore, the authors suggest that these strata were not again habitable by microbes until 140 Ma, when the in situ temperatures at the microbial sampling depth cooled to around 100 °C, providing a habitat where at least hyperthermophiles could survive. However, for the microorganisms that could be cultured from these depths, none could grow at greater than 75 °C (25) and the model for the basin's thermal history developed by Tseng and coworkers (15) suggests that these lower temperatures were not characteristic of the sampling depths until around 60 Ma. Although conclusions based only on culturable microorganisms are tenuous, this could mean that the colonization front of viable cells advancing from the surface strata did not arrive in the deep sandstones and shales of the Taylorsville basin until the early Cenozoic. However, the in situ parameters of a cell's environment can shift the thermal limits for microbial growth and may influence cell survival in the subsurface. For example, high hydrostatic pressure can increase the maximum growth temperature in some microorganisms (39,40). Thus, the estimate that microbes became reestablished in the Taylorsville basin during the early Cenozoic is hypothetical and hinges on uncertainties in microbial survival characteristics.

Another study of the Taylorsville Basin proposes that the tectonic properties of a sedimentary basin determine when and at what rate microorganisms might colonize deep strata (41). Using two-dimensional paleofluid flow and heat transport modeling, Tseng and Onstott speculated on the rates and timing of microbial movement into the deep Taylorsville Basin rocks. This study indicates that during the Jurassic the basin topography, by virtue of regional tectonic uplift and erosion, forced groundwater into the deep strata at a rate of 1 to 100 mm/year. Given that rate of water movement, microorganisms from the surface could have reached the sampled depths in 1 to 20 million years. Thermophilic microorganisms such as those cultured from the cores could have reached the sampled depths even faster during Jurassic groundwater movement if they already resided deep in the formation at the 75 °C isopleth (ca. 1,300 mbls), at the edge of microbially survivable temperatures. More recently (from 140 Ma until today), groundwater flow rates are estimated to be 10 to 100 times slower than during the Jurassic. Because of these lower rates, a factor of the lower topographic relief in the region than in the Jurassic, the minimum time required for cells to make the trip from the ground surface to the microbially sampled intervals is between 50 and 180 million years.

Hydrocarbon-Rich Deep Sedimentary Formations

Because sulfate-reducing bacteria (SRB) can reduce the quality of crude oil by producing sulfide, considerable effort has focused on the presence of these microorganisms in oil reservoirs.

Culturable thermophilic and hyperthermophilic bacteria, including SRB, have been obtained from fluids emanating from newly developed crude oil reservoirs at several locations. In 1993, these organisms were obtained from drilling locations in the North Sea and the North Slope (42). Although novel methods were not used to collect the samples (the investigators relied on collection of reservoir fluids from oil production locations), this study was marked by the application of hyperthermophile cultivation approaches by one of the premier international laboratories for these types of investigations. The oil reservoirs that were investigated had all undergone waterflooding with seawater (up to 127,000 m^3 per day), indicating the potential that these organisms were introduced into these subsurface formations via oil production activities. That these microbial communities had been introduced through drilling or waterflooding is a conclusion that is consistent with characterization studies of microorganisms that were obtained from produced waters from souring oil reservoirs (43).

In contrast, the authors of another study of North Sea subsurface microbial communities concluded that the microorganisms in the reservoir were likely indigenous (44). In that study, thermophilic cells were isolated from formation fluids that were obtained before any water injected into the reservoir had reached the production well. Thus, the seawater used to flood this reservoir could not have served as a source of the microorganisms. The authors could not completely rule out drilling muds or drilling equipment as the source of these microorganisms. However, they contend that the large numbers of thermophilic sulfate-reducers present in the samples speak in favor of indigenous communities in the reservoir because the in situ conditions would have limited the populations of chance contaminants that were inoculated as a part of the original drilling activities. In another study of the North Sea region, a core was obtained from 1,000 meters below sea floor in a pristine location of the United Kingdom Continental Shelf (45). That a sustaining thermophilic enrichment culture of SRB was developed from the inner portions of the core further substantiates the contention that these bacteria are indigenous to deep sedimentary strata that are rich in crude oil.

Until recently, the presence of anaerobic microorganisms in deep oil-bearing strata was difficult to explain because of the limited evidence that such cells could sustain themselves through anaerobic degradation of the hydrocarbon characteristic of crude oils (e.g., long-chain alkanes and alkylbenzenes). However, studies within the last decade have led to a greater appreciation of the number of physiological mechanisms by which microorganisms can cause meaningful anaerobic degradation of higher hydrocarbons (46). Long-chain alkanes can be degraded by classical anaerobic physiologies such as denitrifiers (47,48), sulfate-reducing bacteria (49), and methanogens (50). Alkylbenzenes can be degraded by denitrifiers (48) and sulfate-reducing bacteria (51,52). Thus, although the conditions of many deep sedimentary formations may confine the metabolic activity or even survival of cells, multiple physiological strategies have appeared to evolve for the slow but efficient use of complex organic compounds in such environments.

CONCLUSION

Common themes that exist for microbial survival in deep strata include how cells can weather the enormous constraints associated with isolation from electron donor and electron acceptor supply that is dictated by deep burial and low fluence typical of low-porosity, low-permeability materials. Add to these issues the maximum temperature for microbial survival associated with deep sedimentary rocks and one could conclude that life would be sparse or nonexistent in remote underground locations. Nevertheless, the research summarized earlier indicates that meager populations of microorganisms are found residing in deep sedimentary strata for millions of years at temperatures less than 85 °C. Such systems rarely bear as much biomass as surface soils, but on a volumetric basis, the total biomass of these deep realms is globally significant (53).

An equally important question is how the microorganisms came to exist at great depths. The conclusions from the microbial studies of the Piceance Basin and the Taylorsville Basin are similar in that they ascertain that in the past these rocks were most likely too hostile for life to exist. In each case, the chemical and physical data from these basins indicate that the original cells deposited in prehistoric rivers or lake sediments were probably snuffed out by intolerably high temperatures. Additional data suggest that the current distribution of microorganisms in these deep rock environments is predicated on an uninterrupted route for water to travel from the surface to subsurface strata via a network of fractures, microfractures, and interconnected porosity at scales appropriate for microbial transport. These routes for colonization develop during periods of tectonic deformation, uplift, and the associated cooling that restores the temperatures of the deep strata to a habitable level. Even then, the microorganisms that first reenter these voids must be able to survive the austere surroundings.

Many questions remain unanswered regarding bacteria in these deep strata. What is their primary source of energy? Although many of them appear to be physiologically versatile, what can they really count on in terms of energy supplies? The ubiquitous and highly diffusive nature of hydrogen gas in subsurface environments makes this fundamental nugget of electrons a possible source of energy (27), but from whence does it originate? Are most of the cells that are found in these strata sustaining themselves by low levels of metabolic activity or are they zymogenous [i.e., those that persist but are inactive under present environmental conditions (54)]? And related to this, how long can they actually survive? Recent studies of subsurface salt deposits postulate microbial survival at 250 million years within saline fluid

inclusions (55). Understanding the mechanisms by which microorganisms survive over eons in deep rocks of any nature will continue to challenge scientists more than the investigations that aim merely to recover these cells and define their longevity.

Acknowledgments

Research was funded through Contract DE-AC07–76IDO1570 at the INEEL and through DE-FG02–94ER61821 at Princeton University. For research related to the Piceance Basin, we thank Snyder Oil Co., Fluor Daniel Services, and Rocky Mountain Oil Field Testing Center for sampling assistance and Jeff Raffensperger for computer codes. Specific programs contributing to this research were the U.S. Department of Energy, Office of Science, Subsurface Science Program, and the INEEL Laboratory Directed Research and Development Program.

MICROORGANISMS IN SOIL: FACTORS INFLUENCING THEIR ACTIVITY

Guenther Stotzky
New York University
New York, New York

The objectives of this article are to provide a brief overview of the physicochemical and biological factors that influence the activity, ecology, and population dynamics of microorganisms in soil. Soil differs from other microbial habitats in that it is dominated by a solid phase consisting of particles of different sizes surrounded by aqueous and gaseous phases, the amount and composition of which fluctuate markedly in time and space. The solid phase is a tripartite system composed of finely divided minerals (both primary and secondary); residues of plants, animals, and microorganisms in various stages of decay; and a living microbiota. These particles exist as independent entities and mixed conglomerates. The aqueous phase, in which inorganic and organic substances that serve as nutrients for or inhibitors of the microbiota are dissolved, is normally discontinuous, except when soil is saturated (e.g., after a heavy rain, snow melt, flooding, and extensive irrigation). This discontinuity restricts the movement of microbes, especially of bacteria and other nonfilamentous forms, and results in local accumulations of nutrients and toxicants, escape of cells from grazing predators, a low probability of gene transfer, and other phenomena that do not occur in habitats with a continuous water phase. The pore space not filled with the aqueous phase is filled with air and other gases and volatiles. Because of the low diffusion coefficients of most gases and the quiescent nature of soil, in contrast to the continuous movement and wave action of aquatic environments, some gases (e.g., CO_2, CH_4, CO, NO_x) and volatiles (e.g., short carbon-chain fatty acids, alcohols, and aldehydes, as well as aromatic compounds) may accumulate and other gases (e.g., oxygen) may be depleted. The concentration of gases, in turn, will affect the composition and activity of the microbiota (e.g., aerobes vs. facultatives, anaerobes, and microaerophiles; 1–3).

Despite the vagaries of the environmental conditions that are conducive to microbial growth (e.g., in available nutrients, especially in available carbon and energy sources, although limitations in other nutrients may be as or more restrictive, and in available water, temperature, radiation, nutrients, osmotic pressure), soil probably contains more genera and species of microorganisms than other microbial habitats, because soil is exposed to and eventually receives essentially all microbes present on earth. Some of these species are present in low numbers, probably because the conditions for their survival and growth are restricted to discrete sites where the nutritional and other physicochemical environmental factors necessary for their establishment, growth, and survival are located. This is one of the results of a structured environment with a high solid:liquid ratio. Consequently, on the basis of the numbers and diversity of microbes in soil, soil appears to be a good habitat for microorganisms (*good* being an anthropocentric concept) despite the apparent limitations for their survival and growth, probably because microbes indigenous (autochthonous) to soil are well adapted to this relatively austere environment. However, many exogenous microbes are not naturally adapted to and do not survive in soil. Most microbes indigenous to soil are oligotrophic or zymogenic, which may explain their higher numbers and greater diversity than in other habitats that are more copiotrophic (e.g., skin, oral and vaginal cavities, gastrointestinal and urinary tracts) and why many species from these habitats do not apparently establish, grow, and survive well in soil.

Microorganisms, perhaps more than any other organisms, are highly adaptable, both physiologically and genetically. They have to be as they have been around for more than 10^9 years. In addition, soil obviously selects and enriches for some microbes, and there is a homeostasis in soil that has probably existed for millions, if not billions, of years. It is this homeostasis that human beings are constantly attempting to alter for their presumed benefit (e.g., enhanced production of food and fiber). These alterations have involved primarily inoculation of soil (e.g., with *Rhizobium* sp., including genetically modified strains, to enhance nitrogen-fixation by legumes; with mycorrhizal fungi to enhance the uptake of phosphorus by plants; with white-rot fungi to enhance degradation of toxic and persistent organic pollutants; and with a variety of rhizobacteria and other microbial antagonists of soilborne, root-infecting pathogens).

Although some of these inoculations have been successful and appeared promising in the laboratory and even in the greenhouse, they have generally been less successful in situ, especially in the long term, probably because the emphasis has been directed toward altering — presumably improving — the physiology of the microbes. This emphasis incorrectly assumes that the

physiological characteristics of microbes, which have evolved for millions of years and have adapted to and have been selected by the soil environment, can be changed significantly to improve their establishment, growth, survival, and desired activities in soil. Even when microbes have been genetically engineered, which presumably simulates millennia of evolution, their survival in soil is seldom improved. In the case of genetically modified organisms, the introduced genes usually code for catabolic functions (e.g., degradation of xenobiotics), for markers (e.g., antibiotic resistance, *lux* genes) that enable monitoring their persistence in soil, or for some product (e.g., the insecticidal toxins produced by subspecies of *Bacillus thuringiensis*). However, even in the presence of the specific substrates on which, for example, the products of catabolic genes function, which would presumably provide an ecological advantage to the modified organisms, the introduced genetically modified organisms seldom survive longer in soil than the unmodified parental strains (4–8).

Consequently, the major emphasis should not be on the physiology of potential inoculants but, rather, on the physicochemical characteristics of soil that affect the establishment, growth, survival, and activity of the inoculants, and that of indigenous microbiota, whose importance should not be minimized. For example, control of pathogens (the term *pathogen* is another anthropocentric concept) occurs naturally in soil as part of the normal competitive, antagonistic, parasitic, and predatory interactions between microbes, although often at levels below those desired by human beings. Most organisms that have been introduced into soil as biocontrol agents were originally isolated from soil (e.g., nematode-trapping fungi, antibiotic-producing actinomycetes, antagonistic rhizobacteria, *B. thuringiensis*) in which they were exerting some level of control. The large-scale in vitro cultivations of these organisms and their subsequent reintroductions into soil have been, for the most part, unsuccessful. This lack of success is probably because the physicochemical and biological factors that kept the indigenous organisms at some low level of activity also reduced their numbers and biocontrol activity to the same low levels shortly after their reintroduction into natural soil, either with or without the target pathogen (1,2,9).

The same phenomena have been observed for the introduction of microbes that, for example, degrade xenobiotics, fix nitrogen as either nodule-formers or free-living microorganisms, or establish mycorrhizal associations: the colonization and subsequent activity of these inoculants is not restricted by their physiology but by the physicochemical characteristics of the recipient soil. However, the possibility that in vitro cultivation of microorganisms changes their physiology so that they lose their ability to survive and grow in soil after reintroduction needs to be studied.

If the specific physicochemical characteristics of soil that control the growth and survival of individual species were known, it might be possible to manipulate those characteristics to encourage the growth of desirable microorganisms (e.g., nitrogen-fixers, biocontrol agents, degraders of xenobiotics) and discourage the growth of undesirable ones (e.g., pathogens of plants and animals), which is the ultimate purpose of studying microbes in soil and other natural habitats. Different physicochemical factors differentially affect different groups of organisms (e.g., bacteria vs. fungi) and even different species. Control of organisms in soil by the appropriate manipulation of these factors could decrease the use of pesticides, fertilizers, and other xenobiotics, which have numerous deleterious effects on the biosphere.

The importance and effects of the physicochemical factors of soil, both with respect to the soil microbiota in general (1–3) and, more specifically, to the transfer of genetic information among bacteria in soil (4–8), have been discussed in detail. Consequently, they will be discussed here in only general terms.

MICROHABITATS IN SOIL

Microorganisms can be considered to be aquatic creatures, and their metabolism in soil is restricted to sites where water is available. Hence, their distribution in soil is restricted essentially to sites that contain clay minerals because sand and silt do not retain water against gravitational pull. Clays, because of their surface activity (which results from their unique crystalline structure because they are essentially secondary minerals), retain water against gravitational pull. The water adjacent to their active surfaces and coordinated with charge-compensating ions on the clays becomes sufficiently ordered to form a quasicrystalline structure (i.e., the strong attraction of water molecules to the negatively and positively charged loci on clays and to their charge-compensating ions enhances the hydrogen bonding of adjacent water molecules). The ordering of this clay-associated water decreases with distance from the clay surface until a distance is reached at which water is no longer under the attraction of the clay and is susceptible to gravity (2).

Clay minerals do not generally exist free in soil but exist primarily as coatings, or cutans, on larger sand and silt particles or as oriented clusters, or domains, among these particles. The clay-coated particles cluster together, primarily as the result of electrostatic attraction between the net negatively-charged faces and the net positively-charged edges of clay, into microaggregates, which, in turn, cluster together to form aggregates that can range from 0.5 to 5 mm in diameter and are stabilized by organic matter and precipitated inorganic materials. These aggregates retain water, the thickness and permanence of which depend on the type and amount of clay and organic matter within the aggregates, and this water may form "bridges" with the water of adjacent aggregates. These aggregates or clusters of aggregates, with their adjacent water, comprise the microhabitats in soil wherein microbes function (3).

As a result of the discreteness of microhabitats in soil, interactions between microbes, both positive (e.g., commensalistic, protocooperative, mutualistic, synergistic) and negative (e.g., competitive, amensalistic, parasitic, predatory), probably occur less frequently and more sporadically than in habitats where water is continuous. Even when the pore space is saturated with the aqueous phase

or where water bridges among adjacent microhabitats occur, movement of bacteria among microhabitats may be restricted because the surface tension of the ordered water around aggregates may be too great to allow passive movement of cells or even active movement of flagellated cells. There is no convincing evidence that bacteria are flagellated in soil, although they may have the genetic capability to produce flagella when isolated from soil and cultured in liquid media or on agar. Moreover, if motility was important to the survival of bacteria in soil, all autochthonous species would probably be flagellated. However, filamentous fungi are able to cross pore spaces among microhabitats, even when the spaces are not filled with the aqueous phase. Filamentous fungi grow by apical and lateral extension of hyphae from a food- and water-base in a microhabitat, and because they translocate nutrients and water internally, they are essentially independent of the ambient nutritional and aqueous conditions of the ramifying mycelia. In addition, the hyphae are surrounded by water films in which bacteria, bacteriophages, nutrients, genetic material, and so on, can be transported from one microhabitat to another.

The conditions within a microhabitat can also affect microbial activities. A bacterium that sticks, if it sticks (discussed later), on a clay cutan or domain after its chemotropic attraction to adsorbed organic substances may be nutritionally deprived after it consumes the adsorbed substances, if it can use the adsorbed substances (discussed later) because it will be dependent on the rate of diffusion of new substances for its nutrition. If the adsorbed substances to which it was attracted are toxic, the bacterium may die (3).

The mechanisms by which organic molecules are bound on clay will determine the tenacity with which they are held and the ability of microbes, usually with the aid of extracellular enzymes, to use these molecules as substrates. The presence of chaotropic ions (which decrease the structure of water and tend to disrupt hydrophobic interactions by increasing the accommodation of nonpolar compounds in aqueous solutions) and of antichaotropic ions (which increase the structure of water and, thereby, increase hydrophobic interactions by reducing the ability of aqueous solutions to accommodate nonpolar groups) will affect the nutritional status of the microhabitat. Although clay cutans and domains are relatively stable, some clay particles may become dislodged and get attached to the surface of microbes in the microhabitat. Such attachment reduces the effective surface area of microbes for transmembrane transfer of nutrients inward and of waste products outward (3,10).

In addition to their discreteness, microhabitats in soil are highly variable and heterogeneous. This heterogeneity is a result of the heterogeneity of the surfaces, which are coated, partially or completely, with clay minerals, hydrous metal oxides, and organic matter with pH-dependent and pH-independent charges (11), and of fluctuations in the types and concentrations of organic and inorganic solutes in the soil solution (1–3). Even over small distances, the composition and size of the particles, the amounts and types of solution, nutrients, and gases, and the pH, E_h, ionic strength, and other physicochemical characteristics can vary. This variability in abiotic factors is reflected in the heterogeneity of the microbiota, which is demonstrated by the simultaneous occurrence in the same soil sample of autotrophs and heterotrophs (both oligotrophs and copiotrophs), aerobes and anaerobes, vegetative cells and spores, prokaryotes and eukaryotes, and cells with different requirements for and tolerances to ambient and extreme conditions of pH, E_h, temperature, osmotic pressure, and so on.

These conditions in soil differ markedly from those in sediments of aquatic systems. Although clay minerals in sediments also occur as cutans on larger particles and as domains in aggregates, water-dependent microhabitats probably do not occur as they do in soil, because the water in sediments is continuous from one aggregate to the next. Moreover, microbes in sediments appear to colonize primarily sand and silt particles, rather than clay, because water surrounds these particles, and the need to overcome the electrokinetic repulsion between net negatively charged clay minerals and microbial cells is reduced or eliminated (2).

It is the task of the soil microbiologist to determine the abiotic and biotic factors that control the activity and population dynamics of microorganisms in soil and to devise methods for manipulating the responsible factors to enhance or attenuate the activities of specific components for some desired anthropocentric benefit. A brief discussion of each physicochemical or biological factor follows, along with speculations on how it may be manipulated. These discussions and speculations are not intended to be exhaustive (1,2). Because of limitations in space, references are primarily to reviews in which citations of numerous relevant original papers can be found. In addition, some recent texts on soil microbiology and microbial ecology, which provide more information on the effects of the physicochemical and biological characteristics of soil on microbial processes, are referenced (12–22), as is the classic volume of Brock (23) on microbial ecology.

FACTORS

Carbon and Energy Sources

Although most soils contain considerable amounts of organic matter, much of this material is relatively unavailable as a source of carbon and energy because it has been humified. The addition of a source of readily available carbon, such as fresh plant residues (green manures), bagasses, or sugars, will enhance the growth of the microbiota until the available carbon has been mineralized and the activity and density of the microbiota declines to its original level. Although this stimulation of the microbiota is generally nonspecific, it may result in the degradation of some recalcitrant materials (e.g., some xenobiotics), as a result of a general "priming action," and in some biocontrol of soilborne plant pathogens (1,2). The addition of specific compounds that only desired members of the microbiota can use could enhance degradation, biocontrol, and other beneficial activities. Unfortunately, compounds with such specificity have not been identified,

and many indigenous microbes share the same enzymatic capabilities. Nevertheless, the ability to enhance, even if only temporarily, the growth and survival in soil of genetically modified bacteria by amending the soil with the specific substrates on which the products of the novel genes function suggests that this use of substrates for enrichment of specific indigenous microbes should be explored further (4,8).

Mineral Nutrients

As with carbon and energy sources, most soils contain sufficient total amounts of mineral nutrients, but most are present in unavailable forms. The sequence of requirements of the major inorganic nutrients for optimum microbial growth is N > P > S (1,2). Fertilization of soil with these nutrients will enhance growth but usually nonspecifically. In some cases, too much of a mineral nutrient will suppress the growth or activity of a desired population. For example, the presence of elevated amounts of inorganic nitrogen will inhibit the lignolytic activity of *Phanerochaete chrysosporium* (24). The addition of materials with a high C : N ratio (e.g., saw dust, corn cobs) to immobilize the inorganic nitrogen may be an effective and inexpensive method to enhance the activity of this fungus and its degradation of various recalcitrant xenobiotics (9).

Growth Factors

Because the requirements for specific growth factors differ for different species, the addition of such factors may enhance the growth of desired species better than the addition of nonspecific carbon and energy sources. Unfortunately, too little is known about the specific requirements for the growth factors of specific species, although vitamin B_{12} (cyanocobalamin) and various siderophores (which are here considered to be growth factors) are good candidates. It is unfortunate that the early studies by Lochhead and colleagues (25,26) on the effects of growth factors on microbial events in soil have not been extended. However, even if specific growth factors for specific components of the soil microbiota can be identified, their persistence and activity in soil may be limited; for example, they may be rapidly mineralized, as are other added organic molecules, or, in the case of siderophores, they may bind on surfaces, such as clay minerals, and not perform their function (27).

Ionic Composition

The soil solution is essentially a weak electrolyte composed of a variety of organic and inorganic cations and anions. Because the interface between microbial cells and the soil solution is essentially ionic, even small changes in ionic composition and strength probably have a significant effect on the growth and activity of the microorganisms and on the binding of organic compounds on surfaces. Unfortunately, not enough is known about how the ionic composition of soil affects specific organisms to suggest the manner in which the ionic composition can be manipulated beneficially. However, care must be taken in any such manipulation because large changes in ionic composition may alter the osmotic pressure and the availability of water.

Available Water

Perhaps the most important physicochemical factor that affects microbes in soil is an adequate supply of available water. Microbes are essentially aquatic organisms and even in soil require a sufficiently high water activity (a_w) for growth. Except for short periods after rain, snow melt, flooding, or irrigation, soils usually contain insufficient available water to support a high level of microbial activity because the water is rapidly drained by gravity. The clay fraction has a major role in water retention because of its high surface charge, which holds water against gravity, and this bestows some stability to microbes present in this water. Consequently, the apparent correlation between microbial activity and the amounts and types of clay in soil may be the result primarily of the fact that this is where water is located, and the presumed importance of clays in concentrating nutrients, removing inhibitors, direct surface interactions, and so on, may be only secondary (2). However, some of the water retained by clay is so tightly bound that its a_w is too low for use by microbes (e.g., temperatures in excess of 160 °C are necessary to remove this water). The amount of such tightly bound water depends on the structure of the clay minerals: for example, 2 : 1, Si:Al clays (e.g., smectites) bind water much more tightly than 1 : 1 clays (e.g., kaolinite) (i.e., the matric potential of smectites is higher). Consequently, the total amount of water present in a soil (as determined by drying) or the amount of water that a soil can hold (the water-holding capacity) does not indicate accurately the amount of water available to microbes. Microbes function best at a water potential of −33 kPa (which is close to the field capacity, defined as the amount of water retained by soil 48 hours after its saturation), in which no more water will be removed by gravity and the balance between the amounts of available water and oxygen is optimum for growth (28). This water potential is most easily determined with a pressure plate extractor.

Particulate organic matter also retains ordered water, primarily as a result of the polar groups on the organic matter. This water is also tenaciously held and not all of it is available to microbes. For example, the water-holding capacity of an organic soil (85% organic matter) was 262% (w/w), but only when the water content was at the −33-kPa water tension of the soil (157% w/w) was the a_w sufficiently high for significant microbial activity (1–3). Moreover, drying of soil can render the organic matter difficult to rewet, as a result of its structural reorientation and exposure of hydrophobic regions. This development of hydrophobicity can also cause clay-organic aggregates to become difficult to rewet (29).

Different groups of microbes have different tolerances to a_w (e.g., fungi can metabolize at a significantly lower a_w than can bacteria). The water content of soil is easily controlled by irrigation, but “fine-tuning” of the manipulation of this physicochemical factor for the differential control of microbes will require considerably more study. In many cases, the effects on microbes of

changes in the water content of soil are the result of changes in the oxygen content.

Temperature

Extremes in temperature can result in the majority of the indigenous microbial populations being psychrophilic or thermophilic, depending on the geography of the soil. However, most soils worldwide contain predominantly mesophilic microbes. Regardless of the geographic location of the soils, the temperature of the soil at the surface, a few centimeters from the top, where most of the microbial activity usually occurs, does not fluctuate more than a few degrees centigrade in any season of the year. Consequently, the temperature of soils in situ cannot be conveniently manipulated for extended periods. Although the heating of soil for the control of some plant pathogens (e.g., solar heating or steam after covering the soil with black plastic) can be accomplished relatively easily, this is generally a nonspecific treatment because essentially all indigenous microbes are inhibited and then return to their original population levels after the soil reverts to its normal temperature range. These sites are then naturally inoculated with the same microbes, both pathogenic and nonpathogenic, from adjacent areas. To achieve long-term control, usually requiring the elimination or reduction of specific populations, other critical changes in the physicochemical characteristics of the soil (e.g., change in the clay mineralogy) need to be made before heating.

Pressure

Changes in atmospheric pressure are probably too small to affect the soil microbiota significantly, and the overall solute concentration of normal soil solutions is usually not high enough to suggest that osmotic pressure inhibits the microbiota. However, the osmotic pressure may increase sufficiently to affect some microbes within microhabitats where the solute levels are probably higher because of their concentration at solid–liquid interfaces, especially at charged surfaces, and during periods of drying. This is especially true in saline and alkaline soil. Most microbes in soil are probably stenohaline and, therefore, susceptible to damage by hypertonic osmotic pressures. Moreover, marked increases in solutes will affect the osmotic potential of water and decrease its availability. Altering the osmotic pressure of soil by the addition of organic or inorganic solutes is relatively easy. Some years ago, control of nematodes in soil was achieved by the addition of copious quantities of molasses, presumably because of the increase in osmotic pressure (W. Feder, personal communication). However, because large changes in solute concentrations can affect numerous other physicochemical characteristics (e.g., available water, pH, oxygen content, and mineral nutrients if the solute can be used as a carbon source), caution is recommended when the manipulation of this factor for the control of microbes in soil is considered, especially as the effects may be nonspecific.

Atmospheric Composition

Because air and water share the same pore space among microhabitats, the atmospheric composition in soil can be easily manipulated, at least on an overall gross basis, by altering the water content. Flooding has been used in an attempt to control some soilborne fungal pathogens of plants (e.g., Fusarium wilt of banana) because most filamentous fungi are obligate aerobes (2). However, the various spores of fungi, especially chlamydospores, appear to be able to resist long periods of anaerobiosis, and when the soil subsequently becomes aerobic again, the spores germinate and reestablish the fungal colonies. Moreover, many fungi — especially, but not restricted to, pathogens of animals — are dimorphic and can persist in the yeast form under anaerobic conditions.

The addition of large quantities of available substrates will also reduce the amount of oxygen and increase the levels of carbon dioxide in the soil. However, even under "normal" conditions, the content of carbon dioxide is higher and that of oxygen is lower in soil than in the overlying atmosphere, as a result of microbial metabolism and the slow diffusion rate of these gases. Even in well-aerated soils, anaerobic sites are present, as indicated by the ability to isolate obligate anaerobes from such soils. In addition to O_2 and CO_2, other gases (e.g., CH_4, NO_x) and volatiles (e.g., short carbon-chain organic acids, aldehydes, alcohols, esters, hydrocarbons, ethylene) are present in the atmosphere of soil and can serve as either substrates for or inhibitors of microbes (30,31).

Manipulation of the soil atmosphere for the control of specific components of the microbiota is the basis of the fumigation of soil with a variety of xenobiotics. In many cases, however, the effects of these pesticides are transient, and they often affect nontarget organisms also. Nevertheless, manipulation of the soil atmosphere appears to have a good potential for controlling specific portions of the microbiota in soil, especially if it can be fine-tuned and coupled with the manipulation of other physicochemical factors to enhance the duration of its effects.

Electromagnetic Radiation

Although light probably affects only microbes residing on the surface of soil, it can be important in arid and semiarid soils in which photosynthesis in algal crusts, both prokaryotic and eukaryotic, is probably the major source of carbon and energy (32). In such environments, resistance to ultraviolet radiation (e.g., pigments) is probably necessary. Microbes residing below the soil surface do not generally have such resistance, and manipulation of the soil that periodically exposes these microbes to direct solar radiation (e.g., cultivation) can exert some control, although relatively nonspecific, on the microbiota. Although radiation is a physicochemical factor of major importance in aquatic environments, it is generally of minor importance in soil and, hence, difficult to manipulate for the control of specific species.

pH

The hydrogen ion (H^+) concentration is a major physicochemical characteristic of soil that is amenable to manipulation in situ. In general, fungi predominate in acidic soils (below pH 5.5), whereas most eubacteria, including actinomycetes, predominate in near-neutral or moderately

alkaline soils. The apparent lower numbers of fungi in the latter soils is not because fungi are intolerant to these pH values but because bacteria are efficient competitors at these pH values and prevent the establishment and proliferation of fungi. In contrast, the lower numbers of bacteria in acidic soils is the result of their intolerance to the elevated concentrations of H^+ that fungi can tolerate, and therefore, the fungi can proliferate in the absence of bacterial competition. In addition to numerous effects of pH on a spectrum of physiological, morphological, and metabolic responses of the microbiota, the pH also affects the solubility, availability, and toxicity of mineral nutrients; the speciation of heavy metals (33); the sign of the net surface charge of amphoteric molecules and the negative charge of ionizable molecules, which will affect the adsorption and subsequent binding of cells and organic molecules on surfaces and, hence, their availability as nutrients and their bioactivity (2); and numerous other phenomena. Manipulation of the pH of soil is done routinely, although primarily to enhance the growth of plants, by the addition of lime, to raise the pH, or of gypsum or some other relatively inexpensive source of sulfur, to reduce the pH. A prime example of the manipulation of the pH of soil for biological control is the reduction in pH to control the scab of potato caused by *Streptomyces scabies*.

Oxidation-Reduction Potential

The E_h of soil is related primarily to the oxygen content of soil and, therefore, can be manipulated, to some extent, by cultural practices (e.g., cultivation, irrigation, improvement of drainage) (34). The E_h is also influenced by pH, temperature, pressure, and nutrients. The ability to isolate aerobes, facultatives, and anaerobes (including fermentors, methanogens, and sulfate-reducers) from the same soil sample indicates that microhabitats that differ in E_h by approximately 1,000 mV (e.g., from +700 to −300 mV) can coexist in the same soil. Consequently, fine-tuned manipulation of the E_h of soil to control specific components of the microbiota would appear to be difficult.

Surfaces

Some aspects of the importance of surfaces, especially those of clays, to microorganisms and their activities in soil were discussed earlier. The type of clay present in soil has been shown to have a profound influence on numerous microbial activities in soil (e.g., growth; heterotrophic, autotrophic, and mixotrophic metabolism; organic and inorganic nutrition; spore germination; competition, amensalism, predation, and parasitism; transfer of genetic information; pathogenesis) and provides protection against the toxicity of acid precipitation, heavy metals, organic compounds, gases, volatiles, hypertonic osmotic pressures, elevated temperatures, desiccation, ultraviolet light, and X rays (2). How clays affect these activities is not always clear. In many cases, the effects of clay appear to be indirect by modifying other physicochemical characteristics of the microhabitats (e.g., pH, water potential, nutritional status, activity of toxicants), which either enhances or attenuates the growth and metabolic activities of individual population, which in turn, influence the growth and activities of other populations. The indirect nature of these effects has been demonstrated in studies in which the same results were obtained whether or not the clays and the microbes were separated by a dialysis membrane (2).

The demonstration of direct effects, which involve surface interactions (e.g., adhesion) between clays and microbes, is more difficult. There is empirical evidence to suggest that such surface interactions occur in situ: for example, lack of movement of large numbers of microbes from surface to underlying soil layers and then to groundwater during heavy rains, snow melts, flooding, or irrigation; failure to wash substantial amounts of microbes from soil columns in perfusion or leaching experiments; partial removal of microbes from wastewater in percolation beds; increased release of microbes from soil by sonication, surfactants, and other methods to enhance the number of microbes enumerated. However, there is limited evidence for such surface interactions from carefully controlled studies (e.g., using electron microscopy and changes in particle-size distributions to detect surface interactions) (2). Moreover, on theoretical grounds, direct surface interactions are difficult to understand because the high electrokinetic potentials, of the same net negative charge, on both clays (and humic substances) and cells at the pH of most soils mitigate against such interactions. In fact, such surface interactions can be demonstrated only: (*1*) when the pH is lowered to levels at which most microbes cannot grow (e.g., pH 2 to 3) and the net charge on the microbes (and of some clays and humic substances) becomes positive, whereas the net charge on most clays remains negative because the charge is independent of pH and results from isomorphous substitution within the crystal structure; (*2*) when the electrokinetic potentials of the clay and microbes are reduced by polyvalent cations; or (*3*) when the net charge is reversed to positive at higher pH values (e.g., pH 6 to 8) by the first hydrolysis product of some heavy metal ions (2,35,36). These conditions seldom occur in soil. Moreover, as indicated earlier, it may be detrimental to a microbe if it sticks to a clay-containing aggregate. Consequently, microbes probably reside in the relatively permanent water films associated with such aggregates rather than on the surface of the aggregates. However, the apparent lack of movement of microbes through soil may be the result of hysteresis rather than of direct surface interactions.

Similar questions must be asked about the binding of organic molecules on clay. Because of their small size relative to microbial cells, organic molecules bind on clay, not only by ionic interactions, which are also dependent on the ambient pH and the isoelectric point of amphoteric molecules and the pK of nonampholytes, but also by multiple hydrogen bonds. Although such binding serves to concentrate these molecules at the solid–liquid interface, it also reduces their availability to microbes. Numerous studies of proteins, peptides, amino acids, polysaccharides, nucleic acids, nucleotides, and other organic molecules bound on clay minerals have demonstrated such resistance to biodegradation (2). Despite this resistance to biodegradation, the activity of some of these biomolecules [e.g., enzymes (11,37,38),

transforming DNA (39–42), insecticidal proteins from subspecies of *B. thuringiensis* (43–46)] is not eliminated, although it is usually reduced. Similar relations among binding, degradation, and activity have been reported for antibiotics and other inhibitors (2).

In contrast to organic molecules, inorganic ions on clays are readily exchangeable and can be used as nutrients by microbes. In addition, clays can scavenge H^+ and toxic heavy metal ions by cation and anion exchange and, thereby, reduce their toxicity (2,33,47).

The incorporation of mined clay minerals into soil, especially of montmorillonite (smectite), can affect the establishment, proliferation, and activity of fungal pathogens of plants and animals (i.e., help convert "conducive" to "nonconducive" soils; 2,48), probably by affecting the growth of and competition by bacteria and by binding siderophores necessary for the iron nutrition of the fungi (27). Although such changes may initially appear to be positive, the numerous direct and indirect effects that clay minerals have on many other physicochemical characteristics of soil and, therefore, on the soil microbiota indicates that all possible permutations of altering the clay mineralogy of a soil — a relatively permanent change — should be carefully evaluated before such additions of clay are made.

Many of the effects attributed to clay are probably also caused by organic particles [e.g., humic substances (49,50)] in soil because they share some of the characteristics of clay (e.g., high specific surface area and activity, ion-exchange capacity). However, because these substances are difficult to extract, purify, and characterize, these effects have been insufficiently studied. Moreover, because of their organic nature, the permanence of these particles generally is less than that of clay. However, the association of humic substances with clays and hydrous metal oxides probably increases their persistence in soil (51). Nevertheless, less concern is necessary, compared with clay, before the amount of organic surfaces is increased by the incorporation of plant and other organic residues into soil, as the permanence of such surfaces is more transient because of their susceptibility to biodegradation. However, the relative importance of surfaces of organic matter to microbial events in soil is not as well understood as that of clay.

Because of the profound and multifaceted effects that surfaces, both inorganic and organic, have on microbes in soil, their manipulation for the control of specific portions of the soil microbiota should be extensively investigated.

Spatial Relations

The spatial relations between microbes in soil are primarily influenced by the structure of the microhabitats, as discussed earlier. Although some cultural practices (e.g., cultivation, irrigation) affect these relations, these effects are probably nonspecific and transitory. Hence, manipulation of spatial relations may not be an easy or effective way to control specific microbes in soil.

Characteristics of the Microorganisms

As indicated earlier, autochthonous microbes in soil are highly adaptable, both physiologically and genetically, and they have established a homeostasis in soil. Until recently, attempts to alter this homeostasis have generally been unsuccessful. However, it is now possible to alter the genetics of microorganisms and to introduce these genetically engineered organisms to soil for performing specific functions. However, introduction is not always followed by establishment (i.e., colonization), growth, and survival of the altered organisms. Consequently, until the physicochemical characteristics of soil can be manipulated to ensure a significant and extended expression of the introduced genes, any effects of these genes will be transient. If and when such manipulation becomes possible, other problems, such as the transfer of the genes to the indigenous microbiota, which is probably more adapted to the soil environment than the introduced organisms, and potential ecological and health hazards of the products of the novel genes, need to be considered. Inasmuch as these and other aspects of the release of genetically altered organisms to the environment have been extensively discussed (4–8,42,52,53), they will not be discussed further here.

Interactions Between Microorganisms

Although the physicochemical factors briefly discussed earlier influence the growth and survival of microbes in soil, interactions, primarily negative ones, between microbes within a microhabitat have a marked effect. For example, there are numerous studies that show the survival and growth of a spectrum of microorganisms in sterile soil, including genetically engineered and nonengineered microbes and microorganisms that are not autochthonous to soil, whereas the same organisms do not survive or grow when introduced into the same soil when it is not sterile (4,5,8). Although various positive, negative, and presumably neutral interactions between and among microorganisms have been demonstrated, most studies have been conducted with model systems consisting only of a few species of interacting organisms. Inasmuch as the microhabitats in soil are heterogeneous and their inhabitants also display a high degree of heterogeneity, numerous interactions between inhabitants are undoubtedly occurring simultaneously and are in constant flux. By understanding the specific physicochemical factors that affect positive and negative interactions, it might be possible to manipulate these factors to enhance natural biocontrol of desired and undesired microbes.

CONCLUSION

Increased knowledge of how individual physicochemical factors affect microbes in soil may provide some clues as to the way in which such factors can be manipulated. Unfortunately, there have been few concerted research efforts to determine the influence of these factors, either alone or in various permutations, on organisms in soil, primarily because of the reluctance of funding agencies to support such basic research. Such support could reduce the nonproductive expenditures for trial-and-error (empirical) studies and produce important, unique, and focused information on the factors that control microbial activities

not only in soil but also in other microbial habitats, including animal systems. However, it is obvious that a change in one factor will result in changes in numerous other factors and that this cascade of changes may either augment or cancel the initial effect. Most of the factors, which are constantly fluctuating, are interrelated and, therefore, must be studied, understood, and manipulated in concert. In addition, the presumed effects of such changes must be carefully and critically evaluated (54). For example, the failure to recover an introduced microorganism from soil, especially from nonsterile soil, may only reflect a "viable but nonculturable" stage of the organism. Microorganisms in soil, especially introduced organisms, sometimes become so debilitated or otherwise altered that they cannot be recovered, especially on selective media, although they could be surviving and possibly even growing in soil (4). Consequently, it must be clearly and unequivocally established that the apparent lack of survival and growth is not an artifact of the experimental procedures.

Although soil is a fundamental environment because entire food webs ultimately depend on it, there is still much to learn about soil as an environment for microbial life. There is a plethora of questions, many of which are old but still unresolved and complex. Although some concepts and techniques of molecular biology will undoubtedly be helpful in answering some of these questions, it would be imprudent to forget and not to use older tested methods (e.g., respirometry, assays for enzymes and ATP, plating on selective media, X-ray diffractometry, Fourier-transform infrared spectrometry, electron microscopy, measurement of surface charges). In many cases, the methodology is secondary to asking the pertinent questions. Moreover, it must be remembered that because of the complexity of soil, the concepts and techniques of microbiology, chemistry (ranging from biochemistry to inorganic and physical chemistry), physics, mathematics, and agronomy, in addition to those of molecular biology, must be invoked.

Although the use of molecular techniques has provided new information on the microbiology of soil (22), there is no convincing evidence that the amount and value of this information is commensurate with its cost. Moreover, many paradoxes need to be resolved concerning the relations between these and more classical techniques. For example, the use of DNA probes and immunology is extremely helpful in monitoring the fate and ecology of individual species in soil. However, these techniques require that the species be cultured to obtain their DNA or antigens. The use of the polymerase chain reaction, DNA-DNA hybridization, flow-cytometry, or other methods to measure antigen–antibody reactions, and soon are secondary to being able to culture the organisms in vitro. Inasmuch as only 1 to 10% of the soil microbiota can presumably be cultured, the number of species that can be monitored is limited. Similarly, although 16S rRNA analyses can provide valuable information on changes in the apparent diversity of species of microbes in soil over time, culturing these species will eventually be necessary to identify them. Culturing helps to establish databases relating the RNA patterns to identifiable species, as well as the study of their physiology, functions, production of potential valuable (anthropocentric) metabolites, and so on. Despite these current limitations of molecular techniques in answering many relevant questions relating to microbial life in soil, the application of these techniques, in conjunction with other techniques and with posing correct and relevant questions, should provide much valuable information in the future (3).

In a time when tremendous advances are being made in many biomedical areas, similar advances must be made in the sustained production of food and fiber, especially in many parts of the world where production is too low to sustain the high and burgeoning human population. Many of the current advances in biomedical research have limited impact in these parts of the world because an adequate source of nutrients is the primary limiting factor to human life. Because of the fundamental role of microbes in the production of food, this limit to human life can only be solved by increasing the knowledge of the factors that affect soil as an environment for microbial life.

Acknowledgments

Most of the discussed studies from the author's laboratory were supported, in part, by grants from the U.S. Environmental Protection Agency (most recently R826107-01), the U.S. National Science Foundation, and the NYU Research Challenge Fund. The opinions expressed here are not necessarily those of the Agency, the Foundation, or the Fund. Sincere appreciation is expressed to colleagues and students who contributed greatly to these studies.

MICROSPORIDIA: BASIC BIOLOGY

ELIZABETH S. DIDIER
LINDA C. GREEN
Tulane Regional Primate Research Center
Covington, Louisiana

The microsporidia are single-celled, obligately intracellular eukaryotic organisms that have caused significant economic losses in agricultural industries, have interfered with biomedical research, and are recently emerging as etiologic agents of disease in mammals, including humans. *Nosema bombycis* was the first named microsporidian and was identified by Nägeli in 1857 as the cause of pébrine (pepper) disease in the silkworm, *Bombyx mori* (1). *Encephalitozoon cuniculi* Levaditi, Nicolau, and Schoen 1923 was the first mammalian microsporidian described by Wright and Craighead in 1922 as causing motor paralysis in rabbits (2,3), and three *Encephalitozoon*

Table 1. Species of Microsporadia Identified in Humans

Species	Sites of Infection
Brachiola vesicularum Cali, Takvorian, Lewin, Rendel, Sian, Wittner, Tanowitz, Keohane, and Weiss 1998	Cornea, skeletal muscle
Brachiola connori (syn. Nosema connori) Sprague 1974	Disseminated
Encephalitozoon cuniculi Levaditi, Nicolau, and Schoen 1923	Disseminated
Encephalitozoon hellem Didier, Didier, Friedberg, Stenson, Orenstein, Yee, Tio, Davis, Vossbrinck, Millichamp, and Shadduck 1991	Disseminated
Encephalitozoon intestinalis(syn. *Septata intestinalis*) Cali, Kotler, and Orenstein 1993	Disseminated
Enterocytozoon bieneusi Desportes, Le Charpentier, Galian, Bernard, Cochand-Priollet, Laverne, Ravisse, and Modigliani, 1985	Duodenum, jejunum, bile tract
Microsporidium africanum Canning and Lom 1986	Cornea
Microsporidium ceylonensis Canning and Lom 1986	Cornea
Nosema algerae Vavra and Undeen 1970	Cornea
Nosema ocularum Cali, Meisler, Lowder, Lembach, Ayers, Takvorian, Rutherford, Longworth, McMahon, and Bryan 1991	Cornea
Pleistophora sp.	Skeletal muscle
Trachipleistophora anthropophthera Vávra, Yachnis, Shadduck, and Orenstein 1998	Disseminated
Trachipleistophora hominis Hollister, Canning, Weidner, Field, Kench, and Marriott 1996	Skeletal muscle, nasal sinuses
Vittaforma corneae (syn. *Nosema corneum*) Shadduck, Meccoli, Davis, and Font 1990	Cornea, urinary tract

species have been commonly reported to infect laboratory animals, farm animals, and companion pets (4–7). In humans, microsporidiosis was first documented in 1959 in a nine-year-old boy with headaches, fever, and convulsions (8). Since 1985, microsporidiosis has been recognized as an opportunistic infection associated with persistent diarrhea and systemic disease in immunocompromised individuals, particularly in persons with AIDS, organ transplant recipients, and malnourished children (7–12). In addition, microsporidiosis has been attributed as a cause of traveler's diarrhea. (10,13,14). To date, of more than 1,200 species of microsporidia, 14 have been identified as causing infections in humans (Table 1). The most commonly encountered species that infect humans include *Enterocytozoon bieneusi* Desportes, Le Charpentier, Galian, Bernard, Cochand-Priollet, Laverne, Ravisse, and Modigliani 1985, which is primarily associated with persistent diarrhea, and the *Encephalitozoon* species, *Encephalitozoon cuniculi*, *Encephalitozoon hellem* Didier, Friedberg, Stenson, Orenstein, Yee, Tio, Davis, Vossbrinck, Millichamp, and Shadduck 1991, and *Encephalitozoon intestinalis* (syn. *Septata intestinalis*) Cali, Kotler, and Orenstein 1993, which commonly cause systemic disease (7,15–18). This article purports to describe the biology of these microsporidia in relation to public health.

CLASSIFICATION

Nosema bombycis Nägeli 1857, the first named microsporidian, was originally classified with the Schizomycetes and included yeasts and bacteria. The order Microsporidia Balbiani 1882 was then created, and the microsporidia were later placed into the phylum Microspora Sprague 1977 of the subkingdom Protozoa within the kingdom Protista in 1980 (1,19). In 1998, Sprague changed the phylum name to Microsporidia Balbiani 1882 (20).

The taxonomy of the microsporidia has been based on the life cycle and ultrastructural characteristics such as size of the developing and mature organisms, nuclear arrangement (monokaryon or diplokaryon), the array and number of polar filament coils, interface with the host cell during development (e.g., direct contact with host cell cytoplasm, replication within a host cell–derived parasitophorous vacuole and replication of organisms surrounded by endoplasmic reticulum), the process of sporogony (occurring in the absence or presence of a sporophorous vesicle and the number of sporoblasts generated per sporont), and mode of cell and nuclear division (binary division and karyokinesis with delayed cytokinesis) (4,5,21). Opinions, however, tend to vary for classifying the microsporidia below phylum levels on the basis of structural characters (21).

Structure

Spore and Spore Wall. The spore is the mature and infectious stage of the microsporidia. Spores vary in shape from spherical to oval or rodlike. Mammalian microsporidian spores tend to be smaller, measuring 1.5–4.0-μm long and 1–3-μm wide, whereas some microsporidian species that infect fish, for example, may be as long as 40 μm (5,7,21). Unstained microsporidian spores appear refractile and green under light microscopy.

The general structural features of a typical mammalian microsporidian spore are shown in Figure 1. Each microsporidian spore is enclosed by a three-layer wall that protects the organism from the environment (21,22).

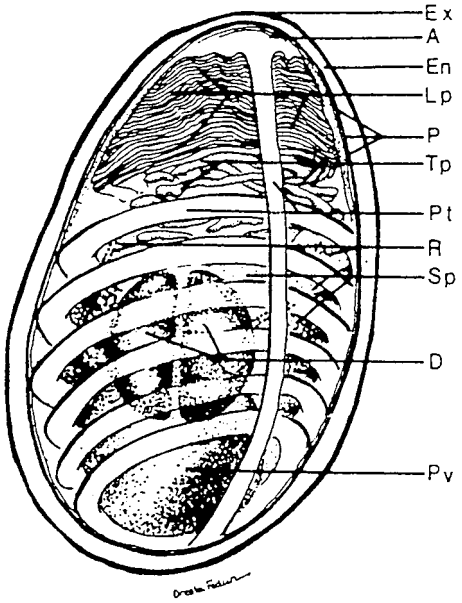

Figure 1. Diagram of a microsporidial spore. The spore wall consists of an electron-dense exopsore (Ex), an electron-lucent endospore (En), and a unit membrane (P). The extrusion apparatus includes an anchoring disc (A), polar tubule (Pt), lamellar polaroplast (Lp), and tubular polaroplast (Tp). Posterior vacuole (Pv), ribosomes (R), sporoplasm (Sp), and nucleus (D) are shown. Reprinted by permission of the publisher from A. Cali and R. L. Owen, in The Laboratory Diagnosis of Infectious Diseases: Principles and Practice, A. Balows, W. Hausler, Jr., and E. H. Lennette, eds., Springer Verlag, New York, 1988, pp. 928–949.

The outer electron-dense exospore is composed primarily of (glyco)proteins and varies in thickness (10–200 nm) and complexity (unstratified or multilayered). The middle electron-lucent endospore is approximately 100-nm thick (though slightly thinner in *E. bieneusi*) and is composed of an α-chitin based on infrared spectroscopy and X-ray diffraction studies (21). Fluorescent brighteners such as Calcofluor White M2R, Uvitex 2B, and Fungifluor have a high affinity for chitin and stained microsporidia fluoresce bright white or turquoise (23–26). The endospore is relatively thin at the apex or anterior region of the spore from where the polar filament everts during germination. The innermost layer of the spore wall is a trilaminar plasma membrane that encloses the spore cytoplasm (21).

Polar Filament/Tube. The polar filament, also referred to as the polar tube, is a tube coiled within the mature spore and is the structure that defines an organism as being a microsporidian (4,28,29). The function of the polar filament is to facilitate infection so that during germination, the polar filament everts or turns inside out and propels the contents of the spore into a host cell (30–33,41). The polar filament arises from the anchoring disc-polar sac complex at the anterior end of the spore and forms coils at the posterior region of the spore (21). The arrangement and number of polar filament coils varies among species and has been used as an aid for classification. A double-array of approximately six coils of the polar filament is characteristic of *E. bieneusi*, whereas a single-array of four to eight polar filament coils is typically observed in mature spores of the *Encephalitozoon* species.

The polar filament is generated from the endoplasmic reticulum and Golgi-like vesicles (21,34–38). In the mature spore, the polar filament is surrounded by a membrane, is filled with electron dense unassembled polar tube proteins(s), and consists of several concentric layers around a central core when viewed by transmission electron microscopy (4,39–42). During discharge, the electron-dense polar tube proteins appear to assemble at the growing tip of the tube so that the polar filament appears like a cylinder within a cylinder (4,39,43). The polar tube is flexible and bulges as the cytoplasmic contents pass through (32,33,41,42). After germination, the extruded polar tube appears hollow and extends approximately 50–100 μm and is approximately 0.1–0.15-μm wide (28,33,42,44,45). An immunofluorescent antibody-stained *E. hellem* spore that has germinated and extruded its polar filament is shown in Figure 2.

Anchoring Disc-polar Sac Complex. The anchoring disc is found in the anterior-most portion or apex of the mature spore and is believed to anchor the polar filament during germination. The anchoring disc appears continuous with the outer covering of the polar filament, and the polar sac, which is filled with electron-dense material, is found in the central region of anchoring disc (21,38). This complex is the most carbohydrate-rich structure in the microsporidia and is responsible for the reason that microsporidia stain acid fast (37).

Polaroplast. Just posterior to the anchoring disc-polar sac complex and surrounding the base of the polar filament is an array of lamellar membranes called the polaroplast that occupies up to one-half the volume of the mature spore. The unit membranes of the polaroplast, polar sac, and polar filament appear to be generated through the same membrane system, and also are carbohydrate-rich (4,21,36). The polaroplast becomes the outer membrane of the sporoplasm that is the sac that becomes filled with the spore contents during and just after polar filament extrusion (32).

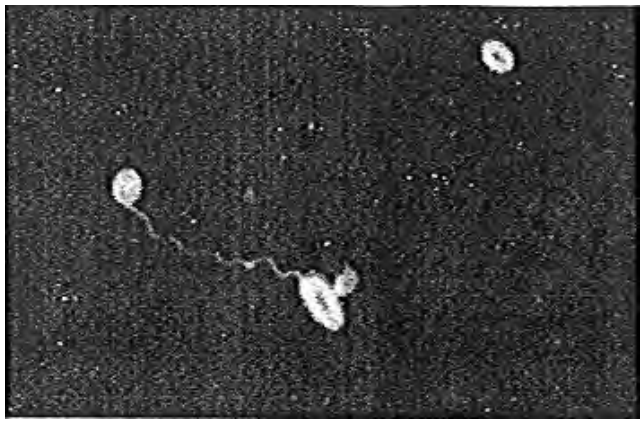

Figure 2. Immunofluorescent antibody-stained *E. hellem* germinated spore. The sporoplasm containing the spore contents is seen at the upper left end of the extruded polar filament. (X 600).

Nucleus. The microsporidian nucleus is found in the central region of the organism and is limited by a double-unit membrane separated by a perinuclear space typical of eukaryotes. The nucleus in microsporidia exists in a single nucleus structure, also termed the *monokaryon* (e.g., *Encephalitozoon, Enterocytozoon, Pleistophora*, and *Trachipleistophora*) or in a *diplokaryon* (e.g., *Brachiola, Nosema*, and *Vittaforma*) arrangement. The diplokaryon consists of two closely aligned nuclei that function as a single unit (4,29). Nuclei divide on mitotic spindles, but microsporidia lack centrioles (4,18). Although rarely observed in most stages, nucleoli may be seen just before spore formation (21).

Endoplasmic Reticulum and Ribosomes. Ribosomes are the predominant structures found in the cytoplasm of microsporidia, suggesting that a high rate of protein synthesis occurs in developing microsporidia (21). During merogony (parasite replication), the ribosomes are dispersed throughout the cytoplasm and during sporogony (parasite differentiation into spores), increasing amounts of endoplasmic reticulum develop to which the ribosomes then attach. Although microsporidia are eukaryotes, their ribosomes are prokaryote-like (46). Vossbrinck and coworkers found that *Varimorpha necatrix* Kramer 1965 (a microsporidian of butterflies) contains the smaller 70S ribosomes, which have 16S and 23S subunits, but lack a separate 5.8S subunit typically found in eukaryotes. The 23S subunit, however, contains sequences of the typical 5.8S subunit (47,48).

Golgi Apparatus. The microsporidia contain Golgi-like membranes consisting of small groups of sacs and opaque vesicles sometimes arranged in parallel arrays in the anterior region of the organisms (4,21). These membranes and sacs contain thiamine pyrophosphatase, an enzyme and histochemical marker that is specific for the Golgi apparatus (49). These structures appear to support polar tube formation, spore germination, and polar filament extrusion.

Posterior Vacuole. The posterior vacuole is a rather large membrane-bound structure formed from the Golgi-like vesicles that coalesce late in sporogony during spore maturation (4). The posterior vacuole provides a diagnostic characteristic for detecting microsporidia in clinical specimens using light microscopy methods (26,50,51). The function of the posterior vacuole is unknown but along with the polaroplast, it swells just before germination, suggesting a role in polar filament extrusion (30,65–67).

Sporophorous Vesicle. In some species of microsporidia, sporoblasts develop into spores within envelope structures called sporophorous vesicles. Often, the sporonts secrete the material that forms the sporophorous vesicles but in some cases the host cell contributes to producing this envelope. These vesicles may be transient structures that degenerate after spore release or they may persist. Freeze fracture studies indicate that the sporophorous vesicles do not form a unit membrane structure (21). Two species of microsporidia that infect humans and generate spores within sporophorous vesicles produced by both the sporonts and the host cell include *Trachipleistophora hominis* Hollister, Canning, Weidner, Field, Kench, and Marriott 1996 and *Trachipleistophora anthropophthera* Vávra, Yachnis, Shadduck, and Orenstein 1998 (55–57).

Genetics

Along with structural characteristics, molecular biology approaches are now being applied toward postulating phylogenetic or evolutionary relationships among the microsporidia that have subsequently affected the taxonomic classification of the microsporidia. On the basis of several gene sequence comparisons as described in the following sections, Cavalier-Smith published a revised six-kingdom system of life in 1998 and transferred the microsporidia to the kingdom Fungi (1,58). Additional changes have occurred in the classification of microsporidia that also infect mammals. At the genus level, *Septata intestinalis* was reclassified into the genus *Encephalitozoon* based primarily on rDNA sequence comparisons (59–61). At the species level, heterogeneity has been detected among isolates within a species by pulsed-field gel electrophoresis and sequence comparisons of rDNA ITS regions, and these variations have led to the designation of strains and genotypes within the species of *E. cuniculi*, *E. hellem*, and *E. bieneusi* (62–71).

Microsporidian Genome. Studies on the genetics of microsporidia are relatively recent, and of the species studied to date, microsporidia possess between 8 (e.g., *Vairimorpha* spp. and *Nosema costelytrae* Hall, Oliver, and Given 1977 that infect various insects) and 16 (e.g., *Glugea atherinae* Berrebi 1978 that infects fish) chromosomal DNA bands based on pulse-field gel electrophoresis (69,72–75). Of the microsporidian species infecting mammals whose chromosomes have been characterized, *E. cuniculi* has 11 chromosomal DNA bands and a genome size of 2.9 Mb (69,75,76). *Encephalitozoon hellem* and *E. intestinalis* each have 10 chromosomes and have genome sizes of 2.4 Mb and 2.5 Mb, respectively (69,75,77). The largest microsporidian genome size measured to date is 19.5 Mb in *Glugea atherinae* (69,74,75,78). It has been hypothesized that the relatively small genome size of the microsporidia reflects their early divergence as eukaryotes (75).

Ribosomal RNA Genes (rDNA). The earliest indication that the microsporidia may have been early branching eukaryotes arose from observations that the microsporidia are nucleated, that they lack mitochondria, and that they possess prokaryote-like ribosomes (47,79). Vossbrinck and coworkers observed that in general, sequences of the large subunit rDNA (LSUrDNA) did not vary greatly between species, that the small subunit rDNA (SSUrDNA) sequences varied moderately, and that the internal transcribed spacer (ITS) region sequences were highly variable between species. Nowadays, species identity between isolates of microsporidia seems to be based on SSUrDNA sequencing, whereas subspecies designations (e.g., strain and genotype) are based on ITS rDNA sequence differences and pulse-field

electrophoresis chromosome studies. For example, distinct genotypes of *E. bieneusi* isolates from humans, pigs, cats, farm dogs, cattle, and nonhuman primates have been identified based on gene sequence differences in the rDNA ITS region (62–66). *Encephalitozoon cuniculi* has a wide mammalian host range, and isolates from rabbits, mice, domestic dogs, and humans were found to differ slightly in their sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Western immunoblot profiles (67,80,81). These isolates also differed in their number of 5′-GTTT-3′ repeats in the rDNA internal transcribed spacer sequences, resulting in the designations of strain I (rabbit prototype with three repeats), strain II (mouse prototype with two repeats), and strain III (dog prototype with four repeats) (67,82,83). These strains, however, are not host-specific and to date only *E. cuniculi* strains I and III have been identified in humans (70,81,84–86). Within these strains of *E. cuniculi*, additional karyotype diversity was identified by Biderre and coworkers using pulsed-field gel electrophoresis (69,75,78,87). *Encephalitozoon hellem* genotype diversity was also identified by pulse-field gel electrophoresis, rDNA ITS sequence data, and Western blot immunoassay profile variations (70,71,77,88). To date, no genetic diversity has been described among isolates of *E. intestinalis* (77,89,90).

Reclassification of Microsporidia from the Protozoa to the Fungi. A number of phylogenetic studies comparing specific microsporidian genes with homologous genes of other organisms have led to the reclassification of the microsporidia from the protozoa to the fungi (90). The α-tubulin and β-tubulin gene sequences of the microsporidia were found to be more closely related to those of fungi than to other protozoans (68,92–96). Studies on gene sequences encoding for translation elongation factors EF-1α and EF-2 and the largest subunit of RNA polymerase II also supported a close relationship between the microsporidia and fungi (97,98). Recently, mitochondrial-type HSP70 gene sequences for the microsporidia *Varimorpha necatrix* and *Nosema locustae* Canning 1953 were identified and found to be more closely related to HSP70 gene sequences of fungi than to protozoa (99–102). Furthermore, a phylogenetic analysis of the TATA box binding protein gene from *N. locustae* also indicated a close relationship between microsporidia and fungi (103). Both fungi and microsporidia contain chitin and trehalose in their cell walls, and both contain distinct genes for thymidylate synthase and dihydrofolate reductase when compared with protists and plants in which these activities are expressed by a single protein (96,104). These observations support the reclassification of microsporidia from the protozoa to the fungi and also indicate that the microsporidia once did possess mitochondria and therefore are not early-branching eukaryotes as first believed (101,102,105). As additional data are analyzed and compared, the criteria for further classifying microsporidia should likewise become clarified.

Biology

The microsporidian life cycle in mammalian hosts is relatively simple. Infections usually begin after ingestion or inhalation of spores. A shift in pH or osmolarity results in calcium influx and posterior vacuole swelling followed by spore germination during which the polar filament everts to propel the spore contents into a host cell (21,30–33,54,106). The spore wall provides some measure of resistance so that sufficient pressure can be maintained within the spore to facilitate polar filament extrusion (30,54). Alternatively, Foucault and Drancourt recently proposed that host cells may instead phagocytose spores under suitable conditions (107). After a host cell becomes infected, the microsporidia proliferate(a process named merogony) and then differentiate into spores (a process named sporogony). Released spores then infect adjacent cells, disseminate to other tissue sites — usually by infecting trafficking monocytes or macrophages — or spores are shed with urine, feces, or respiratory secretions (5,7,50). *Enterocytozoon bieneusi* and *Encephalitozoon* species are the most commonly detected microsporidia in humans and other mammals, and features of their respective life cycles are described below. The life cycles of other species of microsporidia infecting humans may be found in other publications (5,21,40,55–57,108).

Enterocytozoon bieneusi. *Enterocytozoon bieneusi*, the sole and type species in the genus *Enterocytozoon*, is the most commonly reported microsporidian species that infects humans. In addition, *E. bieneusi* has been detected in pigs, nonhuman primates, farm dogs, cattle, rabbits, and cats (62–66,109). *Enterocytozoon bieneusi* primarily causes localized infections of the small intestine and organisms replicates in the supranuclear region of enterocytes. All stages develop in direct contact with the host cell cytoplasm and possess nuclei in monokaryon arrangement throughout their development (16,21,57,110) (Fig. 3). Early stages undergo rapid nuclear division to generate multinucleated merogonial plasmodia that contain electron-lucent clefts as a result of expanding nuclear envelopes and endoplasmic reticulum membranes. With further development, vesicles associate with endoplasmic reticulum to form the polar sacs, and electron dense discs form precursors to the polar filament. Eventually, each nucleus associates with a membrane within which the polar filament precursors combine to form continuous tubes. The polaroplasts begin to flatten, and vesicles of each polaroplast appear to enclose the polar filament. The plasma membrane of the sporophorous plasmodium invaginates and separates into individual spores while simultaneously thickening to form the spore wall. Sporogony is considered polysporous and about 60 spores may develop from one sporogonial plasmodium. The entire life cycle is completed in about four to five days, and because *E. bieneusi* infections tend to remain localized to the small intestine and biliary tract, spores are primarily shed with the feces (11,111).

Encephalitozoon Species. *Encephalitozoon cuniculi* is the type species of the genus *Encephalitozoon*, that infects humans, and has the widest host range among mammals (4,5,18,112). Three other species are contained within this genus. *Encephalitozoon intestinalis* is the

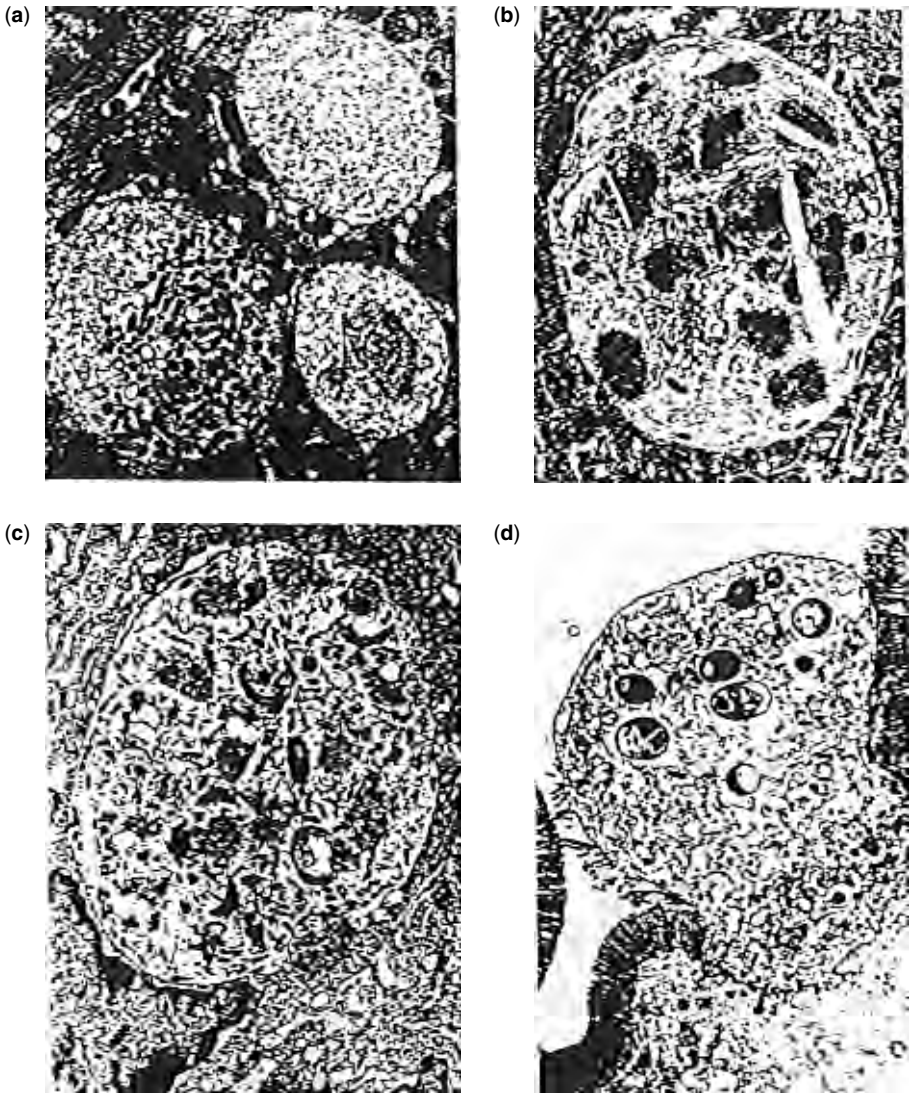

Figure 3. Transmission electron microscopy of *E. bieneusi*. (**a**) Two proliferative plasmodia, a very early one without a nucleus (upper right) and one with a single nucleus (lower right), and a sporogonial plasmodium (lower left) containing electron-dense discs and rod-shaped precursors of polar tubes. Not the intimate association of the cell's electron-dense mitochondria with the plasmodia (X 10,000). (**b**) An early sporogonial plasmodium with several electron-dense nuclei, discs, and prominent electron-lucent clefts. (X 10,000). (**c**) A single late sporogonial plasmodium molding the apical nuclear pole. Future spores are identified by the polar tubes coiling around nuclei and polar vacuoles. When cut on-end, the double layer of three turns is visible. (X 9,000). (**d**) A shedding cell, with few microvilli, contains several spores with polar vacuoles. (X 5,000). Guerrant, eds., Raven Press, Ltd., New York, 1995, pp. 1,129–1,140.

second-most common microsporidian in humans (after *E. bieneusi*) and was recently detected in cows, dogs, goats, and donkeys (113). *Encephalitozoon hellem* was first described and isolated from three AIDS patients with ocular infections and has since been described in psitaccine birds, as well (114,115). The fourth species, *E. lacertae* Canning 1981 was recently described in skinks (African lizards) but has not been detected in mammals (116).

The *Encephalitozoon* organisms develop within membrane-bound parasitophorous vacuoles (PV) that are believed to be of host origin, and single nuclei in monokaryon arrangement are observed in all stages of development (4,5,21) (Fig. 4). Merogony occurs as binary division, and the meronts, which are rounder and larger than the mature spores, are found attached or closely aligned with the PV membrane. Ribosomes are predominant during early development, and endoplasmic

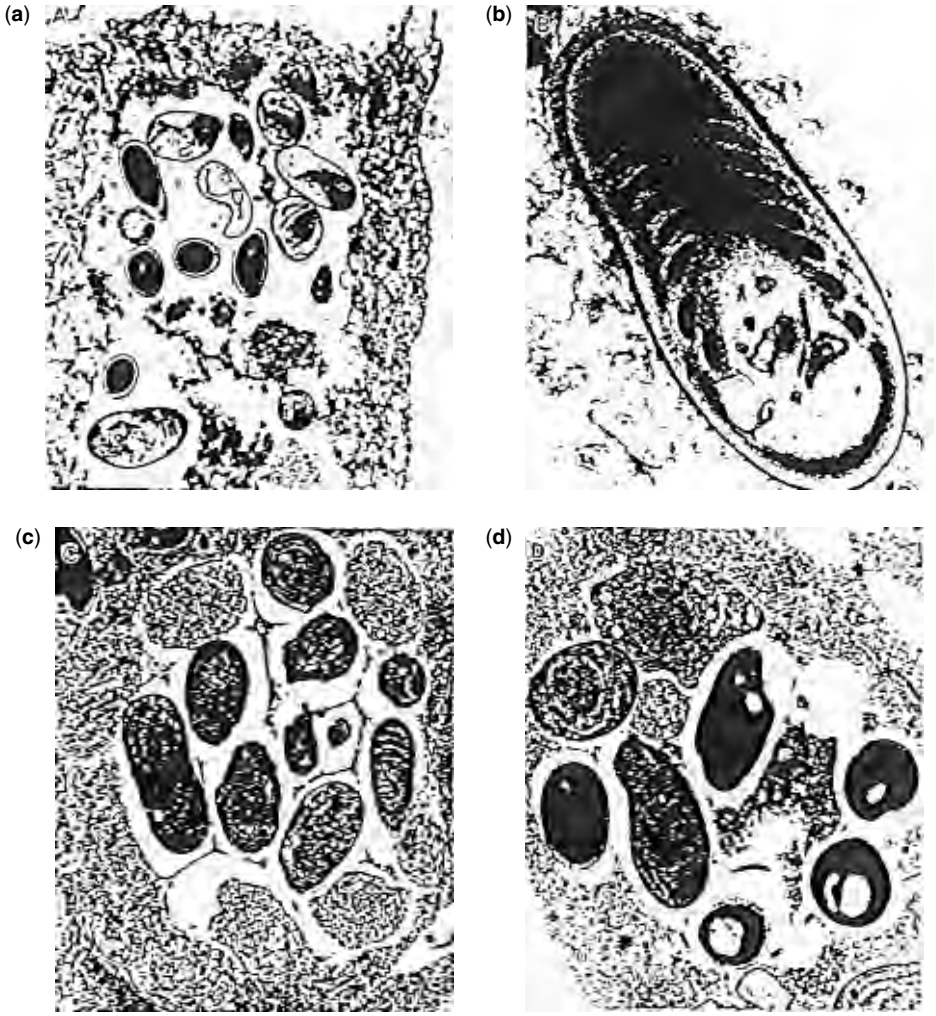

Figure 4. Transmission electron microscopy of clinical and cell culture isolates of *E. intestinalis*. (**a**) Microsporidia consistent with *E. intestinalis* in a cytoplasmic vacuole of necrotic epithelial cell from the bronchoalveolar lavage specimen. Note the few remaining microvilli in the upper right (X 6,000). (**b**) High magnification electron micrograph of a spore in the bronchoalveolar lavage specimen. Note the characteristic coiled polar tube seen in a single row, and the posterior vacuole (X 30,000). (**c**) Microsporidia from the bronchoalveolar lavage specimen and cultured in RK-13 cells develop within septated parasitophorous vacuoles. Meronts and sporonts are located near the edge of the vacuole and sporoblasts are centrally located (X 10,000). (**d**) The microsporidia cultured from the nasal lavage specimen are ultrastructurally identical to those cultured from the bronchoalveolar lavage fluid. This field show appendages (arrows) that were seen in both cultures (X 11,000). Reprinted by permission from the publisher of E. S. Didier et al., *J. Eukaryot. Microbiol.* **43**, 34–43 (1996).

reticulum can be observed during the later stages of merogony. Sporogony begins as the plasma membranes thicken and the polar filaments develop. The sporonts detach or separate from the PV membrane and continue to divide by binary division. Sporogony in *Encephalitozoon* is considered bisporous and sometimes tetrasporous so that two or four sporoblasts develop from one or two divisions of each sporont, respectively (4,21,57). The development of *E. intestinalis* differs slightly from that of *E. cuniculi* and *E. hellem* because an extracellular matrix substance is secreted into the PV that surrounds the developing organisms to form chambers or septa in the PV that is not as pronounced during development of *E. cuniculi* or *E. hellem* (17,39,118). Eventually, the PV membrane and host cell plasma membrane rupture to release spores. During intestinal stages of infection (particularly with *E. intestinalis*), spores are shed in the feces. However, all mammalian *Encephalitozoon* spores can disseminate by infecting trafficking monocytes and macrophages and thereby infect sites that include, but are not limited to, the kidneys and respiratory tract. Subsequently, *Encephalitozon* spores typically are shed in urine or respiratory secretions during the chronic stages of infection (4,5,7,11,50,111).

EPIDEMIOLOGY AND CLINICAL DISEASE

Clinical Symptoms

The clinical syndromes associated with natural and experimental microsporidia infections in mammals tend to be characterized into three groups according to immune status and responses expressed by the various hosts.

Immune-Deficient Hosts. Microsporidiosis is associated with disease and is sometimes lethal in immune deficient hosts (4–6,119). Among animals, immature or underdeveloped immune responses were probably responsible for the spontaneous abortions that were reported in a colony of squirrel monkeys, the renal failure and death of infected puppies, and the stillborn birth of a foal caused by microsporidial placentitis (5,120–125). In addition, chronic diarrhea was observed in neonatal gnotobiotic pigs experimentally infected with *E. bieneusi* (125). Immunodeficient SIV–infected rhesus monkeys (*Macaca mulatta*) that were naturally or experimentally infected with *E. bieneusi* developed chronic diarrhea, and the monkeys experimentally infected with *E. cuniculi*, *E. hellem*, or *E. intestinalis* often developed severe hepatic and/or nephrotic necrosis (127–130). Genetically immune-deficient animals such as athymic mice that lack functional T lymphocytes, and severe combined immunodeficient (SCID) mice that lack functional T and B lymphocytes, developed severe ascites and died after inoculation with *E. cuniculi*, *E. hellem*, or *Vittaforma corneae* (127,131–134). Athymic mice inoculated with *Trachipleistophora hominis* developed severe skeletal muscle disease (55), and interferon-gamma receptor knockout mice developed chronic infections after inoculation with *E. intestinalis*, whereas wild-type mice inoculated with *E. intestinalis* expressed no clinical signs and apparently cleared their infections (135,136). Chemically induced immunosuppression of rabbits chronically infected with *E. cuniculi* and treated with cyclophosphamide resulted in incontinence, loss of motor control, tremor, muscular weakness, and paralysis of the hind limbs prior to death (137).

Humans most susceptible to developing disease associated with microsporidiosis caused by *E. bieneusi* or *E. intestinalis* are AIDS patients with less than or equal to 100 $CD4^+$ T cells/μL blood. These individuals developed chronic or persistent diarrhea and possibly fever, loss of appetite, weight loss, and wasting disease (11,111,138). *Enterocytozoon bieneusi* infections tend to remain localized to the small intestine but biliary tract involvement leading to inflammation of the bile ducts and gall bladder is common. Organ transplant recipients undergoing immunosuppressive therapy to prevent rejection have been reported with microsporidiosis due to *E. bieneusi* and *Encephalitozoon* species and the clinical symptoms in these individuals included fatigue, fever, nausea, and diarrhea (111,139–142). Malnourished children are considered immune compromised and an increasing number of reports have been published describing the detection of microsporidia in the feces of such children with diarrhea (10,13,143–148). In otherwise healthy individuals, microsporidia infections in immunologically privileged sites such as the lens or cornea, can result in visual impairment, blindness, perforation of corneal ulcers, or spontaneous rupture of the lens, as has been described in rats, rabbits, cats, blue foxes, and humans (who were either infected or not infected with HIV) (123,149–154).

Enterocytozoon bieneusi organisms primarily infect enterocytes of the small intestine (jejunum and duodenum) and epithelial cells of the biliary tract. The development of diarrhea may be related to the replication of organisms that is associated with loss of villous enterocytes, villous atrophy (blunting), D-xylose malabsorption, crypt hyperplasia, mononuclear infiltration, and decreased brush-border disaccharidase activity (7,11,111). Tumor necrosis factor, a proinflammatory cytokine, was detected in relatively high levels in stools of AIDS patients with microsporidiosis and may contribute to the wasting associated with microsporidiosis in AIDS patients (155).

Encephalitozoon species often disseminate rather than remain in the small intestines, and may be associated with sinusitis, keratoconjunctivitis, hepatitis, myositis, peritonitis, nephritis, encephalitis (with seizures), and pneumonia. Lesions associated with *Encephalitozoon* infections include necrosis and lymphocytic infiltration of affected organs, particularly of small intestine, liver, kidney, nasal cavities, sinuses, and pancreas (6,7,11,111,119,123).

Hosts That Develop Hyperimmune Responses. Carnivores such as domestic dogs, foxes, and mink commonly become infected with *E. cuniculi* by transplacental transmission, often resulting in neonatal death. Surviving carnivores, or those that became infected after birth, subsequently developed hypergammaglobulinemia that progressed to renal disease via type III hypersensitivity immune responses (4,6,119,124,154,156–160). Perivascular granulomatous lesions were typically observed in infected carnivores and granular deposits containing IgM and IgG were detected in the glomerular basement membranes in *E. cuniculi*–infected mink (161). Lesions in these infected carnivores were characteristic for polyarteritis nodosum and included focal renal cortical lymphocytic and granulocytic infiltrates, fibrosis, and tubular dilatation with fibrinoid vasculitits. Kidney, brain, liver, lung and eye may be affected, and organisms may be found extracellularly in necrotic zones and within parenchymal and endothelial cells (6,119,123). In humans, hyperactive immune responses to microsporidia specifically have not been described.

Immunologically Competent Hosts. Spontaneous (i.e., natural) infections with *E. cuniculi* commonly have been reported in immune competent mammalian hosts that include, but are not limited to rodents, lagomorphs, ruminants, humans, and nonhuman primates (4,5,7,43). During the early or acute stage of infection in otherwise healthy animals, clinical signs of disease may be evident (6,7,119,123). A chronic phase ensues during which few clinical signs are evident, yet the microsporidian infections generally persist. In this context, microsporidiosis represents a balanced host-parasite relationship because the host survives with relatively few symptoms and the parasite persists.

The euthymic murine models for *E. cuniculi* have been particularly useful examples of microsporidiosis in competent hosts because mice are natural hosts of *E. cuniculi*, the organisms disseminate in mice similar to where they spread in humans, the immune responses can be easily studied in mice through the availability of inbred strains of mice and immunological reagents, and the clinical manifestations of *E. cuniculi* infections in immunologically competent and immunodeficient mice parallel those seen in humans infected with *E. cuniculi* (4,5,7,43,119,123). Early after infection with *E. cuniculi*, euthymic mice may develop ascites that resolves within two weeks, and infected rabbits may on occasion develop motor paralysis, convulsions, and torticollis. *Encephalitozoon cuniculi* infections apparently persisted in these hosts as evidenced by the continued expression of microsporidia-specific antibodies, sporadic shedding of organisms, and the observation of microsporidia-associated lesions at necropsy. In addition, microsporidia could later be recovered from chronically-infected mice that were injected with the immunosuppressant, cortisone (162,163). Rabbits similarly develop chronic, life-long infections with *E. cuniculi* and have been used to study the pathogenesis and diagnosis of microsporidiosis (4–6,123,124). Interstitial granulomatous inflammation of kidney, liver, and sometimes, brain, are quite common in animals with encephalitozoonosis (6,119,123).

It is less clear if immune competent humans infected with microsporidia eventually clear their infections or develop chronic life-long infections, as occurs in most other animals. (7,18,43,112,124). Seroprevalence data among various human populations range from 0 to 38% (4,10,164–166), but these earlier studies that utilized *E. cuniculi* as the antigen, and are difficult to interpret now that new species have been identified as causes of infection in humans. Recently, however, a stringent serological study on 300 Dutch blood donors and 276 pregnant French women indicated prevalences of 8% and 5%, respectively, for the presence of *Encephalitozoon*-specific antibodies (167). As diagnostic methods have improved for detecting microsporidian spores or DNA by histochemistry or polymerase chain reaction-based methods, respectively, cases of self-limiting diarrhea of approximately two weeks' duration have been reported in travelers and other persons not infected with HIV (13,143–145,147,148,164,168–173). In addition, microsporidia have been detected in the feces of an asymptomatic child in the Zambia, and in 20 fecal specimens out of 255 asymptomatic individuals in two communities in Mexico (144,174). Such findings suggest that microsporidiosis is probably more common in immune competent human populations than previously believed, but further studies are needed to determine if persons are persistently infected with microsporidia even after clinical symptoms resolve, or whether these individuals clear the microsporidia.

Modes of Transmission

Many infections in mammals occur after ingestion or inhalation of microsporidian spores. Though not reported in humans, transplacental transmission of *E. cuniculi* is common in carnivores, especially blue foxes and domestic dogs, and has occasionally been reported to occur in non-human primates, horses, rabbits, and rodents (4,5,175). Microsporidiosis can be transmitted to humans by trauma or direct contact. In laboratory animals, microsporidiosis has been transmitted by intraperitoneal, intravenous, intrarectral, intratracheal and intracerebral inoculations (6,7,119).

Zoonotic Transmission. Zoonotic transmission of microsporidial parasites from animals to humans has not been proven to date, but appears likely based on the wide range of hosts that become infected with species of microsporidia that also infect man. *Enterocytozoon bieneusi* has been identified in SIV–infected macaques (*Macaca mulatta*), pigs, cows, dogs, rabbits, cats (62,64,66,109,130), and the genotypes that infect pigs are most similar to those that infect humans. *Encephalitozoon intestinalis*, the second most commonly identified human microsporidial infection, has been identified in five different domestic animal species in association with a human survey conducted in a village setting in Mexico (113). *Encephalitozoon hellem* was first identified in AIDS patients as causing ocular, respiratory and systemic infections (11,150,153,176) and recently has been detected in several psittacine pet bird species (5,114,115,123). Anecdotally, at least two of the three AIDS patients from who *E. hellem* was first isolated had pet birds, but these birds were never tested for microsporidiosis (176). *Encephalitozoon cuniculi* has the widest host range among mammals, and isolates from various animals have been characterized as being identical to isolates from humans based on rDNA and western blot studies (70,81,84–86). The strongest evidence suggesting zoonotic transmission was reported in a single case where children were exposed to puppies with overt encephalitozoonosis and one of the three children seroconverted to express antibodies to *E. cuniculi* (123,176).

Vectorborne Transmission. Although no direct evidence presently exists, morphological and phylogenetic studies using small subunit rDNA sequence comparisons among microsporidia of humans and insects supported the possibility that microsporidia may be transmitted from insects to humans (178). Furthermore, a microsporidian species of mosquitoes, *Nosema algerae*, was recently identified in, and isolated from the cornea of an HIV-seronegative individual (179), and *T. hominis*, which was first isolated from a human, was able to infect larval stages of two species of mosquitoes (180).

Waterborne Transmission. Microsporidial spores are remarkably resistant to the environment, and water contact has been identified as a risk factor for microsporidiosis in epidemiological studies (10,164). Analysis of seasonal patterns of diarrhea cases in AIDS patients showed wet-season increases in cryptosporidial diarrheas, but there were no clear correlations between seasonality and microsporidial diarrheas (10,164,181). Drinking water has been identified as a source of exposure for other diarrhea-associated protozoans such as *Cryptosporidium parvum*,

Giardia lamblia and *Cyclospora cayetenensis*, and likewise, *E. bieneusi*, *E. intestinalis*, and *V. corneae* have been detected in sewage, ditch water, groundwater and surface water sources prompting the U.S. Environmental Protection Agency to include microsporidia on the Occurrences Priority List for drinking water safety (182–186). Swimming in pools was also considered a risk factor associated with an outbreak of microsporidiosis (187). Methods for improving detection of microsporidia in water sources are under development and will be important for determining the risk of waterborne transmission (164,185,188,189).

CONCLUSION

Microsporidiosis is a reemerging infection in animals and an emerging infection in humans, particularly in immunologically compromised individuals (190). As awareness of microsporidiosis has increased and as detection methods have improved, microsporidiosis became increasingly recognized in a wider range of animal hosts and human populations. However, much still needs to be learned about the epidemiology and natural history of microsporidiosis in immunocompetent and immunodeficient populations of people. The ubiquitous nature of these organisms and the potential risk for zoonotic, vectorborne, and waterborne transmission suggest that microsporidiosis represents a public health concern that further raises the need for improving surveillance, detection, and treatment of microsporidiosis.

MICROSPORIDIA: OCCURRENCE, FATE AND METHODOLOGIES

Scot E. Dowd
USDA-ARS-LIRV
Lubbock, Texas

Microsporidia is a nontaxonomic term used to describe a group of protozoa that belong to the phylum Microspora. Microsporidia may be the most ancient branch of the eukaryotic tree (1). Although microsporidia have a nucleus, they lack mitochondria and peroxisomes (2), and their ribosomal characteristics are more closely related to bacteria than to higher eukaryotes (2,3). In addition, the human enteropathogenic microsporidia (HEM) are closer in size to bacteria (~1 to 2 μm in diameter) than to most other protozoan parasites such as *Giardia lamblia* (~15 μm diameter) and *Cryptosporidium parvum* (~5 μm diameter). Microsporidia have an environmentally resilient spore wall that consists of a proteinaceous exospore and a chitinous endospore (1)

The HEM cause chronic diarrhea and wasting in HIV-infected individuals. Estimates indicate that about 7 to 50% of these immunodeficient patients are infected with HEM, making it one of the most important intestinal pathogens in these populations (4). No reports on the infective dose of the HEM have been documented, but indications are that it is very low especially in the immunocompromised (4). In immunocompetent individuals, a form of diarrhea, similar to that seen in the immunocompromised, is evident but is self-limited (5). Asymptomatic infections have also been reported in both HIV infected and immunocompetent patients (6). Finally, as improved methods for clinical detection of HEM are developed, increasing reports of infection in the immunocompetent are being described, indicating that the HEM may also be an important pathogen in individuals not infected with HIV (5,7–13). However, as with most pathogens, AIDS patients, individuals on immunosuppressive drugs, the very young and the very old, and pregnant woman should be considered at risk for infection from these emerging pathogens.

At one time, the microsporidia were included in the phylum Sporozoa along with what is now the Apicomplexa. Subsequent research is beginning to show that the microsporidia are a well-defined group with no known relationships with other protists. Recent phylogenetic evidence has even suggested they are more closely related to fungi than protozoa. Modern taxonomies reflect this confusion by placing the microsporidia in its own phylum. For a more detailed history of microsporidian systematics, see Sprague (14), Issi (15), and Canning (16). Initial classification of microsporidia used the morphology of the germination and invasive structures for higher taxonomic characteristics. Another promising approach to systematics is based on molecular characterization. Phylogenetics or the use of genetic information to determine associations and evolutionary lineage appears to be the most promising of these, with particular emphasis given to ribosomal DNA gene sequencing (2,17,18). Interestingly, such analyses of ribosomal sequences tends to indicate that microsporidia are closely related to protozoa (3,17,18), whereas phylogenetic analyses of some other microsporidial genes such as β-tubulin tend to indicate that they are more closely related to fungi (19).

Having risen from relative obscurity to well-recognized human pathogens, HEM, which were most often identified as the etiological agent of disease in the immunodeficient (4,20–22), are increasingly identified with disease in immunocompetent populations (6,7,9–11,21,23–25). Human pathogenic microsporidia are ubiquitous in their geographic distribution, and they have been documented as disease agents on most continents including North and South America, Europe, Asia, Africa, and Australia (21).

Most of the 1,000 and more species of microsporidia are parasites of fish and insects (2), but beginning with the diagnosis of microsporidia in AIDS patients (20), they have become recognized as emerging human pathogens by the United States Environmental Protection Agency, the Center for Disease Control and Prevention, and the National Institute of Health. To date, there are at least six genera of microsporidia that have been identified as the etiologic agents of disease in humans: (*1*) *Enterocytozoon bieneusi*; (*2*) *Encephalitozoon* sp. (*Encephalitozoon intestinalis*, Encephalitozoon hellem, and *Encephalitozoon cuniculi*); (*3*) *Pleistophora* sp; (*4*) *Vittaforma corneae*; (*5*) *Nosema* sp. (*Nosema connori* and *Nosema ocularum*); and (*6*) *Trachipleistophora hominis* (21). These genera cause a variety of infections including infections of the respiratory tract, the urinary tract, and the gastrointestinal tract.

The first documented waterborne outbreak of microsporidia was described recently by Cotte and coworkers (24). They performed an extensive screening of 1,454 stool samples from 1993 to 1996. They found microsporidia in 338 persons: 61 of these were immunocompetent, whereas the rest were either HIV-positive or transplant patients. They also documented a waterborne outbreak involving 200 persons, which occurred in the summer of 1995. They identified that the major factor associated with this outbreak was the use of one of three local water distribution systems. Risk factors associated with infection by HEM have also been described by Watson and coworkers (26) and include swimming in rivers, ponds, and lakes, as well as drinking unfiltered tap water. Finally, Enriquez and coworkers (27) assessed the prevalence of *E. intestinalis* in two rural communities in Mexico. They found that at least one household member from 15 families was infected with this parasite (70 total households were screened) and that the primary factors associated with these infections were the use of untreated indoor faucets or the use of community wells for drinking. These data suggest the potential for waterborne transmission.

Microsporidia that are associated with human infection have also been documented to occur in animals other than humans. The primary microsporidia that may have a definite zoonosis is *E. cuniculi*, which is often associated with infection of several animals including mice, rabbits, foxes, and dogs. Other human pathogens may also have animal reservoirs including *E. bieneusi*, which has been detected in the feces of pigs (28) and primates (29–31), and *E. intestinalis*, which has been detected in the feces of a variety of animals including pigs and cows (32). *Enterocytozoon bieneusi* and *E. intestinalis* are of particular interest because they are associated with gastrointestinal disease. However, in addition to infections of the small intestine, they have also been associated with infection of the nasal (33–35) and bronchial epithelium (36,37). For these reasons, it has been postulated that there may be three probable modes for the transmission of *E. bieneusi* and *E. intestinalis*: (*1*) fecal-oral; (*2*) inhalation; and (*3*) ingestion of contaminated water.

A total of four studies have documented the presence of HEM in various water sources including primary and tertiary wastewater effluents, surface water, groundwater, and drinking water. Studies analyzing surface water, tertiary effluent, raw sewage, and groundwater have found species of microsporidia pathogenic to humans, such as *E. bieneusi*, *E. intestinalis*, *Pleistophora* spp., and *V. corneae*. It has been speculated that because of the small size of microsporidia, they could be transported in the subsurface water over long distances and could occasionally contaminate drinking water wells (38). Microsporidia including *Nosema*, *Pleistophora*, *Telomyxa*, *Vavraia*, and *Vairimorpha* have also been isolated from ditch water (39). Sparfel and coworkers (40,41), have detected *E. bieneusi* in river water in France. They also detected *V. corneae* and *Pleistophora* sp. Finally, Dowd and coworkers (42) detected *E. intestinalis* in drinking water samples taken in Guatemala. These water samples were collected from small reservoirs fed by springs or wells. Local communities use these reservoirs as sources of drinking water. A total of 12 water samples were screened in this study and five of these were positive for HEM.

The issue of the waterborne status of *E. bieneusi* and *E. intestinalis* still remains unclear (43). Occurrence data are slowly accumulating, suggesting that there is a definite possibility that these two microsporidia are waterborne. This combined with the first documented waterborne outbreak, the diagnosis of microsporidia in association with travellers diarrhea, and the risk factors associated with water tend to lean toward these two protozoa having the potential to be waterborne.

In addition to documentation related to the presence of the human enteropathogenic microsporidia (HEM) in water, there is increasing data related to environmental survival and disinfection. The survival of *E. cuniculi* spores suspended in distilled water and exposed at defined temperatures was investigated. Infectivity of *E. cuniculi* spores was tested by animal infectivity. There was no marked loss of infectivity of spores stored at 4 °C for two years or frozen at −12 °C and −24 °C for 1, 8, and 24 hours. Marked loss of infectivity was seen after heating at 60 °C and 70 °C for 5 minutes and 1 minute, respectively. These findings demonstrate that *E. cuniculi* spores suspended in water can survive freezing temperatures but were no longer infective at very high temperatures (44). Spores have been shown to survive for up to four weeks in a dry hospital environment at 2 °C (45) Disinfection with 2% lysol or 10% formalin or 70% ethyl alcohol for 30 minutes have been shown to inactivate spores (46,47). Labeau and coworkers (48) indicate that the HEM appear susceptible to readily achievable oxidant disinfectants. *Septata intestinalis*, was utilized to determine whether chlorine could be used as an effective disinfectant. A rabbit kidney cell culture system was used to determine 50% tissue culture infective dose (TCID) (49) and a minimal infective dose (MID) following exposure to a chlorine concentration of 2 mg/L after a minimum exposure time of 16 minutes. Data suggested that chlorine treatment may be an effective water treatment for *E. intestinalis* (50). Other than these studies, little work has been done related to the environmental occurrence and fate of HEM.

Available evidence suggests that microsporidia have potential environmental transmission routes including air and water. Recently, direct evidence has added credence to these hypotheses. Before this, there had been no documentation of the occurrence of microsporidia in the environment because there was a lack of effective methodologies with the ability to specifically detect and determine the species of the human pathogenic microsporidia. Current methods for the collection of water for recovery of protozoa (*Cryptosporidium* and *Giardia*) involve cartridge filtration of large volumes of water. Such cartridge filters are required to sample large volumes of water (>100 L) (8). Collecting large volumes of water is necessary to detect the low concentrations of protozoa that may be found in many water supplies. Such low concentrations of these pathogens in water sources are known to be significant from a human health perspective (8). After concentration of the water, methods for detection and confirmation of the microsporidia are necessary. The definitive method currently being used for the species determination of microsporidia in clinical samples is transmission electron microscopy (TEM) (49,51). However, the use of TEM for screening environmental samples is not a feasible approach. It is for this reason that other methods for environmental screening are required.

The major problems associated with detection and species determination of HEM in the environment relate to the fact that there are over 1,000 species of microsporidia, many of which can be found in environmental samples at any given time. Of these 1,000 plus species, only a handful are of relevance as human pathogens and only two (*E. bieneusi* and *E. intestinalis*) are considered potential waterborne pathogens. Another problem is the size of the HEM: *E. bieneusi* is approximately 0.5×1 μm, whereas *E. intestinalis* is approximately 1×1.5 μm in diameter. These protozoan pathogens are thus approximately the size of a bacteria, making confirmation by traditional environmental parasitology methods, such as immunofluorescent or light microscopy, difficult if not impossible. The primary methods to visually identify species of microsporidia rely on internal morphology of

the spore, especially the layout of the polar tubules. The visualization of such internal structures is well beyond the resolution of modern light microscopes. Thus, the development of novel methods for environmental detection of these much smaller protozoan pathogens is required.

One of the most promising methods used for environmental detection of the microsporidia is the polymerase chain reaction (PCR). The PCR is a molecular method that involves the enzymatic amplification of specific target DNA from HEM, allowing this target DNA of a known amplified size to be visualized in an agarose gel on staining with an appropriate dye. Thus, if DNA can be extracted from environmental samples and the use of the PCR reveals the correctly sized amplification product, it is a good indication that particular sample contained HEM. Here again the problem becomes that of differentiating the amplified HEM DNA from other microsporidia species potentially present in a given environmental sample. For this reason, the PCR should be designed to be highly specific for only the HEM and combined with a second method to provide confirmation and species determination. However, as with any such method, extensive validation on known isolates of HEM and non-HEM is required.

MICROSPORIDIA SPORES

Microsporidia spores for experimental research can be obtained directly from the American Type Culture Collection (ATCC). These spores included *E. intestinalis* ATCC 50506, *E. hellem* ATCC 50504, *E. cuniculi* ATCC 50503, *V. corneae* ATCC 50505, *Endoreticulatus sherburg* ATCC 50040, *Nosema necatrix* ATCC 30460, and *Nosema trachiplusieae* ATCC 30702.

WATER SAMPLING

Water sampling for microsporidia spores represents the first major obstacle that must be over come in the development of monitoring methods. The small size of the microsporidia as compared with other protozoans, namely, *C. parvum* and *G. lamblia* for whom these methods were developed provides novel challenges in relation to water sampling methods. Since with the other protozoan pathogens mentioned a volume of water between 10 and 1,000 L must be sampled to provide appropriate limits of detection sensitivity, it is necessary to concentrate water samples. This is done primarily through the use of filtration. Methods developed by and for the USEPA were designed for the larger protozoa *Cryptosporidium* spp (5 μm) and *Giardia* spp (15 μm), and typically they use a filter porosity in the range of 2μm. Because HEM are in the range of 0.5 to 2 μm, these methods are not ideal. Thus, methods specific for microsporidia would be able to sample large volumes of raw and finished water and retain particulates in the range of 0.5 to 2 μm. This requires a trade-off because by reducing the nominal porosity of the filters a much smaller volume of water can be effectively passed through the filters. If the porosity is such that larger volumes can be sampled, the porosity of the filters must be increased, reducing the efficiency with which these smaller particles can be retained within the filter matrix. Currently, only a handful of reports have been published related to water sampling for HEM. These reports detail several different methods used for water sampling. Yet, only two of these report sampling efficiencies.

As mentioned, several methods have been used to successfully concentrate water samples for HEM. These methods include the use of wound cartridge filters, pleated membrane filters, dipping rod for grab sampling, and cotton mesh. Other methods that are promising for successful water sampling for microsporidia will also be mentioned. Dowd and coworkers (52) evaluated the use of wound nylon cartridge filters for the concentration of water spiked with known concentrations of *C. parvum* oocysts and *E. intestinalis* spores. In side by side comparison, the efficiency of the Information Collection Rule (ICR) method (53) for protozoan detection in large volumes of water was assessed for its ability to concentrate and purify microsporidia spores.

The mean recovery percentage for *Cryptosporidium* oocysts was similar to the data obtained on the basis of blind laboratory studies performed by Clancy and coworkers (54). In her study, cartridge filters spiked with *Cryptosporidium* sp. oocysts and *Giardia* sp. cysts similar to those described here were prepared and sent to several commercial labs for analysis. These commercial labs displayed recovery percentages for *Cryptosporidium* oocysts, similar to those described here, on the basis of which, the recovery efficiency shown for microsporidia was deemed to be typical when using these methods. The smaller size of microsporidia spores compared with *Cryptosporidium* oocysts may explain the lower recovery efficiency. Thus, until other methods have been evaluated, the ICR method, although it may serve as a method for the collection of microsporidia spores from large volumes of water, is not deemed to be efficient enough for the routine use when screening for human pathogenic microsporidia.

To do this, a comparison was made between microsporidia spores and *Cryptosporidium* sp. oocysts. This provided the first insight into the problems inherent in concentration methods used for HEM. The nominal porosity of the cartridge filters used were 2 μm. The low flow rate was used to assist in retention of the spores in the filter matrix. However, this method proved far from efficient even for the large *C. parvum*. The recovery of *Cryptosporidium* oocysts was 12.5%, whereas the recovery of the microsporidia spores was 4.6%.

The second method, which evaluated recovery efficiency (42), utilized the Gelman Envirochek module, which is a 2 μm porosity absolute membrane that is pleated and contained within a disposable filter housing. Following similar methods described in the previous experiment, concentrated water spiked with known spore concentration were concentrated using the Gelman Envirochek cartridge. These spores were prestained using calcofluor white (Molecular probes, Eugene Oregon), which is a fluorescent label that shows specificity for chitin and reacts well with the chitinaceous endospore layer of the microsporidia. Filters were processed as described in the Envirochek product literature (found on the web at the *http://www.pall.com/gelman/micro_an/papers/*

envirochek.asp), filtered onto black polycarbonate membrane filters, and visualized using a DAPI and a fluorescent microscope.

This method provided improved recovery percentages over the standard wound cartridge method evaluated by Dowd and coworkers (52). The average of four trials with the Envirochek capsule showed 38.6% recovery. This is significantly higher than recovery using wound cartridge filtration. Another advantage is the sample handling time, which is reduced from 240 minutes to only 70 minutes. The cost per sample however is increased from around $20 to over $100. Another aspect to be considered is the volume of water that can be filtered using each method. With the wound nylon membrane, up to 1,000 L can be filtered, whereas with the Envirochek, 10 to 20 L can be filtered. Thus, the volume able to be filtered and the increase in recovery may be balanced out.

Other studies have also used additional methods for the sampling of surface and groundwater. Groundwater samples have been collected using the same filter cartridge apparatus through submersible pumps at the bottom of the wells, which provided sampling pressure. Wastewater samples were collected using dipping rods and sterile one-liter polypropylene bottles, which had been previously coated with elution solution [10 X phosphate buffered saline (PBS), 1.0% Tween 80, 1.0% sodium dodecyl sulfate (SDS), and 1% Antifoam A (Sigma Chemical, St. Louis, MO)]. Two liters of raw and six liters of treated effluent were collected. River samples have been collected using gauze filters (40).

Another method that shows promise for collection of water samples include the Filta-Max system (IDEXX, Inc., Westbrook, Maine). This system uses highly compressed reticulated foam filters. Up to 60 of these foam filters are compressed to provide a nominal porosity similar to previous methods (2 μm). These foam pad filters are placed inside a reusable membrane housing and are used for water concentration. One advantage is that these filters can easily be custom-manufactured using a few additional foam pads, which are compressed to the same size to fit the housing. The added compression lowers the nominal porosity to around 1 μm. Thus, the Filta-max system may be more versatile. Good recovery of *C. parvum* has been reported, and like the Envirochek filter system, the Filta-max is now USDA-approved for monitoring for *Cryptosporidium* oocysts.

DETECTION METHODS

Antibody Based Methods

The use of immunofluorescent assay (IFA) for detection of protozoa such as *Cryptosporidium* oocysts and *Giardia* cysts is routinely used as a primary detection method. Following this fluorescent detection method, there is a confirmation step involving Differential Interference Contrast (DIC) microscopy, which enables visualization of characteristic internal structures with the cyst and oocysts. The routine analyses of drinking water for microsporidia would require that such methods of detection be not only highly sensitive but also very specific. In addition, detection of protozoa on the basis of fluorescent characteristics is not considered a proof positive means of identification. An example of this is the "presumptive" IFA identification of *Cryptosporidium* sp. oocysts and *Giardia* sp. cysts based on the size and shape of their fluorescing cell wall and the subsequent "confirmation" of their identity based on visualization of their internal structures by differential interference contrast (DIC) microscopy. The small size of microsporidia makes the identification of internal structures beyond the resolution capabilities of light microscopy. Thus, any light microscopic assay would need to be extremely sensitive and very specific for routine use in the detection of human pathogenic microsporidia in environmental samples.

Dowd and coworkers (52) assessed two different commercially available antibodies (monoclonal and polyclonal) for their ability to specifically detect human pathogenic microsporidia without cross-reactivity with other environmentally relevant organisms. It was found that available antibodies were able to bind to three of the primary microsporidia pathogens but did not react with *E. bieneusi*. It also cross-reacted with *Endoreticulatus* sp. and was strongly reactive against *Staphylococcus aureus*. A second was found to cross-react with two other species, in addition to the human pathogens of interest. It also showed only sporadic cross-reactivity with *E. bieneusi* (32). Thus, neither of the two antibodies was deemed specific enough to provide confidence in IFA analysis of water. In addition to the cross-reactivity, neither antibody was able to effectively react with *E. bieneusi*.

A second use of antibodies is immunomagnetic separation (IMS), which is used for separation (IMS) of protozoan from complex matrices. As mentioned earlier, the concentration of large volumes of water result in concentration of all particulate matter contained within the water sample. This particulate matter, which also contains the parasites, contains up to 5 ml volume of sediment. In most cases, this is a very complex and heterogeneous matrix. To purify the sample, density gradient flotation (53). However, recent methods utilize IMS to purify the parasites from feces (55) and concentrated water samples (52). There were several problems associated with the spore separation, especially in unpurified water concentrate samples. The magnetic separation nonspecifically extracted a considerable amount of magnetic and paramagnetic materials contained in the sediments, in addition to the immunomagnetic beads. These copurified sediment particles inhibited all subsequent PCR analysis. After purification of water concentrates by Percoll-sucrose floatation, the IMS method showed promising results in initial spiked studies, allowing for amplification of microsporidia DNA. Therefore, a purified water sample, which was shown to be negative for microsporidia by IFA, was used in a limit of detection sensitivity study to determine how effective this method would be for routine use. This limit of detection study was performed with four replicates. Thus, the IMS method for spore separation shows promise for screening water samples for *Encephalitozoonidae*. This method indeed cannot be used for the detection of *E. bieneusi* because the antibodies tested to date do not show consistent cross-reactivity with this

species. This provides some concern because *E. bieneusi* may arguably be the more important human pathogenic microsporidia. Because of these limitations on the use of antibodies for the detection of microsporidia in water samples, another approach using DNA extracted directly from water samples was developed.

Community DNA Extraction

Because the use of IFA as a method of detection has not been shown to be specific nor sensitive enough for routine environmental monitoring, the use of the PCR is required. To use the PCR, it is necessary to extract DNA from concentrated water samples. Most concentrated water samples are turbid and contain large volumes of sediment and other particulate matter. The extraction of total DNA from environmental samples, especially soils and sediments, has always been considered to be difficult. This was because with classic methods much of the DNA from samples was often lost, either through sorption to colloids or in the extensive DNA purification process that is required. In addition, many PCR inhibitory substances are copurified with the DNA. On top of this, processing is time-consuming and labor-intensive. The DNA extraction from environmental water concentrates also presents additional challenges because the samples vary widely depending on the type of water sample collected and where it was collected.

Dowd and coworkers (52) developed a method optimized and standardized for routine screening of water concentrates for microsporidia. They developed a modified protocol using a QIAamp® Tissue Kit (QIAGEN Inc., Santa Clarita, California). Four limits of detection sensitivity experiments with replicates were performed using Percoll-sucrose floatation purified water concentrates and the DNA extraction procedure. The limit of detection was shown to be a mean of four spores. Additional findings suggest that this limit of detection sensitivity can increase to as high as 10^3 spores in some environmental water samples.

Dowd (42) has also evaluated a second method that utilizes the Bio101 soil DNA extraction kit (Bio101). This is a relatively new kit that has been optimized for use in soil samples. Because the sediment of a concentrated water sample is a matrix like soil, this kit shows promise for use in this method. In preliminary studies, the limit of detection sensitivity averaged 200 spores in four very different concentrated water samples. The low was 20, whereas the high was 2,000 spores. Although only preliminary, these results suggest that the use of this DNA extraction kit has the potential for use in detection of the microsporidia in concentrated water samples. Benefits include saving time and cost, increased efficiency, and reasonable detection sensitivity.

Polymerase Chain Reaction (PCR)

The major obstacle hindering the detection of microsporidia in the environment has been the small size of the human pathogenic microsporidia (<2 μm in diameter), which has made it virtually impossible to positively identify the species of isolates visually, without the use of transmission electron microscopy (TEM). Because of the difficulty in using TEM on environmental samples, there has been no confirmed documentation of human pathogenic microsporidia associated with water samples. Another important factor that makes it difficult to correctly identify microsporidia in the environment is the presence of other genera of microsporidia that are not associated with pathogenicity in humans but which do infect nonhuman targets including fish and insects. These other members of the Microspora have been detected in water and have been shown to cross-react with antibodies developed against the human pathogens, thus prohibiting the use of IFA analysis.

Three PCR primers sets have been utilized to analyze water samples for microsporidia (40). The first set is specific for *E. bieneusi* and was utilized to amplify DNA in river water samples. The second set is specific for all of the primary human pathogens (56). Dowd and coworkers (38), used these primers to amplify DNA in a variety of water samples. Forward primer (5′-CAC CAG GTT GAT TCT GCC TGA C-3′) and the reverse primer (5'-CCT CTC CGG AAC CAA ACC CTG-3') amplify the small subunit ribosomal DNA of microsporidia. PCR conditions used for environmental samples were as follows: *Taq* Gold (Perkin-Elmer Corp., Norwalk, Connecticut) induced hot-start cycling conditions, GeneAmp PCR buffer II and GeneAmp dNTPs (Perkin-Elmer Corp). The cycling profile was as follows: 10 minutes of denaturation at 95 °C, followed by 40 cycles of denaturation at 94 °C for 45 seconds, annealing at 55 °C for 20 s, and extension at 72 °C for 40 seconds. A final extension step consisting of 5 minutes at 72 °C was also included. These primers are specific for HEM but are problematic for environmental applications because of their tendency to form primer dimers. Thus, these primers are not as sensitive as they could be for environmental work.

A second set of primers also designed to be specific for the human pathogenic microsporidia, when combined with CDHC, have been shown to confirm identification of PCR-amplified microsporidia to the species level (42). These primers were also shown to be highly sensitive when tested in spiked environmental and clinical samples and do not exhibit serious primer or primer-primer dimerizations as predicted by primer design software (DNAstar, Madison, Wisconsin) or actual testing (data not shown). The forward HEM primer was designated MicF1 (5′ AGG TTG ATT CTG CCT GAC 3′), and the reverse primer was designated MicR1 (5′ GCG CCT GCT GCC RTC CT 3′). All PCR conditions were as follows: *Taq* Gold (Perkin-Elmer Corp., Norwalk, Connecticut)-induced hot-start cycling conditions consisting of 10 minutes of denaturation at 95 °C, followed by 40 cycles of denaturation at 94 °C for 1 minute, annealing at 56 °C for 30 seconds, and extension at 72 °C for 1 minute. A final extension step consisting of 5 minutes at 72 °C is also included. These primers have been shown to be highly sensitive and specific for use in environmental samples including concentrated water samples.

Species Determination

In addition, the use of molecular methods such as the PCR has provided the ability to quickly determine the species

of microsporidia — a task that traditionally required the use of TEM. Currently, there are two methods that show considerable utility. The first is the use of the PCR followed by restriction fragment-length polymorphic (RFLP) analysis to help differentiate species on the basis of varied restriction patterns (56). The second and the most promising is the use of PCR sequencing and computer database homology comparison (CDHC) (42). The use of restriction analysis is only slightly more cost-effective but still leaves considerable doubt at least in environmental samples as to the actual identity of the organisms from which the amplicon was derived. For instance, the *Encephalitozoonidae* (*E. intestinalis*, *E. hellem*, and *E. cuniculi*) can often be distinguished by restriction analysis of their PCR products. However, for environmental samples, there is the potential for other genera of microsporidia to be amplified, some of which could have the same restriction patterns as the human pathogens, thus lending uncertainty to such analyses. This is because a yet uncharacterized organism having the same restriction pattern but a completely different genetic sequence and taxonomic designation could as easily generate such a PCR product and subsequent restriction pattern. Thus, the use of the PCR sequencing and database homology comparison may be the method of choice for species determination of human pathogenic microsporidia, especially when screening environmental samples. This method has also been tested using a statistically relevant population of controls.

Sequencing of PCR products has been described previously (57). Following sequencing, CDHC is used to analyze the sequence. This procedure was briefly described by Dowd and coworkers (42). The initial database search was performed using BLASTn (58) provided by the National Center for Biotechnology Information (NCBI) at their web site (*http://www.ncbi.nlm.nih.gov*). The query sequence or PCR sequencing results from the environmental sample is entered into the BLASTn search engine and the database search is conducted. Results are carefully analyzed in graphic and statistical form as provided by the BLASTn search engine results page. The graphic form was used to ensure that the whole query sequence entered into the search was subsequently aligned with the high-scoring database sequence returned. Following this initial search, the database sequence is downloaded from GenBank and the database sequence and query or unknown sequence are aligned again using pairwise (Martinez-NW Method) alignment. This algorithm identifies regions of perfect match between two sequences, while the Needleman-Wunsch method then optimizes the alignments between regions containing perfect matches. This second alignment is performed separately from the alignment generated by BLASTn, which is often incomplete or inaccurate. This Martinez-NW alignment allows assessment of the entire query sequence alongside the known database sequence.

CONCLUSION

Microsporidia are emerging protozoan pathogens, which may be associated with waterborne transmission. Previously there has been a lack of published methodologies applicable to environmental research. Recently, an assessment of standard methods for protozoan concentration from large volumes of water and the development of improved detection methodologies have been documented. Several problems have been identified in the course of these studies that require further research. The major issue is the development of methods for determining the viability of spores isolated from the environment. Gelman Envirochek provides adequate recovery efficiencies allowing monitoring of finished water for the presence of these pathogens. PCR-detection methodologies appear adequate for detection and species determination. Finally, adequate occurrence, survival, and disinfection data is still lacking in spite of recent studies addressing these issues. This is highly significant, since especially with the recent detection of human pathogenic microsporidia in water, drinking water utilities should have available methods to assess if their facilities can remove or inactivate these pathogens before they reach the consumer. Microsporidia are smaller than other waterborne pathogens and may be more likely to penetrate filters used in conventional water treatment. The methods presented here could be used to assess the effectiveness of current water treatment processes in the removal of microsporidia from water.

There is a definite need for better understanding of the epidemiology HEM and for better management and control measures to ensure the safety of water used for drinking and water-washed produce. Confirmation of these water sources, as a potential source of disease, may rapidly lead to the development of better management practices being implemented by populations in these countries, in order to reduce the prevalence of these parasites in waters used for consumption and irrigation. Little is known about the occurrence or prevalence of HEM in relation to immunocompetent humans, wild, and domestic animals. HEM are being increasingly identified as the causative agent of traveler's diarrhea, most probably caused by the consumption of contaminated food or water. However, the environmental occurrence of these emerging pathogens has not been adequately documented, due to a previous lack of effective methodologies. This emphasizes the need for further research to document the occurrence of these protozoan pathogens in source and treated water.

The presence of human pathogenic microsporidia in surface water may suggest the presence of environmental reservoirs that include domestic and wild animals. Now, the detection of *E. intestinalis* and *E. bieneusi* in surface water may further lend credence to the potential for wild and/or domestic animal reservoirs. Like *Giardia* sp., which has environmental reservoirs including raccoons, and *Cryptosporidium* sp., which has cows as accessory hosts, microsporidia may also have wild and/or domestic animals that are natural or accessory hosts. In any case, the role of water in the transmission of infection to humans could play a significant role, and the microsporidia may be the newest waterborne emerging pathogens.

MODELING OF BIOFILMS

OSKAR WANNER
Swiss Federal Institute for Environmental Science and Technology
Dübendorf, Switzerland

The major difference between microbial systems with single cells in suspension and systems with biofilms or microbial flocs is that in the latter, transport processes usually are of primary importance. As a result of the high density of microbial cells in biofilms, high mass fluxes

are induced, which often make transport the rate-limiting process, and strong spatial gradients are formed, which create a variety of microniches in the biofilm interior (1,2).

There are a number of typical biofilm characteristics that are of relevance for biofilm modeling: (*1*) Biofilms are very complex systems. Various microbial species may coexist in a biofilm, and their behavior is determined by a large number of physicochemical parameters; (*2*) Biofilms are very dynamic systems. Typical time constants of biofilm processes range from seconds to weeks; (*3*) Biofilms have a high spatial heterogeneity. They grow in homogeneous layers of microbial cells or form mushroom-like structures; (*4*) Biofilms can be found in a variety of environmental and technical systems that differ considerably in geometry, hydrodynamic conditions, and properties of the substratum.

In biofilm modeling, this diversity is reflected by the numerous models that have been developed during the last thirty years. This development was paralleled by a dramatic increase in experimentally gained knowledge and a fast-growing computational capacity. The biofilm models existing today differ considerably in their complexity, resolution in time and space, database needed, and purpose for which they were developed. Some models are relatively simple and are used, for example, for the design of wastewater treatment plants, whereas some are rather complex and were developed as research tools to analyze experimental data or to test new hypotheses. Some are simple steady state models, whereas some describe the evolution of the biofilm structure in time, and in one, two, or three spatial dimensions.

In the following, biofilm modeling at three different levels is described. First, an example is given of one of the original, simple design models with one species and one substrate. Then, the one-dimensional, multispecies and multisubstrate models that are mostly used to solve practical problems, are discussed. Finally, new developments of models as tools for biofilm research are reviewed.

ONE-DIMENSIONAL, ONE-SPECIES AND ONE-SUBSTRATE MODEL

In wastewater treatment, numerous design formulas for biofilm reactors have been proposed over the past years (3). These formulas were mostly empirical, that is, they were based on data-fitting. Only in the 1970s, mechanistic models, that is, models derived from physical principles, started to evolve (4). The significance of transport of dissolved substrates in biofilms was then realized and it was found that this process could be described by Fick's first law of diffusion as

$$j = -D_F \frac{dS}{dz} \tag{1}$$

where j is the specific mass flux ($ML^{-2}T^{-1}$), D_F the molecular diffusivity in the biofilm (L^2T^{-1}), and S the concentration of the dissolved substrate (ML^{-3}), and z is a spatial coordinate in the direction opposite to the mass flux (L). To model consumption of the substrate diffusing into the biofilm, there are several alternatives. A very widely used model is the Monod equation for the substrate consumption rate r ($ML^{-3}T^{-1}$),

$$r = -r_{max} \frac{S}{K + S} \tag{2}$$

where r_{max} is the maximum substrate consumption rate ($ML^{-3}T^{-1}$), and K is the Monod or half-saturation constant (ML^{-3}). For a steady state situation, the change of the substrate flux is equal to the rate of substrate consumption at any location in the biofilm:

$$\frac{dj}{dz} = r \tag{3}$$

Substituting Equations 1 and 2 into 3 yields a one-dimensional mass balance equation for the substrate S,

$$\frac{d^2S}{dz^2} = \frac{r_{max}}{D_F} \frac{S}{K + S} \tag{4}$$

This is a nonlinear, second-order, ordinary differential equation, by which the concentration profile and the mass flux of the substrate in the biofilm can be calculated for a steady state situation. The solution has to be obtained by a numerical method and requires two boundary conditions. Usually, these are a no-flux condition at the interface between biofilm and substratum,

$$j = 0 \tag{5}$$

and a given substrate concentration S_{bulk} at the interface between biofilm and bulk fluid:

$$S = S_{bulk} \tag{6}$$

Simplifying Assumptions

The biofilm model as given by Equations 4 to 6 is based on a number of simplifying assumptions. These assumptions form an intrinsic part of the model and therefore are listed here:

- The substrate concentration is constant with time and throughout the bulk fluid of the system or reactor.
- The substrate considered is the only limiting substrate, that is, the concentrations of all the other substrates present are not significantly changed by the microbial activity in the biofilm.
- Transport of the dissolved substrate in the biofilm is by molecular diffusion only.
- There is one relevant microbial species forming a biofilm, that is attached to a plane substratum and consists of microbial cells evenly distributed throughout the biofilm.
- There is an equilibrium between net growth of microbial cells in the biofilm and net detachment of cells from the biofilm to the bulk fluid, that is, the biofilm thickness remains constant.
- The dimensions of the substratum area covered by the biofilm are large compared to the biofilm thickness,

which means that for symmetry reasons, the problem is one-dimensional in space and that the direction of mass fluxes is perpendicular to the substratum.

- The physicochemical conditions in the system or reactor do not change with time and space.

Data Requirements

For the solution of Equation 4 the values of the model parameters D_F, r_{max}, and K, as well as the substrate concentration S_{bulk} and the biofilm thickness L_F must be known. Usually, the spatial coordinate z is taken to be $z = 0$ at the substratum and $z = L_F$ at the biofilm surface. The diffusivity D_F of the substrate in the biofilm is affected by the microbial composition and biofilm density (5,6). Values for D_F given in the literature usually range from 40 to 100% of the diffusivity D in pure water (7–9). In most models, a value of $D_F = 0.8 * D$ is used. The maximum substrate consumption rate r_{max} is determined by

$$r_{max} = \frac{\mu_{max}}{Y} X \tag{7}$$

where μ_{max} is the maximum specific microbial growth rate (T^{-1}), X is the concentration of the microbial cells in the biofilm (ML^{-3}), and Y is the yield coefficient ($M_X M_{S^{-1}}$) that denotes the mass of X produced per unit of S utilized. For most species and substrates, numerical values for the kinetic and stoichiometric parameters μ_{max}, K and Y can be found in the literature (10). However, it becomes more and more clear that the kinetic parameters of a microbial species may vary considerably (11,12) and it seems that the values of the kinetic parameters of planctonic and sessile cells of the same species may be different (13). However, it remains unclear to what extent the observed variations are attributed to metabolic differences between the sessile and the planctonic state of the species.

Modifications and Extensions of the Model

A lot of experimental data can adequately be fitted by Equation 4 based on the Monod rate equation (Fig. 1). Studies of enzyme kinetics by Michaelis-Menten yield a potential theoretical explanation of the Monod Equation 2. With regard to modeling, the attractiveness of this equation is primarily due to its mathematical properties: for substrate concentrations S much larger than K, the rate r asymptotically reaches a maximum, which is reasonable because it must be expected that other substrates subsequently become rate-limiting. For values of S approaching zero, r converges to zero as well, which prevents numerical problems arising with rate equations for which S can become negative. Furthermore, the Monod equation represents a mathematical function, which is smooth for the whole range of substrate concentrations. Nevertheless, some researchers find zero-order rate expressions.

$$r = -r_0 \tag{8}$$

or first-order rate expressions

$$r = -r_1 S \tag{9}$$

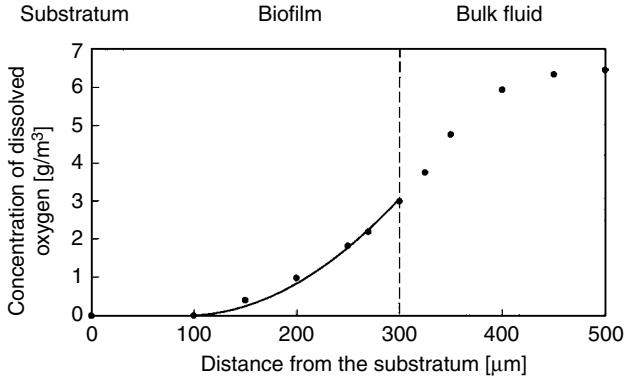

Figure 1. One-dimensional, one-species and one-substrate model: measured (14) and calculated spatial profile of dissolved oxygen.

with the rate constants r_0 ($ML^{-3}T^{-1}$) and r_1 (T^{-1}) adequately fit their data. The advantage of rate Equations 8 and 9, which can be considered to be special cases of the Monod Equation 2, is that they allow the analytical solution of the mass balance equation (15). However, with the computational capacities available today, it is not so advantageous to use Equations 8 and 9.

Mass transport limitation in a liquid boundary layer on the bulk fluid side of the biofilm surface often can have a significant effect on the spatial profile and consumption of the substrate in the biofilm (Fig. 1). Therefore, methods have been developed which allow inclusion of this process in the one-species and one-substrate model (16,17).

ONE-DIMENSIONAL, MULTISPECIES AND MULTISUBSTRATE MODEL

On the basis of the same mass balance principles used to derive the one-species and one-substrate model, a more general multispecies and multisubstrate model can be developed, if some of the simplifying assumptions that have been made in the former model are omitted. Microbial species and substrates will subsequently be referred to as particulate and dissolved components, respectively. For any component, a mass balance can be set up, which states that for any time and location the

change of the concentration in time	=	the change of mass transport in space	+	the transformation (production or consumption) rate

In mathematical terms, this is written as:

$$\frac{\partial C}{\partial t} = -\frac{\partial j}{\partial z} + r \tag{10}$$

where C is the component concentration (ML^{-3}). This mass balance equation is the basis for modeling of multispecies and multisubstrate biofilms. The equation can be applied to any microbial species and substrate, given that an adequate mathematical description of the transport and transformation processes of these components can be provided. Equation 10 describes a non–steady state situation, and as written here is one-dimensional in space.

Transformation Processes

Transformation processes are mathematically described by rate equations, which quantify the mass of a component produced or consumed per unit time and unit volume (18). These rate equations and their parameters have to be known for the dissolved as well as for the particulate components, that is, for all components that are to be considered in the model. Besides microbial species and dissolved substrates these can also include components such as pH, organic and inorganic particles, extracellular polymeric substances, or inactivated cells. In principle, the rate Equation 2, which is used in the one-species and one-substrate model, also applies here. However, because here a large number of interactions can occur between the various components considered, the rate equations in the multispecies and multisubstrate model usually are more complex (12,19). The so called stoichiometric matrix has proven to be a good means to represent the transformation processes and interactions of multispecies and multisubstrate microbial systems.

Stoichiometric Matrix. Table 1 shows an example, which has been taken from the literature (20) and is used here to describe the structure and use of stoichiometric matrices. In the first column of the matrix, the transformation processes considered in the model are listed, in the next columns, the stoichiometric coefficients of all particulate and dissolved components are included, and in the last column, the rate laws of the transformation processes are listed. According to the formula at the bottom of the matrix, the transformation rate r_i of component i is calculated as the sum of the stoichiometric coefficients v_{ij} multiplied by the process rate laws p_j of all transformation processes. The example given in Table 1 describes a biofilm system with two microbial species A and B, and the dissolved substrates acetate, glucose and dissolved oxygen. The processes numbered 1 to 4 describe growth and decay of the microbial species. The parameters Y and b denote the yield coefficients ($M_X\,M_{S-1}$) and decay rate constants (T^{-1}), respectively. The specific growth rates μ_i (T^{-1}) are modeled as

$$\mu_A = \mu_{\max A}\frac{C_{Ace}}{K_{Ace}+C_{Ace}}\frac{C_{O_2}}{K_{O_2}+C_{O_2}}F_{pH_A} \tag{11}$$

and

$$\mu_B = \mu_{\max B}\frac{C_{Glu}}{K_{Glu}+C_{Glu}}\frac{K_{O_2}}{K_{O_2}+C_{O_2}}F_{pH_B} \tag{12}$$

In these equations microbial growth depends on two rate-limiting substrates (12,19,21) and on pH, according to the expressions

$$F_{pH_A} = \frac{1}{(1+10^{5.5-pH})(1+10^{pH-9.5})} \tag{13}$$

and

$$F_{pH_B} = \frac{1}{(1+10^{5-pH})(1+10^{pH-9})} \tag{14}$$

Table 1. Stoichiometric Matrix

Process	Component[a] Particulate		Dissolved								Process Rate Law
	$i=1$	2	3	4	5	6	7	8	9	10	
j	A	B	Ace	Glu	O_2	CO_2	HCO_3^-	H^+	HPO_4^{-2}	$H_2PO_4^-$	$p_j(ML^{-3}\,T^{-1})$
1. Growth of A	1		$\frac{-1}{Y_A}$		$1-\frac{1}{Y_A}$	$\frac{2}{64}\left(\frac{1}{Y_A}-1\right)$		$\frac{-1}{64Y_A}$			$\mu_A X_A{}^b$
2. Decay of A	−1		1					$\frac{1}{64}$			$b_A X_A$
3. Growth of B		1	$\frac{1}{Y_B}-1$	$\frac{-1}{Y_B}$				$\frac{1}{64}\left(\frac{1}{Y_B}-1\right)$			$\mu_B X_B{}^b$
4. Decay of B		−1		1							$b_B X_B$
5. Production of CO_2						1	−1	−1			$\varepsilon_1 k_{f1} C_{H^+} C_{HCO_3^-}$
6. Consumption of CO_2						−1	1	1			$\varepsilon_1 k_{b1} C_{CO_2}$
7. Production of $H_2PO_4^-$								−1	−1	1	$\varepsilon_1 k_{f2} C_{H^+} C_{HPO_4^{-2}}$
8. Consumption of $H_2PO_4^-$								1	1	−1	$\varepsilon_1 k_{b2} C_{H_2PO_4^-}$
Transformation rate ($ML^{-3}\,T^{-1}$):			$r_i = \sum_j v_{ij} p_j$								

[a] Units for microbial species A and B, acetate, glucose and O_2 are gCOD m^{-3}; units for CO_2, HCO_3^-, H^+, HPO_4^{-2} and $H_2PO_4^-$ are mol m^{-3}
[b] μ_A and μ_B according to Equations 11 and 12.

The pH value in this example is the result of the two chemical reactions

$$H^+ + HCO_3^- \underset{k_{b1}}{\overset{k_{f1}}{\rightleftharpoons}} CO_2 + H_2O \tag{15}$$

and

$$H^+ + HPO_4^{-2} \underset{k_{b2}}{\overset{k_{f2}}{\rightleftharpoons}} H_2PO_4^- \tag{16}$$

where k_f ($L^3 M^{-1} T^{-1}$) and k_b (T^{-1}) are the forward and backward rate constants, respectively, of the chemical reactions, which in Table 1 are described by the processes numbered 5 to 8. The example demonstrates that biochemical and purely chemical reactions can formally be treated in exactly the same way. Because the biofilm is a multiphase medium, concentrations can be defined in two different ways. Usually, S and X refer to the concentrations of dissolved and fixed particulate components, respectively, defined as mass per unit biofilm volume, whereas C is the concentration of a dissolved component defined as mass per unit liquid phase volume, and ρ_s is the density of a cell or particle defined as its mass per unit of its volume. The two definitions are related to each other by

$$S = \varepsilon_l C \tag{17}$$

and

$$X = \varepsilon_s \rho_s \tag{18}$$

where ε_l and ε_s are the volume fractions (−) of the liquid phase and solid phases in the biofilm, respectively. The volume fraction ε_l is also referred to as porosity.

Stoichiometric matrices are increasingly used to describe the transformation processes of complex microbial systems (22). They readily allow one to check whether the kinetics and stoichiometry of a model have been set up correctly, that is, to verify, whether the sum of the stochiometric coefficients of each transformation process is zero, if the components are expressed in consistent units (23).

Transport Processes

Transport of dissolved substrates in the liquid phase of the biofilm is in this model also described as a diffusive process according to Equation 1. Transport of particulate species that are attached to the substratum and form the biofilm solid matrix, is the result of microbial growth and decay in the biofilm. Growing or shrinking cells lead to a volume expansion or contraction of the biofilm solid matrix, respectively, and to a displacement of neighboring cells (24). This displacement can be interpreted as advective transport and is formally described by

$$j = u_F X \tag{19}$$

where u_F is the distance by which the cells are displaced per unit time (LT^{-1}). The displacement velocity u_F of a cell at the location z is equal to the added net specific mass production of all particulate components of the biofilm matrix between the substratum and this location:

$$u_F(z) = \frac{1}{1-\varepsilon_l} \int_0^z \sum_i \frac{r_i}{\rho_{si}} dz \tag{20}$$

where r_i is the net transformation rate ($ML^{-3} T^{-1}$) of the particulate component i (20). In the one-dimensional, multispecies and multisubstrate model, the direction of the specific mass flux j is perpendicular to the substratum.

Transfer Processes

Mass-Transfer Resistance at the Biofilm Surface. The exchange of dissolved and particulate components between the biofilm and the bulk fluid is usually affected by the existence of a liquid boundary layer, which creates a mass-transfer resistance outside the biofilm surface and in which mass transport is due to molecular diffusion. This mass transport can be modeled as

$$j = \frac{D}{L_L}(C_L - C_B) \tag{21}$$

where L_L is the thickness of the liquid boundary layer (L), D is the molecular diffusivity of a dissolved or suspended particulate component in water ($L^2 T^{-1}$), and C_B and C_L are the concentrations of the component in the bulk fluid and at the biofilm surface (ML^{-3}), respectively. If flow in the bulk fluid is highly turbulent, mass-transfer resistance can usually be neglected; if it is almost stagnant, the boundary layer thickness may be on the order of several hundred micrometers, and C_L may differ significantly from C_B.

Detachment. In most cases, detachment is a very significant process, which limits biofilm growth (25). Detachment describes the loss of particulate material from the biofilm to the bulk fluid. This loss is primarily due to hydraulic shear forces (26,27) and occurs either as erosion of single cells or particles from the biofilm surface or as disruption of large chunks of biomass from the biofilm solid matrix. The latter phenomenon is referred to as sloughing. (See Biofilm Detachment, this Encyclopedia.) Modeling of both phenomena can be based on a velocity u_{de} (LT^{-1}), which yields a phenomenological description of the decrease of the biofilm thickness per unit time as a result of the detachment process. Because detachment was found to be caused by a variety of factors in addition to mechanical shear stress, such as changes of the physico chemical conditions (28–30), nutrient depletion (31), or release of specific enzymes in the biofilm depth (32), a universal expression for u_{de} does not exist. The expression

$$u_{de} = c_{de} L_F^2 \tag{22}$$

represents a purely empirical equation, chosen for its ability to exclude an infinitely increasing biofilm thickness (20). As already mentioned, two types of detachment are distinguished: erosion is modeled by small values of the detachment coefficient c_{de} ($T^{-1} L^{-1}$), which are constant or varying only slowly, and sloughing by

pulse-functions, that is, values of c_{de} which for short time periods become extremely large.

Attachment. This process refers to the adsorption of cells and particles suspended in the bulk fluid to the biofilm surface and is modeled by an attachment velocity as

$$u_{at} = \frac{1}{1-\varepsilon_l} \sum_i \frac{k_{at} X_{Li}}{\rho_{si}} \tag{23}$$

where k_{at} is the attachment rate coefficient (LT^{-1}) and X_L is the concentration of the suspended particulate component i at the bulk fluid side of the biofilm surface (ML^{-3}). Attachment is seldom explicitly included in biofilm models, simply because detachment usually exceeds attachment, and detachment thus is assumed to model the net mass transfer of cells and particles to the bulk fluid.

Mass Balance Equations

Dissolved Components. Substituting Equation 1 into Equation 10 yields a mass balance equation, which describes the development over time and the spatial profile in the biofilm of the concentration S of a dissolved component as:

$$\frac{\partial S}{\partial t} = D_F \left(\frac{\partial^2 S}{\partial z^2} \right) + r \tag{24}$$

with the boundary conditions

$$\frac{\partial S}{\partial z} = 0 \tag{25}$$

at $z = 0$ and

$$S = S_L \tag{26}$$

at $z = L_F$. Results as they are typically obtained by Equation 24 are shown in Figures 2 and 3, which display spatial profiles calculated for the example defined in Table 1 (20). Due to biofilm growth, the spatial profiles change their position in space (Fig. 3).

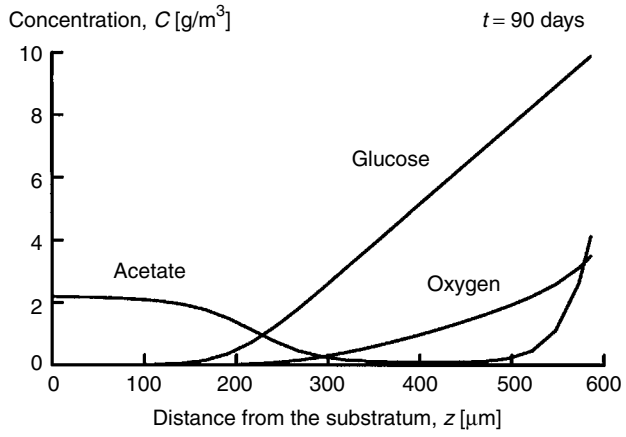

Figure 2. One-dimensional, multispecies and multisubstrate model: spatial profiles of dissolved oxygen, acetate and glucose.

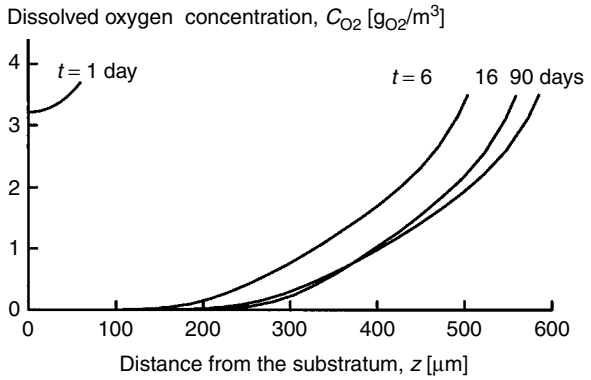

Figure 3. One-dimensional, multispecies and multisubstrate model: shift of the spatial profiles of dissolved oxygen as a result of biofilm growth.

Particulate Components. On the basis of the mass balance Equation 10 and Equation 19 for the mass flux, the development over time and the spatial profile in the biofilm of microbial species, inactivated cells, extracellular polymeric substances, and organic and inorganic particles is described as:

$$\frac{\partial X}{\partial t} = -\frac{\partial (u_F X)}{\partial z} + r \tag{27}$$

where X is the concentration of the particulate component in the biofilm (ML^{-3}) and u_F can be calculated by Equation 20. The boundary condition needed to solve Equation 27 is a no-flux condition at the substratum,

$$j = 0 \tag{28}$$

for $z = 0$. Equation 27 is used to calculate the relative abundance, spatial distribution, and development in time of the particulate components, as illustrated in Figure 4 for the microbial species, whose kinetics and stoichiometry are defined in Table 1. From the spatial profiles of the net specific growth rates

$$\mu_{net} = \mu - b \tag{29}$$

as shown in Figure 5, it can be understood why species A dominates near the biofilm surface, while species B primarily develops in the biofilm depth (Fig. 4).

Biofilm Thickness. The development over time of the biofilm thickness is the result of the net production of particulate components in the biofilm, as described by Equation 20, and of the exchange of cells and particles between biofilm and bulk fluid, as described by Equations 22 and 23. It is modeled as

$$\frac{dL_F}{dt} = u_F(z = L_F) - u_{de} + u_{at} \tag{30}$$

In situations for which only incomplete data is available for the terms on the right-hand side of Equation 30, u_{at} usually is set to zero and u_{de} equal to $u_F(z = L_F)$, having the effect that L_F remains constant at its initial value.

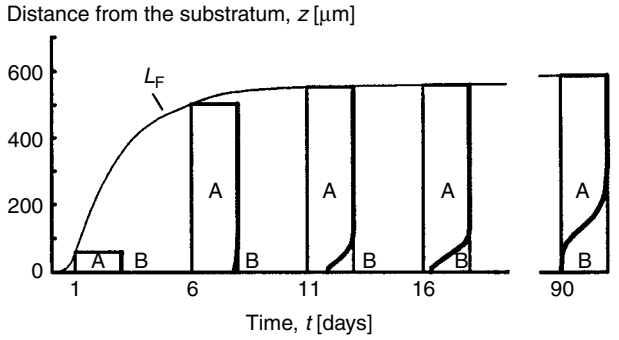

Figure 4. One-dimensional, multispecies and multisubstrate model: progression of the biofilm thickness L_F and the microbial composition of the biofilm solid matrix. Bars show the relative abundance of the two microbial species A and B between substratum (bottom) and biofilm surface (top).

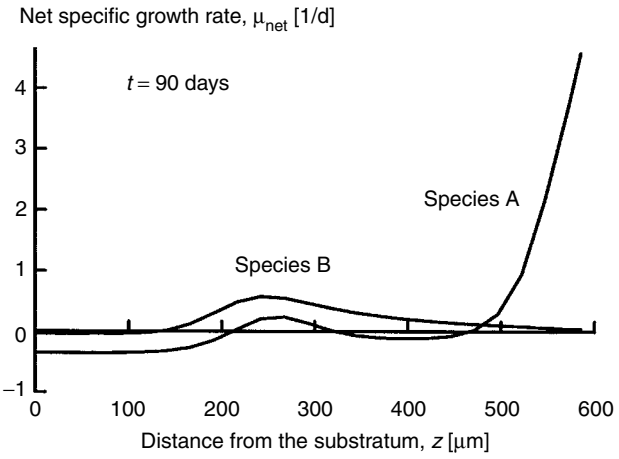

Figure 5. One-dimensional, multispecies and multisubstrate model: spatial profiles of the net specific growth rate of two microbial species A and B. Near the surface, A outgrows B; in the biofilm depth, B outgrows A.

Bulk Fluid. In general, the processes that take place in the biofilm also have an effect on its environment. Usually, this environment is modeled as a completely mixed volume of water, termed bulk fluid. Transformation processes in the bulk fluid can be equally important to those that take place in the biofilm. For each dissolved and suspended particulate component considered, an additional mass balance equation

$$\frac{d(V_B C)}{dt} = Q(C_{in} - C) + A_F j + V_B r \qquad (31)$$

is needed, where C_{in} and C are the influent and bulk fluid concentrations of each component (ML^{-3}), respectively, V_B is the bulk fluid volume (L^3), Q is the rate of flow through the bulk fluid ($L^3\,T^{-1}$), A_F is the biofilm surface area (L^2), j is the mass flux across the biofilm surface ($ML^{-2}\,T^{-1}$), and r is the transformation rate ($ML^{-3}\,T^{-1}$) of the component.

Numerical Solution of the Mass Balance Equations

For each dissolved and particulate component, mass balance equations for the biofilm and the bulk fluid have to be included in the model, together with Equation 30 for L_F and appropriate rate expressions for all the components considered. The numerical solution of the resulting set of nonlinear, partial differential equations requires some skill in numerical mathematics and a considerable computational effort.

Computer Simulation. AQUASIM is a computer program for the identification and simulation of aquatic systems (33–36) and includes the multispecies and multisubstrate model (37). The program is available for several types of computers and solves the mass balance equations for the components and processes, which are specified by the user.

Simplifying Assumptions

The one-dimensional, multispecies and multisubstrate biofilm model as given by Equations 24 to 28,30, and 31 is based on the following simplifying assumptions:

- The bulk fluid of the system or reactor is assumed to be completely mixed.
- The dimensions of the substratum area covered by the biofilm are large compared to the biofilm thickness, which means that for symmetry reasons, the problem is one-dimensional in space and that the direction of mass fluxes is perpendicular to the substratum.
- The biofilm is attached to a plane substratum and is formed by microbial cells evenly distributed throughout the biofilm.
- The volume fraction of the liquid phase in the biofilm, ε_1, does not change with time and space.
- Several microbial species that compete for nutrients and space in the biofilm, can be considered.
- The processes contributing to biofilm growth, that is, to the change of the biofilm thickness in time, are the net production of particulate components in the biofilm, and detachment or attachment of particulate components at the biofilm surface.
- Several limiting substrates can be considered, whose influent and bulk fluid concentrations may vary with time.
- Transport of the dissolved substrates in the biofilm is via molecular diffusion only.

Data Requirements

To set up the multispecies and multisubstrate model, it must be decided which dissolved and particulate components are to be considered. Criteria for this decision are the expected relative abundance of the components forming the biofilm matrix and significance of mass fluxes. Sometimes, specialized microbial species, degrading a xenobiotic organic chemical of interest, also are included. However, it is useless to include components for which rate equations or parameter values are not known. If this is the case, it is better to introduce, for example, components such as "heterotrophic organisms" or "readily degradable organic substrate" instead of several incompletely defined microbial species or substrates. The data required by

the model for all components considered, include the diffusivities in pure water and in the biofilm, and rate laws, kinetic parameters, and stoichiometric coefficients of the transformation processes. Sometimes the rate constants k_f and k_b, as used in Equations 15 and 16, are not known, but the equilibrium constant $K_e = k_f/k_b$ is available. If these equations describe processes that are fast compared to other processes included in the model, it is possible to choose an arbitrary (large) value for k_b and to calculate k_f as $k_f = k_b K_e$. Furthermore, the density of the particulate components, ρ_s, as well as expressions for their attachment and detachment velocities must be given. The latter can seldom be taken from the literature, because they depend on the properties of the reactor or environmental system, and are difficult to measure directly. However, net detachment rates can readily be determined experimentally, if the detached particulates are collected in the effluent of the reactor or system. The volume fraction of the biofilm liquid phase usually is chosen to be $\varepsilon_1 = 0.8$. The geometric and hydraulic data needed are the biofilm surface area A_F, the bulk fluid volume V_B, the thickness of the liquid boundary layer L_L, and the flow rate Q. To start a simulation, the influent and bulk fluid concentrations of all components, the initial spatial distribution of the particulate components in the biofilm, and the initial biofilm thickness must be known. The spatial profiles of the dissolved components in the biofilm develop so fast that the choice of their initial values usually is insignificant. In situations in which only a few dispersed cells are already attached to the substratum, it is no problem to start the simulation with a very small mass of particulate components, that is, with an initial biofilm thickness of a fraction of a micrometer.

Extensions of the Model

A more detailed description of the multispecies and multisubstrate model and examples of its application can be found in the literature (20). In recent years, new experimental techniques have revealed phenomena that cannot be taken into account by the model (38). Therefore, a number of extensions have been made to the original model:

- In the original, multispecies and multisubstrate model, there was either detachment or attachment of cells and particles from or to the biofilm surface, respectively, but the two processes could not occur simultaneously. In the extended model, detachment rates can be specified individually for each particulate species in the biofilm (37). This makes it possible that some species are detached slower than others or even accumulate at the biofilm surface, if attachment is a significant process. For mathematical reasons, simultaneous detachment and attachment is possible only if the particulate components, which form the biofilm solid matrix, are not only displaced by advection, but also by diffusion along the concentration gradient. The latter process allows that particulates that have attached to the biofilm surface can subsequently and slowly penetrate the biofilm (39).
- In the extended model, suspended cells and particles can also be transported in the biofilm liquid phase (39). Consequently, adsorption and desorption of these components to and from the biofilm solid matrix can occur and the kinetics of these processes have to be quantified.
- New experimental data clearly indicate that the physical properties of the biofilm change with time and space. The liquid phase volume fraction, ε_1, decreases with time, especially in the biofilm depth (40). The extended model includes a rate r_{ε_1}, which may be a function of time, space, or other process rates, and thus offers the possibility to test alternative hypotheses about the mechanism underlying the change of ε_1 (37). In the extended model, the diffusivity of dissolved components, which was found to vary considerably over the biofilm depth (9) can be any function of time or space.

With all the additional terms and processes (Fig. 6), the mass balance equations of the extended model have become rather complex (37). However, these additional terms are mainly needed to make the mass balance equations rigorous, and the extensions have little relevance for practice; rather they serve as tools for helping to interpret experimental data obtained in basic research.

The extensions of the multispecies and multisubstrate model are implemented in the computer program AQUASIM (35,36). By default, all the extensions are inactive, thus allowing one to choose the complexity of the model according to the data available. Additional features of AQUASIM are that the substratum may be flat, cylindrical, or spherical, and that the diffusivities in the biofilm may vary with time and over the biofilm depth, accounting for the observation that dissolved components in some cases are transported by advection or turbulent diffusion in parts of the biofilm.

NEW TRENDS IN MODELING

New experimental techniques for the analysis of the structure and function of biofilms have evolved rapidly in the last years, revealing that biofilms are systems that are much more complex and diverse than believed previously (41–43). In parallel to the development of the new experimental tools that provide data at the microscopic scale, new models have been developed to describe biofilm behavior at the level of cell colonies or even individual cells. The objective of these efforts is, on the one hand, to design models able to reproduce the experimentally observed phenomena, and on the other hand, to provide analytical tools to study hypotheses about the mechanisms underlying these phenomena. It is impossible to describe in detail all the modeling work that has been done during the last years. Therefore, in the following text only some of the concepts, objectives, and results of new trends in biofilm modeling are summarized.

Multidimensional Models of Biofilm Structure

Modeling Concepts. One group of new biofilm models primarily deals with the development of the biofilm

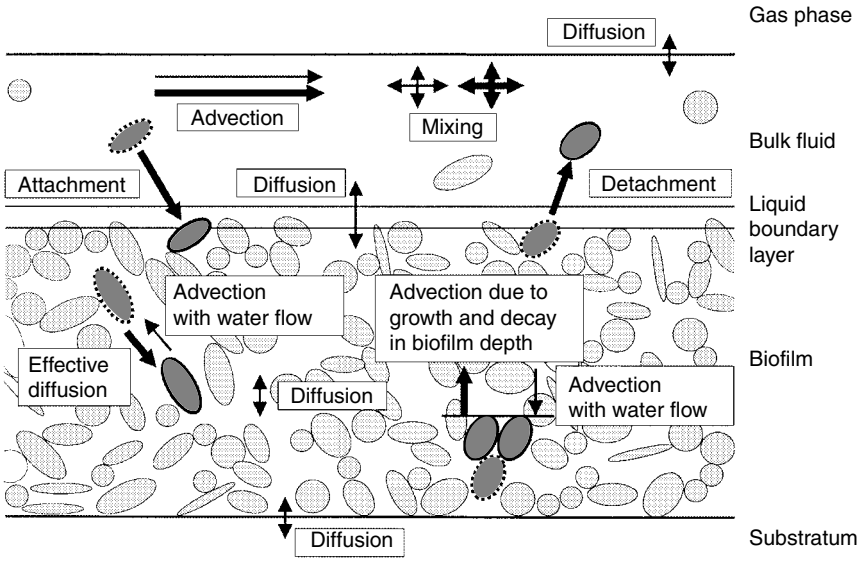

Figure 6. Extended one-dimensional, multispecies and multisubstrate model: transport processes considered in the model. Thick arrows refer to particulate components; thin arrows refer to dissolved components.

structure, which in many cases has been found to be an aggregate of distinct microbial colonies with large pores in between, and does not have the form of a smooth layer of homogeneously distributed cells. Most of these models are so called "cellular automaton" models (44–46). Their concept is to divide the space at the liquid side of the substratum into a large number of very small volume elements in which the changes in time of the concentrations of the dissolved and particulate components are calculated as the result of transformation and transport processes. These processes are the same as those considered in the one-dimensional, multispecies and multisubstrate model described earlier, but the major difference is that here transport is modeled in two or three dimensions. Transport of the particulate components that form the biofilm solid matrix, occurs when, because of the production of mass, the concentration of the particulates in a volume element exceeds a given maximum packing density and any mass produced beyond that limit is displaced to adjacent volume elements. Transport of dissolved and suspended particulate components is also modeled by the cellular automaton approach (45), or by numerical solution of the mass balance Equation 24 in two- or three-dimensional form, for example, by finite difference techniques (47). If the Navier-Stokes equations that provide a multidimensional description of the flow field, are solved simultaneously with the component mass balance equations, advective transport of dissolved and suspended particulate components can also be considered (46,48). Most of these models have been developed for one microbial species, but there are attempts to consider more than one species, interacting by transformation processes (49). To start the calculation, some mass of particulate components usually is attributed at random to a few volume elements, thus simulating the initial colonization of the substratum.

Formulation of Rules. The solution of the model equations for dissolved components primarily requires a lot of computational resources and therefore necessitates a careful selection of appropriate numerical methods (50). However, the most demanding step in the development of the cellular automaton models is the formulation of the rules that determine how the particulate mass is transferred between adjacent volume elements. After each integration step in time, all volume elements are sequentially checked for excess particulate mass, which then is displaced to adjacent volume elements, either selected at random (47,49) or by a given criterion, such as preferential displacement in the direction of the biofilm surface (51). Rules also have to be formulated if additional processes are considered. Detachment is attributed to liquid shear stress exceeding the mechanical strength of the biofilm solid matrix in a volume element (52), or is modeled by simple probability functions based on shear stress and mechanical strength (51), or on empirical coefficients (53).

Results. The new multidimensional models are able to reproduce biofilm structures as they are observed experimentally, even if these models are not based on identical rules, and also may differ in the number of processes and components they consider. It seems that introducing stochastic elements into biofilm models is the key factor for modeling their multidimensional structural development. An interesting model prediction is that dense biofilms are produced if their development is limited by the microbial growth rates, and that porous, mushroom-shaped biofilms are produced if the substrate transport rates are limiting (Fig. 7).

Models Based on the Behavior of the Individual Cells

Modeling Concepts. Inspired by observations of population dynamics made in ecology, it is argued that the development of the biofilm must be the result of the behavior of the individual cells of which it is composed. This idea has led to a number of new modeling approaches, by which properties of the individual cells

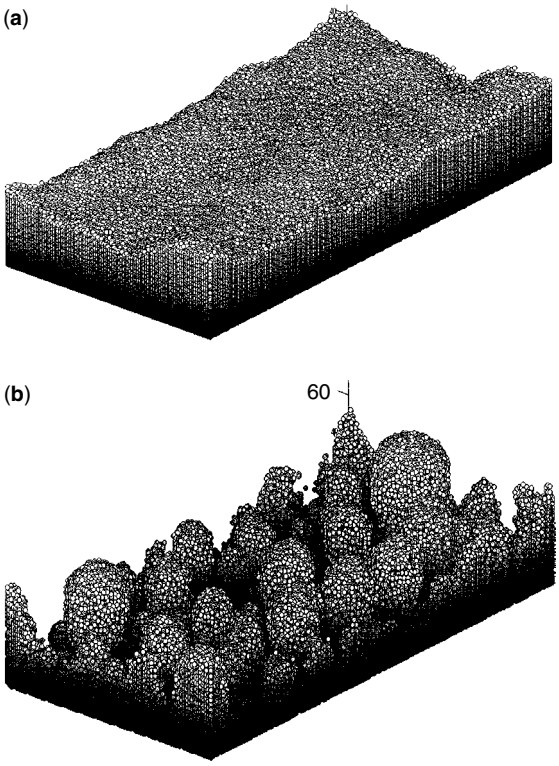

Figure 7. Three-dimensional cellular automaton model of biofilm structure: for high (**a**) and for low (**b**) substrate concentrations, different types of biofilm structures are developing (54).

and processes taking place at the cell level are considered. In one approach, intracellular transformation processes, mass transfer across the cell membrane and extracellular mass transport is modeled at the level of individual cells, and then by averaging, an expression for a growth rate is derived, which is representative for a larger volume element (55). In another approach, called "individual-based modeling," the usually made assumption is abandoned that the behavior of the cells of a microbial species can be modeled by kinetic rate laws and parameters which represent average values not changing with time and space (56). In this model, each cell of the biofilm is described as a distinct object with parameters obtained by random draws from a statistical distribution. As a result of this procedure, the cells of the population do not grow synchronously, leading to the biofilm heterogeneity as it is observed experimentally.

Results. The final objective of individual-based modeling is to explain the behavior of a biofilm at the macroscopic level as the result of the processes that take place at the microscopic level. So far, the approach has suffered from a lack of experimental data on the behavior of the individual cells and on the variability of their kinetic parameters, but with the rapidly increasing knowledge about cells and cell-cell interactions, individual-based modeling could become an important research tool.

Simplifying Assumptions

The multidimensional models of biofilm structure and the one-dimensional, multispecies and multisubstrate model are based on mass balance equations, that is, they all are derived from physical principles. However, knowledge on the mechanism determining the three-dimensional development of the biofilm solid matrix is incomplete. In the one-dimensional, multispecies and multisubstrate model this problem is solved by averaging all variables in planes parallel to the substratum. By doing so, the model complexity is reduced to one dimension in space and to one unknown structural parameter, the liquid phase volume fraction, ε_1. Alternatively, in the new multidimensional models, probability functions are used, and rules are formulated to describe the displacement of microbial cells in various spatial directions as a result of cell growth. This approach is empirical; however, the striking correspondence between observed and modeled development of biofilm structures is an indication that the functions and rules describe the underlying (unknown) physical mechanisms quite well. This also is true for the models describing biofilm behavior at the level of individual cells.

Data Requirements

Among the new models describing the multidimensional development of the biofilm structure and the behavior of individual cells, there are differences in the number of components and processes considered, as well as in the mechanisms by which the processes are modeled. However, for the mathematical description of the geometry of the system or reactor and of the transformation processes, the same data are used by all models, except for the individual-based model, which also needs data on the cell size and variability of the kinetic parameters (56). As compared to the one-dimensional, multispecies and multisubstrate model, the major differences are that in the multidimensional models, the initial and influent concentrations and the inflow do not only vary with time, but also with one to three space coordinates. The complete description of the flow field based on physical laws requires a high computational effort, but avoids the introduction of "artificial" parameters like "diffusivity in the biofilm" or "liquid boundary layer thickness." All models require information on the "packing density" of the microbial cells in the biofilm. In some models this parameter is specified explicitly; in others it is specified indirectly as "porosity" or "biofilm liquid phase volume fraction," or by simple rules such as "cells may not overlap" (56). As mentioned earlier, attachment of cells or particles to the biofilm surface is hardly ever considered, because detachment is assumed to model the net transfer of particulate material between bulk fluid and biofilm. Detachment is modeled as the result of shear stress locally exceeding the mechanical strength of the biofilm solid matrix, as an empirical first-order process, or by use of probability functions, which in one model also are applied to transformation and diffusion processes (53).

CONCLUSION

There are a large number of existing biofilm models. These models differ considerably in their complexity, that is, in the number of processes that they consider and in the accuracy with which these processes are described. Which of these models is appropriate to use for solving a given biofilm problem primarily depends on the objectives and the questions asked (57,58). To make a rough estimate of the amount of biomass needed to eliminate a specific substrate in a biofilm reactor, the simple one-species and one-substrate model may be adequate (17). To calculate the effluent concentrations of a wastewater treatment plant, the one-dimensional, multispecies and multisubstrate model has been applied successfully (59). To identify gaps in knowledge, to analyze differences between experimental observations and model predictions, and to formulate and test alternative hypotheses on processes for which the mechanisms are not yet fully understood, the new generation of biofilm models offers a large potential (46). These new models may serve as powerful research tools to analyze topics such as the role of extracellular polymeric substances, cell-to-cell interactions, gene transfer, and detachment. They also represent a unifying means for the indispensable interaction between biofilm researchers of the many disciplines needed to promote the understanding and control of biofilm systems.

MODELING OF VIRUS TRANSPORT AND REMOVAL IN THE SUBSURFACE

JACK F. SCHIJVEN

Bilthoven, The Netherlands

MAJID HASSANIZADEH
Delft University of Technology
Delft, The Netherlands

Pathogenic viruses are a significant cause for waterborne disease outbreaks attributed to the consumption of contaminated groundwater (1–3). Contamination originates from fecal contaminated sources such as failing septic systems, leaking sewer lines, land application of wastewater, or its mixing with infiltrated surface water. A groundwater well can sufficiently be protected from contamination with viruses, provided setback distances between the source of contamination and the well are great enough. Similarly, viruses can effectively be removed from surface water by passage through soil, provided travel times and travel distances are adequate (4). During passage through soil, viruses are removed from the aqueous phase because of adsorption and inactivation (5,6). Moreover, advection and dispersion affect spreading of viruses, and attenuation. The effectiveness of soil passage for protection of groundwater wells or treatment of surface water can be evaluated by calculating the concentration of viruses at the point of origin from the concentrations in source water by means of a computational virus transport model, which describes the removal processes.

Under field conditions, contamination levels of pathogenic viruses are usually too low to be detected and thus their behavior cannot be easily studied. Therefore, in most studies on subsurface transport of viruses, bacteriophages are used as model viruses. Bacteriophages closely resemble pathogenic viruses, but are not harmful to humans. Bacteriophages can be prepared in large quantities (10^{10}–10^{12} phages per ml) and can be injected or seeded in high numbers into an aquifer. Moreover, bacteriophages can easily be assayed compared to pathogenic viruses.

MODELING SUBSURFACE TRANSPORT OF VIRUSES

Conceptual Model

Processes that must be included in modeling of virus transport in soil and groundwater are adsorption, inactivation, advection, and dispersion. Adsorption of viruses to soil may be irreversible or reversible. In the case of irreversible adsorption, attachment exists and there is no detachment. In the case of reversible adsorption, one may have sites where attachment and/or detachment are fast relative to the flow velocity, allowing equilibrium to occur. For some other sites, adsorption is kinetically limited relative to flow velocity, with constant attachment and detachment rate coefficients. Under the condition of saturated flow, the governing equations of one-dimensional virus transport are as follows:

$$R\frac{\partial C}{\partial t} + \frac{\rho_B}{n}\frac{\partial S_{kin}}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - \nu\frac{\partial C}{\partial x} - Q \tag{1}$$

$$R = 1 + \frac{\rho_B}{n}k_{eq} \tag{2}$$

$$Q = \left(\mu_l + \mu_{s,eq}\frac{\rho_B}{n}k_{eq}\right)C + \mu_{s,kin}\frac{\rho_B}{n}S_{kin} \tag{3}$$

$$\frac{\rho_B}{n}\frac{\partial S_{kin}}{\partial t} = k_{att}C - k_{det}\frac{\rho_B}{n}S_{kin} - \mu_{s,kin}\frac{\rho_B}{n}S_{kin} \tag{4}$$

Here, C is the free virus concentration, that is the number of free viruses per unit volume in the aqueous phase, $[L^{-3}]$; S_{kin} denotes the concentrations of viruses attached to kinetic sites in terms of number of viruses per unit mass of soil, $[M^{-1}]$; ρ is the bulk density of the saturated soil, $[M.L^{-3}]$; n is the porosity; D is the hydrodynamic dispersion coefficient, $[L^2.T^{-1}]$; ν is the pore water velocity, $[L.T^{-1}]$; k_{eq} is a distribution coefficient, $[L^3.M^{-1}]$; R is the retardation coefficient related to equilibrium adsorption; k_{att} and k_{det} are the attachment and detachment rate coefficients, respectively $[T^{-1}]$; μ_l is the inactivation rate coefficient for the free viruses, $[T^{-1}]$; $\mu_{s,eq}$ and $\mu_{s,kin}$ are the inactivation rate coefficients for viruses attached to equilibrium and kinetic sites, respectively $[T^{-1}]$.

Virus adsorption to soil is the most important process for attenuation. However, actual removal, that is, disappearance of viruses, is due to inactivation, and irreversible attachment, whenever it exists. Under steady state conditions, the relative contributions of inactivation and adsorption to the removal of viruses by soil passage

can be compared easily. A steady state situation occurs when input of virus is continuous. This is usually the case during bank filtration, dune recharge, deep well injection, or continuously leaking sewage pipes and may be seen as a worst-case situation. Considering a one-dimensional steady state situation, Equation (1) may be simplified to:

$$\alpha_L \frac{\partial^2 C}{\partial x^2} - \frac{\partial C}{\partial x} = \frac{Q}{\nu} \tag{5}$$

Here, $\alpha_L = D/\nu$ is the longitudinal dispersivity, [L]. Under steady state conditions, it follows from Equation (4) that

$$\frac{\rho_B}{n} S_{kin} = \frac{k_{att}}{\mu_{s,kin} + k_{det}} C \tag{6}$$

Substitution of Equation (6) into (3) gives

$$Q = \lambda C \tag{7}$$

where

$$\lambda = \mu_l + \mu_{s,eq} \frac{\rho_B}{n} k_{eq} + \frac{k_{att}}{1 + \dfrac{k_{det}}{\mu_{s,kin}}} \tag{8}$$

Now, the solution of Equation (5) can be written as

$$\log_{10}\left(\frac{C}{C_0}\right) = \frac{x}{2.3} \frac{\left(1 - \sqrt{1 + 4\alpha_L \dfrac{\lambda}{\nu}}\right)}{2\alpha_L} \tag{9}$$

where C_0 is the concentration at $x = 0$, and $\log(C/C_0)$ is a measure of virus removal. It can be shown that for small values of α_L:

$$\frac{\log_{10}\left(\dfrac{C}{C_0}\right)}{t} = -\frac{\lambda}{2.3} \tag{10}$$

where t is the travel time defined by $t = x/\nu$.

Equation (10) gives the removal rate. From Equations (8, 9), and (10), the relative contributions of adsorption and inactivation to virus removal can be deduced. The first term in Equation (8) gives the removal rate by inactivation of free virus. The second and last terms give the removal rate of virus by interaction with equilibrium and kinetic sites, respectively. Interaction means the combination of attachment, detachment, and inactivation of virus at a particular type of site of the porous medium.

Interaction with Equilibrium Sites

Equilibrium adsorption has been assumed in several column and field studies, whereby kinetic adsorption is neglected (7–10). In some studies, an extra sink term was also included to account for virus removal owing to irreversible attachment (11–13). To show the effect of equilibrium adsorption, some column breakthrough curves were simulated using the CXTFIT-code (14). This code is based on analytical solutions of equilibrium and kinetic transport models, including governing Equations (1) to (4).

For a period of ten days, a virus was seeded on top of a column at a constant concentration. Breakthrough was calculated and is displayed in Figures 1a and b (linear and semilog plots, respectively). The parameter values that were used for these simulations are given in Table 1. Dispersion is basically a characteristic of the porous medium, provided that no size and/or charge exclusion effects are present. Therefore, a virus entering the soil experiences the same dispersion as a conservative salt tracer. This is the case when considering curves A and B. A conservative salt tracer is not retarded and C/C_0 reaches a plateau of one shortly after breakthrough (curve A). A virus that does not attach to the soil shows the same breakthrough as the salt tracer, but the plateau is lower because of inactivation of the virus (curve B). If a virus is also retarded owing to equilibrium adsorption, it shows the same curve as B, but it is shifted to the right (curve C). In addition, the plateau is even lower because more time is available for inactivation to occur. If this virus is subject to a higher dispersion (Table 1), the shape of the curve becomes flatter as is illustrated by curve D. Here, a fraction of the virus breaks through earlier, but the time to peak breakthrough is concurrent with the middle of the plateau of curve C.

Retardation coefficients of about 2–5 have been reported (9,15–17). Retardation coefficients of 1.7–2 were found in a study with five different bacteriophages (18). In that study, it was also found that the fraction of equilibrium sites to the total number of adsorption sites depends on the type of phage. Bacteriophage PM2 did not interact with equilibrium sites, and bacteriophages MS2,

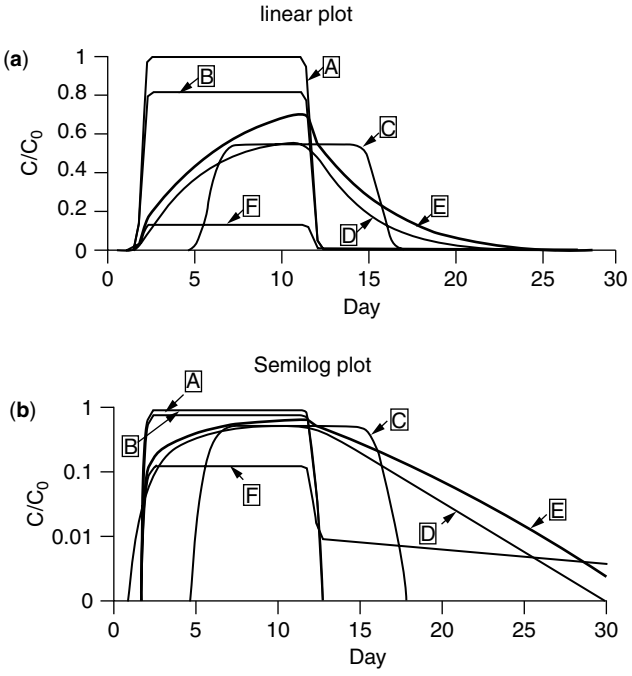

Figure 1. Simulated breakthrough curves of (**a**) a conservative salt tracer, (**b**) a virus that does not adsorb, but that is inactivated, (**c**) a virus that is retarded because of equilibrium adsorption and that is inactivated, (**d**) like (**c**) with higher dispersion, (**e**) a virus that adsorbs to kinetically limited sites, and that is inactivated.

Table 1. Parameter Values Used to Simulate Breakthrough Curves for (a) a Conservative Salt Tracer and (b)–(f) for a Virus Exhibiting Different Types of Adsorptive Behavior. Resulting Breakthrough Curves Are Shown in Figures 1a and 1b. Pore Water Velocity = 1.5 m/day and distance = 3 m.

Parameter	A Salt Tracer	B Virus + Inactivation	C Virus as in B + Equilibrium Adsorption	D Virus as in C + High Dispersion	E Virus as in B + Kinetic Adsorption	F Virus as in E But Slow Detachment
D	0.02	0.02	0.02	1	0.02	0.02
R	1	1	3	3	—	—
k_{att}	—	—	—	—	1	1
k_{det}	—	—	—	—	0.5	0.005
$\mu_l = \mu_s$	0	0.05	0.05	0.05	0.05	0.05

Dimension of D is [m^2.day^{-1}], that of k_{att}, k_{det}, μ_l and μ_s is [day^{-1}].

PRD1, and Qβ only for a minor part. However, a larger proportion (56%) of ϕX174 adsorbed to equilibrium sites. For this latter phage the value of k_{att} was low. Thus for ϕX174, the interaction with equilibrium adsorption sites contributes more to removal than the interaction with kinetic sites. In the case of other phages, the interaction with kinetic sites is far more important in determining removal. Generally, little or no retardation due to equilibrium adsorption of viruses is found (11,15,19–21). Because the value of k_{eq} is generally very low and the values of μ_l and $\mu_{s,eq}$ are of similar order, interaction with equilibrium sites will not contribute significantly to virus removal.

Interaction with Kinetic Sites

At field scale (16,21), attachment rates are relatively fast compared to advection ($k_{att}L/v > 1$, where L is a characteristic travel distance), whereas detachment rates are much slower ($k_{det}L/v < 1$). At very low flow rates, for example, under some natural gradient conditions, kinetically limited adsorption may successfully be described by equilibrium adsorption. To show the differences and similarities between equilibrium and kinetically limited adsorption, various breakthrough curves resulting from kinetic adsorption were simulated using the CXTFIT-code (14) and added to Figures 1a and 1b. Curve E simulates breakthrough of a virus, with the same dispersion as the salt, but now exhibiting kinetically limited adsorption, whereby $k_{att}/k_{det} + 1$ equals the value of R in curve D. The time to peak breakthrough is somewhat retarded. In fact, curves D and E in Figures 1a and 1b have a very similar shape. In some studies (15,22), equilibrium adsorption was assumed, but then an artificially large dispersion coefficient that is much larger than that of the coinjected salt tracer, was needed to fit virus breakthrough curves of shapes similar to curves E and D. Applying the same dispersion coefficient for the salt tracer and the virus, as well as assuming kinetic adsorption is more appropriate. Curve F simulates virus breakthrough, now exhibiting slow detachment. The shape of this curve on linear concentration-scale (Fig. 1a) is now the same as A and B, only the maximum concentration is lower because of attachment. However, when plotted on a semilog scale, a tail becomes visible, which makes it distinct from the other curves (Fig. 1b). Now, if measurements are stopped before the end of the plateau is reached, or if only linear plots are made, one may conclude that there is no reversible adsorption but a very high rate of irreversible adsorption (11,22). These simulations show that description of virus transport by an equilibrium model and a kinetic model may lead to similar results, and that investigation of tailing on a semilog plot is required to tell the difference. A shortcoming of many virus transport experiments is that the tail of the breakthrough curve is not measured, so that the kinetic behavior cannot be observed and quantified (8,9,11).

In several column experiments, adsorption of bacteriophages MS2 and PRD1 was shown to be reversible and kinetically limited; bacteriophages were not found to be retarded by equilibrium adsorption (15,19,23). The same was observed in field studies with MS2, PRD1, ϕX174, and poliovirus 1 (16,21,24,25). Figure 2 shows a typical breakthrough curve of MS2 from a column study (26). Open circles in Figure 2 show the measured breakthrough curve of MS2. A one-site kinetic model was applied to fit this curve. Values for k_{att1}, k_{det1}, and μ_{s1} were obtained by fitting the whole breakthrough curve. These values are given in Table 2 under column A and correspond to curve A in Figure 2. The value of k_{det1} is higher than that of k_{att1} and the value of μ_{s1} is much higher than that of μ. Curve A fits the measured breakthrough curve very well, except for the tail part; this is not considered as satisfactory. In another

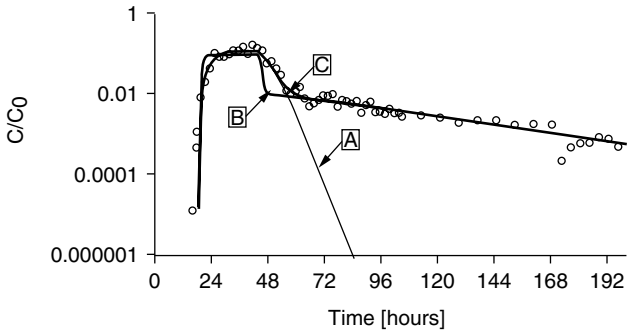

Figure 2. Measured breakthrough curve (open circles) of MS2 fitted with a one-site kinetic model (curves A and B) and a two-site kinetic model (curve C) (26).

Table 2. Parameter Values (in day^{-1}) Estimated from Breakthrough Curves of Column Experiments: A, B, and C in Column Headings Correspond to Curves A, B, and C in Figure 2 (26)

Rate Coefficients	A: One-site Model	B: One-site Model	C: Two-site Model
k_{att1}	4.80	2.64	1.94
k_{det1}	6.72	0.065	0.065
k_{att2}			3.36
k_{det2}			13.7
μ_1	0.07	0.07	0.07
μ_{s1}	5.76	0.43	0.43
μ_{s2}			0.43

set of simulations, again a one-site model was used, but this time, trying to fit both the peak and the tail of the breakthrough curve. The corresponding parameter values are given under column B in Table 2 and the corresponding curve is also shown in Figure 2. It was found that the value of μ_{s1} mainly determines the tail slope, whereas the value of k_{det1} mainly determines its intercept. The end of the rising limb and the start of the declining limb of the breakthrough curves cannot be simulated completely, probably owing to an another reversible adsorption process. The value of k_{det1} is now much less than that of k_{att1} (Table 2, column B). Finally, the breakthrough curve was fitted by applying a two-site kinetic model that is, assuming that there is interaction with two different kinds of kinetic sites. The estimated values are given in column C of Table 2. The resulting curve C, in Figure 2, clearly gives a very satisfactory fit of the measurements. The values of k_{att1}, k_{att2}, k_{det2}, and μ_l mainly determine the height of the breakthrough curve. The value of k_{det2} strongly affects the skewness of the climbing and declining limbs. After the pulse of viruses has passed, site 2 looses its influence on the shape of the curve because of the high detachment rate of this site. The values of k_{det1} and μ_{s1} mainly determine the tail of the breakthrough curve.

Similarly shaped breakthrough curves, that is, with the rising limb skewed to the right and with a smooth transition of the declining limb to the tail, have been found in other studies (15,18,19,23). Possibly, the involvement of more than one type of kinetic site is general. As for parameters that were found for the breakthrough curve in Figure 2, it appeared that δk_{attl} (Eq 8). In that case, attachment mainly determines virus removal, which appears to work as irreversible attachment. In some studies, such an approach was followed, that is, virus inactivation was neglected and virus removal was assumed to be solely because of irreversible attachment (20,25).

Colloid Filtration

According to colloid-filtration theory, the attachment rate coefficient of a colloid (e.g., a virus) can be expressed in terms of a single collector efficiency η and a sticking (or collision) efficiency α as follows (27):

$$k_{att} = \frac{3}{2}\frac{(1-n)}{d_c}\alpha\eta v \tag{10}$$

Here, d_c is the average diameter of the single collector (soil grain), [L]. The fraction of particles that collide with the collector is given by η, the single collector efficiency. Because viruses are small in size, their transport in the immediate vicinity of the collector surface is dominated by Brownian diffusion, and the single collector efficiency can be given by the Smoluchowski–Levich approximation (28):

$$\eta = 4A_s^{1/3}N_{Pe}^{-2/3} \tag{11}$$

Here, $N_{Pe} = d_c n v/D_{BM}$, is a Péclet number that accounts for diffusion; $D_{BM} = K_B(T + 273)/(3\pi d_p \mu)$ is the diffusion coefficient, [L^{2}T^{-1}]; $K_B = 1.38 \times 10^{-23}$ is the Boltzmann constant [J/K]; T is temperature; d_p is the virus particle size; μ is the dynamic viscosity [ML^{-1}T^{-1}]; $A_s = 2(1-\gamma^5)/(2-3\gamma+3\gamma^5-2\gamma^6)$ is Happel's porosity dependent parameter, with $\gamma = (1-n)^{1/3}$.

The sticking efficiency, α, represents the fraction of the particles colliding with the collector which remain attached to the collector (29). The sticking efficiency reflects the net effect of repulsive and attractive forces between surfaces of the particles and the collector. It depends on the surface characteristics of the virus and soil particles. Therefore it depends on pH, organic carbon content, and ionic strength. It is believed that α is independent of hydrodynamic effects (velocity and dispersion). So, if α is known for a given set of conditions, such as type of virus, type of soil, pH, organic carbon content, and ionic strength, then it is possible to calculate the value of k_{att} for a different set of hydrodynamic conditions using Equation (10). This emphasizes the importance of knowing the value of α under a given set of conditions.

Commonly, α is derived from experimental values of k_{att} and calculated values of the single collector efficiency using Equation (10) (15,19,21,23,28,30,31). Alternatively, α has been estimated from relative breakthrough (RB) of the mass of viruses relative to that of a conservative salt tracer (20,25,32) and assuming irreversible adsorption using the following equations:

$$\alpha = \frac{d_c\left[\left[1-2\left(\frac{\alpha_L}{x}\right)\ln(RB)\right]^2-1\right]}{6(1-n)\eta\alpha_L},$$

$$\text{where} \quad RB = \left[\frac{\int_{t_0}^{t_f}\frac{C_{virus}}{C_{0,virus}}dt}{\int_{t_0}^{t_f}\frac{C_{salt}}{C_{0,salt}}dt}\right] \tag{12}$$

FACTORS AFFECTING ADSORPTION OF VIRUSES TO SOIL

Virus Type

Viruses, even strains of the same type, adsorb soil to different extent under similar conditions (3–35). The behavior of different viruses in their interactions with solids is believed to be the result of differences in the electrical charge and the hydrophobicity of the virus surface (36). Virus surface charge is determined by the weakly acidic and basic groups in its protein coat and may vary not only by the type of the virus but also

by the strain (37). For example, at pH values above 5, the surface charge of bacteriophage MS2 is negative and remains constant (38). At pH values above 6, the negative surface charge of vaccinia virus, reovirus, and λ is also relatively insensitive to changes in pH (38). At higher pH, bacteriophage PRD1 (39) and recombinant Norwalk-like virus particle (30), however, show a further decrease in their negative charge. Bacteriophage λ (28) and Norwalk virus-like particles (30) have a stronger negative surface charge than MS2 at pH 5–7, despite the fact that MS2 has a lower isoelectric point (pI) than the other two. Viruses having a stronger negative surface charge will generally attach less owing to stronger electrostatic repulsion in soil at a pH 6–8. Nevertheless, the attachment coefficient of MS2 is found smaller than that of bacteriophage λ and Norwalk virus-like particle, possibly because of steric repulsion of hydrophilic loops that protrude from the surface of MS2 (28).

The coat proteins of a virus may contain spans of amino acids that are hydrophobic. Depending on the way these proteins are folded, such hydrophobic parts may be either on the inside or on the outside of the virus coat (37). Viruses differ in hydrophobicity: Echovirus 7 and ϕX174 exhibit little, if any, hydrophobic character, whereas, echovirus 5, MS2, T7, PRD1, and ϕ6 all are more hydrophobic to a similar extent (36,41). Under conditions of electrostatic repulsion, interaction of the more hydrophobic viruses with hydrophobic surfaces may be a significant factor (15,37).

Soil Type

Generally, soil grains have patchwise distributed surface charges that originate from inherent differences in properties of crystal faces of mineral grains and from minerals having bulk-bound or surface-bound chemical impurities (41). Oxides of iron, aluminum, and manganese are the most common sources of surface charge heterogeneity in the groundwater environment. These oxides carry a positive charge at near neutral pH and are generally present in minor amounts as surface coatings on mineral grains and form favorable sites for negatively charged viruses. It has been shown that minor degrees of charge heterogeneity on grain surfaces result in attachment rates that are orders of magnitude higher than similar surfaces having no charge heterogeneity (41).

The concept that viruses preferably attach to soil grain surfaces with favorable charge characteristics is supported by several studies. Solids having a high pI (isoelectric point) are better virus adsorbents than those with low pI (37). Also, favorable for attachment of viruses are a higher cation exchange capacity (33), the presence of exchangeable iron (42), and iron oxides (20,32,39,43–46). Attachment of viruses has been shown to be better to soils with higher specific surface areas (47). Generally, sandy soils are weaker adsorbents than clays and minerals (3,48). This is because clays may have surfaces with a very heterogeneous charge distribution (49).

pH

The most important factor that affects virus adsorption to soil is pH (34). Generally, viruses adsorb less at higher pH owing to stronger electrostatic repulsion (33,34,42,45,48,50). In fact at higher pH, the attachment rate is lower than the detachment rate. In Figure 3, the sticking efficiency of MS2 is plotted versus pH within the range of 4–8 and at different ionic strengths, using the data from several column studies (15,19,23,28). The pI of MS2 is 3.5, it is therefore negatively charged within this pH range. The figure shows that the value of α decreases with increasing pH, and becomes less than 0.01 at a pH of about 5.5 and above. The sticking efficiency of PRD1 has also been shown to be pH-dependent. In columns with silica beads at pH 5.5 (15), α for PRD1 was between 0.006 and 0.013, and at pH 7, PRD1 did not adsorb at all. In field studies, detachment was very slow compared to attachment at pH 5.4–7.4, but increased strongly at pH 8 or higher (16,32,52). At a pH that is lower than 2.5–3.5 pH units above the pI of the grain surfaces, PRD1 attaches irreversibly, but above this pH, PRD1 attaches reversibly (39).

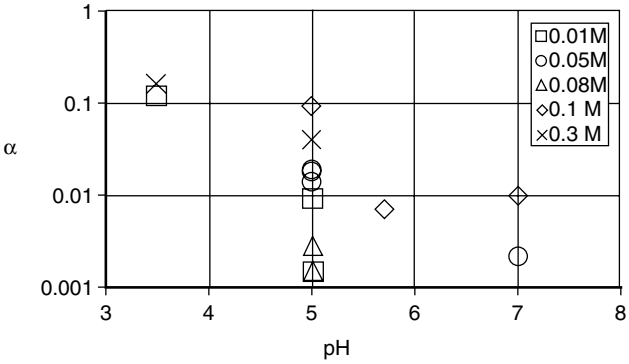

Figure 3. Sticking efficiency α versus pH of MS2 at different ionic strengths (7,16,20,24,29).

Hydrophobic Interactions

At high pH, when both the surfaces of soil grains and viruses are negatively charged, hydrophobic interactions may be the major factor mechanism for virus attachment (15,37,53). Hydrophobic interactions may be seen as a consequence of the thermodynamically unfavorable interaction of hydrophobic substances with water molecules and is not due to interactions among hydrophobic particles themselves (54). For example, the attachment of MS2 is very weak and decreases with pH; but when silica beads are coated with C_{18}-trichlorosilane (a hydrophobic substance), 400 times more attachment takes place, independent of pH (15).

Hydrophobic interactions of viruses with solid surfaces have been suggested to play a role in the interaction between poliovirus 1 and Millipore and Zeta plus filters (55). Similar results have been found for poliovirus 1, echovirus 1, and rotavirus SA 11 with highly organic estuarine sediments (53), for poliovirus 1 with nitrocellulose membrane filters (54), for MS2 and PRD1 with octadecyltrichlorosilane coated silica (15,19), and for MS2, ϕX174, T7, PRD1, and ϕ6 with nitrocellulose and cationic polysulfone membranes (40).

Ionic Strength

Viruses tend to strongly adsorb to various materials in solutions at high ionic strength (44,45). This is in agreement with DLVO (Derjaguin-Landau-Verwey-Overbeek) theory, which describes the attractive and repulsive forces between colloids (e.g., viruses) and grain surfaces (41). A higher ionic strength compresses double layers, thereby increasing attachment rates. As shown in Figure 3, the sticking efficiencies of bacteriophages MS2 and PRD1 were found to increase with ionic strength in the range of 0.01–0.1 M (molarity) NaCl (sodium chloride) at pH 3.5–5 (28).

A filamentous bacteriophage, SJC3, attached more to quartz grains at pH 7 as a result of an increase in the concentration of a particular salt from 1 to 100 mM (56). However, removal of SCJ3 was even higher at the low concentration of 1-mM NaCl that is at low ionic strength. It was suggested that under that condition the filamentous bacteriophage has stiffened and was consequently retained by straining.

If forces between the surfaces of grains and viruses are repulsive at all separation distances, then DLVO theory predicts increased detachment rates at lower ionic strength (41). In agreement with this prediction, detachment of poliovirus 1 was enhanced by deionized water that was applied to simulate heavy rainfall (58). Attached particles of bacteriophage SJC3 were shown to detach easily when the ionic strength was lowered by changing the salt solution from 1 mM $CaCl_2$ (calcium chloride) to 1 mM NaCl (56). However, if forces between the surfaces of grains and viruses are attractive at very short separation distances, DLVO theory will predict an increased detachment rate at higher ionic strength (41). With increasing ionic strength, both the attachment and detachment and detachment rate coefficients of MS2 were found to increase (28).

Multivalent Cations

Multivalent cations can link virus and adsorbents of like charge by forming salt bridges between them (44,47,48) or by charge reversal (45). For example, at pH 5, attachment of MS2 to silica beads was at least 10 times higher in the presence of Ca^{2+} (calcium ions) than without Ca^{2+} (15). Bacteriophage SJC3 attached more to quartz at high ionic strength by a multivalent (Ca^{2+} or Mg^{2+} (magnesium ion)) than a monovalent (Na^{+} (sodium ion)) cation (56). Generally, viruses with higher negative charge attach less to sand, but possibly, this is reversed at high concentrations of multivalent cations (46,58).

Organic Matter

Dissolved and/or suspended organic matter in groundwater exists mainly in the form of humid substances (59). Among dissolved and/or suspended organic matter in the aquifer matrix, humid substances have the highest affinity to nonionic hydrophobic organic compounds (59–60). Other forms of dissolved organic matter consist of proteins, polypeptides, and amino acids. Commonly, dissolved or suspended organic matter is, similar to viruses, negatively charged, and hence it competes with viruses for the same binding sites (37). Dissolved or suspended organic matter can also be used to elute previously attached viruses (48). Thus detachment of viruses may be strongly increased by dissolved or suspended organic matter. Dissolved surfactants increase virus detachment, possibly by disrupting hydrophobic bonds between the soil and the viruses (61) or by causing charge reversal (20,32). If the nature of the soil is more important for adsorption, that is, if there is an excess of adsorption sites available, there may be no effect of dissolved organic matter (57).

The effect of solid and/or bonded organic carbon content (f_{oc}) of the soil is found ambiguous. It depends on the combination of soil type, virus type, and nature of organic matter. On one hand, a soil with bonded organic carbon has fewer sites for virus adsorption, because organic matter already occupies adsorption sites for viruses. Consequently, adsorption of viruses will be less to soils with higher f_{oc} (20,42,43), but this effect may be significant only for soils with high values of f_{oc} (47). On the other hand, the bonded and/or solid organic matter may provide hydrophobic adsorption sites for viruses. This was demonstrated in a study where attachment of MS2 to negatively charged silica beads at pH 7 could be increased considerably by very small amounts of bonded hydrophobic C_{18}-chlorosilane (19).

FACTORS AFFECTING VIRUS INACTIVATION IN THE SUBSURFACE

Viruses may be inactivated because of disruption of coat proteins and/or degradation of nucleic acids (37). The most important factors that influence virus inactivation rates are temperature, adsorption to particulate matter and soil, unsaturated conditions, and microbial activity. These factors are discussed in the following sections. Factors such as pH, ammonia, calcium hardness, magnesium hardness, total hardness, nitrate, total dissolved solids, and turbidity do not significantly affect inactivation of MS2, poliovirus 1, and echovirus 1 (62). Inactivation of MS2, however, increases significantly with calcium hardness (62). The inactivation rates of coxsackievirus A9 and B1, echovirus 7 and poliovirus 1 were reported to be larger in deionized than in untreated groundwater (12). The type of water (groundwater, secondary or primary effluent) was not found to significantly affect inactivation rates of poliovirus 1, echovirus 1, HAV, MS2 and PRD1 (63–64). In some cases, however, a greater value of μ_1 in primary effluent than in groundwater was found for poliovirus 1, HAV, and F-specific RNA bacteriophages (FRNAPH's) (65).

Temperature

Temperature is the most important factor that influences virus inactivation (6,62,66). Inactivation rates increase with temperature (62,64–68). Figure 4 shows a number of bacteriophages for which μ_1 varies with temperature in nonsterilized groundwater (69). The temperature sensitivity of μ_1 depends on the type of virus. Regression analysis suggests a dependence of μ_1 on temperature in the form:

$$\ln \mu_1 = aT + b \tag{13}$$

Table 3. Dependence of μ_1 of Viruses with Groundwater Temperature T (°C) (7)

	Polio 1	Echo 1	HAV	MS2	FRNAPH's	PRD1
Number of observations	10	5	4	8	2	3
Slope a^*	0.033	0.12	−0.024	0.12	0.14	0.09
Intercept b^*	−2.4	−3.0	−1.4	−3.5	−7.6	−4.0
Correlation coefficient	7%	71%	8%	85%	100%	71%

*See Equation 13.

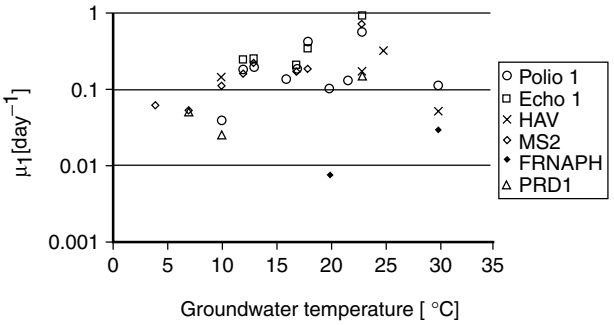

Figure 4. Inactivation rate coefficient μ_1 versus temperature for viruses in nonsterilized groundwater (7). See values in Table 3.

Values of coefficients a and b for six different viruses are given in Table 3. In the case of FRNAPH's and PRD1 these values are only an indication, because only few data were available (69). Its shows that temperature sensitivity of μ_1 depends on the type of virus. Poliovirus 1 is much less sensitive to temperature than MS2 or echovirus 1. HAV may be regarded as insensitive to changes in temperature. MS2 and other FRNAPH's are very sensitive to changes in temperature normally found in shallow groundwater. Estimates of μ_s-values at different temperatures for MS2, PRD1, and poliovirus 1 (64) suggest that μ_s-values change similarly with temperature as μ_1-values (69).

Particulate Matter and Soil

A substantial fraction of viruses is attached to colloidal particles in water with a size of less than 0.3 μm (70–72). These colloidal particles include clays, cell fragments, solids in wastewater effluents, and other miscellaneous debris (73). Virus association with solids has been observed to generally reduce virus inactivation (71,74–79).

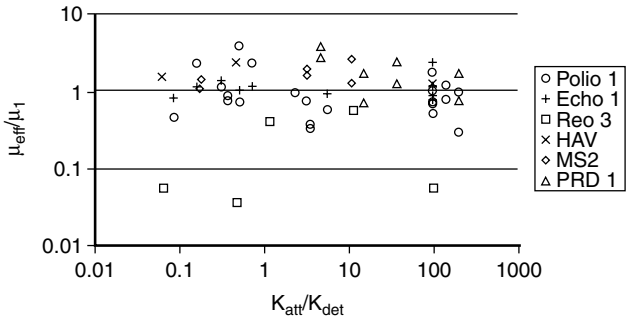

Figure 5. Reduction factor for inactivation rate μ_{eff}/μ_1 versus k_{att}/k_{det} for viruses in a batch system with soil (69).

Reduced inactivation is more pronounced in case of stronger attachment, especially to clays (80,66). However, at low clay concentrations, as in seawater, reduced inactivation has not been observed (78,81). Yet, in some other studies, a larger inactivation rate was measured in the presence of soil (48,64,82). Possibly, the effect is highly dependent on the virus type. This is supported by a large number of batch studies with various viruses and soil types (48,63–64). One may define an effective inactivation coefficient as μ_{eff} (69). This coefficient was calculated from the data of these batch studies and compared with corresponding values of μ_1, as a function of the ratio k_{att}/k_{det} (Fig. 5). A value of μ_{eff}/μ_1 less than one reflects reduced inactivation. It appears that for poliovirus 1, echovirus 1, and HAV the ratio μ_{eff}/μ_1 fluctuates around one, independent of adsorption. This implies that the values of μ_1 and μ_s are similar in these cases. Inactivation of reovirus 3 is reduced in all cases, but that of MS2 is enhanced in all cases, and that of PRD1 is enhanced in most cases. One may expect that in the case of reduced inactivation the ratio μ_{eff}/μ_1 decreases with an increasing ratio of k_{att}/k_{det} ($\mu_1 > \mu_s$), and the opposite in the case with enhanced inactivation ($\mu_1 < \mu_s$). However, Figure 5 shows no clear dependence of inactivation on adsorption.

Microbial Activity

Inactivation of viruses may be enhanced because of microbial activity (6). This is frequently found, when comparing inactivation rates of viruses in sterilized and nonsterilized wastewater (48,63,66). Inactivation of viruses may also be enhanced in toxic groundwater where aerobic bacteria are present (46,67).

Unsaturated Conditions

Under unsaturated conditions, the contribution of inactivation to virus removal is much more important and may be several times higher than under saturated conditions (9,10,23,83). It was suggested that the air–water interface may be retaining and/or inactivating viruses during transport through unsaturated soil. This is in agreement with observations from agitated batch suspensions of viruses. In strongly agitated batch suspensions of viruses, the inactivation rate can be reduced considerably by the addition of organic matter and even more by clay particles (82,84). Addition of organic matter forms a film on the water surface and thus lowers the chance of a virus particle contacting the air. When clay particles are added, viruses will rapidly attach to the clay particles, lowering the chance of entering the

air–water interface even more. Therefore it is believed that contact with the air–water interface increases inactivation. This protective effect of viruses attached to solid particles can even be stronger in a container with hydrophobic polypropylene walls (84,85), suggesting physical forces associated with the air–water–solid contact line that may be responsible for enhanced inactivation. The effect of unsaturated conditions on virus removal is highly dependent on the type of virus (22). MS2 is inactivated more in a container with polypropylene walls than in glass container, but this is not the case for ϕX174 (85). MS2 is more hydrophobic than ϕX174 (36,40) and will, therefore, enter more easily an air–water interface, and attach more to hydrophobic solid surfaces, and is subsequently inactivated because of the unfolding of coat proteins at the interface (22). Under unsaturated conditions in soil, removal of both MS2 and ϕX174 is increased, but that of MS2 is increased the most. The increased removal of MS2 is because of increased inactivation, but that of ϕX174 is due to increased adsorption (22).

ADVECTION AND DISPERSION OF VIRUSES

In relatively homogeneous sand, viruses are transported at the same velocity as a conservative salt tracer (20,21). In porous media with small-scale heterogeneities, for example, fractured media, some of the pore space may be accessible for solutes but not for microorganisms (86). In such heterogeneous soils, therefore, breakthrough of solutes will be partially retarded and much more dispersed than a colloidal particle such as a virus. Breakthrough curves of solute tracers in heterogeneous soils will typically have the shape of curve E in Figure 1a. Diffusion into a matrix with small pores has the same retarding effect as kinetically limited adsorption. Therefore, time to peak breakthrough of the solute will be later than that of the virus because the average flow velocity of viruses is higher than that of the water. By applying a stochastic model for virus transport, it can be shown that a high degree of aquifer heterogeneity can lead to virus breakthrough preceding that of a conservative tracer (87).

Bacteriophages are better tracers for transport of colloidal contaminants than solutes in fractured rock because they are not subject to matrix diffusion (88). Much higher flow rates of bacteriophages than that of solutes have been observed, because of the presence of more permeable pathways in clay (89,90), gravel (91), or limestone (92,93).

MODEL VIRUSES

Model viruses are needed to represent the behavior of pathogenic viruses during subsurface transport and to predict their removal. Bacteriophages MS2, PRD1, ϕX174, and naturally occurring FRNAPH's have been used extensively to study virus transport under various column and field conditions. In this section, the roles of these bacteriophages as model viruses are evaluated.

MS2

MS2 is an icosahedral phage with a diameter of 27 nm and a low pI of 3.5. The three-dimensional structure of its capsid is known at the atomic level (28). MS2 may be considered as a relatively conservative tracer for virus transport in saturated sandy soils with a low organic carbon content in the pH-range of 6–8. Under those conditions MS2 has shown little or no adsorption (8,11,21,23,46,88,94). In most soils, attachment of MS2 is less than or equal to that of most other viruses (11,19,25,28,30,34,94,95,96,97). Possibly because of the presence of multivalent cations, MS2 may attach more than the less negatively charged ϕX174 (18,58). MS2 is less stable than several pathogenic viruses. It is inactivated faster at temperatures of 10–25 °C. But, at temperatures lower than 7 °C, its inactivation rate is very low and similar to that of PRD1 (21,62,64,68). Under unsaturated conditions, MS2 is not a good choice as a relatively conservative virus tracer, because of its strong sensitivity to air–water interfaces and, consequently, strongly enhanced inactivation (22).

PRD1

PRD1 is an icosahedral bacteriophage with a diameter of 62 nm and with an inner lipid membrane (15,98). Its pI lies between 3 and 4 (39). Because of its larger size, PRD1 is of interest as a representative of rotaviruses and adenoviruses (99). Although, adenovirus and PRD1 may differ in surface charge, it is worth mentioning that PRD1 is much closer in structural design to adenovirus than any other known bacteriophage, and vice versa. The major capsid protein (P3) of PRD1 has the same double "jellyroll" fold as the human adenovirus type 2 hexon, despite their very different sequences and sizes. This implies that the basic structure as well as the assembly pathways of complex viruses were perfected very early in evolution and have been retained despite the high mutability of viruses (100). This observation further strengthens the validity of using bacteriophages as model viruses for the less-tractable animal viruses that cause human diseases.

With regard to attachment characteristics, PRD1 seems to behave less conservative than MS2 (15,17,23,58), possibly because it is more hydrophobic than MS2 (15,23,36,40). However, at field scale (21,25) removal of PRD1 is found to be similar to that of MS2. PRD1 may be considered as a relatively conservative model virus, similar to MS2, under field conditions (pH 6–8) in sandy soils with low organic carbon content and low concentration of multivalent cations. PRD1 may be considered as a worst-case model virus because of its low inactivation rate between 10–23 °C (64,68).

Bacteriophage ϕX174

Bacteriophage ϕX174 is less hydrophobic than MS2 (54). In studies on the retention of viruses by barrier materials, such as membranes, condoms, and testing gloves, ϕX174 is regarded as the best model virus, because it exhibits the least electrostatic and hydrophobic interaction (36,40,101). ϕX174 has essentially no charge at neutral pH (pI = 6.6–6.8) and its size is 27 nm (58,101).

Bacteriophage ϕX174 may be a relatively conservative model virus, because of its low hydrophobicity (36) and stability (24–25). In situations, where hydrophobic interactions would significantly increase virus removal, like under unsaturated conditions, ϕX174 could be a better choice as a model virus than MS2 or PRD1. In the presence of multivalent cations, ϕX174 was found to attach the least of five bacteriophages, including MS2 and PRD1 (18,58).

F-Specific RNA Bacteriophages

F-specific bacteriophages have similar physical properties as enteroviruses, especially with respect to size (102,103). MS2 belongs to group I of FRNAPH's (104). As naturally present model viruses, they are good candidates to represent enteroviruses in various treatment processes of surface water, including soil passage (transport through soil). Before entering a treatment like soil passage, enteroviruses and FRNAPH's largely have followed the same path, that is, both have passed the sewerage system, followed by sewage treatment, discharge into surface water, and some kind of pretreatment. It may be reasoned that along this path, from the sewerage system to the point of recharge into an aquifer, viruses that are less stable or that adsorb readily to solid surfaces, have disappeared already. This suggests that a selection has taken place of very stable and poorly adsorbing viruses, that is, worst-case viruses. This selection has been the same for FRNAPH's and enteroviruses.

In surface water, FRNAPH's occur in numbers of 10^2–10^4 times higher than enteroviruses (103). Therefore it has been possible to show 4 to 6 log units removal of FRNAPH's by riverbank filtration (105). Removal of FRNAPH's and MS2 has been shown to be similarly low at field scale (24,31,99).

VIRUS REMOVAL BY TRANSPORT TROUGH SOIL

From Equations (8,9), and (10) with constant rate coefficients for attachment, detachment, and inactivation, it can be deduced that in a saturated soil under steady state conditions, the degree of virus removal [calculated as $\log_{10}(C/C_0)$] should decline in a linear fashion with travel distance and travel time. In field studies, where bacteriophages were seeded as slug injection (16,20,24–25,32,52) or for a period of several days (21,46), steady state was not actually achieved. Nevertheless, simulations show that, for all practical situations, maximum breakthrough concentrations decline linearly with travel time or travel distance as well.

However, several column (57,106) and field studies (16,20–21,24–25,31–32, 46,52) have shown that removal rate often appears to be higher during the first meters of soil passage. Obviously, predictions of virus removal over larger travel times or distances can be severely overestimated if they are based on removal data from column or field experiments where transport was studied over short times and distances.

Higher initial removal of virus may be explained by soil and/or virus heterogeneity. Viral heterogeneity may be a cause for the higher initial removal, that is, the viruses in the suspensions that were used for seeding a column or a field site may have different affinities for attachment sites (20–21). Possibly, viruses that are attached to other colloidal particles behave as particles with different size and density and, therefore, have different single collector efficiencies and different sticking efficiencies (69). Transport of MS2 through sand columns has been shown to be greatly enhanced by its attachment to particles of Na-montmorillonite (107). The extent of such colloid-facilitated virus transport depends on the type and size of colloids, as well as the extent of virus attachment to the colloids (107). The extent of colloid-facilitated virus transport under various environmental conditions is unknown (107).

In a study on the removal of viruses by deep well injection (46), nonlinear removal appeared to have been caused by a change in surface charge of the porous medium. From geochemical mass balances, it was deduced that higher initial removal was caused by preferable attachment of viruses to patches of ferric hydroxides. These were precipitated as a consequence of pyrite oxidation within eight-meters distance from the point of injection, but not at larger distances. In other field studies, the reasons for higher initial removal are not understood (21).

A higher initial removal rate, followed by a residual removal rate can be described by the following empirical equation (108):

$$\log\left(\frac{C}{C_0}\right) = \frac{a}{b}(e^{-bt} - 1) - ct \qquad (14)$$

where, at $t = 0$, the initially high removal rate is determined by $-(a + c)$. In the case that $a = 0$ or $b = 0$, there is no higher initial removal rate. Parameter c gives the base removal rate, that is, there will always remain a certain contribution because of inactivation of free and attached viruses.

Equation (14) has been used to fit the field data and the results are shown in Figures 6a–6c. Values of parameters a, b and c were found by fitting Equation (14) to the field data are given in Table 4. Table 5 gives corresponding values for removal and sticking efficiencies of the bacteriophages, and Table 6 gives hydrologic and chemical properties of the aquifers. The aquifers are denoted A to F and are ordered according to grain size.

In some cases, only two to three measurements of removal with time were available (16,20,25,31,32,46). These removal data are shown in Figure 6d. For these data, Equation (14) was not applied, but for the sake of comparison, removal rates were calculated from the linear change in removal between adjacent pairs of observations in time.

Aquifer A contains very fine dune sand. The initial removal rate was found to be strongly and positively correlated with soil organic carbon content and to a lesser extent with the content of ferric oxyhydroxides. Because of the high pH, conditions for attachment are unfavorable. Aquifer B contains fine sand. Initially, removal rates are higher than in aquifer A because of the presence of favorable attachment sites in the form of

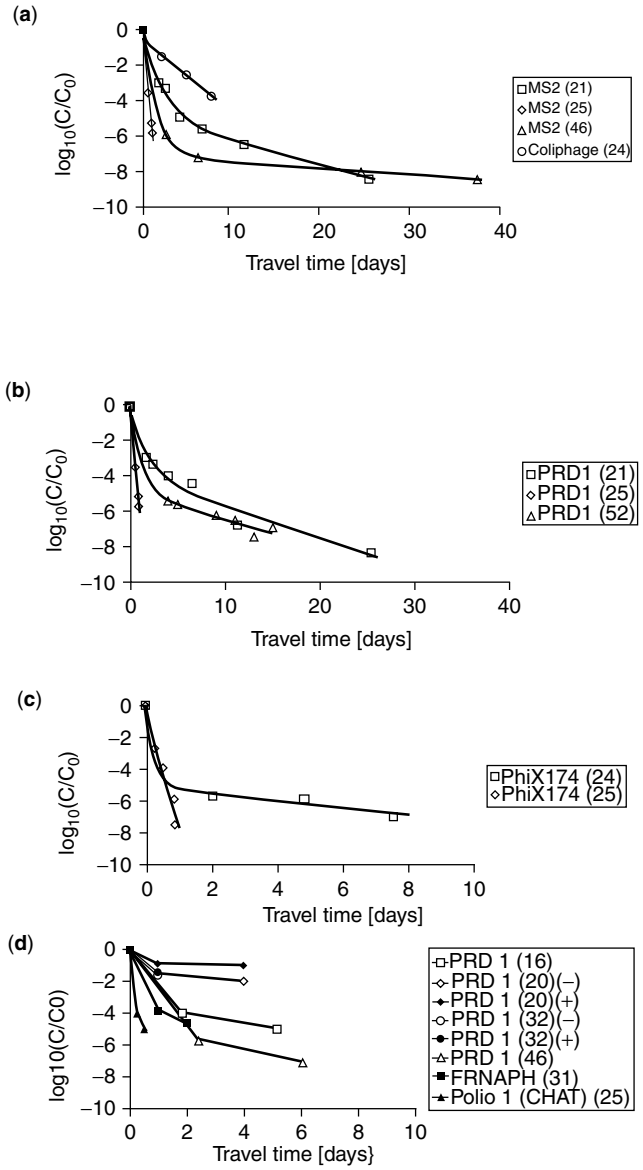

Figure 6. Removal of bacteriophages and poliovirus 1 in relation with travel time in sandy aquifers. See corresponding parameter values in Table 4 and aquifer properties Table 6.

ferric oxyhydroxides together with a lower pH. However, the removal rate coefficient λ in aquifer B is lower than that in aquifer A. This can only partially be explained by a two times lower pore water velocity in aquifer B compared to that in aquifer A, which leads to a lower value of the attachment rate coefficient. The different removal rates can be explained neither by the difference in pH nor by the difference in temperature. Higher pH is less favorable for attachment and at lower temperature the inactivation rate is lower. Therefore there must be fewer sites for attachment in aquifer B than in aquifer A. Note that similar collision efficiencies for aquifers A and B are reported, but these were based on average removal and pore water velocities from the source to each well. In fact, collision efficiencies in aquifer B are initially higher than in A, but finally lower. Eventually, 8-$\log_{10}$ removal was achieved in both aquifers. The sand in aquifer C is coarser but otherwise similar to A. Similar removal rates and collision efficiencies for PRD1 were found in aquifers

*D+ and D−: the same aquifer, but D+ is a sewage contaminated zone, whereas D− is an uncontaminated zone. f_{oc} is soil organic carbon content. DOC is dissolved organic carbon.

A and C. The sand of aquifer D is also coarser than in A or B, and the hydraulic conductivity is much higher. Aquifer D consists of a sewage contaminated (D+) and uncontaminated zone (D-). In D+, organic matter occupies favorable attachment sites. Nevertheless, similar collision efficiencies for PRD1 were reported in aquifer D+ as in A and C. But, removal rates in D+ are lower than in A or C because of a combination of a lower transport velocity and coarser sand (fewer collisions). Organic matter limits attachment in D+ by occupying attachment sites, whereas, a higher pH is the limiting factor in A and C. In aquifer D−, removal rates and collision efficiencies are higher than in aquifer D+ because in D−, attachment sites are not blocked by organic matter. The sand in aquifer E is coarse, the hydraulic conductivity and pore water velocity are higher. Within eight days of travel time, the removal rate of coliphages is lower than the initial removal rates of MS2 in aquifers A and B. Also, the final removal rate of ϕX174 in aquifer E is only about twice that of MS2 in aquifer A. Bacteriophage ϕX174 is expected to attach much more than MS2 because its surface charge is less negative than that of MS2. The relatively low attachment rates in aquifer E are probably because of the coarseness of the soil, which lead to low single collector efficiencies. In aquifer F, we have the coarsest sand and, by far, the highest hydraulic conductivity and pore water velocity. In aquifer F we find the highest removal rates. This is also reflected by the relatively high collision efficiencies, suggesting the presence of favorable attachment sites. The Ground Water Rule of the US EPA (GWR) (2) requires 4-log removal of virus for adequate protection of groundwater, whereas drinking water companies may even require 8-log removal (21) based on a maximum risk of infection of 10^{-4} per person per year (109). From Figures 6a–6d it is apparent that a removal of 4 log or more was achieved within eight days (about 20 meter) in all the studies, with one exception, where measurements were carried out only for four days (20). Within about 40 days or less, 8-log removal of MS2 and PRD1 can be achieved (21,46).

From the data shown in Figures 6a and 6b, it is also possible to identify a relatively worst case situation, where interaction with the soil grains is very low because of the absence of preferable sites for attachment. In aquifers B and D+, very low residual removal rates of 0.035 $\log_{10}$ units per day were found for MS2 and PRD1, respectively. This is equal to a removal rate of 0.081 [day^{-1}] on a natural log scale. In aquifer D+, attachment of PRD1 was limited owing to the presence of organic matter. In aquifer B, a value of 0.024 [day^{-1}] for μ_1 of MS2 was measured at the monitoring well at 8 m, near the outer limits of the toxic zone. Thus, a value of k_{att} equal to 0.057 [day^{-1}], and a value of the collision efficiency equal to 1.5×10^{-5} can be estimated. In this situation, the contributions of attachment and inactivation to removal of MS2 are similar. MS2 may be considered here as a worst case virus tracer, as it attaches less to soil than most viruses. A value of μ_1 equal to 0.024 day^{-1} for MS2 in groundwater at 12 °C is relatively low and similar to that of several human pathogenic viruses in groundwater at 10 °C (69).

In contrast to the removal capabilities of sandy aquifers, removal of viruses in karst, fractured bedrock and gravel aquifers may be very low. Such aquifers are identified as sensitive to fecal contamination by the U.S. EPA's proposed Ground Water Rule (2). These aquifers have in common more permeable pathways that exist, which allow very high flow rates of viruses (91–93). In such pathways, the single collector efficiency will be very low, and consequently there will be little attachment. Because of the high transport rate, inactivation will also be minimal. In gravel, removal of slug-injected bacteriophages T7

and H40/1 was only 2 log over a travel distance of 50 meters (84,91). Nevertheless, considerable removal may also be found, for example about 6-log removal of MS2 over a distance of 20 m in limestone (93) or 1-log removal of MS2 and PRD1 over a distance of 0.5 m in a clay-rich till (90). It is obvious that preferred pathways, such as fractures and breaches, will contribute greatly to the uncertainty in the removal capabilities of a certain aquifer.

CONCLUSION

During subsurface transport, viruses are removed from the aqueous phase by inactivation of free viruses and by attachment to specific sites on the soil grains, followed by inactivation of the attached viruses. Major factors affecting virus attachment to soil and their inactivation that were described in the previous sections are summarized and listed in Tables 7 and 8.

At pH 7 –8, attachment of the viruses to the soil grains proceeds faster than detachment from the grains. At this pH range, as in many sandy aquifers, the net surface charge of most viruses and soils is negative, and thus conditions for attachment are generally unfavorable because of electrostatic repulsion. However, the grains in sandy soils contain patches on their surface that have favorable charge characteristics, like positively charged iron, aluminum, or manganese oxide coatings to which viruses preferably attach. because of the presence of such favorable sites for attachment, removal of viruses may be higher than 2.5 log per day (about one log per meter). In the case of few or absence of such patches of favorable sites, removal of viruses may be as low as 0.035 log per day (about 0.05 log per meter).

Dissolved organic matter may decrease virus attachment to soil because of competition for the same favorable attachment sites. Dissolved organic matter, like surfactants, may disrupt hydrophobic bonds between soil and virus, resulting in an increased detachment rate. At the same time, viruses and many organic materials contain hydrophobic groups on their surfaces. Therefore, once adsorbed, bonded organic matter may provide hydrophobic binding sites for viruses.

Depending on soil heterogeneity, viruses may travel faster than the average water flow and show a smaller dispersion than a solute, because they can be excluded from small pores and, therefore, preferentially follow more permeable pathways. Consequently, removal of viruses may be much less effective in media such as fractured rock or karstic aquifers.

Temperature is the most important factor that influences virus inactivation. Inactivation rates increase with temperature, but the extent depends on the type of virus. Inactivation of some pathogenic viruses, such as HAV, is very insensitive to temperature changes encountered in most groundwater. Probably, inactivation rate coefficients of free and attached viruses change similarly with temperature. Microbial activity may increase inactivation rates of viruses under aerobic conditions. Under unsaturated conditions, inactivation may be strongly enhanced because of physical forces at contact lines between air, water, and solid surfaces and may then be the major factor that determines virus removal.

Bacteriophages MS2 and PRD1 may be considered as suitable model viruses. Mainly owing to their negative charge, they are removed equally or less than most other viruses at pH 6–8 and at temperatures below about 10 °C, provided the soil do not contain too many hydrophobic sites or multivalent cations. PRD1 is more stable than

Table 7. Summary of Major Factors Affecting Virus Attachment to Soils

Factor	Effect on Attachment Rate Coefficient k_{att}
Virus type	k_{att} higher because of
	— a less negative surface charge of a virus
	— higher hydrophobicity of a virus
Soil type	k_{att} higher owing to
	— the presence of favorable attachment sites (patches of positively charged metal-oxides)
	— a less negative surface charge of soil
	— a high cation exchange capacity of soil
	— a high specific surface area of soil
	— the presence of hydrophobic sites
Groundwater	k_{att} higher because of
	— a decrease in pH
	— an increase in ionic strength
	— the presence of multivalent cations
Organic matter	k_{att} lower because of
	— the presence of dissolved, negatively charged organic matter
	— the presence of bonded organic matter occupying favorable attachment sites
	k_{att} higher owing to
	— presence of bonded organic matter providing additional attachment sites

Table 8. Summary of Major Factors Affecting Virus Inactivation in Groundwater

Factor	Effect on Inactivation Rate Coefficient μ_1
Virus type	— The extent of effects of all factors mentioned below depend on the virus type
Temperature	— μ_1 higher because of a higher temperature
Microbial activity	— μ_1 higher because of microbial activity under aerobic conditions
Unsaturated conditions	— μ_1 higher under unsaturated conditions

MS2 at higher temperatures. Bacteriophage ϕX174 may be a relatively conservative model virus, because of its low hydrophobicity and stability. FRNAPH's, as a group of naturally occurring viruses, behave relatively conservative, like MS2 that is also a FRNAPH.

Rate of removal of viruses by passage through soil (logarithmic reduction in concentrations) appears to decline with distance. The nonlinearity of removal with distance has important consequences for prediction of virus removal. Thus it is also important for the calculation of setback distances that are needed to adequately protect groundwater sources and to ensure adequate treatment of infiltrated surface water. Predictions of virus removal at larger distances are severely overestimated if they are based on removal data from column experiments or from small-scale field studies. To improve predictions on the removal of viruses by soil passage, knowledge of the soil heterogeneities at the location of interest is needed.

MODELING THE TRANSPORT OF BIOAEROSOLS

M. V. YATES
University of California
Riverside, California

Bioaerosols can be generated in a number of ways, including the spray irrigation of vegetation using treated

domestic wastewater, humidification of indoor air using evaporative coolers, spray drift from industrial cooling towers, bursting of bubbles as a result of wave action, and rain splash. There has been considerable interest in being able to predict the atmospheric concentrations of microorganisms in the resultant bioaerosols for purposes such as assessing the potential human health risks associated with exposure to the microorganisms and transmission of plant pathogens. Predictive models range from fairly simplistic exponential models that are the results of fitting experimental data to more sophisticated particle-tracking models. In this article, several types of bioaerosol transport models are discussed.

BIOAEROSOL SURVIVAL MODELS

Exponential Decay Model

A very basic survival model can be developed by fitting experimental data to a simple mathematical expression, such as the exponential equation. For example, an experiment that measures the number of viable microorganisms in a bioaerosol as a function of the age of the bioaerosol is conducted. The resultant data are then plotted on a semilog plot. Assuming that the resultant plot produces a straight line, the viability of microorganisms at time t, V_t, can be expressed as:

$$V_t = V_0 e^{-kt} \tag{1}$$

where V_0 is the concentration of microorganisms at time 0 and k is an experimentally derived decay rate. Obviously, a model such as this does not allow one to predict the survival of the microorganisms under other environmental conditions, as there is no attempt to account for the individual effects of the various factors that affected their survival.

Regression Decay Model

A more complex model of microbial survival in a bioaerosol can be expressed using a multiple regression model. Such a model is based on the recognition that there are a number of factors affecting the survival of microorganisms in aerosols. A series of experiments is conducted to study the viability of microorganisms in a bioaerosol as a function of a variety of chemical and physical factors, including relative humidity, temperature, radiation, and oxygen (1,2). The results of these experiments will then be statistically analyzed and expressed as a multiple regression equation of the form:

$$V = a + bx_1 + cx_2 + dx_3 + ex_4 + \ldots zx_n \tag{2}$$

where x_1, x_2, x_3, x_4, $\ldots x_n$ are the measured effects of the varied parameters.

The regression decay model may be more useful than the exponential decay model, as it may be used to predict the survival of microorganisms under conditions that were not studied in the experiments performed to derive the equation. For example, knowing the values of relative humidity, temperature, radiation, and oxygen concentration for a given environment, one could calculate V using Equation 2. The validity of the calculated value of V would have to be verified independently to have a high degree of confidence in the value. It is likely that the results of such a prediction would be highly dependent on a number of factors. These factors include (*1*) the similarity of the microorganisms used in the experiments used to derive the equation and the microorganisms of interest, (*2*) whether the parameters of interest are within the numerical range of the parameters used in the original experiments, and (*3*) the numbers of values of each parameter examined in the original experiments.

DISPERSION MODELS

In order to predict the concentrations of microorganisms in the atmosphere some distance downwind form a source, it is necessary to use relatively complex models, which require one to have a great deal of information about the conditions of the environment being modeled. There are two main types of these models, the Gaussian plume model that is believed to be valid for the simulation of bioaerosol dispersion from 100 m to 10 km and particle-tracking (or random-walk) models, which are used for simulations at distances of 10 m to less than 1 km (3).

Gaussian Plume Model

The Gaussian plume model can be used to describe the statistical distributions of microbial concentrations in an aerosol downwind from a contaminant source. This model is used extensively to model downwind concentrations of atmospheric chemical contaminants from industrial sources. The Industrial Source Complex (ISC) Short-Term model is accepted by the U.S. Environmental Protection Agency (4) as it provides options to model emissions from a wide range of sources, which might be present at a typical industrial source complex.

The model uses the steady-state Gaussian plume equation for a continuous elevated source and assumes that the mean concentrations of particles in a bioaerosol are normally distributed (both vertically and horizontally) around the downwind axis of the plume from a point source. For each source and each hour, the origin of the source's coordinate system is placed at the ground surface at the base of the stack. The x-axis is positive in the downwind direction, the y-axis is crosswind (normal) to the x-axis, and the z-axis extends vertically. The fixed receptor locations are converted to each source's coordinate system for each hourly concentration calculation. The hourly concentrations calculated for each source at each receptor are summed to obtain the total concentration produced at each receptor by the combined source emissions.

For a steady-state Gaussian plume, the hourly concentration of microbes per unit volume of air at ground level, at downwind distance x (meters), and crosswind distance y (meters), χ, can be simply expressed as:

$$\chi = ABCD \tag{3}$$

where the variables A, B, C, and D can be verbally described as representing the following. A represents the concentration of particles on the plume axis at a distance x from the source; B describes the lateral dispersion (i.e., spreading out from the point source in the horizontal direction) of the particles; C describes the vertical dispersion (i.e., spreading out from the point source in the vertical direction) and the vertical settling of the particles; and D accounts for the inactivation of the microorganisms.

Mathematically, the Gaussian plume model is expressed as (5):

$$\chi = \left(\frac{bQ}{2\pi u\sigma_y\sigma_z}\right)\left[\exp\left(\frac{y_2}{2{\sigma_y}^2}\right)^2\right] \times \left\{\sum_i q_i \exp\left[\frac{-\left(H - V_{si}\frac{x}{u}\right)^2}{2{\sigma_z}^2}\right]\right\} \exp\left(-\lambda\frac{x}{u}\right) \quad (4)$$

where b is the number of microorganisms per unit volume of source (m^{-3}) at the source, Q is volume emission rate of the source (m^3s^{-1}), u is the mean wind speed for a 1-hour period of time (ms^{-1}), σ_y and σ_z are the standard deviations of the horizontal and vertical plume spread (m) and are functions of downwind distance and atmospheric stability, y is the lateral distance from the mean plume axis (m), q_i is the mass-weighted proportion of particles in the ith size category, H is the height above the ground of the plume axis after the initial rise of the plume (m), V_{si} is the settling speed of the average microorganism-containing droplets in the ith size category (ms^{-1}), and λ is the death rate of the microorganisms (s^{-1}).

This model makes the following assumptions (6): (*1*) there is a Gaussian distribution of the plume in both the horizontal and vertical direction; (*2*) particles are emitted from the source at a constant rate; (*3*) wind velocity and direction are constant; (*4*) the terrain is flat; (*5*) the particles are smaller than 20 μm, making the effects of gravity negligible; and (*6*) diffusion in the downwind direction is negligible.

Several of the critical parameters in the model will now be discussed in more detail.

Dispersion. The plume spreads or disperses as it moves downwind from the source (Fig. 1). The variability in plume spread is highly dependent on the turbulence of the air in the vicinity of the plume. The turbulence disperses the plume both vertically and horizontally; however, the dispersal in the horizontal direction tends to be greater than in the vertical direction, due to the lesser amount of energy needed to counteract the force of gravity in the horizontal direction. The amount of turbulence is dependent on the atmospheric stability, heating or cooling of the air by the ground, wind strength, and the roughness of the terrain (3). Rough terrain tends to increase turbulence, hence faster dispersion of the plume. Vertical spread varies much more as a function of turbulence than horizontal spread. Plume spread expressions are divided into several categories, 1–4 (3) or A–F (4), based on the level of turbulence present, with one being the highest level of turbulence.

The dispersion of the plume is expressed in the model in the form of parameters σ_y and σ_z. The equations used to calculate values for these parameters were derived empirically, based on available data of plume spread and approximately fit the Pasquill-Gifford curves (7). The equations used to calculate σ_y (in meters) are of the form:

$$\sigma_y = 465.11628(x)\tan(\mathrm{TH}) \quad (5)$$

where

$$\mathrm{TH} = 0.017453293[c - d\ln(x)] \quad (6)$$

In Equations (5) and (6), the downwind distance x is in kilometers, and the coefficients c and d are constants based on the level of turbulence in the system. The equation used to calculate σ_z (in meters) is of the form:

$$\sigma_z = ax^b \quad (7)$$

where the downwind distance x is in kilometers. The coefficients a and b are constants based on the turbulence of the system and the downwind distance. Values of a may range from 0.31 for relatively stable conditions to 0.40 for highly turbulent conditions; values of b range from 0.71 v for stable to 0.91 under highly turbulent conditions (3). These expressions were determined by Briggs as reported by Gifford (8) and represent a best fit to urban vertical diffusion data reported by McElroy and Pooler (9). Although the Briggs functions are assumed to be valid for downwind distances less than 100 m, the concentrations at receptors less than 100 m from a source may be suspect.

The U.S. EPA's ISC model (4) can be used to describe much more complex plume dispersion behavior, such as

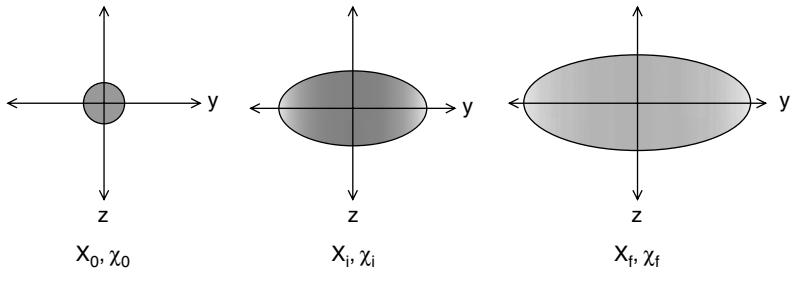

Figure 1

that imposed by the effects of downwind buildings, and so on.

Wind Speed. The wind power law is used to adjust the observed wind speed, u_{ref}, from a reference measurement height, z_{ref}, to the release height, H. The stack height wind speed,u_s, is used in the Gaussian plume (Eq. 4). The power law equation is of the form:

$$u_s = u_{ref}\left(\frac{H}{z_{ref}}\right)^{p} \tag{8}$$

where p is the wind profile exponent. Values of p depend on the turbulence of the system, and may vary based on whether the environment is rural or urban. Typical values of p have been found to vary between 0.07 and 0.55 for rural settings and between 0.15 and 0.30 for urban settings (4).

Plume Height. The maximum height to which the axis of the plume will rise is determined by a number of factors, including the characteristics of the source, the temperature of the bioaerosol, the wind speed, and the vertical stratification of the atmospheric temperature (3).

Calculation of the plume height can be a very complex matter because of the difference in behavior of the plume based on the temperature of the plume relative to that of the environment. The plume rise is considered to be buoyancy dominated if bioaerosol temperature is greater than ambient air temperature. Where stack gas temperature is less than or equal to ambient air temperature, it is assumed that the plume rise is dominated by momentum.

For buoyancy-dominated conditions, the distance downwind from the source to the receptor is assumed to be less than the final height of the plume axis. In this situation, the final height of the plume axis, H_e, can be calculated from the following equation (11):

$$H_e = h'_s + 1.60\left(\frac{F_b{}^{1/3}x^{2/3}}{u_s}\right) \tag{9}$$

where F_b is the Briggs buoyancy flux factor and can be calculated from the bioaerosol temperature, the ambient air temperature, the diameter of the source, and the initial velocity of the bioaerosol as it leaves the source.

For momentum-dominated conditions, the following equations (11) are used to calculate a distance dependent momentum plume rise:

(a) turbulent conditions:

$$H_e = h'_s + \left(\frac{3F_m x}{\beta_j{}^2 u_s^2}\right)^{1/3} \tag{10}$$

where F_m is the momentum flux parameter (calculated based on the bioaerosol temperature, the ambient air temperature, the diameter of the source, and the initial velocity of the bioaerosol as it leaves the source.), β_j is the jet entrainment coefficient (calculated from the initial velocity and the wind speed), and x is the downwind distance (meters).

(b) stable conditions:

$$H_e = h'_s + \left[3F_m\frac{\sin\left(\frac{x\sqrt{s}}{u_s}\right)}{\beta_j^2 u_s\sqrt{s}}\right]^{1/3} \tag{11}$$

where x is the downwind distance (meters).

Death Rate. The death rate term, D, in Equation (3) is a simple method of accounting for microbial removal by biological, physical, or chemical processes. As shown in Equation (4) it is of the form:

$$D = \exp\left(-\psi\frac{x}{u_s}\right) \quad \text{for } \psi > 0$$

or

$$= 1 \quad \text{for } \psi = 0 \tag{12}$$

For a microorganism that exhibits first-order inactivation rate kinetics, if $T_{1/2}$ is the microbial half-life in seconds, one can obtain λ from the relationship:

$$\psi = \frac{0.693}{T_{1/2}} \tag{13}$$

Another method that can be used to determine the value of λ is described by Lighthart (12). In this case, data from experiments examining the inactivation of 16 different bacteria as a function of temperature and relative humidity were analyzed. A linear regression relationship was then developed to enable a calculation of λ:

$$\log_{10}\lambda = -0.245 - 0.892\log_{10}(\text{aerosol age[hours]}) + 0.0055 \times \text{temperature (C)} - 0.15 \times \text{gram reaction} \times \text{RH(\%)} \tag{14}$$

where the value for the gram reaction is zero for gram-negative bacteria and one for gram-positive bacteria. When the calculations of the regression equation were compared with the reported experimental data, R values ranging from 0.33 to 0.98 were found.

Bioaerosol Particle-Tracking Model

In this model, the movement of the droplets in the bioaerosol are tracked over discrete time steps as they are moved through the air after being sprayed into the environment. The airflow can be either laminar or turbulent. After a specified time step, t, the position (x_i, y_i) of the bioaerosol and the number of microorganisms in the bioaerosol downwind from the source are calculated (3). The position of the bioaerosol is calculated by multiplying the horizontal or vertical droplet velocity at a given time step,V_t, by the time in that time step. The droplet velocity is calculated using the equation:

$$V_t = V_f - (V_f - V_0)E^{-t/\tau} \tag{15}$$

The various parameters in this equation are as follows.V_f is the wind velocity. V_0 is the initial spray droplet velocity and can be calculated using the pressure in the spray nozzle, P, and the density of water at ambient temperature, ρ_p:

$$V_0 = \sqrt{\frac{2P}{\rho_p}} \tag{16}$$

The parameter τ is the relaxation time, and describes the time necessary for an aerosol droplet to change from its initial velocity to its final velocity (13). The relaxation time depends on the size and density of the droplet and the density and viscosity of the atmosphere. It can be calculated using the following equation:

$$\tau = \frac{\rho_p {D_p}^2 C_c}{18\eta} \tag{17}$$

where C_c is the Cunningham slip factor (a correction factor for the velocity of particles less than 1 m in diameter whose molecular slip at the droplet's surface causes them to fall faster than would be predicted by Stokes' law), D_p is the diameter of the particle, and η is the coefficient of velocity of ambient air.

The number of microorganisms present in the bioaerosol after a given time step can be calculated as the packed bacterial particle diameter:

$$D_{pack} = 3\sqrt{\frac{v}{0.71}} \tag{18}$$

where D_{pack} is the residual packed bacterial diameter, assuming rhombohedral packing, and v is the volume of the mean number of bacteria, n, that would be suspended in an initial spray droplet with an initial diameter, D_p. The parameter v can be calculated from:

$$v = n\left[\frac{4}{3}\pi\left(\frac{D_p}{2}\right)^3\right] \tag{19}$$

The model uses the above equations to calculate the position (x_i, y_i) of the bioaerosol (i.e., $V_t \times t$) and the number of microorganisms in the bioaerosol (i.e., D_{pack}) for a given time period. Note that both the horizontal and vertical position of the plume must be calculated using Equation 15. This process is repeated until the desired length of time has been modeled or until there are no bacteria left in the aerosol (i.e., $D_p < D_{pack}$). A schematic view of the model output is given in Figure 2.

During each time step, the number of microorganisms remaining in the bioaerosol is determined by considering a number of factors. Evaporation has a large effect on the change in droplet size over time. This change is calculated using the following equation (14):

$$\frac{dD_p}{dt} = \frac{4D_v M}{R\rho_p D_p}\left(\frac{p_\infty}{T_\infty} - \frac{p_d}{T_d}\right) \times \left(\frac{2\lambda + D}{D_p + 5.33\left(\frac{\lambda^2}{D_p}\right) + 3.42\lambda}\right) \tag{20}$$

where D_v is the diffusion coefficient of water in air at ambient temperature, R is the universal gas constant, M is the molecular weight of water, p_∞ is the ambient water vapor pressure, p_d is the saturation water vapor pressure at the droplet surface temperature, T_∞ is the ambient temperature, T_d is the droplet surface temperature, and λ is the mean free path of the air molecules.

The droplet surface temperature, T_d, changes in each time step. This change is calculated using the equation:

$$dT = \frac{3t}{r^2\rho_p C_p}\left[\frac{D_v MH}{R}\left(\frac{p_d}{T_d} - \frac{p_\infty}{T_\infty}\right) - k(T_\infty - T_d)\right] \tag{21}$$

where r is the radius of the droplet, C_v is the specific heat of vaporization of water at ambient temperature, H is the latent heat of fusion of water at ambient temperature, and k is the thermal conductivity of the air.

The droplet temperature for each time step is calculated by subtracting dT from the current T_d. The resultant droplet surface temperature is then used as the initial temperature for the next time step.

The initial number of microorganisms in a droplet is modeled randomly as a function of the diameter of the droplet generated by the sprayer. The diameter of particles in the initial bioaerosol is assumed to vary and may be calculated based on information from the sprayer manufacturer. The number of microorganisms in the particles will change over time as a result of evaporation, as discussed earlier. Their survival has also been found to depend on the initial number of microorganisms in the droplets and therefore the initial size of the droplet (14).

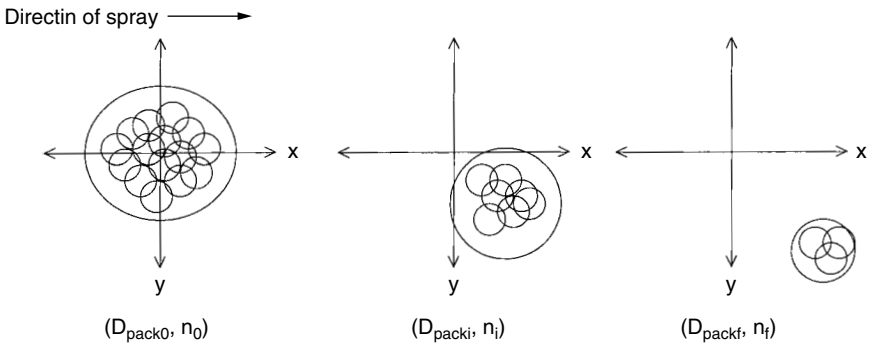

Figure 2

Microorganisms suspended in larger droplets have been found to survive for longer periods of time than those in smaller droplets. Presumably this can be explained by the larger surface area:volume ratio of smaller particles compared to that of larger particles, so that exposure to detrimental environmental factors would be enhanced in the smaller particles.

CONCLUSION

The dispersal of microorganisms in bioaerosols is well documented, and models to simulate their dispersal have been developed. However, the widespread application of these models has not been observed, probably due to the large number of input data that would be required to produce an output in which there could be a high degree of confidence. The use of the Gaussian plume model is widely used, however, for predicting the fate of chemical contaminants in the atmosphere. In addition, these models have been developed for the outdoor environment where large spatial scales are of interest. Data to support a large-scale field model of bioaerosol dispersal is very limited. As interest in the land application of biosolids increases, it is likely that the need for models such as this and interest in this area will increase.

MYCOBACTERIUM AVIUM COMPLEX

Joseph O. Falkinham
Virginia Polytechnic Institute and State University
Blacksburg, Virginia

THE *M. AVIUM* COMPLEX

M. avium and *Mycobacterium intracellulare* are members of the *M. avium* complex. Though separate species, they share 40 to 50% DNA relatedness (1) and many cultural, biochemical, enzymatic, and structural features.

Because there are so few phenotypic characteristics that distinguish the species, identification requires DNA probes or analysis of PCR products or restriction fragment length polymorphism (RFLP) analysis. Cells of the *M. avium* complex have a complex, multilayered outer membrane that is rich in lipid (2). The lipid-rich wall contributes to the hydrophobicity (3) and impermeability (2) of members of the *M. avium* complex. Both those factors contribute to the slow growth rate of members of the *M. avium* complex (i.e., one generation per day in rich laboratory media) as does the presence of a single chromosomal copy of the genes for ribosomal RNA (4). Hydrophobicity and impermeability are also major determinants of the antibiotic (5) and disinfection resistance (6) of the *M. avium* complex. The hydrophobicity of the *M. avium* complex also contributes to their aerosolization from water (7).

Though *M. avium* and *M. intracellulare* are related to *Mycobacterium tuberculosis*, they are not obligate pathogens requiring complex media for their growth. Members of the *M. avium* complex are environmental opportunistic pathogens that are free-living saprophytes found in water, soil, and aerosols. *Mycobacterium avium* complex strains can grow in drinking water (8) and natural water (9). They are intracellular pathogens, able to grow in human macrophages (10) and amoebae (11). Human and animal infection results from exposure to environmental compartments containing *M. avium* or *M. intracellulare*.

M. avium includes four distinct subspecies that share 100% DNA similarity (12). *Mycobacterium avium* subspecies *avium* is a human and animal pathogen. This review focuses on that subspecies because of its importance to public health. *Mycobacterium avium* subspecies *silvaticum* is common in animals (e.g., deer), rarely causes infection in humans (12), and is distinguished from subspecies *avium* by the presence of the insertion sequence IS901. *Mycobacterium avium* subspecies *paratuberculosis* is the causative agent of Johne's disease in cattle, and can be distinguished from other members of the species by the presence of multiple copies of the insertion sequence IS900 (12). *Mycobacterium avium* subspecies *paratuberculosis* has been implicated as the etiologic agent of Crohn's Disease in humans (13). It grows extremely slowly and requires mycobactin for growth (14). Finally, *M. avium* subspecies *lepraemurium* is the causative agent of a leprosy-like disease in mice. It is a fastidious microorganism and only limited *in vitro* multiplication of this subspecies has been observed (15). Throughout this review, *M. avium* refers to *M. avium* subspecies *avium*.

M. avium and *M. intracellulare* are just two species of environmental mycobacteria. There are many other species of the genus *Mycobacterium*, which are found in water and soil and are opportunistic pathogens of humans, animals, and birds (16). Many of the ecological and physiologic features of the *M. avium* complex are shared by those other environmental mycobacteria (e.g., *Mycobacterium kansasii*, *Mycobacterium marinum*, *Mycobacterium xenopi*, and *Mycobacterium chelonae*). Those features include hydrophobicity, impermeability, and antibiotic and disinfection resistance (16). This review focuses on the *M. avium* complex because of its widespread occurrence in the environment, and its importance as a pathogen of humans, animals, and birds. However, many of the principles taught here are applicable to the other mycobacterial species.

EPIDEMIOLOGY OF THE *M. AVIUM* COMPLEX

Infections in Humans and Risk Factors

Infection by the *M. avium* complex is usually associated with existence of a preexisting condition that disposes the individual to infection (Table 1). Among individuals with competent immune systems, *M. avium* and *M. intracellulare* pulmonary infections are found in patients with predisposing lung conditions that include silicosis and black lung (17), and patients with pulmonary alveolar proteinosis (18) and cystic fibrosis (19). Elderly women without any of the known risk factors for *M. avium* complex infection have also been described (20). *Mycobacterium avium*, but not *M. intracellulare*, infections are

Table 1. Patient Types and Risk Factors for *M. Avium* Complex Infection

Patient Type	Infection	Route of Infection
Nonimmune Deficient		
Children (1–3 years, erupting teeth)	Cervical Lymphadenitis	Oral
Pulmonary Alveolar Proteinosis	Pulmonary	Aerosol
Women (Chest Architectural Defects)	Pulmonary	Aerosol
Preexisting Lung Disease (Occupational)	Pulmonary	Aerosol
Cystic Fibrosis	Pulmonary	Aerosol
Trauma (surgical or injury)	Granuloma at Site	Liquid or Device
Immune Deficient		
Interleukin-12 Receptor Deficiency	Bacteremia	Oral to GI tract
Malignancy (e.g., Leukemia)	Bacteremia	Oral to GI tract
Immune-suppressive Therapy (Transplantation)	Bacteremia	Oral to GI tract
HIV-infection (AIDS)	Bacteremia	Oral to GI tract

found in (and limited to) the cervical lymph nodes of young children with erupting teeth (21). *Mycobacterium avium* and *M. intracellulare* infections have also been associated with contaminated medical equipment (22,23).

Immune-deficiency resulting from human immunodeficiency virus (HIV) infection (24), IL-12 deficiency (25), malignancy (26), or from immunosuppression associated with transplantation (27) are also risk factors for *M. avium* infection. Unlike the pulmonary infections, infections in the AIDS patients are almost entirely (i.e., 95%) due to *M. avium* (28,29). The reason *M. intracellulare* infections are rare among AIDS patients has not been identified. Infections in immunodeficient individuals are not limited to the lungs, but occur throughout the body and are commonly diagnosed by the appearance of *M. avium* in blood (bacteremia).

One source of *M. avium* infection in AIDS patients is water. DNA fingerprints of *M. avium* isolates from water to which the AIDS patient was exposed were identical with those of the patient (30). Further, an extraordinarily high frequency of *M. avium* infection in AIDS patients in Finland was associated with very high numbers of *M. avium* in drinking and environmental waters (31). In 10 to 30% of *M. avium*-infected patients with the acquired immunodeficiency syndrome (AIDS), more than a single strain has been isolated from individual patients based on differences in serotype (32) or DNA fingerprint pattern (33). That is not surprising, in light of the profound immunodeficiency of the patients and the ubiquity and diversity of *M. avium* types in the environment (33).

Infections in Animals and Risk Factors

Though *M. avium* was originally recovered and described as a pathogen of birds, infection is seldom encountered in poultry. This is probably due to the fact that broilers are six to seven weeks old at slaughter. That is insufficient time for infection to be manifest. More commonly, *M. avium* infection is found in pigs (34). Infection in pigs can appear in the cervical lymph nodes and then the mesenteric lymph nodes (34). Infection is diagnosed by the appearance of tuberculous lesions in the lymph nodes. Because tuberculous lesions result in loss of profit, factors leading to *M. avium* infection have been identified. Two factors associated with higher frequencies of *M. avium* infection are the use of pine bark mulch as bedding (35) and the presence of birds in the pig sties (36). Substitution of straw for bedding and erection of barriers to birds reduce the incidence of *M. avium* infection. Stress is also a likely factor in *M. avium* infection. By manipulating the level of stress of chickens, it was shown that chickens under either abnormally high or low levels of stress were more susceptible to *M. avium* infection (37). This might be an important factor in the morbidity and mortality of animals captured in the wild and transported to zoos (38).

Water can be a source of *M. avium* infection in captive animals. Macaques infected with simian immunodeficiency virus (SIV) were infected with *M. avium* strains that were present in their drinking water (39).

ECOLOGY OF THE *M. AVIUM* COMPLEX

Members of the *M. avium* complex are found in almost every environmental compartment. They have been isolated from natural waters (40–42). Because *M. avium* complex organisms can be isolated from freshwaters and those of moderate to high salinity (4) and grow in waters of moderate salinity (9), the *M. avium* complex may be estuarine. Drinking waters also yield the *M. avium* complex (42–45). Drinking water may be a more important source of the *M. avium* complex than natural water because of more possibilities of human exposure. Members of the *M. avium* complex have been shown to occur in high numbers in hospital hot water systems (46), and persist for as long as 18 months in hospital water systems (30). They have also been recovered from biofilms that form on pipes in drinking water systems (47), and from the dialysis membranes used in treatment of drinking water by reverse osmosis (48). Groundwater seldom contains the *M. avium* complex (49). *Mycobacterium avium* complex bacteria have also been recovered from biofilms collected at the air-water surface of natural bodies of water (50), droplets ejected from the surface of a river (50), and aerosols (51). Ejection of droplets enriched with cells of the *M. avium* complex is one mechanism for the aerosolization of the *M. avium* complex. Long-term exposure to aerosols generated in swimming pools may be responsible for granulomatous pneumonitis found in swimming pool attendants (52). *Mycobacterium avium* complex cells of higher hydrophobicity were more highly enriched in droplets than cells of mycobacterial strains of lower hydrophobicity (7).

In addition to water, *M. avium* and *M. intracellulare* have been recovered from soils (41,53–55). Soils rich in humic and fulvic acids have high numbers of *M. avium* complex bacteria whether they have been collected from the coastal acid, brown water swamps of the eastern United States (41) or from peatlands or boreal coniferous forests of Finland (55). *Mycobacterium avium* complex isolates have also been recovered from sphagnum vegetation (56) and pine bark mulch (35). Their presence in the latter undoubtedly contributes to the association of the use of pine mulch bedding and *M. avium* lymphadenitis in pigs (34). As noted earlier, members of the *M. avium* complex have also been isolated from medical instruments (22,23). It has been presumed that their presence in such devices is due to insufficient disinfection of these disinfection-resistant bacteria (22,23).

TRANSMISSION OF THE *M. AVIUM* COMPLEX

One route of *M. avium* complex infection is via aerosols. Cells of *M. avium* complex bacteria are readily aerosolized from water suspensions (57) and are associated with natural aerosol fractions containing particles of a size (i.e., 1 μm diameter) that can enter human alveoli (50,51). The route of *M. avium* complex infection leading to pulmonary infection is logically via the aerosol route. Aerosolization of *M. avium* complex cells can occur either through the natural process of ejection of droplets (57) or physical or

mechanical agitation (52). Cell surface hydrophobicity is the major determinant of aerosolization (7) with little or no contribution from cell surface charge (58).

It has not been determined whether the route of infection in immunodeficient patients is via the pulmonary or gastrointestinal tracts or both. Studies in AIDS patients have implicated both routes (59,60). The appearance of *M. avium* in blood (i.e., bacteremia) was equally likely to have been preceded by pulmonary or gastrointestinal tract infection or colonization (59,60). The difficulty of identifying a specific route is due to the fact that the required specimens (i.e., sputum and feces) contain microorganisms in addition to the *M. avium* complex. To detect, identify, and enumerate *M. avium* complex, specimens must be decontaminated to permit colony formation of the slowly growing mycobacteria. However, decontamination also reduces mycobacterial numbers such that the sensitivity of detection is reduced.

Drinking either natural or potable water containing *M. avium* is the likely route of cervical lymphadenitis in children (21). Because the age of the children coincides with the eruption of teeth, it is compelling to hypothesize that the trauma of the gums leads to entry of the mycobacteria and their migration to the cervical lymph nodes. What is interesting is that until 1975–1985, the majority of cases of childhood cervical lymphadenitis were caused by *Mycobacterium scrofulaceum*, another environmental opportunist (21). However, since 1985, almost all the cases are caused by *M. avium*. Further, recent environmental surveys (42,44,45) have not reported recovery of *M. scrofulaceum* although the methods of isolation and identification of mycobacteria had not changed. It appears that *M. scrofulaceum* has disappeared and its niche has been occupied by *M. avium*.

Introduction of *M. avium* complex microorganisms into patients via contaminated instruments (22,23) or kidney dialysis units (8) are additional routes of infection. In the cases published in the literature, disinfection resistance of the mycobacteria (8,22,23) has been suggested as the major factor leading to contamination of the vector.

MOLECULAR EPIDEMIOLOGY OF THE *M. AVIUM* COMPLEX

A variety of typing methods has been developed for studies of the epidemiology and ecology of members of the *M. avium* complex. These methods are necessary because it is insufficient to simply isolate *M. avium* or *M. intracellulare* from a particular sample, and say that the sample's origin is the source of human or animal infection. The isolated strains must be members of the same clone. Serotyping and restriction fragment length polymorphism (RFLP) based typing methods have proven the most useful. Serotypes are based on the presence of carbohydrate-containing antigens on the surface of *M. avium*, *M. intracellulare*, and *M. scrofulaceum* (61). Serotypes of the *M. avium* complex correlate with species assignments based on DNA probes (62) and certain serotypes are found more commonly in AIDS patients (63).

DNA fingerprinting of *M. avium* complex isolates has been performed using pulsed field gel electrophoretic (PFGE) separation of large restriction fragments (33,64). Though time-consuming, PFGE patterns are discriminatory and have led to the proof that *M. avium* isolates from patients share the same PFGE pattern with isolates from water to which the patient was exposed (30). They have also demonstrated that AIDS patients can be infected with more than a single clone of *M. avium* (33). One advantage of PFGE fingerprinting is that any species and isolate can be typed.

Typing of *M. avium* isolates can be performed rapidly by restriction fragment length polymorphism (RFLP) analysis, using the insertion sequence IS1245 as a target or probe (65,66). Between 5 and 25 copies of this insertion sequence are found in the genome of *M. avium* (65,66) Thus, IS1245 typing is quite discriminatory. IS1245 typing can also be carried out with the polymerase chain reaction (67). Primers have been designed, that amplify the DNA sequences between IS1245 copies, and the resulting patterns of amplified bands (i.e., intervening sequences) can be compared (67). Unfortunately, IS1245 is only found in *M. avium* strains (65,66) and there have been no reports to date of IS-elements suitable for typing *M. intracellulare* or *M. scrofulaceum*.

METHODS FOR WORKING WITH THE *M. AVIUM* COMPLEX

Recovery, Growth, and Isolation

Though cultivation of the *M. avium* complex is difficult because of their slow growth and the attendant risk of contamination, they are not fastidious. They grow on a variety of media and will even grow in water (8,9). Inclusion of oleic acid, either with albumin or as part of a detergent (e.g., Tween 80®) to reduce the toxicity of the fatty acid stimulates growth. Inclusion of a detergent in mycobacterial media has also been used to reduce the formation of cell aggregates. Not only does the detergent reduce the aggregation, but also it accelerates growth, probably through an increase in permeability (2). Unfortunately, detergent also increases the susceptibility of mycobacterial cells to disinfectants and antimicrobial agents (5).

To reduce the chance of overgrowth of *M. avium* colonies by those of other microorganisms, samples are often decontaminated. The success of decontamination relies on the relative resistance to the killing action of acid (e.g., oxalic acid), base (e.g., NaOH) or detergent (e.g., cetylpyridinium chloride, CPC). However, decontamination does reduce the number of viable mycobacterial cells (68). Cetylpyridinium chloride (0.005% for 30 min to 24 hr) appears to be most useful, based on its ability to reduce colony counts of non-mycobacterial cells while reducing mycobacterial numbers very little. Filtration following decontamination has been used to isolate mycobacteria in drinking water (44,45). In that approach, filters are placed on media and mycobacterial colonies grow on top of the filters (44). A number of publications have compared different methods for the recovery of *M. avium* complex microorganisms from water (69–71) and soil (54,68,72,73). Methods for the recovery of *M. avium* complex from aerosols, ejected droplets, air-water biofilms (50), and from biofilms on

pipe surfaces (47) have been published. Immunomagnetic beads coated with antimycobacterial antibody have been used to isolate *M. tuberculosis* from sputum samples (74), and there is no reason to believe that such an approach might not work for isolation of *M. avium* complex from water samples and soil suspensions. Based on the fact that *M. avium* survives following phagocytosis by *Acanthameoba castellani* (11), it might be possible to use phagocytic amoebae or protozoa to scavenge and concentrate mycobacteria in water or a soil suspension.

Identification of the *M. Avium* Complex

Commonly, the identification of putative mycobacterial colonies from a patient or environmental sample is initiated with the acid-fast stain. *Mycobacterium avium* complex strains can form interconvertible opaque (i.e., 1 to 2 mm diameter, domed cream, or yellow-pigmented colonies) or transparent (0.5 mm, flat, transparent) colonies. The transparent colonies are especially difficult to see, even on a transparent medium. Acid-fast isolates can be characterized as rapidly growing (i.e., colony formation in less than seven days at 37 °C) or slowly growing (i.e., colony formation in greater than seven days at 37 °C). The ability to form pigment in the dark (scotochromogenic), or only in the light (photochromogenic), can also be assessed with growth rate. Though, identification of mycobacteria is possible by cultural, biochemical, and enzymatic tests, current practice uses DNA probes or PCR amplification with or without restriction endonuclease digestion of PCR products. This is particularly important for the *M. avium* complex because *M. avium* and *M. intracellulare* cannot be distinguished reliably with cultural or biochemical tests. DNA probes are commercially available for *M. avium, M. intracellulare,* and other mycobacteria (Gen-Probe, San Diego, CA). A nested PCR amplification of the 16S rRNA gene can be used to identify members of the genus *Mycobacterium* and *M. avium* and *M. intracellulare* (75). PCR amplification of the *hsp-65* heat shock protein gene of mycobacteria followed by restriction endonuclease digestion with *Hae* III, and *Bst* EII has been used for identification of many mycobacterial species (76,77). It is also possible to use PCR to detect *M. avium* complex cells in water samples, though the limit of detection is only 10^4 per ml.

Measuring Virulence of the *M. Avium* Complex

Virulence of *M. avium* complex isolates can be measured in chickens (78), mice (79), or in the beige mouse (80). Animals can be infected by a variety of routes (e.g., intraperitoneal or intravenous), and the establishment and progression of infection assessed by measuring the number of colony-forming units (CFU) in lung, spleen, and liver (78,79,80) after different periods of time following infection. In beige mice, LD_{50} values can be measured (80). In the chicken, *M. avium* strains are considerably more virulent than are strains of *M. intracellulare* based on comparison of mortality and microbial numbers (as colony-forming units, CFU) in organs (81). In mice, *M. intracellulare* strains are more virulent than *M. avium* strains, again using the same criteria (82). Because members of the *M. avium* complex are intracellular parasites, it is possible to measure growth in alveolar or peritoneal macrophages (83) and epithelial cells (84).

The growth conditions of the *M. avium* complex strains influence virulence. The mortality and CFU per gm of organ was higher when strains were grown at 42 °C compared to 37 °C (85). *Mycobacterium avium* complex cells grown under reduced oxygen tension (i.e., microaerobic) were significantly more virulent compared to cells grown under normal oxygen levels (86).

Genetic differences in addition to species assignment are also determinants of virulence in the *M. avium* complex. *Mycobacterium avium* complex strains form interconvertible colony types (i.e., transparent and opaque) that differ in virulence. Transparent variants have been shown to be of greater virulence (i.e., mortality and CFU per gm of organ) in chickens (87–90), rabbits and guinea pigs (89), and mice (90) compared to their isogenic opaque variants. It has also been shown that infection with the more virulent transparent type does not trigger release of the interleukins IL-1 and IL-6 (91,92) and TNFα (92). That data suggests that the reduced virulence of opaque colonial variants of *M. avium* complex strains is due to their inability to suppress initiation of the host immune system (91,92).

Two factors have been identified that contribute to the survival and growth of *M. avium* complex cells in phagocytic cells of the mammalian immune system. Vesicles containing *M. avium* complex cells are not acidified as are the vesicles containing other bacteria that do not survive phagocytosis (93,94). In addition, the *M. avium* complex-containing vesicles do not fuse with lysosomes, thus preventing exposure of the cells to bactericidal proteins and lytic agents (95). It is likely that those characteristics also contribute to the survival of *M. avium* complex cells in phagocytic amoebae (11).

GROWTH AND PHYSIOLOGICAL ECOLOGY OF THE *M. AVIUM* COMPLEX

Members of the *M. avium* complex show evidence of adaptation to survival in the natural environment. In addition, those adaptations result in the ability of cells to persist in drinking water and drinking water distribution systems, resist disinfectant, and antibiotic action, and survive and grow in human and animal macrophages.

Members of the *M. avium* complex grow in natural and drinking water (8,9). They grow in fresh and relatively saline waters of 2% salt (9), in keeping with their isolation from estuarine environments (40). They grow over a wide temperature range (i.e., 10°–45 °C) (9). Optimum growth occurs at pH 4.5–5.5 (96,97). Because the isoelectric point of *M. avium* complex cells is near pH 4 (58), their cells would carry no net charge in mildly acidic environments such as encountered in brown water coastal swamps of the eastern United States and peat bogs and boreal coniferous forests of Finland. Highest numbers of *M. avium* complex bacteria are associated with reduced dissolved oxygen (41,53) suggesting they are microaerophilic. *Mycobacterium avium* complex numbers are also correlated with high levels of zinc (41,55),

suggesting that the group has a high requirement for this metal.

High numbers of *M. avium* complex microorganisms were associated with high concentrations of humic and fulvic acids (41,55). That discovery led to the demonstration that the growth of *M. avium* complex strains is stimulated by humic and fulvic acids (98). Growth stimulation by humic and fulvic acids and a preference for acidic, microaerobic environments are consistent with, and in fact explain, their high numbers in the acidic, brown water coastal swamps of the eastern United States (41), and in the waters and soils of boreal coniferous forests and peat bogs in Finland (55).

Members of the *M. avium* complex are the most hydrophobic of microorganisms (3,7). The high cell surface hydrophobicity is a major determinant of their enrichment in droplets ejected from the waters (57), and their concentration at the air-water interface (50). Though not proven, their hydrophobic surface (3,7) is likely a major contributor to the disinfection (6), antibiotic (5), and heavy metal resistance (99). It may also contribute to the formation of biofilms (47,48). The combination of high hydrophobicity and heavy metal resistance may allow *M. avium* complex cells to be pioneers of biofilm formation in drinking water distribution networks, and hot and cold water systems in hospitals, especially if galvanized (i.e., zinc-coated) pipes are employed.

In summary, members of the *M. avium* complex are adapted to life in marginal environments. Marginal environments include those of low nutrient or acidic pH. They also include three human-influenced environments, water subject to disinfection, medical equipment requiring sterilization, and patients undergoing antibiotic therapy. In each of those environments, rapidly growing microorganisms are killed and members of the *M. avium* complex and other mycobacteria can invade and proliferate.

DISINFECTION RESISTANCE OF THE *M. AVIUM* COMPLEX

Mycobacterium avium and *M. intracellulare* are resistant to disinfection. Strains of *M. avium* are at least 500-fold more resistant to chlorine, 100-fold more resistant to chlorine dioxide, and 50-fold more resistant to ozone than *Escherichia coli* (6). Though some *M. avium* strains were relatively resistant to chloramine (6- to 25-fold) compared to *E. coli*, some strains (2 of 5) were just as susceptible (6). Susceptibility of *M. avium* strains to chlorine was strongly correlated with growth rate. The slower growing strains were more resistant (6). Cells of *M. avium* grown in water were, on average, 10-fold more resistant to chlorine than were cells grown in laboratory medium (6). This could be due to the fact that growth rates in water are lower than rates in laboratory media. *Mycobacterium intracellulare* strains are slightly more chlorine-resistant and *M. scrofulaceum* strains much more sensitive to chlorine (fivefold) compared to *M. avium* strains. The relative susceptibility of *M. scrofulaceum* to chlorine may contribute, in part, to its disappearance from water.

Members of the *M. avium* complex are resistant to disinfectants that are used for surface and instrument sterilization. Concentrations of gluteraldehyde and phenolic-based disinfectants that kill other microorganisms have little effect on strains of *M. avium* complex and other mycobacteria (100).

ANTIMICROBIAL RESISTANCE OF THE *M. AVIUM* COMPLEX

Members of the *M. avium* complex grow at concentrations of heavy metals (e.g., Hg^{2+}, Cd^{2+}, and Cu^{2+}) that are approximately 10-fold higher than concentrations that inhibit the growth of other bacteria (99). In addition, some strains express specific resistance mechanisms. A mercury-resistant (grew at 1 mM Hg^{2+}) strain of *M. avium* isolated from a metal-polluted portion of the Chesapeake Bay was shown to produce a mercuric reductase (101). That same strain was shown to be resistant to Cu^{2+} (grew at 1 mM Cu^{2+}) by virtue of its ability to sequester copper in the membrane fraction as an insoluble sulfide (102). Not only do those two mechanisms result in survival of cells of the *M. avium* complex strain, but they also permit survival of metal-sensitive microorganisms in the immediate environment because the toxic heavy metal is removed or sequestered.

Members of the *M. avium* complex, along with the entire genus *Mycobacterium*, are relatively resistant to antibiotics. High cell surface hydrophobicity (3,5,7,103) and membrane impermeability (2,5) both contribute to resistance to a wide spectrum of antibiotics. Reduction of cell surface hydrophobicity through the use of detergents, significantly, reduces antibiotic resistance (5). Permeability of β-lactam antibiotics (e.g., penicillins) is significantly lower in mycobacteria than it is in other bacteria (2,104). To overcome these two cell surface barriers, cells have been exposed to an antibiotic whose target is the cell wall (e.g., ethambutol) and a second, whose target is not the cell wall (e.g., rifamycin) (105,106). In a number of cases, the combination resulted in killing above the level (i.e., synergistic) of either antibiotic alone (105,106). A second successful approach has been the development of hydrophobic or tissue-trophic variants of antibiotics. The erythromycin derivatives, clarithromycin and azithromycin, are more hydrophobic than their parent and have demonstrated effectiveness *in vitro* and *in vivo* against members of the *M. avium* complex (107,108). Amphipathic derivatives of isoniazid showed higher anti *M. avium* complex activity compared to isoniazid itself (109).

In addition to broad spectrum antibiotic resistance of the *M. avium* complex due to high cell surface hydrophobicity and membrane impermeability, strains of the *M. avium* complex have been isolated that have mutations leading to resistance to specific antibiotics. For example, clarithromycin- and azithromycin-resistant strains have been isolated from patients undergoing therapy with one of those drugs. Those strains have been shown to carry mutations in the sequence of the 23S rRNA, one of the targets of their action (110,111). Interestingly, there have been no reports of antibiotic-resistant *M. avium*

complex strains whose resistance is due to an antibiotic inactivation, though a strain of *Mycobacterium smegmatis* was shown to inactivate rifampicin by ribosylation (112). Such a mechanism of resistance is common amongst gram-negative, plasmid carrying bacteria. However, the modest increases in minimal inhibitory concentrations resulting from such antibiotic-inactivation mechanisms, may not be of adaptive utility to the mycobacteria with their high level of broad spectrum resistance.

CONCLUSION

Members of the *M. avium* complex are environmental opportunistic pathogens that are well adapted to survival and growth in natural and human-influenced habitats. Their ability to grow in natural waters and drinking waters, and drinking water distribution systems, coupled with their resistance to disinfection suggests that they will remain hazards to individuals with conditions that predispose for *M. avium* complex infection. Because the number of immunosuppressed individuals throughout the world is expected to continue to rise as a consequence of organ transplantation, malignancy, and chemotherapy, the number of *M. avium* complex susceptible individuals will also increase. Eradication from drinking water distribution systems will be difficult because of the ability of these microorganisms to form biofilms. Present disinfection practices also have the disadvantage that they result in selection of the *M. avium* complex, and other mycobacteria. Because the *M. avium* complex and the other environmental opportunistic pathogens of the genus *Mycobacterium* are ubiquitous, it is likely that they will emerge as a leading occupational hazard in the workplace. Already members of the *M. avium* complex and other mycobacteria have been implicated as causative agents of hypersensitivity pneumonitis among swimming pool attendants (52) and metal workers in the automobile industry (113).

MYCORRHIZAE: ARBUSCULAR MYCORRHIZAE

MICHAEL F. ALLEN
University of California
Riverside, California

WHAT IS AN ARBUSCULAR MYCORRHIZA?

Mycorrhizae form as a result of mutualistic symbioses between plants and fungi localized in the root or rootlike structures. Their major function is that the fungi form a fine, absorbing network of hyphae that transport resources in the substrate to the host in exchange for carbohydrates.

The arbuscular mycorrhiza is the most widespread type of mycorrhiza and it is the most ancient. This type of mycorrhiza has been described as an endomycorrhiza, a vesicular-arbuscular mycorrhiza (VAM), a phycomycetoid mycorrhiza, and, currently, an arbuscular mycorrhiza (AM). Generally, this type of mycorrhiza is named on the basis of the structures formed. Arbuscules are widespread and known to be important in resource exchange between host and fungus. These are presumably ubiquitous across taxa, but are very transitory and sometimes are not formed. Vesicles are formed by the *Glomus*/*Acaulospora* lineage, but again, are not found for all genera. The predominant features of an AM are shown in Figure 1. Vesicles and hyphal structures found in fossils from the Devonian are indistinguishable from modern structures.

The fungi forming AM are a monophyletic group, the Glomales, which appears to go back to an ancestral fungus forming an association with algae in the Ordovician or Silurian epoch. The divergence between *Geosiphon* (a related fungus forming a symbiosis with *Nostoc*) and *Glomus* occurred sometime during the Silurian or Devonian epochs. A further divergence between the *Gigaspora* and the *Glomus* lineages occurred sometime between 350 and 400 million years ago. Today, six genera are recognized: *Glomus, Acaulospora, Sclerocystis* and *Entrophospora* (Glomaceae), and *Gigaspora* and *Scutellospora* (Gigasporaceae).

AM are a particularly important linkage between plant and soil. They appear to have been a critical step in the invasion of land. Algae and plants in saturated

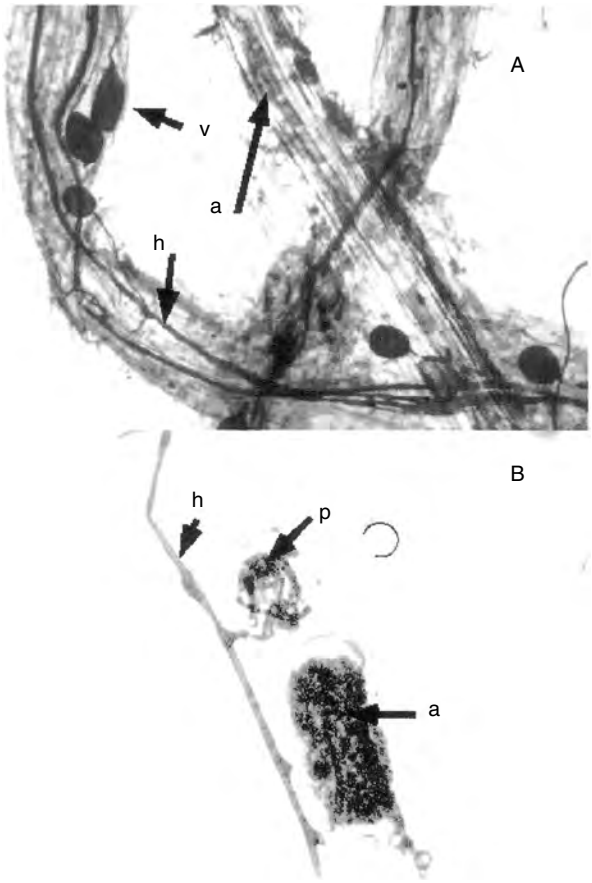

Figure 1. Illustrations of AM structures. **A**) Infected root segment with internal arbuscules (a) and extramatrical hyphae (h) and vesicles (v) extending from the root into the soil. These structures are involved in nutrient uptake and carbon storage. **B**) A greater detail of the intercellular hyphae (h), peletons or coils (p), and arbuscule (a). These structures are all involved in nutrient and carbon exchange between host and fungus.

environments are bathed in a nutrient solution and nutrients are taken up by diffusion. Rhizoids are relatively inefficient structures for obtaining soil resources as the soil dried out at long distances. Taking the symbiosis between the ancestral plant and fungus to the land enabled the hyphae to efficiently spread into soils extracting soil resources in exchange for carbon.

BASIC STRUCTURE/FUNCTIONING FOR AN INDIVIDUAL PLANT

The basic functioning of an AM is tightly coupled to both its internal (within the host) and external structures (within the soil). An AM forms as a runner hypha growing through the soil intercepts a susceptible root section. Susceptible roots are those uninfected segments located just behind the region of elongation (Fig. 2). This hypha penetrates a susceptible root and forms an appressorium. The internal hyphae then proliferate forming either an Arum-type mycorrhiza, in which intracellular arbuscules emerge from intercellular hyphae, or a Paris-type mycorrhiza, in which sequential coils and infrequent arbuscules emerge from

inter- or intracellular hyphae. In all cases, there remain intact membranes separating the plant and the fungus cytoplasm.

As the internal portion of an AM forms, carbon is transported back into the external hypha. The external hyphae appear to form two distinct architecture types. The first is the mycelial network of runner hyphae that continues to spread, looking for new root segments, or forming vesicles or spores accumulating carbon. Associated with the internal network is also a dichotomously branching, external hyphal network that spreads outward searching for soil resources. There are limits to this extension as at each branching, the hyphae decrease in diameter.

This means that there are three structural elements to the AM fungal mycelium. The first element is the internal hyphae. Carbon is taken up by the fungal hyphae within the plant. Evidence to date shows that much, if not all, of the internal hyphae can take up sugars, although adenosine triphosphatases are concentrated in the arbuscules. Importantly, fungi generally convert the simple sugars to trehalose or other complex sugar to prevent or reduce reabsorption. Within the root cortex, hormonal composition also changes. These are probably primarily associated with loading and unloading of carbon and nutrients. However, these hormone shifts also lead to other changes in rooting morphology, such as increased lateral root formation. These changes can affect the entire dynamics of root form and chemistry.

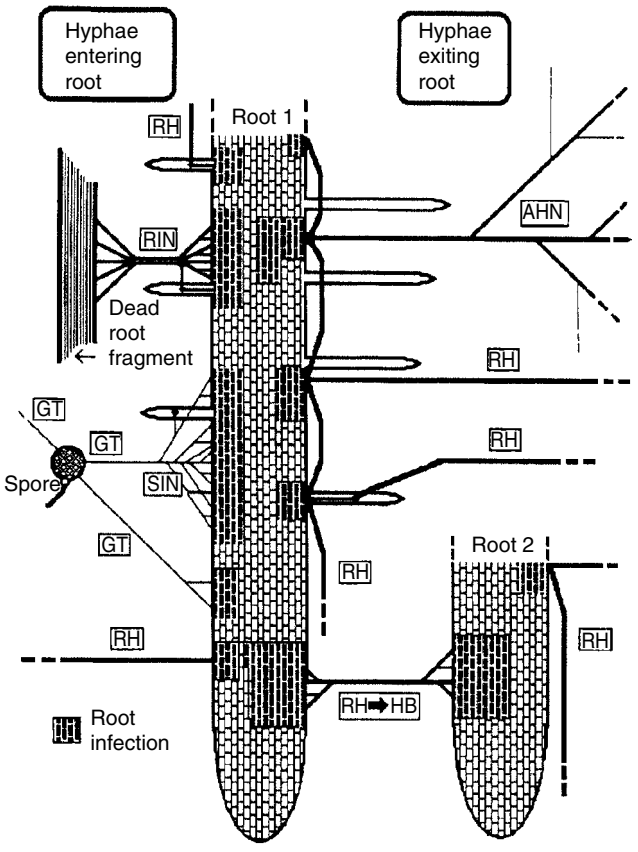

Figure 2. Architecture of the external hyphae forming AM. The primary hyphal types observed in soils include the runner hyphae (RH), hyphal bridges between plants (HB), and absorptive hyphal networks (AHN). New AM infections can be formed by germ tubes (GT) arising from spores either as individual hyphae, or as infection networks (SIN), or from infected root fragments (RIN). When many hyphal bridges are formed between plants, a common mycorrhizal network (CMN) is formed.

The second element is the external absorbing network. This is a dichotomous branching mycelium that starts as a single thick hypha extending out beyond the root hairs, then dividing into ever-finer hyphae. This network consists of 80 to 120 cm of hyphae per root penetration in up to an eighth-order branching structure. At the base, this hypha is 10 to 12 μm in diameter. Towards the hyphal tip, it may be as fine as 2 μm. The outward limit appears to range from 2 to 8 cm, corresponding to a depletion zone surrounding each individual mycorrhizal root. These external hyphae pick up soil resources and transport those resources to the host in exchange for carbon. Most soil resources are transported to the plant via this network, including phosphorus, nitrogen, water, iron, calcium, zinc, manganese, magnesium, and sulfur.

The third element is the runner hyphal network. These hyphae consist of single large (10 to 15 μm in diameter) hyphae, or multiple hyphae wrapped around each other in a primitive, rhizomorph-like structure. The actual functions of these hyphae are not well understood. These hyphae clearly are involved in searching out new roots to form new mycorrhizae. The external hyphae do not appear to have the enzymatic capacity to take up sugars, but they do move carbon and water. They transport nutrients depending on the flow rates, direction, and sink strength. Importantly, it is this mycelium that connects multiple roots of a single plant and multiple plants in a complex network of mycorrhizal partners, called the common mycorrhizal network (Fig. 2). We do not know the extent of any single mycelium, or the amount of transport of this network. Carbon, nitrogen, and phosphorus (and probably many other resources) are transported between plants through these hyphae but the amounts and significance remains controversial (Fig. 3). In some cases labeled carbon from one plant can be found in the fungal hyphae within a neighboring plant but appears not to be transported to the shoot. In other cases, the data show label appearing in the shoot. It could be directly transported or respired and refixed. Clearly, this is an important topic in need of additional research.

Physiologically, AM plants are very different from nonmycorrhizal plants. Some of these differences are a direct consequence of their increased resource uptake and ability to be a carbon sink, but others are indirect, caused by the mechanisms regulating resource transfer. An example is the hormonal balance of the host. Several studies have demonstrated changes in the host hormonal balance beyond that expected by direct production and transport from the fungus to the plant. This is likely because of the roles of phytohormones in carbon and nutrient loading and unloading. However, the resulting shifts can affect everything from stomatal opening to root branching. Generally, the shifting balances are beneficial to both the plant and the fungus.

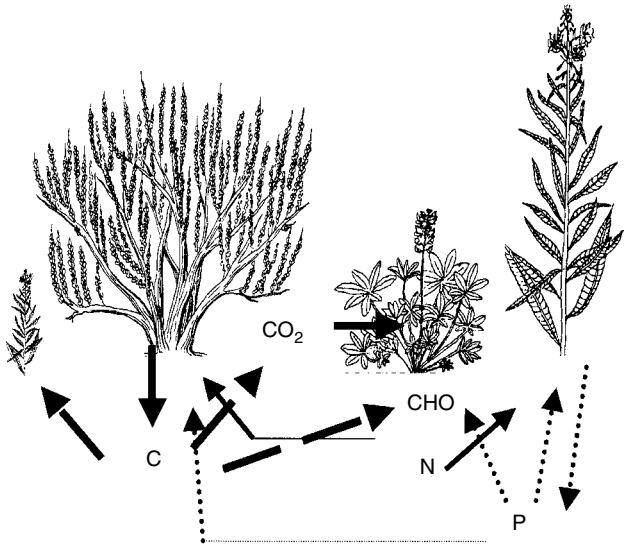

Figure 3. Complex resource transfers among common mycorrhizal networks in a community. Each arrow shows an elemental transport between plants via mycorrhizal hyphae demonstrated in the literature. Resources may be exchanged depending on the sink strengths, resource concentrations, and diversity of fungal and plant partners. The quantitative extent of resource transport is still an open research question.

Thus, our understanding of mycorrhizal dynamics and mechanisms at the individual plant/fungus scale is rapidly improving. What we know comes largely from pot, chamber, and petri dish experimental systems. However, there are subtle mechanisms that are associated with fungal growth and maintenance, infection, and plant and fungal genetic differences. In the field, these can add up to quite different roles when viewed at the larger scales of a stand, community, or landscape.

SCALING AND COMMUNITY AND ECOSYSTEM EFFECTS

AM are not evenly distributed along a root or across a field, they are also not benign sealed tubes extending into the soil from the roots. They are organisms with their own needs, physiology, and patterns. Thus, the generalized models of AM action (nutrient transport from the fungus to the plant and of carbon from the plant to the fungus), developed largely from pot culture studies, must be recast in the context of larger-scale field dynamics.

When plants occupy a stand, there are multiple individuals, and generally, several species. In many cases, the soil is rich in resources. In pot studies, mycorrhizal density declines with increasing fertility. However, in a competitive field environment, the level of nutrients available per plant can remain low. Mycorrhizal infection is regulated by the nutrient status of the leaves. Thus, plants in soils that appear to be high in nutrient levels may still have a high mycorrhizal infection. Just as important, roots can grow rapidly during certain conditions and outgrow the mycelial network. In these cases, the percentage of mycorrhizal infection can be low, but can occupy a large number of root segments. Thus, in the field, the percentage of root infection at the community level depends on a much larger number of variables than in pot cultures.

Research continues to focus on nutrient uptake by individual mycorrhizae. However, in many cases all plants in a community form AM, potentially with the same fungus. Why, then, do mycorrhizae matter? At the stand level, AM are often important to a lesser extent for the nutrient transport to an individual plant, and to a greater extent for the differing species of AM fungus select among the resident plants, favoring some but not others. In other cases, some plants have evolved to reject AM. AM fungi preferentially support plants forming mycorrhizae. A century ago, Stahl divided the world into mycotrophs (plants that are capable of forming mycorrhizae) and nonmycotrophs (those that do not). More recent research has clearly demonstrated that this is an advanced genetic trait mostly found in some weedy species that preferentially survive in highly disturbed lands.

Thus, the importance of AM is not in increasing productivity overall, but in altering the competitive outcomes among plants. These effects can range from minor shifts in nutrient allocation, to situations in which the hyphae colonize and reduce the growth of some species. For example, in some communities, AM increase the growth of mycotrophic plants in competition with nonmycotrophs, thereby increasing the total plant diversity. In other cases, when all plants form AM, as the richness of AM fungal species increases, up to five to eight species, more plant species survive, presumably occupying slightly different niches.

In extreme cases, AM fungi may actually inhibit the growth of certain species. In relation to competition between grasses and chenopodiaceous weeds, AM improve the growth of grasses and reduce the growth of weeds. This can affect succession outcome and overall plant production. This phenomenon was apparent in an experiment in the Great Basin where a dominant early colonizer is *Salsola kali* L., a chenopodiaceous shrub that does not form AM. We found that inoculated AM associated with grasses colonized and parasitized the *S. kali*, reducing the height, density, and productivity of the overall stand. However, the grass establishment was enhanced.

At the ecosystem scale, the extramatrical mycelium has multiple functions within the soil. The hyphae not only increase the surface area for uptake, but also affect nutrient availability. In some instances, nutrients in the soil solution can be increased. The hyphae themselves respire carbon dioxide that, upon contact with the soil solution, becomes HCO_3^-. This pH effect weathers phosphorus and other minerals from clay particles. Under some conditions that we do not understand, the hyphae also produce organic acids, such as oxalates, that bind cations that otherwise would immobilize the PO_3^-. This can, in turn, enhance phosphorus uptake.

The hyphae themselves require nutrients for their own growth, which could affect nutrient availability for plants.

In the case of nitrogen, its concentration in most fungi is approximately 10%. This is contrasted with plant leaves where it is present at 2 to 4%. When the hyphal matrix is dense up to 1 to 5% of the total "soil" nitrogen can be bound in fungal tissue. This amount is equal to or exceeds the available nitrogen in soil.

AM hyphae extend outward from the root into the soil. Some or all of these hyphae produce a glycoprotein called glomalin that is both relatively recalcitrant and sticky. This compound "glues" together many soil particles forming soil aggregates. At an ecosystem scale, this aggregate formation may be among the most important functions of AM fungi. These aggregates also appear to be important for carbon sequestration. With elevated carbon dioxide, more carbon flows into hyphae, and newly fixed carbon is found preferentially in aggregates. Preliminary calculations suggest that up to 25% of the recalcitrant soil organic carbon is made of glomalin.

At the scale of a stand of plants, there are multiple species of AM fungi. Whereas species richness varies among sites, estimates range from 8 to 50 taxa per site. This suggests that the soil community consists of a shifting matrix of AM fungi. Individual studies have shown that improvement in plant diversity approaches an asymptote at about five fungal species in a small sward. Plants establish and preferentially associate with and increase one or two species of fungi. When any of those individuals die, a gap is opened for the establishment of other plants or fungi. This can result in a legacy of plant/AM fungi in time that may affect the overall community structure.

In tillage agriculture, a simpler system develops. As the mycelia network does not remain intact following soil disruption, the dynamics of agricultural AM fungi and plants may be quite different from wildland ecosystems. The mycelium must re-form with each cropping season and, if crop rotation is practiced, with differing plant species.

MYCORRHIZAE AND OTHER SOIL ORGANISMS

AM do not exist in a vacuum. They perform three distinct functions in the soil food web. First, AM fungi comprise a large and rich resource of carbon and nitrogen. Grazing is indicated by holes in spores and nematodes curled up inside old spores. Bacteria cover dead and dying spores. Hyperparasites colonize and utilize these large, lipid-rich bodies. However, collembola and mites appear to prefer other fungi and there are hints that bacteria do not colonize the surface of living AM fungi as they would other fungi. The mechanisms of resistance are not known; they may include the presence of fast-sealing compounds, high C/N ratios, antibiotics, or other factors. This is an open research area. There are even hints in the literature that AM fungi can be predators of soil animals. Predation of collembola, nematodes, and other animals could be important in nitrogen-limited ecosystems.

Because AM are a distinct part of the soil food web, they play a crucial role in carbon cycling. With elevated atmospheric carbon dioxide, both hyphal production and turnover increase. This is reflected in the increasing glomalin and carbon within soil aggregates. Carbon loss from soil declines. With fertilization, particularly nitrogen, AM hyphal mass declines. In several data sets, these environmental changes result in reduced carbon through the AM channel and more through the saprophytic and facultative parasitic fungal web, and through the bacterial web. The increasing grazer activity means that carbon turnover remains high or can increase (Fig. 4).

AM fungi form a mycorrhizosphere extending outward from a root and creating a chemically and physically different environment than either the root surface or the bulk soil. In fact, in many ecosystems, there may be no truly bulk soil. In grasslands and many shrublands, the AM mycelial network completely extends between roots, colonizing all soils and changing the chemical environment. A myriad of bacteria and fungi, and their food webs, depend upon the carbon extending into these areas.

Finally, if AM fungi are largely involved in soil aggregation, then the entire structure of the soil physical/chemical composition of the soil is dependent on the formation, species composition, and survival of these interesting and crucial fungi.

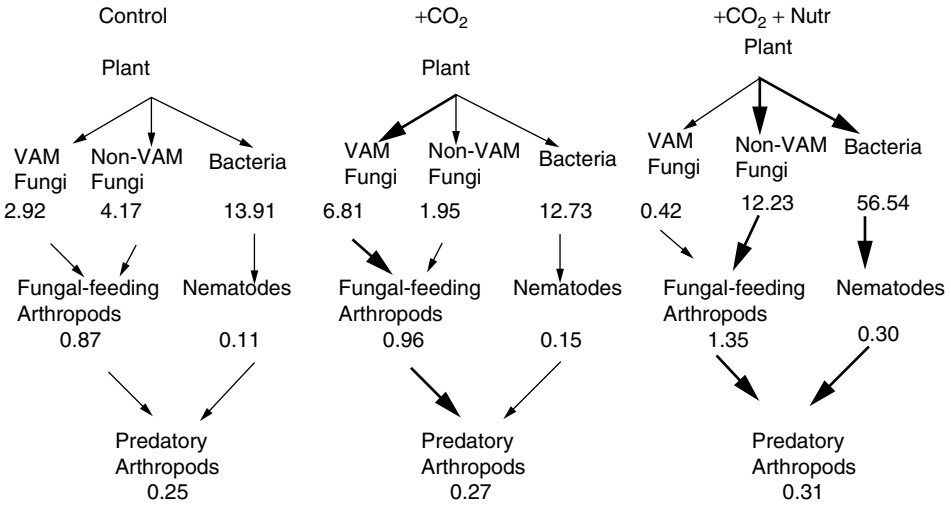

Figure 4. Standing crop of soil organism groups in soil trophic webs. AM are a major channel for carbon under ambient conditions. With added atmospheric carbon dioxide, more carbon is channeled into the AM fungi. With increasing nitrogen, more goes to saprophytic and facultative parasitic fungi, and bacteria. This also increases soil grazers respiring more carbon dioxide back into the atmosphere.

CONCLUSION

AM fungi are crucial components of soil environments. These organisms regulate much, if not the majority, of nutrient and carbon flow pathways. We basically understand how AM increase nutrient uptake from soil to host plant. The mechanisms of carbon transfer from plant to fungus are being studied in detail. However, there are many species of plants and fungi that interact with each other and with the other soil biota in complex and interconnected ways. These include soil aggregation, nutrient weathering, altered competitive outcomes, and altered food web dynamics. Together, the complexity of these interactions deserves considerably more research to understand how AM affect plant production in agriculture and regulate the structure and functioning of wildland ecosystems.

Thomas Horton
Jane E. Smith
PNW Research Station
Corvallis, Oregon

"Mycorrhiza" literally translates as "fungus root" and represents the symbiotic association between plant roots and specialized soil fungi (mycorrhizal fungi). The fungi act as extensions of root systems and benefit host nutrition by their ability to extract nutrients, especially phosphorus and nitrogen, and water from a volume of soil hundreds to thousands of times greater than the roots alone can explore. Other general host benefits include protection of fine roots from pathogens, increased resistance to drought and heavy metal toxicity, and increased root development and longevity. In return, mycorrhizal fungi depend on the host for carbon, primarily in the form of simple sugars, and some vitamins. Mycorrhizal symbioses have strongly coevolved over the millennia such that each partner depends on the other for survival and fitness in natural ecosystems. There are four major classes of mycorrhizae: ectomycorrhiza, ericoid mycorrhiza, arbuscular mycorrhiza, and orchid mycorrhiza. In this Encyclopedia entry, we focus on ectomycorrhizae (EM) and briefly discuss four related subtypes, ectendomycorrhizae, arbutoid, pyroloid, and monotropoid mycorrhizae. We provide general reviews of hosts and fungal associations, structure and function, ecology, ecosystem function, physiology, and practical applications in forestry. Readers are referred to books by Allen (1,2), Harley and Smith (3), Safir (4), Smith and Read (5), and Varma and Hock (6) for greater detail on mycorrhizae. A two-volume, 42-chapter treatise edited by Norris and coworkers (7) and a book by Brundrett and coworkers (8) provide detailed methodological approaches in mycorrhiza research and applications in agriculture and forestry.

HOST–FUNGUS ASSOCIATIONS

Many tree species in temperate forests form EM, including all members of the Betulaceae, Fagaceae, Myrtaceae, Pinaceae, Salicaceae, and Tiliaceae. In tropical regions, EM hosts occur in the Caesalpiniaceae and Dipterocarpaceae. Additional genera in other families also form EM, for example, *Arbutus, Arctostaphylos, Albcausuarina*, and *Cercocarpus*. Some EM hosts form both arbuscular mycorrhizae and EM, for example, *Alnus, Eucalyptus, Populus, Salix*, and some Pinaceae species (9), but in these situations, EM is typically the dominant type, particularly on mature trees.

Ectomycorrhizal fungi number in the thousands and are primarily Ascomycotina and Basidiomycotina. Well-known genera include *Amanita, Astraeus, Boletus, Cantharellus, Cortinarius, Elaphomyces, Gomphidius, Hebeloma, Hymenogaster, Hysterangium, Inocybe, Laccaria, Lactarius, Leccinum, Paxillus, Piloderma, Pisolithus, Rhizopogon, Russula, Scleroderma, Suillus, Thelephora, Tricholoma*, and *Tuber*. Cairney and Chambers (10) provided an excellent review of the taxonomy, ecology, and physiology of several of these genera. A few species of *Endogone* in the Zygomycotina also form EM. Molina and coworkers (9) listed the major genera, number of species, and host ranges of EM fungi.

STRUCTURE AND FUNCTION

EM form primarily on the short, fine roots rather than on long, structural, lateral roots. EM are characterized by an often colorful sheath or mantle of fungus mycelium that envelops the root. The mantle varies in structure and can range from a thin, loosely interwoven structure to an organized pseudoparenchymatous or parenchymatous tissue, typically 10- to 100-μm thick. The fungus penetrates the root epidermis and cortex, growing intercellularly to form the Hartig network, a differentiated tissue composed of interwoven and anastomosed hyphae (Fig. 1). Nutrient and metabolite exchange occurs within this extensive zone of root cell–fungus mycelial contact. In angiosperms, the Hartig net surrounds only the epidermal cells. Ectomycorrhizal

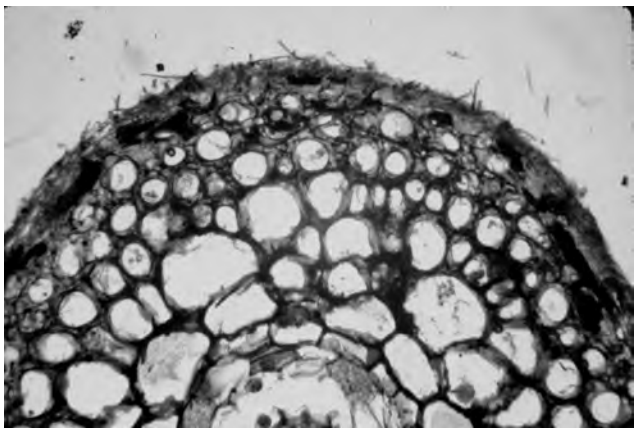

Figure 1. Crosssection of a Douglas-fir ectomycorrhiza showing the fungal colonization on the root surface (mantle) and growth between cortical cells (Hartig net). See color insert.

fungi do not penetrate past the endodermis into vascular tissue.

EM vary tremendously in size and branching patterns, characteristics determined by the host–fungus combination (11). EM begin as simple, unbranched structures, but most elongate and branch in various ways (Fig. 2). For example, *Pinus* EM branch dichotomously, sometimes repeatedly to form compound structures. Other host genera develop pinnately branched structures, and still others develop irregular, variously branched patterns. Ectomycorrhizal fungi produce several classes of plant growth promoting hormones (auxins, cytokinins, and gibberellins) that enhance root elongation and longevity. Such enhancement effectively increases root surface area for nutrient and water absorption.

Ectomycorrhizal fungi ramify extensively through the surrounding soil, forming fungal colonies of various size and structure (12). Many EM fungi develop complex mycelial strands or rhizomorphs that function in nutrient and water movement and storage. Mycelial growth is most prolific in the humus layer and in the humus–mineral soil interface; however, some fungus species specialize in specific substrate colonization, such as buried wood, deep humus, or bare, mineral soil. Sexual reproduction occurs within sporocarps produced by soil mycelium, and many EM fungi produce prolific fruitings of mushrooms or truffles (hypogeous sporocarps).

Figure 2. Douglas-fir EM showing pinnate branching pattern. See color insert.

Most EM hosts and fungi are obligate symbionts, depending on one another for survival and reproduction in natural ecosystems. For example, attempts to establish exotic plantations of EM trees often fail unless compatible EM fungi are present. Many EM hosts depend on the fungus for phosphorus uptake. Other host benefits from EM include nitrogen and potassium uptake, water uptake and enhanced drought tolerance, promotion of rooting and root longevity, detoxification of soil and heavy metal tolerance, and protection against root pathogens.

Many, but not all, EM fungi can be isolated and grown in pure culture. Thus, a wealth of information is available regarding their nutritional requirements and response to environmental conditions. Ectomycorrhizal fungi are most commonly isolated from sporocarp tissue. In this procedure, young sporocarps are brushed free of dirt, carefully broken to expose interior tissue, and then a small amount of tissue is aseptically removed and placed on artificial media in test tubes or culture plates. Various media are used, the most common being the modified Melin-Norkrans medium (13), a fully synthetic medium with glucose as the carbon source. Cultures also can be obtained from surface sterilized EM root tips, but the success rate is usually low. *Cenococcum geophilum*, one of the more common of EM fungi, is not known to produce sporocarps but can be easily isolated from its large, black sclerotia. Sclerotia are retrieved from the soil by wet-sieving and decanting, then are surface sterilized, and placed aseptically on nutrient agar in tubes or plates (14).

Ectomycorrhizal fungi grow slowly in culture compared to saprophytic or pathogenic fungi, and may take 4 or more weeks to cover a 10-cm diameter culture plate. Some EM fungi grow even more slowly and are difficult to maintain in culture. Still others have never been isolated, thus indicating strong differences in the obligate need for host association. Most EM fungi, however, have limited ability to degrade complex organic compounds and thus depend upon the host for their energy (carbon) (15), as well as for other metabolites, such as thiamin.

Ectendomycorrhizae

Ectendomycorrhizae are a subtype of EM and share in common the colonization of short fine roots, mantle, and Hartig net development, and an association with typically EM hosts. The mantle is typically sparse and thin, however, and the Hartig net may only irregularly penetrate between cortical cells. The primary difference from ectomycorrhizal fungi is their intracellular hyphal penetration into the cortical cells, at times completely filling the lumen with hyphal coils, although the plasma membrane is not breached.

Only a few fungal species are known to form ectendomycorrhizae and most are ascomycetes. Known genera include *Wilcoxina* (commonly called *E-strain fungi*), *Phialophora, Chloridium*, and *Sphaerosporella* (9). Known host genera include *Pinus, Larix, Picea, Abies, Pseudotsuga, Tsuga, Betula, Shorea*, and *Lithocarpus*.

Though less is known about the ecology of this group of mycorrhizal symbionts than EM fungi, they have been demonstrated to provide similar nutritional benefits as EM. Ectendomycorrhizae are most commonly reported on seedlings, particularly in bareroot nurseries in which they may be the dominant mycorrhizal type. They also inhabit forest soils but appear to be a minor component compared to EM.

Arbutoid and Pyroloid Mycorrhizae

Arbutoid mycorrhizae are those typical of two genera of Ericaceae, *Arbutus* and *Arctostaphylos*. These mycorrhizae resemble ectendomycorrhizae in that hyphae colonize both intercellularly and intracellularly. The Hartig net and intracellular coils, however, are restricted to the root epidermis as opposed to ectendomycorrhizae, in which hyphal colonization may extend to the endodermis. Most fungi that form arbutoid mycorrhizae on *Arbutus* and *Arctostaphylos* also form EM on other hosts (16–18).

Mycorrhizae on *Pyrola* (pyroloid) resemble arbutoid mycorrhizae anatomically, having an epidermal Hartig net, a disorganized fungal sheath, and intracellular penetration restricted to the epidermis (3,19). Both ascomycetes and basidiomycetes appear to associate with *Pyrola* (19).

Monotropoid Mycorrhizae

Monotropoid mycorrhizae form on achlorophyllous members of the Ericaceae (the Monotropoideae). They resemble arbutoid mycorrhiza, with a Hartig net restricted to the epidermis and a thick fungal sheath. In addition, fungal pegs develop in the epidermal cell walls, at least in *Monotropa, Sarcodes*, and *Pterospora* (19–21). As in the case of arbutoid and ectendomycorrhizae, the monotropoid type seems to be a host-mediated variant of EM.

Achlorophyllous monotropes are often mistakenly called *saprotrophs*; however, they are strongly mycoheterotrophic (22). They develop mycorrhizae with EM fungi that are connected to and functioning with neighboring forest trees. Transfer of labeled carbon has been demonstrated from tree photosynthate to the monotrope via the interconnecting EM fungus (23).

ECOLOGY OF ECTOMYCORRHIZAE

Generalizing about the ecology of EM is difficult because of the physiological diversity of fungi, the wide range of host–fungus compatibilities and specificities, and the various ecological conditions EM experience. Ectomycorrhizal fungi show strong differences between and within species in their tolerance of environmental extremes and production of degrading enzymes. Some fungi are also common to specialized soil niches or successional stages of community development, whereas others are less specific, occurring in a wide variety of habitats and developmental stages. Many EM fungi are broad-host-ranging and can form EM with taxonomically diverse hosts. Others associate with only angiosperms or gymnosperms. Still others will form EM only with a specific host genus as seen in repeated fruiting of sporocarps with particular hosts (9). EM hosts typically associate with many EM fungus species at any one time, and the composition of fungus associates changes as the plant matures and plant and fungal community develops. We poorly understand the interactions of EM fungi and hosts in natural soils and the functional ecologies of these diverse fungi in dynamic forest ecosystems. Given the coevolved nature of these symbionts, however, the dynamics of forest and fungal communities are likely strongly interrelated through the mycorrhizal links. Considerable research is needed to document the nature of these mycorrhizal links between plants and how they function in determining forest ecosystem resiliency after disturbance and maintaining long-term ecosystem productivity. In the next section, we summarize various aspects of ecology and ecosystem function.

Autecological Considerations

Ectomycorrhizal fungi respond to various biotic and abiotic factors, including vegetation, climate, topography, disturbance, and soil parent material. Responses are measured by observing changes in mycelial growth and EM development in the soil, and in the production of sporocarps, such as mushrooms and truffles (1,2,5). Disturbances such as fire affect fungal species through alterations to the plant community, as well as to the soil environment. The vegetative state of EM fungi exists as a mycelium exploring the soil substrate and via extensive colonization of root tips. As such, conditions in the soil environment likely impact fungi more than conditions above the ground. Climatic factors, such as temperature and precipitation, however, influence the soil environment and therefore influence fungal growth and reproduction. Generally, it is believed that EM fungi respond best to moderate temperatures and relatively high, but not saturated, soil moisture levels. Nevertheless, EM fungi also occur and function in arid forest ecosystems worldwide. Topographic factors, such as elevation, slope, and aspect are thought to influence the occurrence of fungi by moderating climatic factors. High levels of soil organic matter, including humus and coarse woody debris, positively influence the abundance of EM roots for many fungal species (24).

Community Dynamics and Succession

Changes in plant species composition during primary or secondary succession affect EM species composition owing, in part, to the host specificity phenomenon mentioned previously (9). Ectomycorrhizal plants and fungi influence each other in community development, and the dynamic nature of this influence involves feedback between the aboveground and belowground components of the system (25). Indeed, interspecies and intraspecies plant connections via fungal links have been demonstrated in the laboratory and in the field, and these links support nutrient transfer between plant individuals (5,26). Evidence of fungal succession often is observed in the occurrence of sporocarps as trees age under old field successional conditions (27), leading to interesting

hypotheses about where fungal species fall on the ruderal—competitor continuum of Grime (28). As belowground data are gathered, our understanding of fungal community dynamics and succession is necessarily being refined.

Biodiversity of Ectomycorrhizal Fungi

Biological diversity commonly means the number of species (species richness) in a particular location or habitat. Methods of measuring EM fungal species richness differ and provide a different understanding of fungal community dynamics. The biodiversity of fungi affects and is affected by the plant community structure (29,30). Bruns (31) hypothesized that EM fungal diversity is regulated predominantly by resource partitioning, response to disturbance, and interaction with other organisms.

Sporocarp and EM root tip sampling methods each provide knowledge of the vast diversity of EM fungal species. Sporocarp studies typically show a high diversity in a small area and are critical to our understanding of food web dynamics. In recent studies in old growth stands of Douglas-fir (*Pseudotsuga menziesii*) and western hemlock (*Tsuga heterophylla*) in the Pacific Northwestern United States, fungal species richness of epigeous EM sporocarps ranged from 19 to 70 (32, Smith, Molina, and Castellano, unpublished data). Sporocarps in these studies were collected over multiple years within stands 30 to 50 ha in size. Fungal species richness of truffle-like sporocarps ranged from 8 to 14 species per stand (Smith, Molina, and Castellano, unpublished data). Sporocarp studies, however, fail to estimate total EM fungal species richness. Direct sampling of EM fungus root symbionts, with molecular methods, is necessary to detect the many species of fungi that go undetected in sporocarp sampling because some fruit in hidden places, such as on the underside of wood, fruit infrequently, or may not fruit at all. Although insight into the biological diversity and community dynamics of EM fungi has been gained from both sporocarp and EM root tip sampling methods, we are a long way from understanding the functional roles of the many species.

Like many other biological systems, EM fungus communities are dominated by one or a few EM fungus species, with most species occurring with low frequency and abundance in the community. Interestingly, dominance of fungi, as revealed by sporocarp production, is not congruent with the dominant species indicated by EM root tips (5). Thus, species that are most important to the production of sporocarps for small mammals may be of little importance to the tree for nutrient uptake. Although we have progressed from our "black-box" approach in terms of how EM fungi are distributed and function in ecosystems, it remains risky to consider different species as redundant members of the same guild. It is increasingly clear that species matter, and that fungal diversity is a result of each species playing important roles in ecosystem function and resiliency.

ECOSYSTEM FUNCTIONS

Nutrient Cycling

It is well documented that EM fungi mobilize nutrients from the soil and transfer them to host plants (5). Initially, phosphorus was identified as the main nutrient that fungi acquired for plants, but increasing evidence reveals that fungi also mobilize nitrogen, calcium, potassium, and other nutrients. Fungi are also directly involved in carbon cycling, having access to approximately 15% of carbon assimilated by a tree (5). Ectomycorrhizal fungi are thus directly involved in cycling and retention of most nutrients in ecosystems. The physiology of these pathways is covered later in this article.

Food Webs

Ectomycorrhizal fungi are critical food members of soil webs in forest ecosystems and provide food for various microbes and animals. Fungal mycelium and exuded carbohydrates support diverse soil organisms, such as fungal-feeding arthropods, bacteria, and microbial-feeding nematodes (30). About 80% of soil microarthropods are fungivores; these small animals are the primary shredders and mobilizers of organic nutrients in forest soils (33). Sporocarps produced by EM fungi are important food for various wildlife, including small and large mammals, and mollusks (34,35). Some rodents, such as the California red-backed vole (*Clethrionomys californicus*) and northern flying squirrel (*Glaucomys sabrinus*), rely on EM fungal sporocarps, especially the truffle fungi, for as much as 90% of their food supply (36,37). Because small mammals are primary prey for many birds (e.g., owls, hawks, etc.) and larger mammals, the availability and consumption of truffle EM fungal sporocarps is a key link in forest ecosystem food webs.

Soil Structure

Ectomycorrhizal fungi contribute to soil structure through various mechanisms (5). Some carbohydrates from plants leak into the mycorrhizosphere, which increases populations of soil microorganisms. Soil particles adhere to mucilage on the surface of hyphae, thereby increasing the soil structure. Fungal hyphae physically bind soil particles, as do the roots of the plants. Siderophores and other chelators produced by fungi also cause soil particles to aggregate, which contributes to soil porosity and facilitates air and water movement. Because the roots of most plants and soil microbes are strongly aerobic, this is a vital function that EM fungi perform.

Ecosystem Resiliency

Ectomycorrhizal fungi perform critical processes at the ecosystem level that influence plant productivity and soil fertility (5), and therefore are essential to ecosystem resiliency (25,38). It is now clear from plant communities involving Douglas-fir in the Pacific Northwest that plant succession is directly influenced by EM fungi (26,39). This interaction between plant species via their EM fungi was

predicted by studies of Douglas-fir and members of the Ericaceae that form arbutoid EM (*Arctostaphylos* and *Arbutus*) that showed much overlap in their EM fungus associates (16). These plant communities undergoing secondary succession were found to be still developing decades after a disturbance event. Studies of fungal communities continue to provide data for how EM fungi influence the development and recovery of the plant communities. A critical phase in ecosystem resiliency immediately follows a disturbance event, such as that caused by a stand replacing fire. Here, recovery was driven less by interplant links via EM fungus hyphae discussed earlier than by the survival of resistant fungal inoculum, likely in the form of spores or sclerotia, which supported the growth of regenerating seedlings (40,41). Regeneration of Douglas-fir stands has been shown to fail after clear-cut harvest and if establishment of early successional shrub species that harbor suitable EM fungus inoculum is prevented. The soil microbial community in clear-cut sites is thought to have crossed a critical threshold such that the site can no longer support an EM community (25). Douglas-fir seedlings planted into such a site will fail without EM on the roots; however, the survival of the seedlings is increased if soil taken from beneath EM hosts is added to the planting holes. It is thought that fungal propagules in the introduced soil provide the EM fungus inoculum needed by the seedlings.

Additional evidence for the contribution of EM fungal propagules to ecosystem recovery comes from a plant community following a stand replacing fire. Here, *Pinus* seedlings established in the first year after the fire were largely colonized by fungi in the genera *Rhizopogon* and *Tuber* (41). A previous study by Taylor and Bruns (40) had shown that *Pinus* seedlings grown in soils collected before the fire were colonized by a different group of fungi than those observed after the fire, and included species of *Russula, Tomentella*, and *Amanita*. Species of *Rhizopogon* and *Tuber*, which were present in the prefire stand, but in low relative abundance, likely produced a resistant spore bank that responded to disturbance in much the same way seed banks do for plants.

PHYSIOLOGY

Early physiological studies have been extensively reviewed by Marks and Kozlowski (42), with chapters on mineral nutrition (43), carbohydrate physiology (44), and hormonal relations (45). This fundamental reference has been followed by other books with sections updating advances in EM physiology (2,3,5,6,10). Specific reviews also have been published on carbon and nitrogen metabolism (46–48) and physiological ecology (38,49–51). Cairney and Chambers (10) have recently summarized major taxonomic, physiological, and ecological characteristics of 15 major EM fungal taxa.

Because EM fungi represent such a diverse taxonomic and genetic base, there are many apparent contradictions reported in their physiology, which reflects the extreme functional diversity of the group.

Nutrition

Carbon. As heterotrophic organisms, EM fungi derive energy and carbon for growth from organic sources. In vitro growth studies of many EM fungi have demonstrated a wide diversity in the ability to use various simple sugars and polysaccharides (10,44,52,53). The most commonly used sugars are glucose, fructose, and mannose, and the most commonly reported polysaccharides are starch and pectin, although many EM fungi also can use cellulose. Growth responses of ectomycorrhizal fungi can be complicated when small "starter" amounts of glucose are available and allow substrate adaptation, significantly expanding the range and amount of carbohydrates used (44,54–56). Although sucrose is the main carbohydrate transferred from the host plant, EM fungi may not be able to use sucrose directly (44,52), but rely on host enzymes (57) for hydrolysis to glucose and fructose.

Evidence for use of phenolic compounds as a carbon source for respiration and growth has been limited. Although EM fungi can significantly modify various phenols (58–60), this reaction is thought to be a detoxification response. Production of $^{14}CO_2$ from ^{14}C-lignin (61,62) and xenobiotics (63,64) indicates that certain EM fungi can actually metabolize phenolic compounds. There is also indirect evidence that, based on decoloration of polymeric dyes, certain EM fungi can break down lignin (65,66); these results, however, have recently been questioned as possible artifacts (67).

Hydrolysis of fatty acid esters by various EM fungi (68) suggests that energy-rich fatty acids could serve as an additional source of carbon for EM hyphae and rhizomorphs distal to the host tree.

Nitrogen. Nitrogen is essential for the synthesis of proteins, including enzymes, nucleotides, and many minor cellular components. Of the inorganic forms, ammonium salts have been most frequently used, although nitrate is also used, but with slower uptake and growth rates (69,70). Organic nitrogen sources include amino acids (43,53,71,72), peptides and proteins (43,53,70,72,73), glucosamine (74), nucleic acids (74), and urea (53,72). Certain EM fungi use the nitrogen in proteins complexed with tannins (65,75), a trait that may become increasingly important when polyphenol complexation is thought to limit nitrogen availability (38). Both chitin (52,76) and humic materials (74) appear to be poor nitrogen sources for pure cultures.

Phosphorus. Phosphorus, like nitrogen, is also a major nutrient required for cellular components, mainly nucleic acids, membrane phospholipids, and energy-transferring nucleotide phosphates. Although inorganic phosphate is the most commonly used form in culture media, organic phosphorus forms, such as soluble and insoluble phytates (43,77) and nucleic acids (43,65,78) can also be used. Most of the work on organic phosphorus has involved measuring phosphatase enzymes (see section on Products, discussed later).

Other Compounds. Unlike nitrogen and phosphorus, sulfur metabolism of EM fungi remains largely unexplored, although certain EM fungi have been found capable of oxidizing elemental sulfur (79).

Growth Limits

In addition to the chemical form of various nutrients, growth rates and yields of EM fungi also can be affected by nutrient concentrations (80,81), pH (82), temperature (83–85), and moisture (86,87). Examples of environmentally significant compounds that can affect the growth of EM fungi include natural polyphenols (88) and applied fungicides (89) and herbicides (90). The effects of "heavy" or toxic metals on EM fungal growth, EM formation, and plant uptake have recently been summarized (91).

Products

Although the in vitro traits described earlier provide insight into the nutritional requirements and physiological potentials of EM fungi, the extent to which EM fungi interact with their soil environment is of critical importance to the symbiosis. Ectomycorrhizal fungi affect their nutritional environment by releasing extracellular enzymes to utilize detrital nutrient pools and mineral weathering agents to obtain mineral nutrients. Ectomycorrhizal fungi also can affect their biotic environment by production of substances that either inhibit or stimulate the activities of competing or associative microorganisms.

Interactions with Organic and Mineral Resources

Production of polysaccharide- and glycoside-hydrolyzing enzymes and polyphenoloxidases with the potential to break down detrital plant cell wall barriers has been measured in pure cultures of EM fungi (10,51), EM-containing microcosms (92,93), and field samples in which EM are prevalent (65). Production of proteolytic enzymes to obtain nitrogen from peptide and protein sources also has been reported for cultures (94,95), microcosms (92,93), and field samples (65). Phosphatase enzymes, which release inorganic phosphorus from organic sources, are the most extensively studied group of EM enzymes. Well over 40 publications have reported enzyme production in culture (95–99), tree syntheses (100–102), microcosm studies (92), and field samples (65,77,103–105).

Ectomycorrhizal fungi are involved in weathering minerals and solubilizing mineral phosphates (106–108) by production of organic acids (109) and iron-chelating siderophores (110).

Interactions with Other Organisms

Ectomycorrhizal fungi secrete various plant-growth regulating compounds to control host plant root development and morphology, including auxins, cytokinins, gibberelins, and indole acetic acid (45,111–113). Vitamin production by various EM fungi may stimulate associated decomposer microorganisms in the mycorrhizosphere (45,114). Alternatively, EM fungal cultures also have been shown to inhibit bacteria, other fungi, and grazing fungivores (115–118).

PRACTICAL APPLICATIONS IN FORESTRY

Nursery Inoculation

In the late 19th century, the failure to establish introduced pines in the Southern Hemisphere stimulated research into inoculation of seedlings with EM fungi (119). The premise was that forest seedlings destined for field sites lacking apparent adequate EM fungi would benefit from introduction of appropriate EM fungal partners in the nursery. Early inoculations predominately introduced forest soil containing EM fungus propagules (120,121). Nursery inoculations with pure cultures of EM fungi did not begin until the 1950s, specifically to address the difficulties in reforestation of steppe lands and mine spoils. Subsequently, large-scale nursery inoculations in the developed world began to exclusively use single-species fungal inoculum from pure cultures or spore-bearing tissues (121). More than 70 different EM fungal species have been tried as inoculum, either as pure culture or spore inoculum (122,123). Earlier, it became apparent that specific fungal species are considerably more effective than other fungal species for particular plant species (124). Individual EM fungal species and even ecotypes (strains) can differ strongly in physiological characteristics and response to environmental conditions that affect inoculum performance. Matching EM fungal ecotypes, host species, and abiotic conditions is important to a successful inoculation program.

Currently, several commercial companies in North America produce pure mycelial cultures or spore inocula (125). Each inoculum type has benefits (both economically and performance-wise) and restrictions as to its use. For some fungal species, only spore inoculation works successfully; for other species, only inoculation with pure cultures of vegetative mycelium works (125). Benefits of EM inoculation programs in commercial forest nurseries include reduction in percentage of culled seedlings, increases in stem caliper or leader growth, protection against seedling root pathogens, rapid EM colonization to reduce stunting, and improved performance of seedlings upon field planting (122,123,125). Additional work is needed in multispecies inoculation and expanding the cadre of EM species that work effectively in nursery inoculation programs, particularly on a regional basis.

Field Performance of Inoculated Seedlings

Enhancing field performance of planted seedlings has been the overriding catalyst for EM inoculation programs. Over the last 30 years, more than a 100 papers have been published on the field performance of EM-inoculated seedlings (123). Experiments include nearly 600 unique combinations among 66 host plants, 70 EM fungal species, and 5 different types of inoculum. Of the many field trials, only one-half showed improved seedling performance after inoculation. Successful trials occurred on difficult sites to reforest such as mine spoils and hot, dry sites. Worldwide, *Pisolithus tinctorius* is the most extensively studied EM fungus, and *Pinus* spp. have received the most attention for host plants (123). In western North America, *Rhizopogon* species have received considerable

attention. Likewise, in Europe, *Rhizopogon* species and other species, such as *Laccaria bicolor*, have received significant attention. Additional work is needed to discover under what circumstances any particular fungus helps seedling field performance. Finding one fungus that will benefit numerous hosts in diverse ecological settings is not a reasonable expectation. Even where the specific attributes of a fungus seem desirable, that is, drought resistance, an ecotype or ecostrain of the target fungus may perform better under local conditions than a superstrain.

CONCLUSION

As noted throughout this encyclopedia entry, mycorrhizal fungi contribute to healthy ecosystems by forming mutualistic, symbiotic associations with plants, contributing to nutrient cycling, providing food for animals, and creating habitat diversity for many forest organisms. While the basic structure and functions of EM fungi are delineated, species-level functions of EM fungi, habitat requirements, and interactions with particular plant species represent large knowledge gaps needing research attention. Knowledge of the ecological requirements of EM fungi, particularly their relation to forest community succession and disturbance events, is essential for making science-based decisions about issues in fungal conservation worldwide.

NEUSTON MICROBIOLOGY: LIFE AT THE AIR–WATER INTERFACE

JAMES S. MAKI
Marquette University
Milwaukee, Wisconsin

One of the first things that can be noted when examining the air–water interface as a habitat for microorganisms is its size, water covers 71% of the Earth's surface. Oceans, lakes, rivers, ponds, and even puddles make a contribution to the habitat, although briefly in some of the latter cases. However, widespread as the habitat may appear, it is limited in its thickness to just a few micrometers for microorganisms. An interface has been defined in physicochemical terms as the boundary between two phases in a heterogeneous system (1). As such, the physicochemical properties of the air–water interface are different from those found in either of the phases that meet there: the atmosphere and the water column. It is these properties that make this a unique habitat for neuston microorganisms.

Although it is unique, it has been described as an exposed habitat (2), subject to a variety of forms of intense environmental stress, including solar radiation and toxic substances (3–5), and has been considered an extreme environment (6). Ecologically, habitats have been considered extreme when they are at the ends of environmental gradients such as temperature, pH, salinity, nutrients, or pressure (7), or when they had a low diversity of organisms (8). However, with the advent of noncultural, molecular techniques, these extreme environments have been demonstrated to be more diverse than originally believed (9). The bottom line is that it is hard to come up with a good definition of extreme environment (10).

Shilo (11) presented an alternative to the aforementioned considerations suggesting that habitats that are subjected to regular and sporadic fluctuations in environmental conditions, many of which could be extreme in themselves, merit consideration as extreme environments. Furthermore, he suggested that organisms surviving in these habitats would require great plasticity to accommodate the changes that occur. This idea, combined with the presence of a variety of forms of environmental stress, led to the consideration of the air–water interface as an extreme environment for microorganisms (6). Because of the potentially hostile nature of this habitat, the characteristics that would aid microorganisms, particularly bacteria, to be successful there will be considered.

THE NEUSTON

The term *neuston* (from the Greek $\nu\varepsilon\omega$, to swim) was introduced by Naumann (12) to indicate that the microorganisms associated with the air–water interface. This was in contrast to the word *pleuston* (from the Greek $\pi\lambda\varepsilon\omega$, sail, float, swim in a semisubmerged condition) that was introduced by Schröter and Kirchner (13) to encompass the whole assemblage of floating plants that are both submerged and interfacial. Modifications to the definition of neuston were made by Geitler (14) who separated them into the epineuston, to distinguish organisms on the upper side of the air–water interface, and the hyponeuston, to distinguish organisms that are on the underside. More recently, the term *neuston* has expanded to include a wide range of organisms associated with the air–water interface, particularly in marine environments (15,16) including organisms large enough to be collected by nets. Size ranges of the expanded concept include the following: piconeuston (<2 μm) = bacterioneuston, nano- and microneuston (2 to 200 μm) = phytoneuston and protozoan zooneuston, mesozooneuston (0.2 to 20 mm) = copepods, isopods, amphipods, fish larval stages; macroneuston (>2 cm) = coelenterates and floating organisms, also referred to as the *pleuston* (16). For the purposes and limitations of this discussion, the terms *bacterioneuston*, *phytoneuston*, and *zooneuston* (for protozoa) will be used. Larger organisms will not be directly addressed.

SAMPLING

The information gathered on the microbiology and chemistry of the air–water interface has been largely dependent on the type of sampler employed for collection. In general, the aim of sampling this habitat is to collect the microorganisms and molecules associated with the interface and none or the least possible quantity of the underlying bulk-phase water (17). This has led to a fairly large number of samplers or sampling techniques being designed for collection (Table 1). The thickness of the water sample that is collected at the air–water interface depends on the collecting technique employed and the type of material that the sampler is constructed from. Many of the sampling devices function through adsorption, and samplers composed of different materials will adsorb different air–water interface components (18). Thus, samplers can have both qualitative and quantitative

Table 1. Sampling Methods for the Air-Water Interface

Sampling Method	Thickness of Sample	Reference
Paper filter	8–100 μm	Amies (22)
Calcium alginate gauze		Amies (22)
Screen sampler	300–400 μm	Garrett (23)
Rotating drum	34–100 μm	Harvey (24)
Bubble microtome	0.5–10 μm	MacIntyre (25)
Germanium prisms	30 nm	Baier (26)
Glass plate	20–100 μm	Harvey & Burzell (27)
Teflon plate	50–100 μm	Larsson and coworkers (28)
Teflon disk		Miget and coworkers (29)
Membrane filters	8–100 μm	Crow and coworkers (30)
Electron microscope grids		Young (31)
Freezing probe	1,000 μm	Hamilton and Clifton (32)
Polyvinylchloride film	1 μm	Hamilton and Clifton (32)

differences in their ability to collect material at the air–water interface, and direct comparisons between samplers are at best difficult and at worst should not be contemplated (19). To compare the sample collected at the air–water interface to the corresponding bulk-phase sample, the term enrichment has been used. Determining enrichment is one way that the samples collected at the air–water interface have been compared to the bulk phase. Enrichment (E) is calculated by the ratio between a component (X) at the air–water interface and in the bulk phase: $E = X_{\text{interface}}/X_{\text{bulk}}$. When E is greater than one, the interface has a positive enrichment, and when E is equal to one there is no accumulation. However, E less than one indicates that the interface is depleted in the component compared with the bulk phase. E will depend on the type of sampler used and the thickness of the layer that it collects. Further discussions of sampling the air–water interface, which cover this subject wholly or in part, are presented by others (6,16,18,20,21).

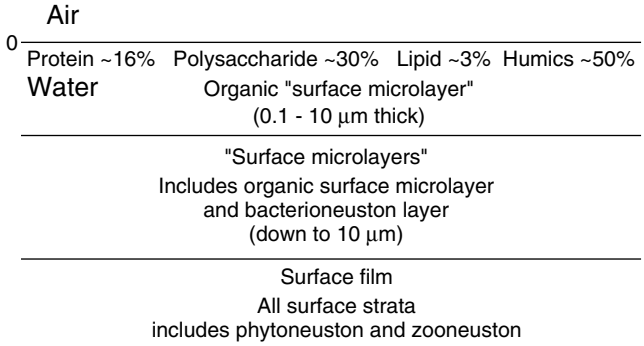

Figure 1. Model of the structure of the water surface strata at the air–water interface showing an "organic surface microlayer" of a gel-like matrix composed of proteins, polysaccharides, lipids, and humic substances. A "surface microlayer" consisting of the organic surface microlayer and the bacterioneuston layer can be up to 10 μm thick. Surface film refers to these layers and all additional surface strata. Adapted from J. McN. Sieburth, in P. S. Liss and W. G. N. Slinn, eds., *Air-Sea Exchange of Gases and Particles*, D. Reidel Publishing, Hingham, Mass., 1983, pp. 121–172.

THE NATURE OF THE HABITAT: MODEL OF THE STRUCTURE

As a habitat, the structure of the air–water interface has been modeled on the basis of the chemical components and the biological organisms that have been collected and characterized from it. As pointed out earlier, sampling and samplers have a bias to what and how much interface material is collected. Thus, the actual thickness of the various layers is only estimated, always doubtfully and should be treated with caution. One model of the air–water interface structure was proposed by Sieburth (33; Fig.1). Several terms are important in discussing the structure: the organic layer has been termed the *organic surface microlayer* (3,5) or alternatively, the *surface nanolayer* (16) and may be on the order of micrometers thick in its hydrated form; an additional thickness, down to approximately 10 μm, is the bacterioneuston layer (33); layers of additional thickness, including the phytoneuston and protozoan zooneuston, have been termed the *surface film* (3,5) or alternatively, the *surface microlayer* (16). The devices and techniques used to sample the air–water interface (Table 1) collect a much thicker layer than the organic surface microlayer or the bacterioneuston layer. Thus, air–water interface samples generally are diluted by underlying bulk-phase water.

The organic surface microlayer was initially considered to be largely composed of lipid material (3). However, subsequent investigations revealed that lipids were not present in concentrations high enough to form a distinct layer (33–35). The model proposed by Sieburth (33; Fig. 1) indicates that the organic surface microlayer consists of a matrix of lipids, proteins, polysaccharides, and humic substances. The source of this material at the air–water interface in open areas of large bodies of water is considered to be largely autochthonous, mainly from planktonic sources. In contrast, in coastal areas and smaller bodies of water, there is a considerable terrestrial, or allochthonous, contribution. The smaller the body of water, the greater may be the terrestrial input. The concentrations of these components at the air–water interface vary both spatially and temporally from one water body to the other and also within each water body (35–37). The organic surface film material

may be compressed by wind action or internal waves into surface slicks that are visible (areas that show damping of capillary waves) to an observer (38–40). These occur frequently in coastal waters and lakes. However, whether a visible slick is present or not, there is an organic surface microlayer and a surface film on all waters (33). A wind velocity less than 5 to 7 m ms^{-1} but greater than 2 to 3 m ms^{-1} can create surface slicks (41,42). As the wind speed increases, the slicks will continue to be compressed to a point at which they will collapse and form fibers and particulate material that can be carried down into the bulk phase (43,44). Along with wind, Langmuir circulation will also cause a concentration of surface film material into bands (45). Wind and wave action will be more important to surface slicks and chemistry in larger bodies of water (46).

The air–water interface and adjacent surface films are dynamic, continually accumulating, and losing material to and from both the atmosphere and the bulk-water phase through a number of mechanisms (Fig. 2). Inputs to the surface film from the atmosphere include precipitation and dry deposition, whereas wind-generated aerosol, bursting bubbles, and evaporation are outputs from the surface film back to the atmosphere. The bulk-water phase contributes to the surface film through upwelling, convection, and bubbles, whereas wave action, dissolution, and sedimentation can transfer surface film material back to the bulk phase. Both Brownian and eddy diffusion can work to input or output material to or from the surface film. The main mechanisms for transformation of material within the surface microlayer are photodegradation and biological action.

Of the neuston microorganisms, the bacteria, once they arrive at the air–water interface, are most unlikely to be able to escape under their own power. This would suggest that they must adapt to the extreme conditions or perish, unless they are transported away by physical means into the bulk phase or the atmosphere (Fig. 2). As a result, most of the following discussion will concentrate on the bacterioneuston. Although some phytoneuston may also be found immobilized, motile forms of phytoneuston and protozoa may play a more transient role in surface films and be able to choose the times when they are members of the neuston.

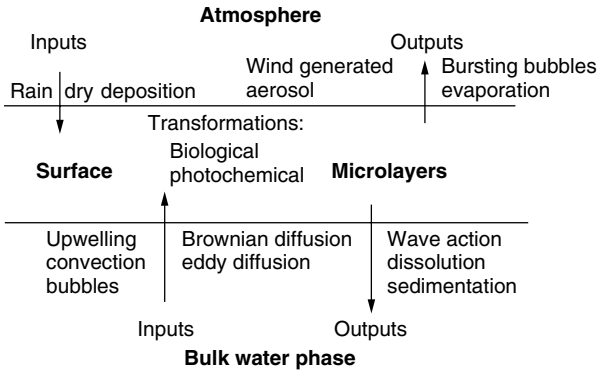

Figure 2. Factors involved in the input and output and transformation of dissolved and particulate material in surface films. Adapted from K. A. Hunter, in P. S. Liss and R. A. Duce, eds., *The Sea Surface and Global Change*, Cambridge University Press, Cambridge, U.K., 1997, pp. 287–319.

BACTERIONEUSTON (PICONEUSTON)

The thickness of the bacterioneuston layer will depend on how the bacteria are distributed at the surface (33). The bacteria at the air–water interface can be epineustonic or hyponeustonic, can be spread out as a single layer of cells (Fig. 3a), exist as microcolonies (Fig. 3b), or be attached to particulate matter (Fig. 3c), the size of which will effectively increase the thickness of the bacterioneuston layer (Fig. 1).

The microenvironment of an aquatic bacterium is dominated by low Reynolds numbers, and thus, viscosity (49,50). Because of the viscosity, and surface tension, the air–water interface for a bacterium could have characteristics similar to a solid substratum (17,33). It follows then that the cell surface characteristics that can play a role in the attachment of bacteria to solid substrata (51) could be of importance at the air–water interface. Cell surface hydrophobicity and charge have been demonstrated in the laboratory to be important to bacterial accumulation at the air–water interface in situations both with (52,53) and without (54) artificial organic surface films. In the presence of organic films, the architecture of the film and its thickness influenced the enrichment of certain bacteria (52,55). Without an organic film, accumulation by hydrophilic bacteria was particularly influenced by cell surface charge (54). In a study comparing bacterioneuston and bacterioplankton isolated from natural samples, Dahlbäck and coworkers (56) demonstrated that the bacteria from the air–water interface had a higher degree of cell surface hydrophobicity than the corresponding planktonic cells.

Firm adhesion of bacteria to solid substrata is generally mediated by extracellular polymers, fibers, and fimbriae (51). Studies using either scanning or transmission electron microscopy of bacterioneuston from natural environments have indicated the presence of these materials or structures associated with the bacteria (48,57–60). Thus, it appears that the bacterioneuston use similar mechanisms to get attached to the air–water interface as they would to get attached to a solid surface. In fact, bacterioneuston readily get attached to solid materials that are passed through the air–water interface (61), although in some situations this may only be reversible attachment (62). Although attachment may be an important factor for the bacteria at the air–water interface, there is the possibility of an exchange between the interface and bulk phase (63), suggesting that motile bacteria may be able to move in and out of the surface microlayer, perhaps to scavenge nutrients. This is supported in freshwater habitats by reports of changes in the numbers of bacterioneuston over a diel period (64,65). However, this exchange may be masked by cells trapped in thick organic films at the air–water interface (66). In larger bodies of water, wind can compress organic material and cells in surface slicks resulting in higher enrichment of bacterioneuston (67). The bacteria in the slicks can be

readily transported by wind (68), possibly over long distances (69).

The major advantage for bacterioneuston at the air–water interface is the availability of nutrients. The model depicted in Figure 1 indicates the presence of proteins, carbohydrates, and lipids. Dissolved organic carbon (DOC) has often found to be enriched in the surface microlayer in both marine (35,70–73) and freshwater samples (47,66,74). In addition, dissolved phosphorus and inorganic nitrogen have also been reported to be enriched in both marine (35,75–78) and freshwater (66,74,79–84) surface films. It has been suggested that by adjusting these nutrients to a microlayer thickness of 0.1 μm, the concentrations approach those found in laboratory culture media (70). Furthermore, starving bacteria resume growth when they come in contact with the nutrients at an air–water interface in the laboratory (85) and greater enrichments of bacteria have been found in surface films in oligotrophic lakes rather than in eutrophic ones (86).

However, the presence of high levels of nutrients at the air–water interface does not always guarantee a high level of bacterial activity in comparison with the plankton. Uptake or turnover of labeled compounds has been reported by investigators in some situations to be similar in both the neuston and the plankton (35,77,87–89) and in others to be lower in the neuston than the plankton (65,90–92). Higher neuston activity has been observed in the presence of surface slicks (93), in more oligotrophic waters (35,87), and, in one case, dependent on the device used to collect the air–water interface sample (84). In addition, use of direct microscopic counts of total bacteria and either formazan dyes to determine respiring bacteria or microautoradiography to determine active bacteria showed enrichment of either respiring or active bacterioneuston at the air–water interface in marine or freshwater habitats (63,66,93). The conclusion appears to be that there is always some activity in the bacterioneuston, indicating that irrespective of the kinds of environmental stress that are present, there are some cells that can cope with them. The mechanisms they may use to cope, although not always directly assessed using bacterioneuston, will be examined in the following sections.

BACTERIONEUSTON AND ENVIRONMENTAL STRESS

Many of the forms of stress that will be discussed can and will have effects on microorganisms throughout the water column. However, with its exposed position at the top of the water column, the air–water interface and the associated neuston microorganisms will often face the brunt of these forms of stress. Thus, the neuston must have mechanisms to contend with the stress to remain viable (Fig. 4). In addition, fluctuations of these various environmental parameters may only affect the air–water interface and not the rest of the water column.

Solar/UV Radiation

Of the different forms of environmental stress that the neuston at the air–water interface are exposed to, the most obvious is intense solar radiation (3,46) with its visible (400 to 750 nm) and ultraviolet (UV, approximately 100 to 400 nm) components. The most biologically important are UV-A (320 to 400 nm) and UV-B (280 to 320 nm),

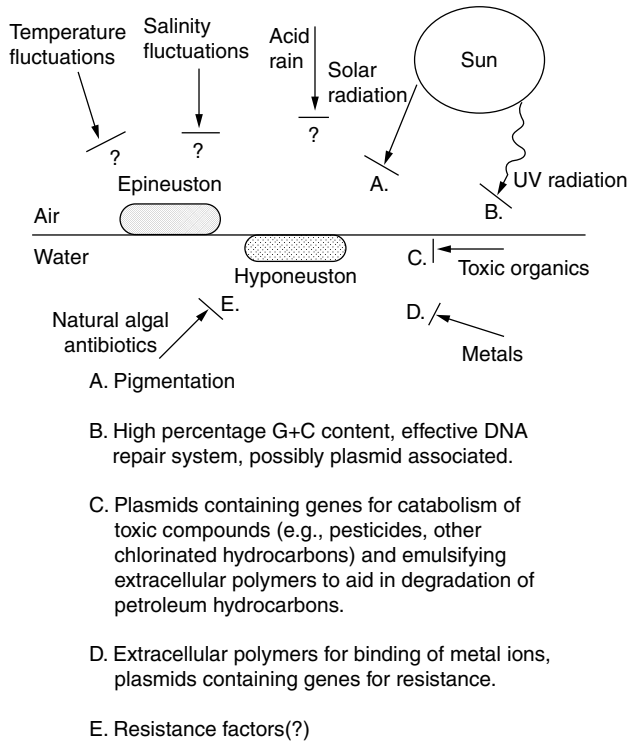

Figure 4. Compilation of the various forms of environmental stress that microorganisms encounter at the air–water interface and possible adaptive mechanisms for the survival of bacterioneuston. Adapted from J. S. Maki, in T. E. Ford, ed., *Aquatic Microbiology*, Blackwell Scientific Publications, Boston, Mass., 1993, pp. 409–439.

although harmful effects can be caused by wavelengths up to 700 nm (94). These wavelengths can act directly on the bacterioneuston or indirectly on them through photodegradation of organics and its resulting products. The overall effect of solar radiation on neuston can be lethal or nonlethal. The direct lethal effects are primarily caused by lesions in the DNA. Nonlethal effects include growth delay, growth inhibition, inhibition of induced enzyme synthesis, reduced active transport, and mutagenesis (95–98).

The effects of solar radiation on the viability and activity of bacterioneuston or very near surface bacteria have been indicated to be deleterious by some investigators (99–101). However, additional investigations have shown little or no difference in activity between intense sunlight and cloudy conditions (63) and little effect of UV and visible light on the total activity (35,87–89,102). These results indicate that in spite of the negative effects of solar radiation, metabolically active bacterioneuston exist. The implication is that they are capable of resisting or are tolerant to these negative effects.

Mechanisms for tolerance and/or resistance in bacterioneuston could include: (*1*) physical screening by UV-absorbing molecules, (*2*) interference or protection of hazardous photoproducts like singlet oxygen by carotenoid pigments, and (*3*) systems for the repair of DNA damage (95). Among UV-absorbing molecules, mycosporine-like amino acids (MAAs), which have absorbance maxima in the range of 310 to 360 nm, have received a lot of attention (103). These types of molecules have not been reported in bacteria. However, a recent report has indicated that some dinoflagellates secrete MAAs and that they can be quantified in dissolved organic material (104). Whether these can be found at the air–water interface where they could potentially protect bacterioneuston has not been reported.

The heterotrophic bacterioneuston from both marine and freshwater habitats has been reported to contain a large portion of pigmented cells (61,105–110), but not always in the highest frequency (30,111). The proportion of pigmented bacteria can increase after exposure to UV-B (112), which may be one reason pigmented bacteria have been isolated at the air–water interface. Generally, carotenoid pigments can protect from the effects of visible light by quenching the products of photochemically induced oxidations (113) but are not effective in blocking UV-caused DNA damage (114).

As stated earlier, the lethal effects of UV light involve DNA damage and the formation of thymine dimers on strands of DNA. One possible protection mechanism would be to possess DNA with a high guanosine with cytosine (G + C) content to avoid thymine damage from UV radiation (115). An examination of common bacteria isolated from surface films showed that 10 out of the 16 genera represented had mol% G + C in excess of 50 (6). In addition, DNA repair systems (photoreactivation, excision repair, recombination repair, and SOS repair) would be important to bacterioneuston survival. Resistance to UV radiation may be encoded on plasmids (116) and the presence of plasmids has been reported in both marine and freshwater bacterioneuston (108,110,117,118).

Photodegradation is one of the major mechanisms for the transformation of materials at the air–water interface (Fig. 2). It can also can affect bacterioneuston indirectly. On the positive side, it can cause the breakdown of recalcitrant compounds making more usable compounds for the bacterioneuston. On the negative side, photolysis of crude oils was shown to have a toxic effect on bacterial activity (119).

Toxic Substances

The surface film is known to accumulate toxic substances including hydrocarbons (Table 2) and heavy metals (Table 3). Materials collected from the air–water interface from marine and estuarine habitats have been shown to be toxic to eukaryotic organisms in a variety of bioassays (120–124). These substances may also have an effect on the bacterioneuston.

Among the organics, petroleum, pesticides, and other chlorinated hydrocarbons have been reported from air–water interface samples from both marine and freshwater habitats (Table 2). By themselves, they may affect cell membranes, nucleic acid synthesis, amino acid and protein synthesis, enzyme activity, and may cause mutations (126). It has been demonstrated that the presence of a number of different organic compounds at the air–water interface can inhibit the growth of heterotrophic bacterioneuston (Fig. 5). There are also interactions between these organics and UV radiation. As stated

earlier, photolysis of crude oil was shown to result in a toxic effect on bacterial activity (119). UV light has also been shown to increase the photoinduced toxicity of PAHs (127), although this can be improved by the presence of humic acids (128). The presence of humic acids also has been reported to increase the photodegradation of pesticides (129).

Many of these organic compounds, in addition to photodegradation, may also be subject to biodegradation. Actually, the microorganisms may more rapidly deal with the products of photodegradation than with the hydrocarbons themselves (131). The presence of petroleum hydrocarbon degrading bacterioneuston has been demonstrated in a variety of situations (132–135), although they may be inhibited by the presence of pesticides (136). The biodegradation of hydrocarbons and PAHs by the neuston may be less than in the plankton (109,134,137). When bacterioneuston that degrade hydrocarbons have been examined, they generally possess extracellular polymers (59,138), which may have an emulsifying effect on petroleum hydrocarbons and aid in their degradation (135,138). Exopolymers may also act to accumulate pesticides (139).

Metals have álso been measured in air–water interface samples (Table 3). Some of these metals are essential for growth, reproduction, and survival of bacteria (125). Inspite of the with measurements of dissolved trace metals at the air–water interface, there has been some concern about contamination because of the sampling techniques (21). However, even high levels of essential metals can be toxic. Metals can affect microbial growth, morphology, and metabolic activity (140) and can alter microbial community structure quantitatively and qualitatively (141). Metal toxicity is caused by the ionic form and for the most part metals at the air–water interface are associated with organic molecules and/or particulates. Obviously, this may reduce the toxicity to microorganisms, but enough ionic forms may be present in concentrations high enough to cause problems (142). In addition, many bacterioneuston are associated with particulates and may be exposed to particulate-bound metals (143,144).

Bacterioneuston have been shown to be more resistant or tolerant to metals than bacteria from the bulk phase (108,110,145), but not in all cases (117). Metal resistance mechanisms have been recently reviewed (146–148) and many resistance factors are plasmid-associated. As pointed out earlier, many bacterioneuston possess plasmids (108,110,117,118). However, there has been no direct

link established between the presence of these plasmids and any respective metal resistance. In the future, use of specific gene probes may be able to establish this relationship.

Temperature Fluctuations

Microbial neuston are exposed to heat from the water and from direct absorption (3). Changes in temperature include regular diel and seasonal fluctuations (3) and rapid sporadic changes due to factors like cloud cover (149). The effects of these changes have not been extensively studied regarding bacterioneuston. The number of total bacteria positively correlated to changes in air temperature and colony-forming units positively correlated to surface water temperature in the neuston of an Antarctic freshwater pond (65). Short-term temperature fluctuations increased the bacterial diversity in chemostat enrichments of sediment bacteria, indicating that separate temperature niches may be used by different bacteria (150). Thus, temperature fluctuations at the air–water interface may affect single types of bacteria but may not adversely affect the bacterioneuston population as a whole.

Ice formation is one seasonal temperature effect that bacterioneuston may have to deal with. It is clear that some bacteria possess the ability to survive in ice habitats (151). However, it is unknown if any of these bacteria are neustonic. In one study, nocturnal ice formation was suggested to have an inhibitory effect on the activity and community size of the bacterioneuston of an Antarctic freshwater pond (65). They suggested that the bacterioneuston needed time to recover after the nocturnal freezing. The direct effects of ice formation on bacterioneuston have not been reported.

Precipitation

Precipitation in the form of rain can disrupt surface films (152). In addition, precipitation can have effects on neuston microorganisms. First, in marine systems, it can cause changes in salinity. Second, probably more noticeable in freshwater environments, acid precipitation could cause changes in the pH. In each case, the air–water interface faces the initial brunt of the precipitation.

Not much is known about the effects of precipitation and salinity changes on marine bacterioneuston, although some marine bacteria are sensitive to changes in salinity (3). In one study, it was noted that rain caused a decrease in bacterioneuston densities, but a stimulation in activity (153). The changes in salinity were not determined and whether or not this had any effect on the increase in activity was unknown. However, others have reported that in marine coastal water, many bacterioneuston isolates did not require added salt for growth, suggesting that they were of terrestrial or freshwater origin (107,135). Whether these could respond to a decreased salinity brought about by precipitation is unknown.

Acid rain has been a long-term problem for many freshwater ecosystems (154). Acid precipitation may have effects on the chemistry of the surface microlayer by increasing particle formation and by acid degradation of the higher molecular weight organics (155,156). Lower pH will also work to make metal ions more available, perhaps to more toxic levels (157). pH stress on bacteria can result in acid damage and/or cell death (158). Mechanisms to avoid pH stress include (*1*) decreased membrane permeability, (*2*) internal buffering, (*3*) modification of external pH, (*4*) proton extrusion or uptake, and (*5*) prevention of metal ion toxicity (157). Bacterioneuston affected by acid rain may use some or all of these mechanisms to remain successful. However, the specific effects of acid rain on bacterioneuston viability and activity have not been addressed.

Natural Algal Antibiotics

Cases of inhibition of bacterioneuston in the marine environment have been reported (70,159). Although anthropogenic materials may have caused this inhibition, it is also possible that it may have been as a result of the production of natural toxic substances from marine algae (33).

A Freshwater Bacterioneuston Example: *Nevskia ramosa*

A number of different bacteria have been found enriched at the air–water interface under various circumstances. Examples include bdellovibrios (160) and *Aeromonas salmonicida* (161,162). In the case of *A. salmonicida*, its presence in the air–water interface may be related to its high cell surface hydrophobicity (161). One of the best examples of a freshwater bacterioneuston and its adaptations to its habitat is the gram-negative, slightly bent rod-shaped bacterium *N. ramosa* (Figs. 6a and 6b). This epineustonic bacterium was first described by Famintzin (163) from the water surface of an aquarium and since then has been repeatedly established in enrichment cultures (105). Recently, it has been isolated in pure culture (164) allowing physiological experiments to be conducted. Phylogenetically, on the basis of 16S rRNA sequencing (165), *N. ramosa* is the only member of a deep branch of the γ-subclass of the class *Proteobacteria*.

Nevskia ramosa is not obligately a member of the neuston. Motile cells develop in the bulk water and become neustonic, losing their flagella, when the availability of combined nitrogen (ammonia, nitrate, or amino acids) is depleted (164). The cells form rosettes of dichotomously branched slime stalks with single cells at the tips (Fig. 6) and live outside the water phase (i.e., epineustonic). When the cell divides, the stalks form branches. The stalk is secreted from the concave side of the cell and analysis of its exopolysaccharides indicates that it is primarily rhamnose with small amounts of glucose and mannose (164). The metal binding capacity of these exopolysaccharides has not been determined. These films with exopolysaccharide stalks appear to have a high hydrophobicity (164). The bacterium has a high G + C content (67.8 to 69 mol% G + C) and, although sensitive to UV radiation, can overcome damage through photoreactivation (164). Thus, it appears that this bacterium is well-adapted to existence in the neuston. It is also worthy of note that it takes a form of stress (i.e., combined nitrogen depletion) for what could be considered a planktonic organism, to change its habitat to the air–water interface and the neustonic life. This would suggest a certain amount of genetic plasticity

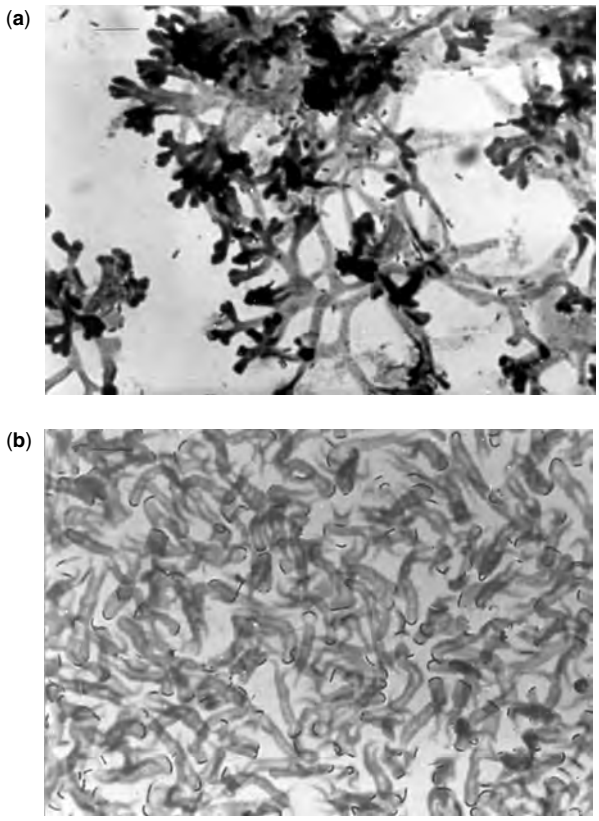

Figure 6. Photomicrographs of *N. ramosa*. (**a**) From the air–water interface of a bog lake. Bar = 15 μm. (**b**) From a formaldehyde-fixed and toluidine blue-stained enrichment culture. Bar = 15 μm. The thin bent rods are at the tips of the branching slime stalks. Photomicrographs courtesy of H.-D. Babenzien (unpublished).

to adapt to the different conditions that are present in both types of habitat.

OTHER MICROORGANISMS

The bacterioneuston are not the only microorganisms that are found at the air–water interface. Each type of microorganism that resides or can be found in the surface microlayer faces the same inhibitory conditions that the bacterioneuston do and must have strategies for dealing with each one. Both the effects and the strategies for dealing with them have not always been investigated directly with neuston organisms.

Phytoneuston and Protozoa (nano- and Microneuston)

Because of their size, algae (phytoneuston) and protozoa in the neuston are normally excluded from the thinnest layers at the air–water interface. As pointed out earlier, when they are at the air–water interface, they are subject to the variety of conditions that exist there. For example, when the effect of UV-B was examined on pelagic microbial communities, it severely limited both ciliates and large phytoplankton (166). This would most probably have its greatest effect on neuston microorganisms. However, because of their mobility, they may be able to avoid the hazardous effects of solar radiation. A diurnal migration of motile microorganisms in and out of the neuston has been reported for both marine and freshwater environments (167–169).

Algae in the neuston (phytoneuston) have two potential roles in surface films: (it 1) they are involved in transfer of carbon dioxide from the atmosphere and (it 2) they produce dissolved organic material (47). Their presence has been reported in surface films either through cell counts or by measurements of chlorophyll *a* (81,82,170–175). There can also be seasonal changes in the phytoneuston populations (173,175–177), which may be linked to changes in the phytoplankton or benthic algal communities (175). The activity of these populations has been under some question. Reports have indicated the presence of primarily dead cells (99) and lower photosynthetic activity at the air–water interface compared with bulk-water samples (35,178,179), although the latter may be influenced seasonally, by the presence of contaminants or of surface slicks (172,180–182). Alternatively, one study has shown higher primary production per unit volume at the air–water interface than in the bulk phase when membrane filters were used to obtain a very thin sample (182). Photoinhibition has been suggested to be one of the main causes of lower viability and activity of phytoneuston at the air–water interface (35,171,174,182). However, Cullen and coworkers (183) reported that the phytoneuston at the air–water interface were physiologically photosynthetically competent like cells examined at a 10-cm depth. They suggested that there may have been a possible mild inhibition of photosynthesis, because of these populations being well-adapted to bright light (183).

The protozoa may provide the link between the bacterioneuston and the rest of the community of organisms associated with the air–water interface (15,33,184). Both ciliate protozoa (167,185,186) and amoebae (70,187) have been reported to be present and at times more concentrated in the neuston of both marine and freshwater ecosystems. They have been observed to have a spatial heterogeneity in surface films (185,186). This patchy distribution by the protozoa has been shown to be related to the distribution of surface film bacteria (186).

Viruses

Viruses have been demonstrated to be present in high numbers in aquatic habitats (188) and could play a negative role in affecting both microbial neuston viability and activity. In addition, lysogenic viruses can be involved in gene transfer through transduction (189). Virions have been reported to adsorb to rising bubbles and when the bubble bursts can be transferred to the atmosphere in jet drops (190,191). This could also act as one mechanism for virus enrichment at the air–water interface. Other factors at the air–water interface, including high levels of UV light and the presence of mutagenic/carcinogenic compounds, could inactivate the repressors, which maintain the temperate virus in a lysogenic state (189) and cause a release of virions. In addition, UV radiation has been demonstrated to result in the destruction of viral particles in marine surface

water, with a decrease in destruction with increasing depth and corresponding attenuation of UV-B (192). This would suggest that the virions at the air–water interface would be the most affected by solar radiation.

In a study of viruses at the air–water interface in Lake Superior, Tapper and Hicks (193) found that free virus particles at the surface ranged from 0.7 to 9.2×10^6 ml^{-1}, between 2 and 15 times more abundant than in bulk-phase samples. They attributed this in part to the increased number of bacteria that were also more abundant at the surface. After treatment of samples with UV light or mitomycin C to induce temperate phage into a lytic state, an increase in viral particles and a decrease in bacterial number was observed. They estimated that three times more bacteria in the surface film may contain temperate viruses compared with those in the bulk phase in this environment. It is also interesting to note that exposure to air liquid interfaces (194) and solar radiation (195) have been reported to lead to the inactivation or removal of viruses. So, although increased numbers of phage may be associated with the air–water interface (193), their ability to be infective is questionable.

CONCLUSION

The air–water interface is subject to a number of different forms of environmental stress that undoubtedly limits the survivability of all the different types of microorganisms that may end up there. The air–water interface is also a dynamic and patchy habitat and, although it appears easy to make generalizations, it must be emphasized that each individual situation must be examined on its own. However, it is clear from the aforementioned text that some organisms are capable of not only surviving there but may also be able to flourish. Shilo (11) pointed out that microorganisms in extreme environments would have to possess a certain amount of plasticity to survive, which would be evident from the earlier discussions of neuston microorganisms. The studies of *N. ramosa* provide an intriguing example of how a bacterium can adapt to a neustonic life. More examples of this type, not only of bacteria but of other microorganisms as well, are needed to be able to provide a greater understanding of how they cope with the various forms of stress in this extreme environment.

NITRIFICATION IN AQUATIC SYSTEMS

B. B. WARD
Princeton University
Princeton, New Jersey

Nitrification is the process whereby ammonium is oxidized to nitrite and then to nitrate. It, thus, links the most oxidized and most reduced forms of nitrogen, and helps determine their overall distributions. Ammonium rarely occurs at significant concentrations in oxygenated habitats. It is recycled rapidly between heterotrophic organisms (which excrete ammonium directly, or release organic nitrogen that is microbially degraded to ammonium) and photosynthetic phytoplankton (which use ammonium as a nitrogen source) in the surface ocean. Ammonium can accumulate in anoxic sediments and in stratified water in which oxygen concentrations are very low.

Similarly, nitrite rarely accumulates in oxygenated habitats (see the following text for exceptions), although nitrite is an essential intermediate in several oxidation and reduction processes in the nitrogen cycle. Nitrate, the end product of nitrification, however, accumulates in the deep ocean, and seasonally in the deep water of lakes, where there is no demand for inorganic nitrogen by phytoplankton.

The oxidation of ammonia to nitrite and of nitrite to nitrate, although thermodynamically favorable when linked to reduction of oxygen, has long been considered a biological process, with no known abiotic contributions. Oxidation of ammonia and amino-level nitrogen in organic compounds to nitrogen gas linked to the reduction of manganese oxide has been demonstrated in sediments, and this pathway may have significant ramifications for the nitrogen cycle of sediments. Whether this represents an example of abiotic nitrification or anaerobic biological nitrification (discussed in the following text) remains to be resolved.

The most important organisms in nitrification are the so-called nitrifying bacteria. This group includes several genera of bacteria, all within the Proteobacterial phylum. These genera are not all closely related to each other, but appear to have arisen from a photosynthetic ancestor, diverging before the ability to nitrify was developed in the various groups (1). There are two functionally distinct groups of nitrifiers: those that oxidize ammonium to nitrite [ammonia-oxidizing bacteria (AOB)] and those that oxidize nitrite to nitrate [nitrite-oxidizing bacteria (NOB)]. No organism is known to carry out both reactions. These unique metabolic traits are not without costs; the nitrifiers are chemolithoautotrophic for the most part, a lifestyle that enables them to exploit a unique niche in natural systems, but apparently confers a constraint of slow growth and inflexible nutritional requirements.

Nitrification is closely coupled with other important steps in the nitrogen cycle, such as nitrogen assimilation by phytoplankton and loss of fixed nitrogen by denitrification. Thus nitrification is part of the linkage between the carbon and nitrogen cycles at several levels. These and other aspects of nitrification and nitrifying bacteria in marine systems are explored in this article. The emphasis is on the last 10 to 20 years. Other useful reviews are found in References (2–5).

PHYSIOLOGY AND ENERGETICS OF NITRIFYING BACTERIA

Autotrophic Nitrification

Obligately autotrophic, or in a few cases, mixotrophic bacteria are thought to perform most of the nitrification

that occurs in natural habitats, but the diversity of known nitrifying physiologies is rapidly expanding. We shall consider the classical autotrophs first.

Most of our knowledge of autotrophic nitrifiers derives from studies on cultivated strains, and the best-known of those are the ammonia-oxidizing genus *Nitrosomonas* and the nitrite-oxidizing genus *Nitrobacter*. The cultured autotrophic nitrifiers, both ammonia-oxidizers and nitrite-oxidizers, depend on carbon dioxide as their major carbon source, and fixation is carried out by the Calvin cycle. It is estimated that carbon dioxide fixation, accounts for about 80% of the energy budget of an autotroph (6,7). In addition, the use of ammonium or nitrite as the sole source of reducing power for this autotrophic growth is relatively inefficient: about 35 moles of ammonium or 100 moles of nitrite must be oxidized to support fixation of a single mole of carbon dioxide (8). This "perverse insistence "on fixing their own carbon dioxide, using a unique but low-yield energy source (9), accounts for their well-deserved reputation for slow growth, even under optimum conditions in the laboratory. Minimal generation times of 7 to 13 hours are usual for *Nitrosomonas* and *Nitrobacter* (10).

The overall reaction for ammonia oxidation (Eq. 4) shows that the process consumes molecular oxygen and produces hydrogen ions, in addition to nitrite. A requirement for molecular oxygen occurs in the first step of the oxidation (Eq. 1), which is catalyzed by a monooxygenase [ammonia monooxygenase, (AMO)]. The uncharged gaseous ammonia is the actual substrate for AMO, as demonstrated by the pH dependence of the reaction rate (11,12). AMO has never been completely purified and assayed in cell-free conditions, although its gene sequence has been derived for both *Nitrosomonas* and *Nitrosococcus* type AOBs (13–15). AMO contains copper and probably also iron in its active form (16).

The immediate product of AMO is hydroxylamine, which is further oxidized by hydroxylamine oxidoreductase (HAO) to nitrite (Eq. 2). Oxygen is also consumed by the terminal oxidase (Eq. 3), as a result of electron transport generating ATP for cellular metabolism.

$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O \quad (1)$$

$$NH_2OH + H_2O \rightarrow NO_2^- + 5H^+ + 4e- \quad (2)$$

$$2H^+ + 0.5O_2 + 2e^- \rightarrow H_2O \quad (3)$$

$$NH_3 + 1.5O_2 \rightarrow NO_2^- + H_2O + H^+ \quad (4)$$

Although the overall reaction is energy yielding, the initial oxidation of ammonia to hydroxylamine involves the consumption of reducing power, which is supplied by linkage to the second step, hydroxylamine oxidation, which yields four electrons. The nitrogen oxidation and electron transport pathways in *Nitrosomonas* are incompletely known, but involve several unique and interesting components that are linked in the cytoplasmic membrane and periplasmic space (17). Depending on conditions (and enhanced at low-oxygen concentrations), nitric oxide (NO), nitrous oxide (N_2O), and even dinitrogen gas (N_2) have been reported as secondary products in autotrophic ammonia oxidation. Although nitrous oxide and nitric oxide can be produced in vitro by HAO from hydroxylamine (18), reduction of nitrite appears to be the dominant pathway in whole cells (17,19,20). Nitrite reductase activity has been demonstrated in *Nitrosomonas europaea* (21,22), and a gene with homology for the copper type nitrite reductase of heterotrophic denitrifiers was recently detected in a group of marine *Nitrosomonas* isolates (23).

The biochemistry of nitrite oxidation is simpler than ammonia oxidation because it is only a two-electron transfer and involves no intermediates. The additional oxygen atom in nitrate is derived from water (Eq. 5), and the molecular oxygen that is involved in the net reaction (Eq. 7) results from electron transport involving cytochrome oxidase (Eq. 6).

$$NO_2^- + H_2O \rightarrow NO_3^- + 2H^+ \quad (5)$$

$$2H^+ + 0.5O_2 \rightarrow H_2O \quad (6)$$

$$NO_2 + 0.5O_2 \rightarrow NO_3^- \quad (7)$$

The energy yield of nitrite oxidation is even less than that of ammonia oxidation, necessitating the oxidation of vast amounts of nitrite to fix small amounts of carbon dioxide. For both processes, therefore, the biogeochemical impact is greater on the nitrogen cycle than on the carbon cycle.

The biomass produced by primary fixation of carbon dioxide by nitrifiers is probably not significant, except in a few unusual habitats. Areas under the sea ice in the Antarctica (24), an anchialine cave in the Yucatan Peninsula, Mexico (25), and the Mississippi River Plume in Gulf of Mexico (26) are cited as exceptions. In all the three cases, the significance of autotrophic nitrification as an in situ source of organic carbon is enhanced relative to the production of organic matter by photosynthesis. Photoautotrophic carbon production is minimal, because of the absence of light caused by the ice cover, the geometry of the cave itself, and in the Mississippi River system, high levels of suspended matter, respectively. Chemoautotrophy might also be a significant source of in situ production in hydrothermal plumes in which elevated ammonium (and perhaps methane) concentrations could support ammonia-oxidizing bacteria (27).

Heterotrophic Nitrification

Many denitrifying bacteria, other heterotrophic bacteria and fungi have been reported to perform heterotrophic nitrification. Heterotrophic nitrification refers to several different oxidation reactions that parallel parts of the autotrophic nitrification process, including reactions, which release nitrate or nitrite from the breakdown of organic nitrogen compounds. It has been argued that heterotrophic nitrification involves quite different enzyme systems (28), and that it cannot serve as an energy-generating mechanism (29), as does the autotrophic process. In the aerobic denitrifiers, which are also capable of nitrification, the initial enzyme, AMO, appears to be quite similar to the enzyme in autotrophic nitrifiers. However, HAO differs significantly and in

the heterotrophs is a smaller, simpler enzyme that performs a two-electron transfer (instead of the four-electron transfer of the autotrophic HAO), and releases nitroxyl as the product, rather than nitrite (30). Thus, no electrons are available for reverse electron transport in the heterotrophic system, and the purpose of the process appears to be a means of disposing of excess reductant in times of redox stress, rather than harvesting that reductant for cellular energy.

In aquatic systems, the most important heterotrophic nitrifiers are thought to be a class of denitrifiers, which are capable of aerobic denitrification, and which can also oxidize ammonia. The organism in which these physiologies were first described is now known as *Paracoccus pantatrophus* (formerly known as *Thiosphaera pantotropha*). *Paracoccus pantotrophus* oxidizes ammonia to nitrite using an enzyme that exhibits important similarities and differences compared with AMO from autotrophic nitrifiers (31). The nitrite so generated can be released into the medium or denitrified to dinitrogen gas. Denitrification of nitrite or nitrate can occur under atmospheric levels of oxygen (32). Aerobic denitrifiers have mostly been isolated from wastewater treatment systems, and their prevalence and ecological significance is unknown in natural aquatic systems.

Because autotrophic nitrification is such a hard way to make a living, it seems strange that heterotrophic nitrification is not more common. Thermophilic heterotrophic nitrifiers, capable of oxidizing ammonia to nitrite, were isolated from several hydrothermal vent habitats (33). Most of the isolates were nitrate reducers or denitrifiers, and exhibited a wide diversity related to the genera *Thermus* and *Bacillus*. Because they are able to ammonify, nitrify, and reduce nitrate, they would seem to possess most of the physiologies of importance in the nitrogen cycle. Such organisms may be common in mesophilic aquatic habitats, but have not been quantitatively investigated.

Heterotrophic strains capable of oxidizing nitrite have also been reported. Sakai and coworkers (34) described several classes of heterotrophic strains that oxidized nitrite to nitrate with variable amounts of nitrate accumulation, depending partly on the denitrification capabilities of the strains. Strains that were capable of both oxidation and reduction of nitrogen oxides were shown to switch between the two directions of conversion depending on the oxygen tension of the culture (35).

Heterotrophic nitrification has been studied in terrestrial systems, especially acid forest soils, in which it has been difficult to document autotrophic nitrification. Experiments using isotopes to differentiate production of nitrate from inorganic and organic substrates in a forest system found that heterotrophic nitrification accounted for less than 10% of the total nitrification rate (36). No information of this sort is available on the occurrence or significance of heterotrophic nitrification in aquatic systems. The potential for ammonia and nitrite oxidation by heterotrophic bacteria in aquatic systems warrants further exploration, and the capability may be present in many strains already in culture. If heterotrophic nitrification is common in nature, a focus on autotrophic nitrification as the model system and the basis for estimation of rates is too narrow and unrealistic. On a per cell basis, heterotrophic nitrification is much slower than is autotrophic nitrification, and the relative impact on nitrogen turnover must be greater by autotrophs because of their total dependence on nitrogen oxidation for energy. Nevertheless, widespread abundance of more numerous heterotrophic nitrifiers could compete in importance with the smaller number of slow-growing autotrophs.

Anaerobic Nitrification

The interest in anaerobic nitrification and aerobic denitrification arises mainly from the necessity to treat large volumes of wastewater to reduce nitrogen loading before release into natural water. Classical nitrification and denitrification are environmentally incompatible processes, the first being obligately aerobic and the second induced only under conditions of anoxia. It is, therefore, usual to involve two steps in wastewater treatment: an aerobic step to convert ammonia to nitrate and a subsequent anaerobic step to convert the nitrate to dinitrogen. If the two steps could be combined in one organism under either aerobic or anaerobic conditions, much time and money would be saved in wastewater treatment. And clearly, if a single organism is capable of combined nitrification and denitrification in a bioreactor or water treatment plant, such an organism could be of considerable importance in the natural environment as well.

The heterotrophic nitrifier mentioned earlier, *P. pantatrophus*, carries out at least part of both processes under aerobic conditions. *Paracoccus pantatrophus* was originally isolated from wastewater and its ability to denitrify aerobically in several other conventional heterotrophic denitrifiers has been confirmed (32).

Autotrophic nitrifying bacteria exhibit some abilities for anaerobic metabolism as well. Enrichment cultures under chemolithotrophic conditions and very low oxygen concentrations catalyzed the net removal of ammonium as nitrogen gas (37). Bock and coworkers have shown that *Nitrosomonas eutropha* produces gaseous products, mainly nitric oxide and dinitrogen gas, during growth on nitrogen dioxide gas (NO_2) and ammonia (38). The process proceeds at a slower rate than ammonia oxidation in the presence of a normal air atmosphere and supports cell growth. Additions of nitrogen dioxide gas and nitric oxide enhanced the complete removal of nitrogen in the form of ammonia and organic nitrogen, without the addition of organic carbon substrates (39).

A completely novel process in which ammonia and nitrite are converted, anaerobically, to dinitrogen gas has recently been reported, the process has been quantitatively described (40,41), and the organisms responsible for this novel metabolism have been identified as relatives of *Planctomyces* (41). Referred to as *anammox*, the process probably involves a consortium of the planctomycete organism and an autotrophic ammonia-oxidizer such as *N. europaea* or *N. eutropha*. Ammonia is oxidized to nitrite by the autotroph under microaerophilic conditions. The nitrite so produced is reduced to dinitrogen gas by the planctomycete. Both oxygen and nitrite concentrations

are maintained at nearly undetectable levels by the metabolism of the members of the consortium, and although both organisms grow quite slowly (generation times, for the planctomycete, of two weeks are reported), the net removal of ammonium occurs at a rate 25 times faster than that reported for nitrogen removal by anaerobic autotrophic nitrification alone (40).

The anammox process was discovered and characterized in anaerobic wastewater treatment systems, and 16S rRNA sequences identified as belonging to the planctomycete member have been detected in several such systems. Research into the occurrence of the process and presence of the organisms in natural aquatic systems has not yet been reported. Anammox would constitute a shortcut in the conventional nitrogen cycle similar to that proposed by Codispoti and Christensen (42), who suggested that nitrous oxide produced by nitrifiers might be denitrified by denitrifiers, thus linking nitrification and denitrification without going through nitrate. In the anammox process, the linkage occurs at the level of nitrite. It is suggested, therefore, that places where ammonium and nitrite both occur in the presence of low oxygen concentrations might be suitable habitats for anammox. Such environments include oxic–anoxic interfaces, such as those found at sediment–water interfaces in hemipelagic and shallow sediments, and in stratified lakes and in the water columns of stratified basins, such as the Black Sea and the Cariaco Basin. At first consideration, the anammox consortium seems unlikely to dominate processes in these environments, on the basis of the observation of chemical distributions. Ammonium builds up to very high levels in anoxic sediments and stratified water column, in both freshwater and marine environments. Microaerophic autotrophic nitrification, linked to anaerobic denitrification across the oxic–anoxic interface, has been used to interpret the chemical distributions that typically show depletion of oxygen and nitrate above the interface and accumulation of ammonium below. Denitrification produces a net loss of fixed nitrogen, which would presumably be much larger if anammox were also involved. Mass balance measurements might provide insight into the potential for anammox involvement in natural systems.

In addition to the unconventional activities of conventional nitrifiers and denitrifiers and the discovery of novel nitrogen metabolisms in new organisms, it has also been recently proposed that a short circuit of the nitrification/denitrification couple can also be accomplished abiotically. In marine sediments that typically contain relatively high manganese levels, dinitrogen gas can be produced by the oxidation of ammonia and organic nitrogen by manganese dioxide in the air. The reduced Mn^{++} thus formed can be reoxidized by oxygen to continue the oxidation of ammonium, or can reduce nitrate to dinitrogen gas (43). Although the free energy of these coupled reactions is shown to be favorable, it remains to be seen whether the abiotic process can be unequivocally identified in natural systems, and the degree to which it may compete with the biologically catalyzed processes. Hulth and coworkers (44) detected anoxic production of both nitrite and nitrate in marine sediments, concurrent with the production of reduced manganese. The nitrate production was directly proportional to the initial manganese oxide content, and the nitrate was subsequently depleted, apparently by denitrification. Hulth and coworkers (44) proposed a series of linked redox cycles in which anoxic nitrification, coupled to manganese reduction, was linked in series to anoxic organic matter oxidation through several biogeochemical reductants, including iron and hydrogen sulfide. These authors proposed that the lithotrophic nitrification they observed is biologically mediated, and potentially of significance in the nitrogen cycle at sites where oxidized metals are reworked into anoxic sediments.

Anoxic ammonia oxidation, whether it results directly in dinitrogen gas formation (as in anammox) or in nitrate production (when linked to manganese reduction), would introduce new links to the aquatic and sediment nitrogen cycle. Failure to account for anoxic ammonia oxidation might lead to an underestimate of ammonium removal, because the products do not accumulate; they are either lost to the atmosphere immediately, or rapidly reduced by the next step in the anaerobic cycling of organic matter.

PHYLOGENY OF BACTERIA INVOLVED IN NITRIFICATION

Discovery and Description

Autotrophic nitrifiers were first isolated and characterized by Winogradsky (45), the "father of chemolithoautotrophy", in the late 1800s (1890). Winogradsky's organisms were derived from soils; the first reported isolation and characterization of marine nitrifying bacteria was by Stanley Watson in the 1960s (46). Nitrification had been detected in seawater before that time and nitrifiers had been implicated in the production of nitrite in seawater (47,48). The first marine ammonia oxidizer to be cultured was originally called *Nitrosocystis oceanus*, and is now referred to as *Nitrosococcus oceani*, the lone ammonia-oxidizing species in the γ-subdivision of the Proteobacteria. Watson also isolated marine strains of the best-known terrestrial genus of ammonia-oxidizing bacteria, *Nitrosomonas*, and he also reported the first isolations and characterizations of marine nitrite-oxidizing bacteria (49,50). His culture collections have formed the basis of much of our modern knowledge of the biochemistry, physiology, phylogeny, distribution, and activity of nitrifiers in seawater and terrestrial systems. Koops and coworkers recently summarized the history and general characteristics of these genera (51). Isolates, identified as *Nitrosomonas* and *Nitrobacter*, are the nitrifiers most commonly obtained from lake water using classical enrichment techniques (52). When PCR and DNA sequencing techniques retrieved a preponderance of *Nitrosospira*-like sequences from freshwater habitats (53), the representativeness of these isolates was seriously questioned (discussed in the following text). Later isolations and descriptions of new species have increased the physiological and phylogenetic diversity of cultured nitrifiers to include halophilic, alkaliphilic, and psychrophilic strains, for example, *Nitrosococcus halophilus* (54), *Nitrobacter alkalicus* (55), *Nitrospira moscoviensis* (56), *Nitrosomonas cryotolerans* (57). In fact, it is relatively simple, although also relatively tedious, to isolate nitrifiers using standard techniques in liquid

culture (growth on plates is very slow and not very reproducible). So far, there have been no isolations reported that were accomplished under very low substrate conditions or "trace-metal clean "conditions, which might be more realistic for many aquatic environments.

Phylogeny of Nitrifying Bacteria

The number and diversity of bacterial strains that are identified as autotrophic nitrifying bacteria is rather limited, in comparison with the number and diversity of organisms that are capable of denitrification or of heterotrophic growth. A description of the species of ammonia oxidizers and nitrite oxidizers recognized on the basis of morphology (cell shape and distribution of internal membranes) and physiology can be found in References 51,58, respectively.

The generic and species' affiliations of nitrifiers were reassessed on the basis of DNA sequences of the 16S ribosomal RNA genes from the cultured strains (1,59). The phylogeny of nitrifiers (1) shows that most of them are descendents of a common ancestor that was photosynthetic, rather than descending from a common ancestral nitrifier. The ammonia oxidizers are found in the β- and γ-subdivisions of the Proteobacteria (Fig. 1). The nitrite oxidizers are found in the α-, β-, and γ-subdivisions.

The ammonia-oxidizing bacteria (AOB) comprise two main groups in the Proteobacteria, one in the β-subdivision and one in the γ-subdivision. The β-subdivision species, containing genera known as *Nitrosospira* and *Nitrosomonas*, have been the subject of many recent studies. The main tool for investigating them in both culture and field conditions is polymerase chain reaction (PCR) followed by DNA sequencing. On the basis of 16S rRNA sequence analysis, several clusters, and a large amount of microdiversity within clusters, has been detected in a wide variety of environments, both terrestrial and aquatic. Few generalities linking species or strains to environmental conditions have emerged. For example, McCaig and coworkers (60) investigated the community structure of β-subdivision AOB in marine sediments underlying fish farms and found a novel *Nitrosomonas* group whose distribution correlated with elevated ammonium concentrations. Hiorns and coworkers (53) could detect *Nitrosospira* in lake water and lake sediments by direct PCR, but could detect *Nitrosomonas* only after enrichment culturing, suggesting that *Nitrosomonas* preferred the higher ammonium concentrations of batch culture to the variable and lower concentrations in the lake. Hastings and coworkers (61), working in the same system, found evidence for distinct sediment and lake water population, with high and low ammonium preferences, respectively. However, it was *Nitrosopsira* sequences that were associated with high ammonium concentrations derived from sediments. Following up this study, Whitby and coworkers (62) were able to retrieve *Nitrosomonas* sequences directly from lake samples without enrichment, but only during the summer months, and different sequence clusters were associated with different sediment regimes. Stephen and coworkers (63) surveyed enrichment cultures and gene libraries of soils and marine sediments and found that *Nitrosomonas* sequences were more often associated with enrichment cultures and *Nitrosospira*s with libraries. *Nitrosospria* -like sequences were dominant in ammonia-oxidizer sequences retrieved

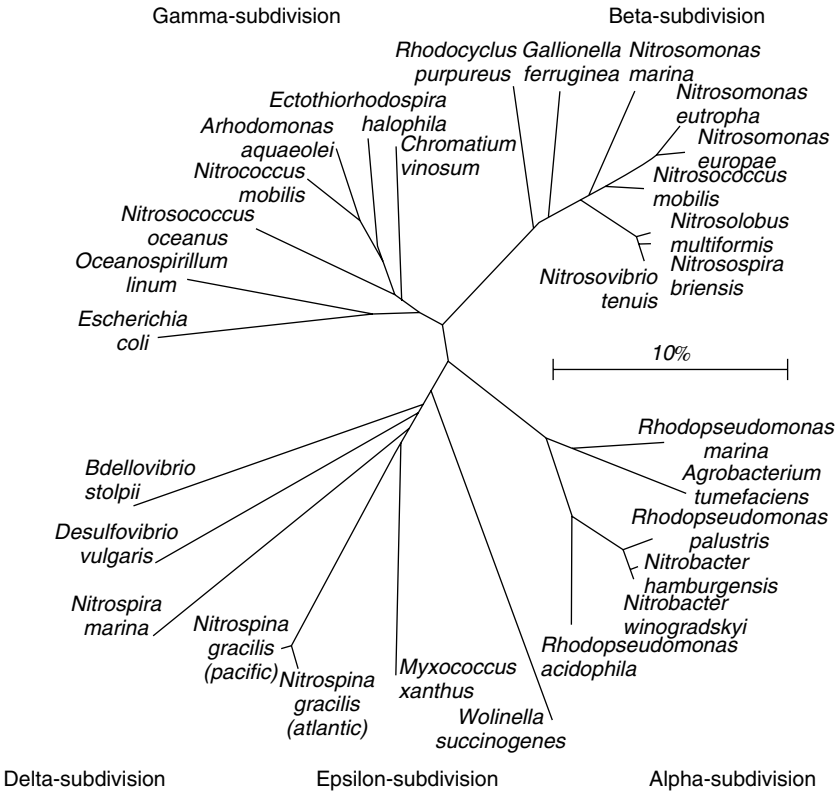

Figure 1. Distance tree for the proteobacteria, including ammonia and nitrite-oxidizing isolates. Scale bar corresponds to 0.1 estimated fixed mutation per sequence position. With permission from A. Teske, *J. Bacteriol.* **176**, p. (1994).

from the Arctic Ocean (64). These findings suggest that the *Nitrosomonas* lineages are less common in natural samples than *Nitrosospira*s, and raise concerns about biases introduced by relying on pure culture techniques. *Nitrosomonas* sequences, however, have been derived directly from the environment including freshwater lakes (62,65) and an alkaline lake. Hovanec and DeLong (66) were unable to detect *Nitrosomonas*-like AOBs in fish aquaria, and concluded that novel, as yet unidentified and uncultured, AOBs must be present.

The γ-subdivision ammonia oxidizers are represented by a single genus and species, *N. oceani*, which has only been reported from marine or saline environments. Several different strains exist in culture, but they all appear to be closely related. They have been detected by PCR in saline lakes in Antarctica (67) and by immunofluorescence in various marine systems (68,69) and in the Mediterranean Sea (70).

The new phylogeny of nitrite-oxidizing bacteria, based on 16S rRNA sequences, shows that the best-known autotrophic nitrite oxidizer, *Nitrobacter*, comprises a coherent genus in the α-subdivision of the Proteobacteria. This genus is most closely related to the genera that contain autotrophic members and strains capable of denitrification (1). Like *N. oceani*, *Nitrococcus mobilis* belongs to the γ-subdivision of the Proteobacteria, the only example of both ammonia- and nitrite-oxidizing phenotypes occurring in the same subdivision. *Nitrospira* and *Nitrospina*, two strains originally isolated from marine environments, are assigned to the γ-subdivision of the Proteobacteria. A novel *Nitrospira* strain, *N. moscoviensis*, isolated from a heating system in Moscow, Russia, was assigned to a new genus outside the Proteobacteria (56). These authors reanalyzed the *Nitrosomonas marina* sequence that Teske and coworkers (1) had placed in the γ-Proteobacteria, and concluded that *Nitrospira* belonged outside the Proteobacteria, in a deeply branching cluster related to *Leptospirilla*.

Except for *Nitrospira* and *Nitrospina*, all the autotrophic nitrifiers cluster in phyla that are characterized by photoautotrophic ancestry, and are themselves characterized by the possession-complex intracytoplasmic membranes. These membranes are thought to be the site of the redox proteins involved in nitrogen oxidation, and therefore homologous with the photosynthetic membranes of photosynthetic bacteria and cyanobacteria. Nevertheless, the autotrophic nitrifiers are polyphyletic, and the phenotype has apparently arisen independently numerous times. The homology of the functional genes (*amo, hao*) involved in their physiology implies gene transfer events, however, rather than independent evolution of these enzymes. An understanding of the phylogeny of nitrifying bacteria is relevant to the study of nitrification in aquatic habitats because it has implications for detection and quantification methods. Although the nitrifiers are polyphyletic, they are not so diverse as to be unmanageable; their affiliation within a small group of lineages makes them amenable to identification and detection using a relatively small suite of molecular probes. This approach forms the basis of much current knowledge on the diversity and distribution of autotrophic nitrifying bacteria. A comprehensive reevaluation of the phylogeny and evolution of nitrifying bacteria should appear in the new edition of Bergey's Manual of Determinative Bacteriology, which is being prepared for publication at the time of this writing.

The phylogeny of heterotrophic bacteria is much more complex, and less well known. Various forms of heterotrophic nitrification have been reported for bacterial genera including *Bacillus*, *Paracoccus*, *Pseudomonas*, *Thermus*, *Azoarcus*, and the fungus, *Aspergillus*. The ability appears to be widespread, but no phylogenetic pattern has yet emerged, nor is there a consensus on the biochemistry of heterotrophic nitrification among these different groups.

The autotrophic ammonia oxidizers show significant metabolic and morphological similarities with another group of autotrophic bacteria, the methane oxidizers. They are also closely related phylogenetically to the methane oxidizers, in both the γ- and β-subdivisions (1). Before the availability of ribosomal RNA sequence data for determination of phylogenetic relationships, it had been reported that ammonia-oxidizing nitrifiers were capable of methane oxidation and vice versa (12,71,72). Thus, it was an interesting verification of the metabolic studies when it was reported that the central genes in the two pathways, that is, genes encoding AMO in the nitrifiers and methane monooxygenase in the methanotrophs, were evolutionarily related (73). It has not been possible to unequivocally determine the process that is the natural or predominant one for some nitrifiers and methanotrophs in nature (discussed in the following text).

ROLE OF NITRIFICATION IN THE NITROGEN CYCLE

The role of nitrification in the nitrogen cycle, whether on land or in aquatic systems, is to convert ammonium, a common nitrogenous waste product of heterotrophic metabolism, to nitrate, the most oxidized form of fixed nitrogen. Nitrate is the most abundant form of nitrogen in the ocean, and depending on the season and thermal stratification of the water column, can accumulate to very high levels in freshwater as well. Plants can use many forms of organic and inorganic nitrogen, and the transformation of ammonium into nitrate does not change the absolute availability of nitrogen for plant or algal nutrition. In soils, the different ionic properties of ammonium and nitrate are important in determining the availability of inorganic nitrogen in the soil solution, but in aquatic systems, the properties of these ions are less important to their distributions. Unlike nitrogen fixation, which introduces new fixed nitrogen into the system, and denitrification, which removes it from the system, nitrification simply changes the chemical nature and oxidation state of inorganic nitrogen. Because of the different chemical properties and varying preferences, abilities, and metabolic costs of using ammonium versus nitrate, and the role of nitrate as a substrate for denitrification, however, this transformation is very important in both agricultural and natural systems.

In aquatic systems, ammonium is often the first metabolic product of the breakdown of organic nitrogen; it is an excretory product of zooplankton and protozoans, and is released from the microbial degradation of

complex organic compounds. Because ammonium contains nitrogen at the oxidation level of proteins, it is readily assimilated by both phytoplankton and bacteria, and is a preferred nitrogen source. Therefore, it rarely accumulates in surface waters, it is assimilated as rapidly as it is produced by various members of the microbial food web. In fact, ammonia-oxidizing bacteria may be in competition for ammonium with other planktonic organisms. The different physiological requirements of phytoplankton and nitrifying bacteria, probably, play a role in determining exactly where in the water column ammonium assimilation and ammonium oxidation occur. As explained later, most nitrification occurs near the base of the euphotic zone in the upper 100 or so meters of the ocean. However, there is usually very little nitrate in the surface ocean, because of utilization by phytoplankton. The nitrate in the deep water of oceans and lakes has accumulated from nitrification in the absence of phytoplankton assimilation. It is because of nitrifying bacteria that nitrogen accumulation in the deep water is in the form of nitrate, rather than ammonium. The deep nitrate reservoir can be made available to phytoplankton by mixing and upwelling, and in lakes by seasonal overturn. These physical processes bring cold, deep nitrate-rich water up to the surface where, in the presence of light, phytoplankton can assimilate the nitrate. Thus, although nitrate is not usually abundant in surface water, it is a very important nitrogen source for phytoplankton.

The nitrate, which is produced by nitrification, especially that which accumulates below the euphotic zone, may have a fate other than assimilation by phytoplankton. Denitrification is another step in the nitrogen cycle that is also controlled by bacteria. Denitrifying bacteria are usually heterotrophs, and the capability for denitrification is widespread across the bacterial and archaeal domains (74). Denitrifiers use oxides of nitrogen as electron acceptors in the place of oxygen. In the process, nitrate is reduced sequentially to nitrite, then to nitric oxide and nitrous oxide, and finally, to dinitrogen gas. The last three products are all gases. Most organisms, which require nitrogen for nutrition, are unable to assimilate the gases; thus, denitrification results in a net loss of fixed nitrogen, that is, biologically available nitrogen, from the system. Although denitrification involves several semi-independent steps that need not function together, it is common for denitrifiers to begin the sequence with nitrate and to produce varying amounts of the other products depending on the environmental conditions. Thus, although denitrifiers might appear to have little in common with nitrifiers, the former are in fact dependent on the latter; other than lightning and fertilizers, nitrifiers are the only source of nitrate. The links between nitrification and denitrification will be discussed further in the context of the environments in which they occur (illustrated in the following text). The link is mentioned here to emphasize that, although nitrifiers by themselves do not change the fixed nitrogen inventory of the ecosystem, their activity makes possible the activity of denitrifiers, which are responsible for the major loss term in the global nitrogen budget.

Thus, the role of nitrifiers in the nitrogen cycle of aquatic systems is to link the oxidizing and reducing processes of the nitrogen cycle by converting ammonium to nitrate. This conversion is responsible for the fact that the major fixed nitrogen pool in the ocean is in the form of nitrate. The deep nitrate reservoir of oceans and lakes is a huge pool of nitrogen whose availability to phytoplankton is controlled largely by physical processes. The nitrification link also makes possible the loss of fixed nitrogen by denitrification, by converting nitrogen released as a waste product of animal metabolism into a form that can be respired by denitrifiers.

DISTRIBUTION AND ABUNDANCE OF NITRIFIERS IN AQUATIC HABITATS

Although most strains of ammonia-oxidizing and nitrite-oxidizing bacteria have characteristic intracytoplasmic membrane structures that can be visualized by electron microscopy, it is not possible to distinguish the otherwise nondescript cells from other bacteria in water samples using microscopic techniques widely used to visualize and enumerate bacteria, that is, epifluorescence microscopy with DNA fluorochromes. Most probable number (MPN) methods, relying on the appearance or disappearance of nitrite in dilution media, have been used to estimate the abundance of ammonia oxidizers and nitrite oxidizers, respectively, in aquatic environments. MPN approaches are widely used to estimate abundances of nitrifying bacterial population in soil, but there are very few modern reports using this technique in the water column of aquatic systems. Its application is only marginally more common in sediment studies (Table 1); McCaig and coworkers (60) used MPN to estimate the abundance of ammonium- and nitrite-oxidizing bacteria in polluted sediments underlying marine fish farms. In the sample taken from directly underneath the fish cage, nitrite oxidizers were abundant and ammonia oxidizers were not detected. Further away from the cage, ammonia oxidizers were detected, but nitrite oxidizers were not present above detection level at these stations. Using MPN in freshwater eutrophic lake sediments, Smorzewski and Schmidt (75) found that nitrite oxidizers always outnumbered ammonia oxidizers, by up to a factor of 8.1. Pauer and Auer (76), using MPN, found very low nitrifier population in the water of a hypereutrophic lake, whereas sediments harbored much higher population densities. Hall (52) estimated from the data in a number of lake studies that the efficiency of recovery for MPN was 0.05 to 0.001% for ammonia oxidizers. He also concluded that MPN abundances showed little correlation with observed nitrifying activities. This technique should, however, yield isolates of the most abundant cell type present, assuming it can grow under the enrichment culture conditions.

Schmidt and coworkers applied immunofluorescence (IF) to the study of nitrifying bacteria in soil and lake systems (83, 84,77). In many cases, IF was used to study the diversity of population (75,83) and not directly for enumeration. IF did provide, however, one of the first methods for the enumeration of specific populations that did not require enrichment culturing. The specificity

Table 1. Abundances of Nitrifying Bacteria Reported from Aquatic Systems

Location	Depth (m)	AOB Cell Abundance	NOB Cell Abundance	Method	Reference
		Sediments			
Freshwater lake sediments	Surficial sediments	$8–37 \times 10^5$ cells g^{-1}	$21–67 \times 10^5$ cells g^{-1}	MPN	75
sediments under marine fish farm cages	0.5-cm core top	Up to 0.2×10^6 cells m^{-2}	Up to 25×10^6 cells m^{-2}	MPN	60
hypereutrophic lake	Water column	10 cells mL^{-1}		MPN	76
	Sediments	10^5 cells mL^{-1}			76
Water Column Environments		*Cells mL^{-1}*	*cells mL^{-1}*		
Lake Itasca (MN, U.S.A.)	Oxic water column		*Nitrobacter* up to 1,000	IF	77
	Anoxic water column		*Nitrobacter* up to 100	IF	77
Rhine River	Wastewater effluent		*Nitrobacter* $10^6–10^8$	IF	78
Tamar River	0.5 m	Up to 90		MPN	79
Lake Plussee (Germany)	Oxic water column	*Nitrosomonas* 2.5×10^3		IF	80
Belauer Sea (Germany)	Oxic water column	*Nitrosomonas* 5×10^3		IF	80
Lake Bonney (Antarctica)	Oxic water column	*Nitrosomonas* 2×10^3		IF	81
	Oxic water column	*Nitrosococcus* 0.8×10^3		IF	81
Mediterranean lagoon	Oxic water column	*Nitrosococcus* $1–10^3$		IF	70
Peru upwelling	Ave over water column	*Nitrosomonas* + *Nitrosococcus* 0.3×10^3	*Nitrobacter* + *Nitrococcus* 0.2×10^3	IF	69
Southern California Coastal waters	Ave over water column	*Nitrosomonas* + *Nitrosococcus* 0.3×10^3	*Nitrobacter* + *Nitrococcus* 0.3×10^3	IF	68
Chesapeake Bay	Ave over water column	*Nitrosomonas* + *Nitrosococcus* 10^7		IF	82

Note: AOB — Ammonia-oxidizing bacteria, NOB — Nitrite-oxidizing bacteria, IF — Immunofluorescence, MPN — Most Probable Number.

of the assays could be optimized to distinguish among serotypes of the same species or to detect all serotypes within a genus. Stanley and coworkers (77) used a cocktail of antisera specific for different serotypes to enumerate *Nitrobacter* in the oxygenated-near surface and the anoxic deep layers of Lake Itasca (Minnesota, U.S.A.) (Table 1). Similarly, Montuelle and coworkers (78) detected several serotypes of *Nitrobacter* in wastewater effluent enter the Rhine river, and reported that the diversity of serotypes in the river varied with wastewater input. Feray and coworkers (85) compared IF with a standard MPN technique and an MPN/PCR method for enumeration of nitrite-oxidizing bacteria in freshwater sediments and found that immunofluorescence performed the best overall, although all of the methods suffered from low recovery of added cells. Sediments may be more problematic for the enumeration of bacteria than water samples, but such quantitative evaluations of enumeration techniques have not been routinely reported. Use of IF in soils has been less successful, and low detection levels have been attributed to the specificity of IF assays, such that many different antibody preparations are required to detect the multitude of serotypes present. PCR-based methods might be an improvement, if their specificity could be manipulated to include all variants within the physiological type of interest (e.g., all *Nitrobacter* strains) and no cells of any other group (discussed later).

Ward and coworkers have used IF to enumerate nitrifiers in several different aquatic habitats (Table 1), having shown initially that IF enumeration was accurate and precise when compared to acridine orange counts at dilute cell concentrations (86). In Lake Bonney, a permanently ice-covered lake in Antarctica, *Nitrosomonas* serotype cells were present at maximum concentrations just above the oxic–anoxic interface, and *Nitrosococcus* serotype cells were present in a similar distribution but at lower levels (81). *Nitrosomonas* type cells were also enumerated by fluorescence in situ hybridization (FISH) using oligonucleotide probes designed to be specific for the *Nitrosomonas*/*Nitrosospira* group of ammonia oxidizers (87). Maximum abundances detected by FISH were slightly higher than those detected by IF (81), and the distribution of cells detected by FISH differed slightly from that detected by IF, perhaps reflecting the different specificity of the antibody and nucleotide probes. FISH has been applied in systems in which higher cell numbers and higher growth rates are found [e.g., sewage sludge; (88)], but has not been widely reported for nitrifiers in natural waters.

In a small survey of marine and estuarine sites, Ward (82) reported that *Nitrosomonas* serotypes were more abundant than *Nitrosococcus* and that total abundance of ammonia oxidizers (*Nitrosomonas* and *Nitrosococcus* serotypes) ranged from 10^4 cells mL^{-1} in Chesapeake Bay to 10^2 cells mL^{-1} in inshore ocean waters and 10 to 10^2 cells mL^{-1} offshore. Maximum abundances occurred near the bottom of the photic zone in the vicinity of the primary nitrite maximum in some environments (69), but such characteristic patterns are not always detected (Table 1). *Nitrosococcus oceanus* abundance, determined by IF, was positively correlated with temperature, particulate organic carbon and nitrogen, and total bacterial abundance, and negatively correlated with dissolved oxygen, in brackish Mediterranean lagoons (70). There was no relationship between IF and MPN counts over the 20-month sampling period of this study.

The results from FISH and IF measurements show that nitrifiers, generally, do not contribute a very significant portion of the total bacterial assemblage to natural water, leading to the conclusion that individual species of nitrifiers represent on the order of 0.1% of the total bacterial assemblage in the water column. Even in lakes where nitrifying abundances were higher, nitrifying cells contributed less than 0.01% of the total bacterial abundance. Even in recirculating aquaculture biofilters, supplied with high levels of ammonia, nitrifiers represent only 20% of the total eubacterial rRNA (88). This generalization is consistent with the autotrophic nature of nitrifiers, which requires that individual cells process relatively large amounts of nitrogen for minimal return in terms of carbon assimilation.

METHODS FOR MEASURING NITRIFICATION IN WATER AND SEDIMENTS

Direct measurement of the rate of nitrification is problematic for several reasons related to the sensitivity of the methods and potential artifacts introduced by incubation methods. The easiest experimental design might be simply to incubate samples and measure the concentrations of nitrite or nitrate over time. This approach provided some of the earliest evidence for the occurrence of biologically mediated nitrification (47,89). Vaccaro (48) estimated nitrification rates by measuring changes in nitrite and nitrate in incubated samples, from depths up to 800 m in the Sargasso Sea, in the presence of added ammonium or mixed whole plankton. He reported that both additions stimulated the net production rate of nitrite or nitrate. In such an experiment, accumulation of nitrite or nitrate indicates net nitrification. A decrease in the concentration over time could be observed, however, even when nitrification is occurring, if consumption of nitrate or nitrite exceeds production in the incubation bottle. The low concentration relative to high biological demand for fixed nitrogen in the surface water of the ocean and many lakes means that tight coupling between production and consumption terms can obscure large fluxes.

The addition of specific inhibitors has been used as a modification of the simple nutrient-measurement approach just described. In this approach, chemicals that specifically inhibit either ammonium oxidation (e.g., acetylene, allylthiourea, methyl fluoride, N-serve) or nitrite oxidation (chlorate) are added to replicate incubation bottles (90,91). The method assumes that the nitrite concentration is at a steady state in the sample, and that nitrification is the only process that produces or consumes nitrite. Clearly, the bottles must be incubated in the dark to prevent consumption by phytoplankton. One needs to only measure the concentration of nitrite over time in the bottles in which ammonium oxidation was inhibited to estimate the nitrite-oxidation rate (equal to the rate of nitrite decrease). The rate of nitrite increase in the bottles to which the nitrite-oxidation inhibitor was added equals the rate of ammonium oxidation. There are some potential problems with this approach: (*1*) preventing production by phytoplankton, probably, has cascading effects on the activities of other microbes in the bottle, such that the rate of ammonium mineralization is reduced, thus changing the source term for the nitrification substrate. (*2*) Incubating in the dark may release the nitrifying bacteria from light inhibition such that the measured rate exceeds the in situ rate. (*3*) Incubations typically last 48 hours, which is sufficient to overcome the lag induced by light inhibition, but is also long enough to create quite unnatural conditions. The search for precisely specific inhibitor compounds has been extensive and has resulted in a plethora of potentially useful compounds. Many are problematic, for reasons not directly related to nitrification. For example, acetylene inhibits both nitrifiers and denitrifiers (92,93). Thus, its use to measure one process will also inhibit the other, and when one depends on the other (as is the case when denitrification depends on nitrification for nitrate), both rates are affected and the independent measurement of one is not possible. It is reported that the length of exposure to acetylene can be optimized to differentiate between its effects on nitrification and denitrification (94). N-serve is a commercial preparation that specifically inhibits ammonia-oxidizing bacteria (95) and it serves as the basis for the sensitive $^{14}CO_2$ method for the measurement of nitrification rates (discussed later). Being chemolithoautotrophs, nitrifiers fix carbon dioxide while oxidizing nitrogen. The amount of carbon dioxide fixation due to nitrifiers can be computed by difference between incubations, with and without addition of an inhibitor that specifically removes the contribution of nitrifiers (90,96,97). Then, a conversion factor is used to translate the carbon dioxide fixation into ammonium and nitrite-oxidation rates. This conversion factor has been shown to vary in the case of ammonia oxidizers by a factor of five in pure cultures (90,98), and thus its use introduces some uncertainty because the factor cannot be directly determined in field samples.

In addition, N-serve is not soluble in water, and so its addition to samples requires that it be dissolved in an organic solvent. This solvent can affect the other members of the community, and the use of ethanol has been shown to stimulate dark carbon dioxide incorporation by heterotrophic bacteria (3,79). Thus, in systems in which

nitrifiers are a very small part of the overall assemblage, the N-serve approach may yield artifacts (3,99,100).

Unfortunately, a direct radioisotope-tracer method is not very useful for measuring rates of nitrification in the environment. Capone and coworkers (101) demonstrated the use of ^{13}N to quantify nitrification rates, but the isotope is so short-lived (10 minutes) that its use is usually impractical. The other main approach to measuring nitrification rates directly is to use the stable isotope, ^{15}N, as a tracer (102,103). This approach is not without its problems, mainly due to the facts that ^{15}N has a significant natural abundance and that it must be measured using a mass spectrometer or emission spectrometer, both more expensive and difficult than using a scintillation counter for radioisotopes. Somewhat shorter incubations are possible (a few hours to 24 hours are commonly used). The signal of transfer of the tracer from substrate to product pool (e.g., $^{15}NH_4$ to $^{15}NO_2$) can be detected regardless of what other processes are occurring in the incubation (so in situ light conditions can be used) and no assumptions of steady state need be made. The major drawback of this method is the necessity to add a tracer, sometimes in excess of the natural concentration of substrate. This problem has been largely overcome by the advent of more sensitive mass spectrometers, however, and estimates obtained under conditions approaching in situ may be possible.

The ^{15}N approach is most useful in water samples because complete mixing of the tracer is possible. In sediments and soils, rate measurements are constrained by the inhomogeneous nature of the sample and the dependence of rates on the structure of the environment. In this situation, fluxes between overlying water and sediment cores can be analyzed to obtain areal rates. In conjunction with ^{15}N tracer addition, estimates of nitrification rates can be obtained from the dilution of nitrite or nitrate in the overlying water because of its production in the sediments (104). The isotope-pairing method for the measurement of denitrification (105,106) is essentially a modification of an isotope-dilution approach and provides information on nitrification rates as well. Inhibitor approaches similar to those described earlier for water samples have been used in sediments (107,108). The methylfluoride method (108,109) seems particularly promising because the gas can diffuse thoroughly into the core with minimal disturbance of microzones and gradients. This ammonium oxidation inhibitor is added to cores and the accumulation of NH_4^+ over time is assumed to represent the net rate of nitrification. Other processes that consume ammonium would lead to an underestimate of the rate.

To overcome the biasing resulting from uneven dispersal of tracer or inhibitor, sediment rate measurements are often made in slurries, which destroy the gradient structure of sediments, which is essential to the in situ fluxes. Slurries may provide useful information on potential rates, but not in situ rates. Even if rate measurements in sediments are made using whole-core incubations, for example, when the inhibitor is a gas, it is still difficult to obtain a depth distribution of the rate (usually, an areal rate is obtained). A sophisticated measurement and model-based system that avoids direct rate measurements has been used to overcome this problem. Microelectrodes that have very high vertical resolution are used to measure the fine-scale distribution of oxygen and nitrate in freshwater sediments. By assuming that the observed vertical gradients represent a steady state condition, reaction-diffusion models can be used to estimate the rates of nitrification, denitrification, and aerobic respiration, and to compute the location of the rate processes in relation to the chemical profiles (110,111). The major drawback to this approach is the lack of microelectrodes for nitrate that can be used in seawater (although recent developments in biosensors may overcome the carbonate interference that is problematic in seawater).

Incubation methods, whether enclosing water in a bottle or bag or sediment in a coring tube, may introduce unavoidable artifacts. Approaches that avoid incubations altogether are therefore attractive, but they are largely limited to measuring changes in chemical concentrations over time, and therefore can detect net transformation rates only. The compromise made by most investigators is to maximize the size and minimize the length of incubations to minimize artifacts associated with wall growth or preferential inclusion or exclusion of grazers.

DISTRIBUTION OF NITRIFICATION IN WATER AND SEDIMENTS

It was long ago recognized that nitrification must be a process of some consequence in aquatic systems; the major nitrogen product of organic matter decomposition is ammonium, but the huge volume of the deep ocean contains nitrate at 40 μM concentrations and ammonium at trace or undetectable levels. Therefore, it seemed obvious that nitrification must be occurring in the deep ocean. Nitrate concentrations in the surface ocean are usually maintained at low levels because phytoplankton assimilate nitrate more rapidly than it can be supplied by mixing or diffusion from the deep nitrate reservoir. Ammonium, which is produced in the photic zone by heterotrophic processes, is also usually immediately assimilated by phytoplankton before it can be nitrified. The recognition that ammonium and nitrate have different sources, and that the differences are important both physically and biologically, led to the application of the New Production Paradigm (112,113) as a way to understand phytoplankton nitrogen demand and growth in the surface ocean, and the subsequent flux of nitrogen to the deep sea and ocean floor (Fig. 2). Ammonium is considered a "regenerated" source of nitrogen because it is produced largely in situ, in the same water where phytoplanktons live and use it. The nitrogen in ammonium is recycled rapidly and repeatedly between living biomass (phytoplankton, the zooplankton which graze on them, protozoans, bacteria) and the inorganic nutrient form, which is released from heterotrophic metabolism and grazing.

Nitrate, on the other hand, is considered to be "new" nitrogen because it is not present in the euphotic zone most of the time. For phytoplankton to use it, nitrate must be

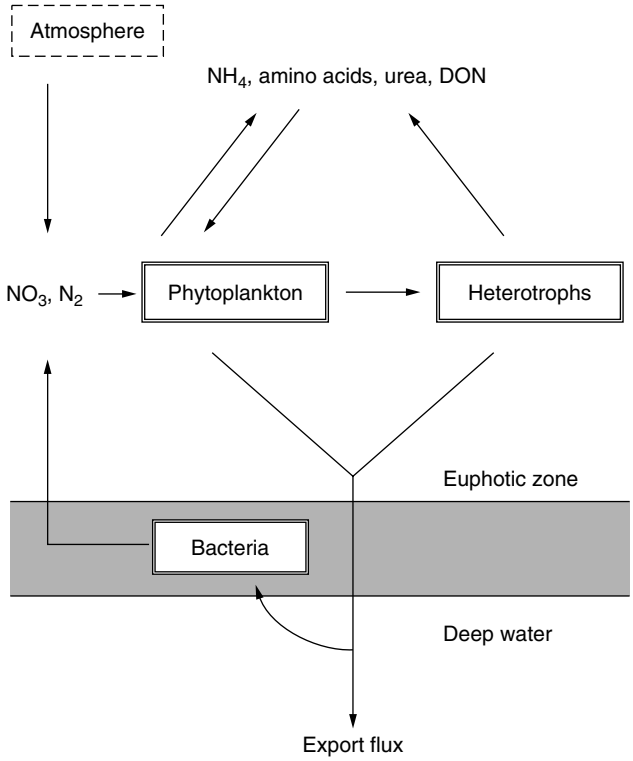

Figure 2. Schematic representation of the New Production Paradigm to explain the processes, which supply nitrogen to the euphotic zone of the ocean (after Eppley and Peterson, 1979). If the shaded area is below the euphotic zone, the nitrate produced there will enter the surface layer as a new nutrient (by physical processes). If the shaded area is within the euphotic zone, the nitrification occurring there will supply regenerated nitrate.

transported into the system by physical means, that is, by mixing or upwelling from deep water or falling in rain, and the rate of nitrate supply can be equated with the steady state rate of primary production on the basis of nitrate as a nitrogen source (113). This equality makes it possible to measure "new production," and by inference, the sinking flux of nitrogen, by measuring the assimilation of nitrate in incubated samples. This perception of nitrate as a new nutrient is consistent with the idea that nitrification, leading to the accumulation of nitrate, occurs in deep water, and not in the euphotic zone itself.

Nitrification Rates in Marine Systems

Actual measurements of the depth distribution and rate of nitrification, however, showed this picture, with most of the nitrification occurring in the deep ocean, to be an oversimplification. The greatest nitrification rates, both ammonium oxidation and nitrite oxidation, occur not in the deep ocean, but in a region near the bottom of the euphotic zone. In this depth interval, the light intensity is very reduced and phytoplankton are light-limited, and their rates of nutrient assimilation are therefore reduced. It is in this interval that nitrifying bacteria can compete with phytoplankton for ammonium; one often observes a sharp peak in nitrification rate at a depth in the water column where light intensity has been reduced to 5 to 10 % of surface light intensity (114,115).

Rates of nitrification reported for the open ocean are in the range of a few to a few hundred nanomolar per day, and have been detected as deep as 3,000 m (116). Rates of nitrification reported in various aquatic environments are presented in Table 2. Where profiles extending to a depth of several hundred to a few thousand meters are available, the main pattern that emerges is the association of the highest rates of ammonia oxidation with the lower region of the photic zone (Fig. 3). In the eastern tropical North Pacific, ammonia-oxidation rates at the maximum were no more than 20 nM d^{-1} (116). In the Peru upwelling region, a maximum rate of 747 nM d^{-1} was reported (115). In the temperate eastern Pacific Ocean, off western North America, maximum rates of 45 nM d^{-1} were reported (114). Nitrite oxidation shows a less predictable distribution with depth; in the Peru upwelling system, maximum rates of 600 nM d^{-1} were observed near the lower boundary of the euphotic zone, but high rates (e.g., nearly 300 nM d^{-1}) were observed within the oxygen-minimum zone (115).

Several studies of nitrification rates have focused on the primary nitrite maximum, rather than attempting complete depth profiles. Dore and Karl (97) reported a few rate measurements on the basis of inhibitor experiments from the central Pacific Ocean. Ammonium- and nitrite-oxidation rates were usually comparable, and were maximal just below the primary nitrite maximum. Bianchi and coworkers (128) reported nitrification rates up to 1 to 2 μM d^{-1} in the Rhone River Plume, with rates decreasing to the usual oceanic levels with increasing distance from shore in the Mediterranean Sea.

The rate of nitrification in deep ocean water is minimal, because of the decreasing flux of ammonium from organic matter decomposition with increasing depth. Thus, in many parts of the ocean, the typical depth-distribution of nitrification shows a subsurface maximum that occurs near the bottom of the euphotic zone, and very low rates persisting to great depths. The great accumulation of nitrate in the deep sea is, therefore, due to a small production term and a lack of any significant consumption terms.

Based partly on anecdotal evidence from culture work, observations in waste water treatment systems with very high particulate loads, and the prevalence of small particles in natural water, it has been suggested that nitrification occurs mainly on particles and is mediated by particle-attached bacteria (5). Phillips and coworkers (129) found nitrifier sequences associated both with particles and in the water (planktonic) in the northwestern Mediterranean Sea. The relative distribution of *Nitrosomonas* versus *Nitrosospira* clones differed between particles and planktonic samples, indicating niche preference by different species. The relative contribution to nitrification rates by particle-associated versus truly planktonic-nitrifying bacteria is difficult to assess. The distribution of rates as a function of depth indicates that rapidly sinking, that is, large, particles cannot be the main site of the process; nitrification associated with suspended small particles could be consistent with the typical subsurface rate maximum that is characteristic of oceanic water. Lavrentyev and coworkers (130) found that nitrifiers appear to escape predation

Table 2. Nitrification Rates Reported from Aquatic Systems

Location	Depth (m)	NH_4^+ Ox Rate (nmol l^{-1} d^{-1})	NO_2^- Ox Rate (nmol l^{-1} d^{-1}	Method	Reference

by protozoans by aggregating into particles that are too large to be grazed. Thus, a trophic effect on nitrification is implied, which also has ramifications for the planktonic versus particle-associated question.

Distribution of Nitrification in Lakes

Nitrification is also recognized as an important nitrogen flux in lakes, but seasonality and individuality of lakes makes impossible generalizations, such as those that apply to the ocean. Hall reviewed studies before 1986 (52), and relatively few studies focused on rate measurements in lakes have been published since that time. Hall referred the reader to the review (52) and a short summary of that work is presented here. For typical temperate lakes that undergo seasonal stratification, nitrification rates are maximal at overturn or during the winter circulation period. Thus, nitrate builds up in the water column, and is subsequently depleted in the surface water after summer stratification sets in. Nitrification activity tends to be low in the summer, and to increase with depth. All of these aspects of the pattern of nitrification activity can be at least partially explained by ammonium availability. During stratification, ammonium is depleted in surface water by algal assimilation, and it builds up in the deep water as a result of organic decomposition. If the decomposition depletes oxygen in the deep water, nitrification is inhibited. When overturn occurs, ammonium and oxygen are mixed throughout the water column, stimulating nitrification. Ammonium concentrations may be greatest near the sediment–water interface, even in hypolimnions where oxygen is not completely exhausted, thus explaining the increase of nitrification rates with depth. Light inhibition has also been invoked to explain the increase in nitrification rates with depth (131) (illustrated later). The hypolimnion of seasonally stratified lakes is relatively isolated for months at a time, during which nitrate often accumulates. Nitrification is, generally, accepted as responsible for the accumulation, but whether it is mediated by planktonic bacteria or by bacterial population in the sediments apparently varies with ecosystem type. In more eutrophic lakes, the accumulation of nitrate is rapid after stratification, but a long period of stratification promotes depletion of the nitrate by denitrification.

Much recent work on nitrification in lakes and shallow systems has focused on the sediments in which where most of the nitrification activity is believed to occur. Sediments are typically layered systems in which nitrification and denitrification are closely coupled across the oxic/anoxic gradient. Pauer and Auer (76) concluded from their work in a hypereutrophic lake that the water column did not contribute significantly to nitrification in the system, and that the major site for nitrification was the sediment. Use of microelectrodes and isotope-pairing studies and reaction-diffusion models (106,110,111,132,133) mainly intended to quantify denitrification, and have quantified the close linkage between the two processes in lake and estuarine sediment systems. The main role of nitrification is to oxidize ammonium to nitrate, which is then consumed by denitrification. Nitrate does not buildup in the system. Concentrations of oxygen, ammonium, and nitrate are all important in regulating rates of nitrogen cycling, often in counterintuitive ways (discussed later).

The magnitude of nitrification rates in sediments can be much higher, and is certainly more variable than those reported from water column measurements (Table 2). The variability arises not only from the small-scale heterogeneity inherent in sediments (partly also because of bioturbation and association of nitrification with the walls of faunal tubes in the sediments), but from the wide range in the level of organic matter input into sediments in shallow water. Irrigation by worm tubes and sediment infauna has been shown to increase nitrification rates

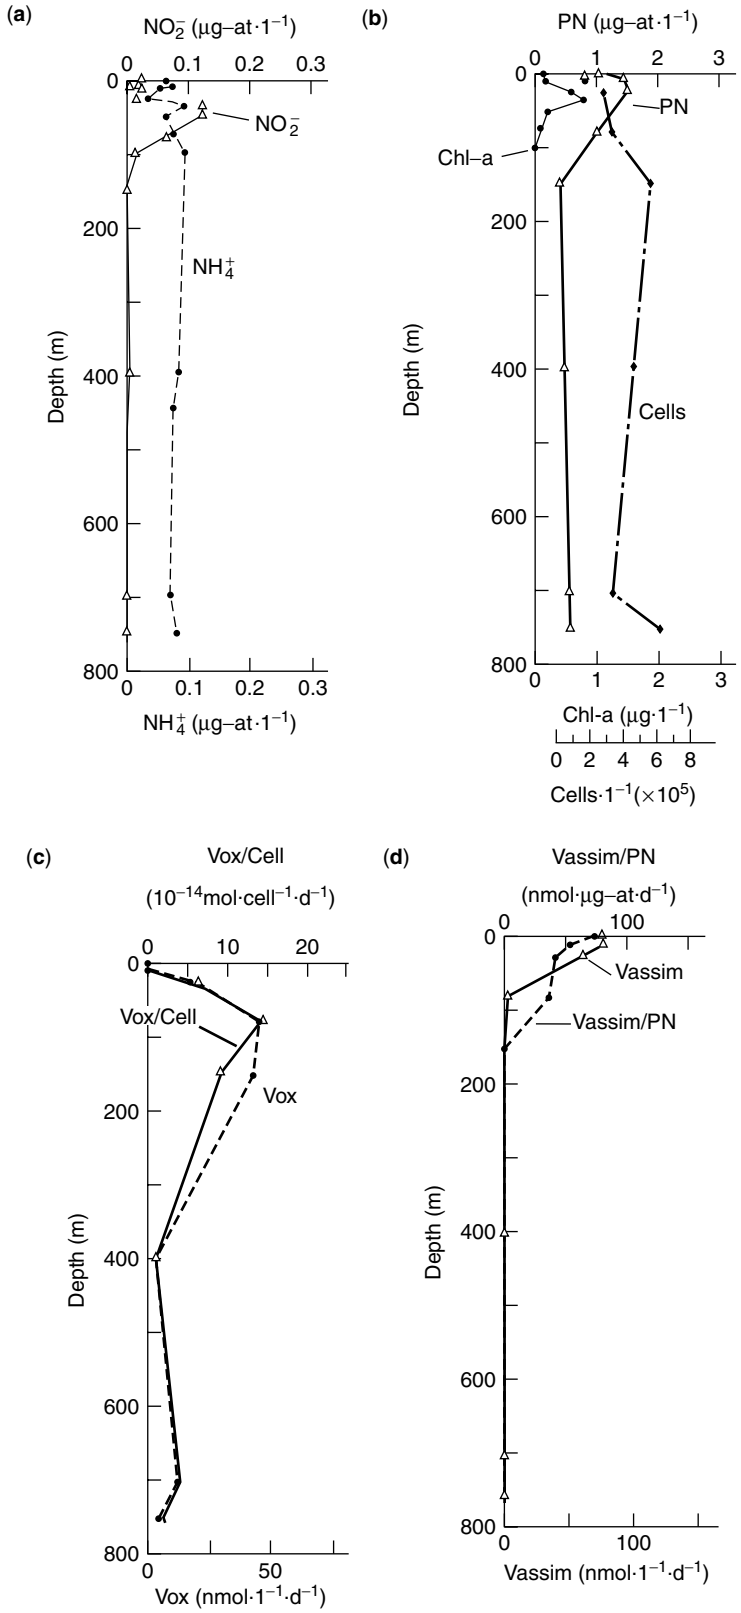

Figure 3. Distribution of variables at a station in the Southern California Bight. (**a**) Ammonium and nitrite. Microbiol.* **50**, (1985).

by increasing oxygen availability (134–136). In both deep and shallow sediments, nitrification can be one of the main sinks for oxygen in sediments (137,138). Very high nitrite and nitrate fluxes to the water column from sediments, including coral reefs (101,126) and sponge-dominated reef surfaces (127), have been attributed to nitrification associated with invertebrates and biotic sediments.

ENVIRONMENTAL VARIABLES THAT AFFECT NITRIFICATION RATES AND DISTRIBUTIONS

As mentioned earlier, in the general discussion of the depth distribution of nitrification rates, variables such as light intensity and substrate concentration are important determinants of the magnitude and location of nitrification rates. These are the kinds of variables that determine much of the biogeochemical cycling in the environment, and so their influence on nitrification is not surprising. Their effects have been studied, in both laboratory culture experiments and in field samples, using incubations and measurements of natural assemblages. Two useful overviews of research into the ecological and environmental factors that influence nitrification were published (2,5).

Temperature

The effect of temperature, although of potential importance in wastewater systems in which nitrifying bacteria are cultured under artificial conditions, is not generally considered to be an important environmental variable for nitrification because bacterial populations are generally adapted to the temperature of their environments. Thus, one can demonstrate a classical dependence of the rate of nitrification on temperature in any particular environment, but temperature is not generally the limiting factor. The optimum rate is usually attained at temperatures exceeding ambient temperature, but the observed rate of nitrification indicates that the in situ population is adapted to its ambient temperature. In other words, nitrifiers adapted to low temperature can nitrify under low-temperature conditions at rates comparable to the rates attained by nitrifiers adapted to higher temperatures living under high-temperature conditions. Thamdrup and Fleischer (139) found that the nitrification rate was highly adapted to temperature in arctic sediments, with temperature optima ranging from 14 to 40 °C, depending on the temperature of the environment. In the sediments of a eutrophic lake, bioturbation-stimulated nitrification rate and associated N_2O release at 15 °C, but there was no stimulation at 10 °C, implying perhaps complex trophic interactions and temperature in determining biogeochemical rate processes (136). Although temperature is an important master variable for biological processes, nitrification is, if anything, less sensitive to regulation by temperature than other processes, and is usually regulated in the environment by some other variable.

Inhibitory Compounds

Nitrifying bacteria, both ammonia oxidizers and nitrite oxidizers, but especially the former, are susceptible to inhibition by a wide range of compounds, and several different modes of action have been suggested (140). The two most common modes of action are (*1*) interference with the active site of the primary enzyme (i.e., AMO in ammonia oxidizers) by compounds that share structural homology with ammonia and (*2*) metal-binding compounds, which interfere with the action or availability of copper in the ammonia-oxidizing enzymes. In both ammonia and nitrite oxidizers, the susceptibility of key enzymes in the nitrification pathways form the basis of methods used to measure the rate of nitrification (as mentioned earlier).

In terrestrial systems, the presence of certain organic compounds (e.g., monoterpenes produced by plants) has been proposed to limit the rate of nitrification and the inhibition of nitrification in acid soils has long been of concern. The potential of naturally occurring organic compounds to inhibit nitrification in seawater has not been considered very much. Inhibition by organosulfur compounds has been demonstrated in cultured marine ammonia oxidizers (141) and the inhibitory effect of sulfide on nitrification is thought to limit nitrification and coupled nitrification/denitrification in marine sediments [discussed later (142)]. Although naturally occurring organic compounds have not been investigated as potential inhibitors in seawater, the product of their photodecomposition, carbon monoxide, has been implicated (143). Although carbon monoxide, like methane, acts as a substrate analog or a suicide inhibitor for ammonia oxidizers, the direct inhibitory effect of light on nitrifiers (see in the following text) is considered to outweigh the potential effect of carbon monoxide inhibition in surface water. As a substrate analog, carbon monoxide can be oxidized by ammonia-oxidizing bacteria, and R. D. Jones (144) proposed this method for quantification of ammonia-oxidation rates in natural systems. Like methane oxidation (12), however, the rate of carbon monoxide oxidation by nitrifiers depends on the relative concentration of alternative substrates, which may cause artifacts in relating overall rates of carbon monoxide oxidation to nitrification.

Light

The inhibitory effect of light was reported by German researchers in the 1960s (145,146), verified in enrichment cultures in seawater (147) and later described in more detail (148). Horrigan and coworkers (147) showed that even in enrichment cultures of nitrifiers derived from the sea surface film, nitrification was severely inhibited by light, such that periods of more than 12 hours darkness were necessary to allow net nitrification to occur over a 24-hour period. Vanzella and coworkers (148) found evidence that nitrite oxidizers were more sensitive to sunlight than were ammonia oxidizers, on the basis of single culture studies, but Guerrero and Jones (149) showed that species-specific responses might obscure any generalizations among major groups. Horrigan and Springer (150) reported that oceanic strains of ammonia oxidizers were, generally, more sensitive to light inhibition than were estuarine strains. Degree of inhibition was inversely correlated with ammonia-oxidation rate, but the mechanism of this relationship could not be determined.

Horrigan and Springer (150) argued that the greater sensitivity of oceanic ammonia oxidizers might be responsible for the generally lower rates of ammonia oxidation observed in oceanic versus river or estuarine environments, but the complex of other factors such as overall rates of material processing could not be independently evaluated.

Ammonia- and nitrite-oxidation rates are often reported to be highly coupled and to occur at about the same rate. This coupling would be consistent with the observation that neither ammonium nor nitrite accumulates at high levels in most natural waters. For nitrite, the exceptions to this rule are the primary nitrite maximum of near-surface water, and the secondary nitrite maximum characteristic of oxygen-minimum zones. The surface water feature has been attributed to two possible processes. Because the primary nitrite maximum is usually associated with low light intensities at the bottom of the euphotic zone, some interaction between biological processes and light is suspected. In one scenario, phytoplanktons are responsible; assimilation of nitrate (by reduction to nitrite and then to ammonium) requires energy, especially the step at which nitrite is reduced. Under low light intensity, phytoplankton might not have sufficient energy to reduce the nitrate completely, and some of the intermediate nitrite is allowed to leak out of the cell. In the alternative scenario (151), nitrifying bacteria are responsible; nitrite oxidizers are more sensitive to light inhibition than are ammonia oxidizers, and so ammonia oxidizers are able to be active at slightly shallower depths in the water column than are nitrite oxidizers. This leads to an accumulation of nitrite in the interval between the depths at which ammonia- and nitrite-oxidizers are released from light inhibition.

Several studies of nitrification rates in surface seawater from various geographic regions show profiles that are consistent with light inhibition (68,103,114,115,119). Simulated in situ rate measurements (i.e., measured under simulated in situ light conditions) show a clear negative relationship with ambient light intensity (Fig. 4). Nitrifiers may be somewhat protected from light inhibition in surface water by the presence of absorbant organic compounds in seawater. However, the data from simulated in situ rate measurements are consistent with light inhibition in surface water, and the well-verified sensitivity of nitrifiers in culture strongly suggests an influence of light in the environment. Dore and Karl (97) did not directly assess the effect of light on nitrification rates (all rates were measured in the dark) but they attributed two distinct features within the primary nitrite maximum to phytoplankton (the upper primary nitrite maximum) and nitrifiers (the lower primary nitrite maximum). Mortonson and Brooks (152) concluded that phytoplankton were responsible for a primary nitrite maximum in Lake Michigan, on the basis of seasonal correlations between chlorophyll and nitrite; however, direct experimental evidence was not available. The relative contribution of phytoplankton versus nitrifying bacteria to the maintenance of this feature is apparently still unresolved and both may be involved.

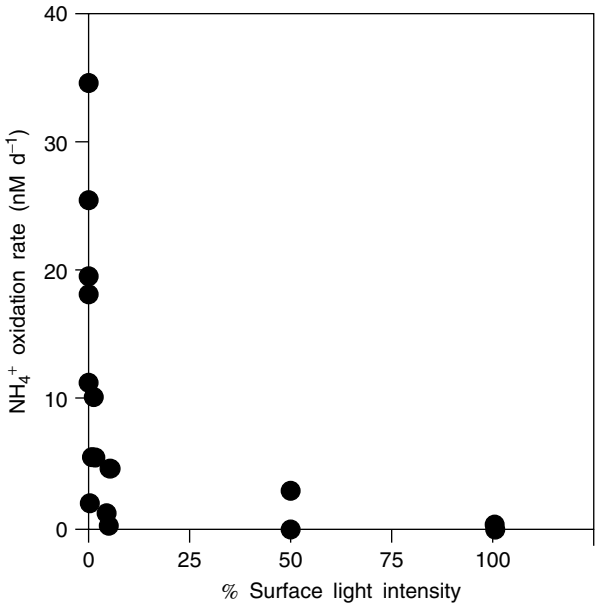

Figure 4. Ammonium-oxidation rate versus surface-light intensity for combined data from three stations in the Southern California Bight (approximately 33°20 N', 118°30′ W). Rates measured using ^{15}N tracer methods. With permission from B. B. Ward and A. F. Carlucci, *Appl. Environ. Microbiol.* **50**, (1985).

Lipschultz (153) documented the light inhibition of ammonia oxidation in the Delaware River, and concluded that this effect influenced the spatial distribution of nitrification in the estuary. Depending on their depth, light is not usually a problem for nitrification in sediments. In shallow sediments, light may have an indirect positive effect on nitrification rates by increasing photosynthesis, and thus increasing oxygen supply to the sediments [see in the following text; (124)].

Nitrification in the Euphotic Zone. Independent of their potential involvement in the primary nitrite maximum, it is significant for other reasons that nitrification rates are often maximal in the vicinity of the bottom of the euphotic zone. The important distinction made in the new production paradigm (as mentioned earlier), between ammonium, which is the "regenerated" nutrient and nitrate, the "new" nutrient is the basis of ^{15}N-tracer methods to assess new and regenerated primary production. However, if nitrification occurs in the same depth interval in which nitrate assimilation occurs, then nitrate too is a "regenerated" nutrient. Then, total nitrate assimilation would depend on a combination of nitrate supplied by nitrification and that supplied by mixing from the deep reservoir. Several studies have addressed the question of whether significant nitrification occurs in the euphotic zone and have concluded that in situ nitrification could supply 100% or more of the phytoplankton nitrate demand (91,97,154). Thus, nitrification and nitrate assimilation by phytoplankton can be closely coupled, although the two processes are favored by quite different environmental conditions.

Substrate Concentration

The influence of light may be compounded by the necessity for ammonia oxidizers to use ammonium, which is in short supply at those depth intervals in the water column where light is most intense. When ammonium assimilation and ammonium oxidation are measured in the same incubation, it is seen that assimilation occurs in the upper portion of the euphotic zone and nitrification in the lower portion (Fig. 3). This pattern suggests that in the well-lit upper water, phytoplankton are able to assimilate ammonium but nitrifiers are either unable to compete for ammonium in the presence of phytoplankton or else, light inhibition prevents them from using ammonium in that environment. In the lower portion of the euphotic zone, phytoplankton may be light-limited and unable to assimilate ammonium, whereas nitrifiers are released from light inhibition and able to use the ammonium being released by heterotrophic decomposition in that interval.

The influence of substrate concentration on nitrification rates is expected to be a first-order dependence and, indeed, this response is usually observed in culture. The instantaneous rate of ammonium oxidation or nitrite oxidation increases predictably with increasing ammonium or nitrite concentration in culture experiments. However, researchers often have been unable to demonstrate consistent substrate dependence for ammonia oxidizers in natural assemblages. A general relationship between measured ammonium-oxidation rate and ambient ammonium concentration supports the importance of substrate concentration (Fig. 5). Vaccaro (48) found that net nitrite and nitrate accumulation in samples from the Gulf of Mexico were stimulated by the addition of ammonium. In ^{15}N tracer experiments on water samples, when substrate additions are made, the micromolar level representative of the environment, ammonium oxidation, is usually independent of substrate concentration. Lack of response to substrate perturbation (102,155) has led to speculation that the affinity of ammonia oxidizers for ammonium may be so great that current experimental methods cannot detect a response to enhanced substrate concentrations. In contrast to ammonia oxidation, nitrite oxidation in natural samples usually shows a more conventional response to added substrate (102), but this second step in the nitrification process has received somewhat less attention.

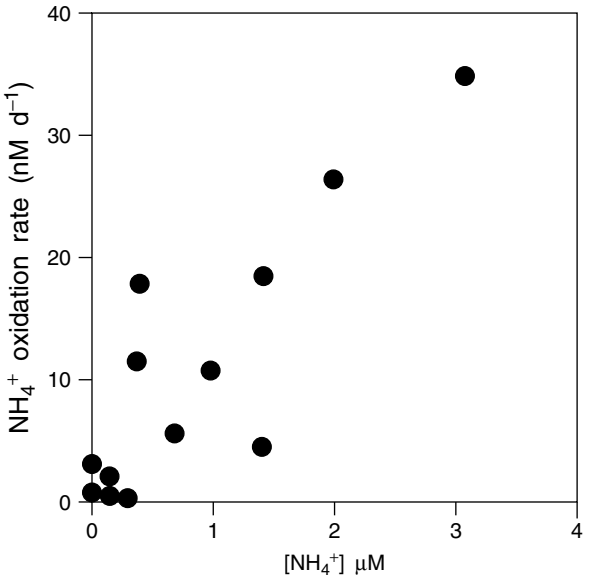

Figure 5. Ammonium-oxidation rate versus ambient ammonium concentration for combined data from four stations in the northeastern Pacific Ocean (approximately 47°07′ N, 125°W). Rates measured using 15 N tracer methods. With Permission from B. B. Ward and A. F. Carlucci, *Appl. Environ. Microbiol.* **50**, (1985).

Ammonium has been shown to have a direct effect on nitrification rates in freshwater sediments. In the absence of added ammonium, nitrification was restricted to a narrow interval in the sediment just above the denitrification zone. When ammonium was added to the core, oxygen became limiting and nitrification occurred throughout the oxygenated region of the core (125).

Oxygen Concentration

Oxygen concentration is also an important variable in determining nitrification rates; nitrifiers are reputed to be microaerophiles. Although requiring molecular oxygen for reactions in the nitrogen-oxidation pathways and for respiration, they are considered to thrive best under relatively low oxygen conditions. For example, Goreau and coworkers (156) reported that *Nitrosomonas* sp. marine grew best under an oxygen concentration of 1% in the headspace (compared with 20% in air) and this result has been extrapolated to nitrifiers in general. The proportion of ammonium that is oxidized to nitrite versus released as gaseous intermediates also varies with oxygen tension (see in the following text).

Microaerophily may be important in interface environments such as the sediment–water interface and in the oxygen-minimum zones of the ocean. In the sediment environment, for example, ammonium (derived from anaerobic decomposition in deeper layers) diffuses up toward the sediment–water interface and oxygen diffuses into the sediments from the overlying water. At the interface, nitrifiers find an optimum environment. In such an environment, nitrification can be directly linked to denitrification through their common intermediates (including nitrite, nitrate, nitrous, and nitric oxides). The nitrate produced during nitrification, along with the nitrate that diffuses into the sediments from the overlying water, helps support denitrification in subsurface sediments. In the sediment interface environment, the zone in which nitrification occurs may be less than a millimeter thick, or it may extend for several centimeters into the sediments, depending on the environment and the organic loading to the system.

The coupling between obligately aerobic nitrification and facultatively anaerobic denitrification is the classical way in which oceanographers view the linkage between the two processes in the environment. Vertical gradients of oxygen, nitrate, nitrite, and ammonium are consistent with the stratification of the processes imposed by the physiological constraints of the organisms in relation to the distribution of variables in the environment. The dependence of the depth distribution of nitrification and

denitrification on oxygen distribution has been shown elegantly in freshwater sediments (124). In this experiment, the oxygen penetration into microbial mat sediments varied on a diel light/dark cycle as photosynthesis proceeded at day and ceased at night. Oxygen and nitrate concentrations were measured using microelectrodes or biosensors and nitrification and denitrification rates were modeled using a reaction/diffusion model. Nitrification occurred only in the daylight when oxygen was available from photosynthesis. At night, photosynthesis ceased and oxygen penetration into the mat was insufficient to support nitrification. The counter effect of light potentially inhibiting nitrification was apparently not a problem; light penetration in sediments even during the day was not sufficient to inhibit. The absence of nitrification in surface sediments at night was mysterious, and was attributed to inhibition of nitrifiers by unknown chemical components of the sediments and pore water. Such direct demonstration of these interactions among photosynthesis and nitrification has not been possible in marine sediments to date, but it seems likely that the same relationships pertain, except for the confounding effect of sulfide.

Nitrifying bacteria living in marine sediments that are periodically or persistently exposed to anoxic conditions would need to be able to survive periods of inactivity or even serious inhibition to recover when conditions improved. The physiological basis of this survival or tolerance of anoxic conditions is unknown, and the degree to which nitrifiers can recover from serious anoxia is questionable. Joye and Hollibaugh (142) showed in microcosm studies that nitrification was almost completely inhibited by sulfide, the end product of bacterial sulfate reduction that occurs widely in anoxic marine sediments. A pulse of sulfide, which was detectable in the sediments for only a few hours, inhibited nitrification for at least 24 hours. Thus, in marine sediments in which sulfate reduction occurs, the ability of nitrifiers to respond to daily oxygen fluctuations may be impeded. Even when the oxygen–sulfide interface deepens during the day, nitrifiers may be unable to recover from the sulfide poisoning. In that case, both nitrification and denitrification (which is partially dependent on nitrate supply from nitrification) may occur at slower rates than would be predicted for similar environments in freshwater sediments (in which sulfate, and therefore sulfide, release from sulfate reduction is much less prevalent). In contrast, Jensen and coworkers (125) reported that nitrification could be stimulated essentially instantaneously by the addition of oxygen to sulfidic freshwater sediments. Using microelectrodes to measure oxygen and nitrate profiles in a sediment core, Jensen and coworkers (125) detected an almost immediate increase in nitrification rate when anaerobic sediments were aerated, implying that nitrifiers are inhibited but not poisoned by sulfide. When sediments were allowed to equilibrate with overlying water of differing oxygen concentrations, the zones of nitrification and denitrification stabilized at greater depths with increasing oxygen concentration, reflecting oxygen penetration into the core (Fig. 6; 111).

This picture may be further complicated by the suggestion that nitrifiying bacteria are in fact not obligate aerobes (as mentioned earlier). Although net nitrification and growth at the expense of inorganic nitrogen occurs only under aerobic conditions in autotrophic nitrifiers, both ammonia- and nitrite-oxidizing nitrifiers are apparently capable of partial or even complete denitrification. Loss of fixed nitrogen has been observed in cultures of nitrifying bacteria growing on reduced oxygen tension, including the report by Goreau and coworkers (156) cited earlier. Not only did the ammonia oxidizers grow best at 1% oxygen on a lithotrophic medium (no organic substrates), but they also produced the greatest amount of nitrous oxide relative to nitrite under those conditions. The annamox process leads to loss of fixed nitrogen as dinitrogen gas production from ammonium. Production of nitrous oxide, nitric oxide, and dinitrogen was reported for *Nitrosomonas* growing in the presence of organic compounds in the absence of oxygen (157). *Nitrosomonas* could also grow using hydrogen as an electron donor and nitrite as its electron acceptor (158). Nitrite oxidizers can grow by dissimilatory nitrate reduction in the presence of organic matter and the absence of oxygen (159).

The potential ecological impact of this physiological versatility in nitrifying bacteria has not been widely investigated in natural systems. (They have received much more attention in connection with sewage and wastewater treatment, in which there is economic incentive to enhance the conversion of ammonium to nitrogen gas under totally anaerobic or totally aerobic conditions.) The conditions that are conducive to denitrification by nitrifying bacteria are the same ones that induce denitrification in classical denitrifying bacteria. It is conceivable that both metabolic types are involved in the process. Thus, the net inorganic nitrogen distribution that we observe might be a more complex function of multiple processes than presently appreciated.

NITROUS OXIDE AND NITRIC OXIDE PRODUCTION DURING NITRIFICATION

The aspect of the nitrifiers' reductive metabolism that has received the most attention is the potential contribution of nitrifying bacteria to the production of trace gases such as nitrous and nitric oxide in the water column and sediments. Ammonium oxidizers produce both N_2O and nitrogen monoxide in culture, and the relative proportion of product that appears as gas increases at low oxygen concentrations (156,160). These gases are also intermediates in denitrification, but could derive from nitrification under low or zero oxygen concentration. Both N_2O and NO are involved in important atmospheric processes; they contribute to greenhouse warming and to catalytic destruction of stratospheric ozone. Thus, understanding processes that are responsible for their production could prove to be important for understanding or potentially regulating their fluxes.

A significant positive correlation between apparent oxygen utilization (AOU) and N_2O accumulation is often observed in marine systems (161,162). The relationship implies that nitrification is responsible for N_2O accumulation in oxic water, where it is released as a by-product

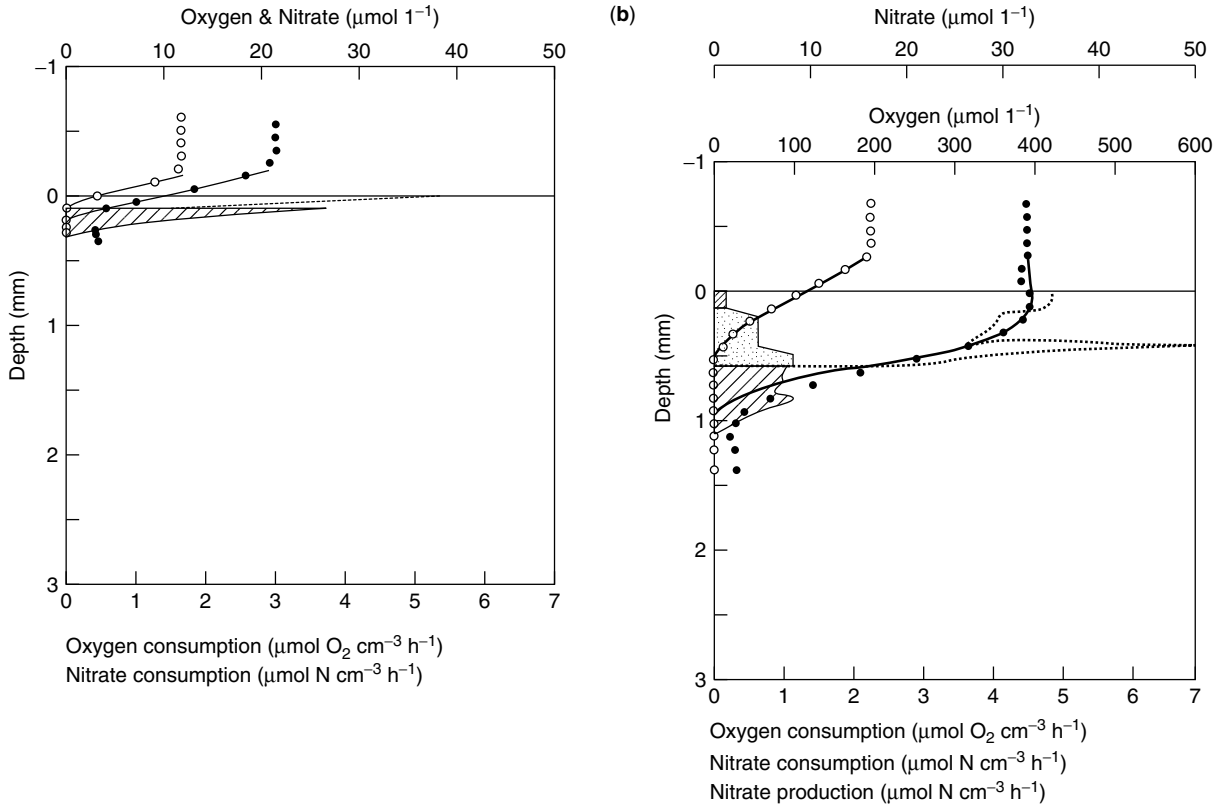

Figure 6. Steady state concentration profiles of oxygen (O) and NO_3^- (•) measured in sediment incubated in a continuous flow-through system with 10 (A), 200 (B), 400 (C), and 600 (D) μ MO_2 in the overlying water. The modeled oxygen and NO_3^- profiles are indicated by solid lines (diffusion-reaction model). The distribution and magnitude of the volume-specific activities of oxygen consumption, net NO_3^- production, and NO_3^- consumption are indicated by the white (enclosed by the broken line and the axes), the stippled, and the hatched areas, respectively. Note the differences in scales. The sediment was incubated with no NH_4^+ in the overlying water. With permission from K. Jensen et al., *Appl. Environ. Microbiol.* **60**, 2,094–2,100 (1994).

of mineralization going to completion by nitrification. The relationship breaks down at very low oxygen concentrations, in which N_2O is usually below atmospheric saturation because of consumption by denitrification. In a few special places in the open ocean, oxygen concentration is depleted to a level low enough to allow denitrification to occur in the water column. These regions, referred to as *oxygen-minimum zones*, occur off the coast of Peru (eastern tropical South Pacific), in the Arabian Sea, and the eastern tropical North Pacific Ocean (off the west coast of Mexico). The coupling between nitrification and denitrification has also been studied in these systems, which are essentially analogous to the sediment environments described earlier, except that the oxygen and nitrate gradients extend over tens to hundreds of meters. Suboxic and anoxic water and sediments tend to have large fluxes, and sometimes large accumulations, of the gaseous intermediates of nitrification and denitrification. This is probably caused by the sensitivity of the various organisms and enzymes involved in their production and consumption to oxygen concentration in the local environment of the microorganism.

In studies of nitrogen cycling in oxygen-minimum zones, nitrification and denitrification appear to be linked, as might be expected from analogy with sediment systems. A schematic that describes the approximate locations of nitrifying and denitrifying activities relative to the chemical distributions typical of an oxygen-minimum zone are shown in Figure 7. Ammonium oxidation typically is maximal near the bottom of the euphotic zone close to the upper boundary of the oxygen-minimum zone (115), but nitrite oxidation is detected within the oxygen-minimum zone itself. This finding is consistent with the ability of nitrite oxidizers to persist and metabolize at very low or zero oxygen conditions, but their metabolism under these conditions would be expected to be dissimilatory rather than oxidative. The nitrous oxide that typically accumulates in the suboxic (low but not zero oxygen concentrations) regions of the oxygen-minimum zones is thought to be caused by nitrification because nitrous oxide is depleted in the core of the oxygen-minimum zone where denitrification rates are thought to be greatest. A direct tracer confirmation of this pathway in nature has not yet been accomplished. Stable isotope measurement of nitrous oxide from oxygen-depleted water in the Arabian Sea imply that both nitrification and denitrification may contribute to the signal (116,163) attributed the nitric oxide production they observed in the oxygen-minimum

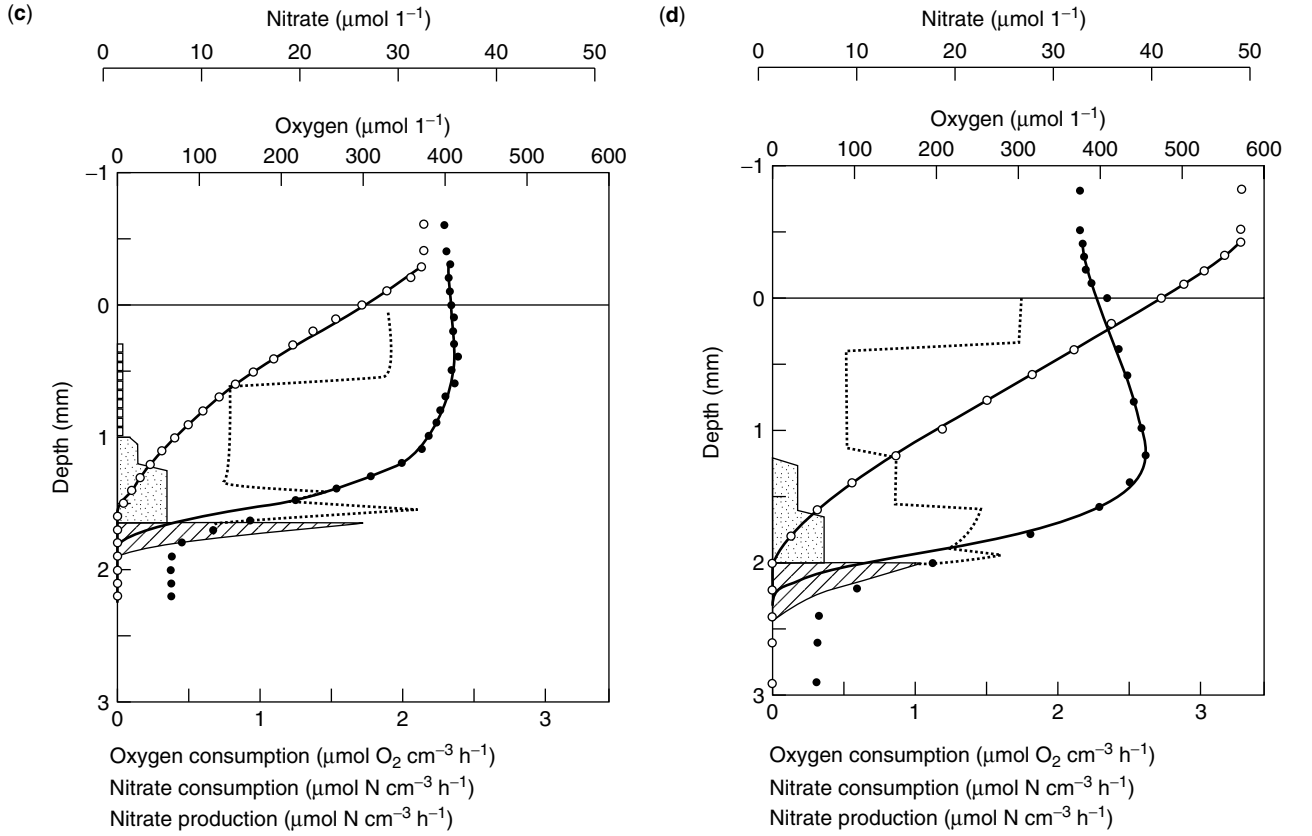

Figure 6. (*Continued*)

zone of the eastern tropical North Pacific to nitrification and found that it was equivalent to 18% of the total ammonia-oxidation rate.

Nitrous oxide accumulations have also been reported in lakes; the most notorious of these are the lakes in the McMurdo dry valley region of Antarctica. Priscu and coworkers (164) reported concentrations of N_2O in Lake Bonney that were equivalent to 580,000% saturation with respect to the global average atmospheric N_2O concentration. In incubations of several days duration with added acetylene, the concentration of N_2O did not change, leading Priscu and coworkers (164) to conclude that nitrification, rather than denitrification, was responsible for the buildup of the gas. Nitrous oxide is present in several of the dry valley lakes at much lower, but still supersaturated, levels, and the source is likely to be nitrification. These lakes show a relationship between nitrous oxide accumulation and AOU similar to that observed in the ocean, except that the ratio of N_2O production to AOU is much greater, implying that a higher proportion of ammonium is nitrified to the trace gases, rather than completely to nitrate (165).

NITRIFICATION AND METHANE OXIDATION

As mentioned earlier in connection with the physiology of nitrifying bacteria, the ammonia oxidizers and the methanotrophs have important biochemical similarities. These similarities extend to the nature of the primary enzyme in the ammonia- and methane-oxidation pathways, the sensitivity of the enzymes to a wide range of metabolic inhibitors, the metabolic capabilities of the cell and to the ultrastructure of the cell (140). Methanotrophs, like ammonia oxidizers, depend on two substrates with, generally, opposite sources. Methane, like ammonium, accumulates in anoxic habitats where it is produced by strictly anaerobic methanogens. Oxygen diffuses into surface water or surface sediments from the overlying oxygenated habitats. The classical environment for significant contributions by methanotrophs to system-wide carbon cycling is stratified lakes, in which a large fraction of the annual carbon fixation is cycled through methanogenesis and methane oxidation. The methanotrophic activity is highest at the interface where oxygen and methane coincide. As described earlier for sediments, such an interface would also be an interface for ammonium and oxygen and might be expected to harbor high nitrification activity as well.

Because of the presence of high sulfate concentrations in seawater, methanogenesis is not as important in marine sediments and seawater as it is in freshwater systems. Nevertheless, there are a few marine environments in which methane is found. The situation in Scan Bay or Cape Lookout Bight sediments, or in the water column of the Black Sea or the Cariaco Basin, is largely analogous to that in stratified lakes (as mentioned earlier).

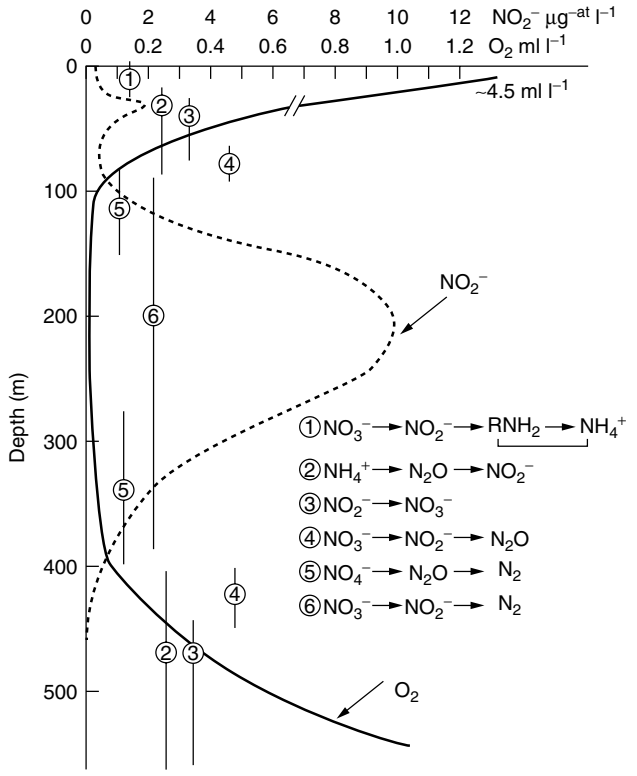

Figure 7. Schematic or expected chemical and activity distributions in the oxygen-minimum zone off Peru. Numbers in circles represent simplified pathways (shown in the figure) and the lines associated with each circled number denote the depth interval over which the activity is expected to occur. With permission from L. A. Codispoti and J. P. Christensen, *Mar. Chem.* **16**, 277–300 (1985).

The observation from culture studies that methane oxidizers are capable of oxidizing ammonia, and that ammonia oxidizers are capable of oxidizing methane, has led to uncertainty about the organisms that are responsible for observed methane and ammonium fluxes in nature. Although both groups of microorganisms show similar regulation by environmental variables and similar sensitivities to a variety of inhibitors (140), the possibility for differential regulation based on substrate affinity or competition suggested that "cross oxidation" might have important implications for the rate of ammonium or methane oxidation in nature. On the basis of a combination of simulated in situ rate measurements, inhibitor studies, and kinetic experiments with natural assemblages, it has been concluded largely that methanotrophs are mostly responsible for methane oxidation and nitrifiers for ammonium oxidation in both freshwater and marine environments (155,166). These conclusions do not rule out a role of cross oxidation or participation by both groups in some environments, and the two processes remain problematic to separate entirely in the environment.

CONCLUSION

The nitrogen cycle warrants study in aquatic environments because of this element's role as the macronutrient most likely to be limiting for primary production. The diverse compounds and wide range of oxidation states in which nitrogen occurs allow this element to play many different roles in the chemistry of the atmosphere and aquatic systems, and in the biochemistry of organisms. Most of the transformations in the nitrogen cycle are solely the domain of microorganisms, and classical autotrophic nitrifying bacteria exemplify this. The diversity and phylogeny of microbes involved in nitrification includes a variety of heterotrophs, and may include as yet unidentified organisms with novel metabolisms, yet to be elucidated. This is particularly true for sediment systems in which anaerobic reactions, either biotic or abiotic, may have been underestimated in the past.

In recent years, our understanding of the rates and distribution of nitrification in the open ocean has converged on a model in which the rates are greatest in the upper water column, within the euphotic zone, such that nitrification is linked to nitrogen assimilation by phytoplankton. The other major site for nitrification in the ocean is the sediment–water interface and surficial sediments, where nitrification is tightly linked to denitrification. Sediments are, usually, the dominant site for nitrification in many freshwater habitats. The metabolic diversity of nitrifiers, although limited compared with many other microorganisms, is greater than that usually admitted by simple models of processes in relation to environmental variables such as oxygen. These aspects of environmental regulation of nitrification and the diversity of organisms involved in nitrification remain interesting areas of fruitful research.

NITRIFYING BACTERIA IN DRINKING WATER

Roy L. Wolfe
Nancy I. Lieu
Metropolitan Water District of Southern California
Los Angeles, California

Nitrification is an important step in the global nitrogen cycle. During nitrification, ammonia is converted sequentially to nitrite and nitrate. This process can be performed either by heterotrophic or lithotrophic organisms. In the case of lithotrophic nitrification, the genera of bacteria that convert ammonia to nitrite are referred to as ammonia-oxidizing bacteria (AOB), and those that oxidize nitrite to nitrate are termed nitrite-oxidizing bacteria (NOB). These bacteria, collectively referred to as nitrifiers, are ubiquitous in aquatic and soil habitats and can grow under a variety of environmental conditions. Heterotrophic nitrification is carried out in soil and freshwater environments by fungi and several bacterial genera.

Nitrification via the growth of AOB and NOB in drinking water can have a deleterious effect on water quality. Studies have shown that many of the environmental conditions favoring the growth of nitrifying bacteria also occur in many drinking water distribution systems. These include the presence of ammonia as a nutrient source, warm temperatures, and neutral or slightly basic pH conditions. The proliferation of these bacteria in the distribution system can result in the production of nitrite and nitrate from ammonia, the breakdown of the ammonia-based disinfectant monochloramine, and an increase in heterotrophic plate-count (HPC) bacteria.

Although water agencies have observed the effects of nitrification, relatively sparse information exists in the literature on the ecology and occurrence of nitrifying bacteria in water systems. This topic is gaining importance with the growing number of water agencies converting from chlorine disinfection to monochloramine disinfection in the distribution system in order to limit the production of chlorinated by-products. Identification of favorable growth conditions can lead to the development of prevention and control measures. Improved methods for the measurement of bacteria are also needed because current culture-based methods greatly underestimate the actual numbers of nitrifiers present, are cumbersome, and require weeks of incubation before results are available. Early identification of nitrification symptoms in water is important for a utility to prevent the occurrence of nitrification and its subsequent effects on water quality.

BIOLOGY AND PHYSIOLOGY

Lithotrophic nitrifying bacteria are found in a variety of shapes, including straight or curved rods, spheres, spiral, and lobular forms, ranging in size from approximately 0.3 to 11.7 μm (Fig. 1). They typically form aggregates in nature and are motile by polar or peritrichous flagella (1–3). They are gram-negative facultative aerobes and are characterized by intracellular membranes. These bacteria, once classified in the family *Nitrobacteraceae,* have been reclassified into three separate subdivisions (alpha, beta, and gamma, under the division *Proteobacteria*), based on 16S ribosomal RNA analysis (1,2).

There are five genera of AOB and four genera of NOB, which are classified by the cell shape or arrangement of intracytoplasmic membranes (Table 1). All AOB except *Nitrosococcus oceanus* are categorized in the beta subgroup of purple photosynthetic bacteria. *Nitrosococcus oceanus* is in the gamma subdivision. NOB are found in the alpha, beta, and gamma subdivisions (2).

Table 1. Lithotrophic Nitrifying Bacteria Genera

Ammonia-Oxidizing Bacteria
Nitrosomonas — straight rods, intracellular membrane in peripheral cytoplasm
Nitrosococcus — spheres, intracytoplasmic membranes in peripheral or central cytoplasm
Nitrosospira — tightly wound spirals
Nitrosovibrio — slender, curved rods; lacking extensive intracellular membranes
Nitrosolobus — pleomorphic lobate cells partially compartmentalized by the cytoplasmic membrane
Nitrite-Oxidizing Bacteria
Nitrobacter — pleomorphic rods to coccoid cells
Nitrospina — straight slender rods
Nitrococcus — spheres
Nitrospira — spiral to vibrio

AOB are obligate chemolithoautotrophs and obtain their energy source by oxidizing ammonia (NH_3) to nitrite (NO_2^-) through the intermediate step, hydroxylamine (NH_2OH). NOB then oxidize nitrite to nitrate.

Ammonia-oxidation reactions are illustrated in the following equations (5):

$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O \quad (1)$$

$$NH_2OH + H_2O \rightarrow NO_2^- + 5H^+ + 4e^- \quad (2)$$

Conversion of NH_3 to NH_2OH is believed to be catalyzed by a monooxygenase (3). The oxidation of NH_2OH to NO_2^- is catalyzed by hydroxylamine oxidoreductase (HAO). The energy produced during the oxidation of NH_2OH to NO_2^- is NADH (3).

AOB use carbon dioxide as the main source for cellular carbon via the reductive pentose phosphate cycle. However, all ammonia oxidizers are able to metabolize selected organic compounds to a limited extent in the presence of an inorganic energy source. In media supplemented with formate and acetate and, to a lesser extent, pyruvate, the growth of AOB was enhanced by 130% (3). However, these compounds may inhibit growth at elevated concentrations (3).

With the exception of *Nitrobacter*, NOB are obligate lithoautotrophs. In the presence of organic substances, some strains of *Nitrobacter* can grow mixotrophically or heterotrophically (2,3,5), but at a slower rate and with less efficiency. *Nitrobacter* have been shown to be closely related to *Photopseudomonas palustris* by cell morphology, ultrastructure, and 16S rRNA. Some strains of *Nitrobacter* have been found to be facultative aerobes (3).

Nitrite oxidation occurs via the following reaction:

$$NO_2^- + H_2O \rightarrow NO_3^- + 2H^+ + 2e^- \quad (3)$$

Energy is derived from the oxidation of nitrite to nitrate, providing NADH and ATP for carbon dioxide fixation. Nitrite oxidoreductase (NO_2^-–OR) catalyzes this process. NOB fix carbon dioxide via the reductive pentose phosphate cycle (2,3,5). In the genus *Nitrobacter*, ribulose-1,5-bisphosphate carboxylase/oxygenase (Ribulose BisCO) is responsible for fixing carbon dioxide. Interestingly, nitrite oxidation appears to be reversible; NO_2^-–OR can reduce nitrate to nitrite under anaerobic conditions (3,5). In addition to growing heterotrophically on acetate, formate, and pyruvate, *Nitrobacter* can utilize glycerine (3,5).

Environment

Nitrifiers are ubiquitous in nature and can grow in a variety of habitats under a range of conditions. They are found in freshwater, soil, brackish water, sewage, and potable water. Nitrifiers can be found in temperatures ranging from 4 to 60 °C and at pH levels ranging from 4.6 to 9.0. Optimum growth, however, occurs at temperatures between 25 and 30 °C, at pH levels between 7.5 and 8.1,

and at substrate concentrations between 1 and 25 mM (6). The generation time for AOB ranges from 8 to 24 hours (3), depending on the genus and environmental conditions. For NOB, the generation time is slower, typically between 10 and 150 hours. The optimum pH and temperature for NOB are 7.6 to 7.8 and 28 to 30 °C, respectively. *Nitrobacter* is very sensitive to high oxygen partial pressure and to the presence of ammonia and nitrite. In the nitrification process, acid is produced by AOB, thus reducing the pH, making an enclosed environment (i.e., batch culture) less desirable for AOB, and inhibiting growth (3).

Nitrifiers are very sensitive to visible and ultraviolet (UV) irradiation and even fluorescent lighting (5). Alleman and coworkers (7) found that *Nitrosomonas* was completely inhibited after 10 minutes of exposure to light, but recovered 40% by excision repair.

Identification and Enumeration

Nitrifiers can be identified by function, morphology, and location of intracellular membranes. Transmission electron microscopy can be used to determine the location of the membrane characteristic of each species. Because nitrifiers grow slowly, the culture or enumeration of nitrifiers is a lengthy and tedious procedure, requiring several weeks to several months of incubation. Colony formation on agar plates is typically small (0.2 mm) and tan-brown in color. Enrichment media containing either ammonia or nitrite are used to confirm AOB or NOB metabolic processes. Selective media are also used in enumeration by most-probable-number (MPN) methods (1,2,6,8). After incubation on enrichment media, wells or tubes inoculated with AOB or NOB samples are spot-checked for the presence of nitrite or nitrate. Recovery with selective media has been reported to have a low recovery efficiency of 0.1 to 1% for environmental samples (9).

Other methods of detection include immunofluorescent and molecular-based technologies. Labeled bacterial cells can be detected by epifluorescent microscopy or enzyme-linked immunosorbent assay (ELISA). Quantification may be obtained by estimating positives from serial dilutions or MPN methods. Because of the strong strain specificity of the antibodies, the practicality of immunobased methods is limited for environmental monitoring, as numerous serotypes of nitrifying bacteria are found in nature. Future development of these techniques may involve monoclonal antibodies with more general specificity (5). Molecular methods for detecting nitrifiers target either the genes for the 16S ribosomal DNA or a specific functional gene such as ammonia monooxygenase or nitrite oxidoreductase (5). Because nitrifiers are in three subdivisions (based on 16S ribosomal DNA), group-specific probes based on 16S ribosomal sequences are more difficult to make. However, molecular methods do have a number of advantages for detection of nitrifiers in the environment. Polmerase chain reaction (PCR) technology can be used to detect low levels of nucleic acid in the environment, and targeting mRNA makes it possible to detect viable or metabolically active nitrifying cells.

ECOLOGY AND OCCURRENCE IN POTABLE WATER

Ecology in Water

Depending on the treatment application and the disinfectant, biological nitrification can be either a benefit or a nuisance in potable water. Nitrification is beneficial whenever the elimination of natural sources of ammonia or nitrite is desirable because ammonia and nitrite exert considerable chlorine demand and produce biologically unstable water in distribution systems (10). Under this scenario, nitrifying bacteria are allowed to increase to high levels in the filter beds or in the clarifiers, where they convert the ammonia to nitrate (10,11). Because nitrate does not exert an appreciable chlorine demand on chlorinated water, nitrification results in lower chlorination costs.

Partial or incomplete nitrification in distribution systems that use chloramines can adversely affect water quality. Inorganic chloramines are disinfectants formed by combining chlorine and ammonia. Inorganic chloramines form fewer chlorinated by-products and have a more persistent residual in the distribution system than chlorine. When nitrification occurs in chloraminated water, the total chlorine residual and ammonia residual decay rapidly, and an increase in nitrite levels is observed (Fig. 2; 10,12,13). This is because AOB oxidize the excess ammonia to nitrite, which has significant chlorine demand (10). Nitrite has also been shown to accelerate breakdown of the chloramine residual (14). Other evidence of nitrification may include a decrease in pH and dissolved oxygen level in the water (10,15). A loss of disinfectant residual can lead to a substantial increase in HPC bacteria (12). Nitrite accumulates because the conversion of nitrite to nitrate appears to occur slowly in chloraminated potable water. The oxidation of nitrite to nitrate has been observed to occur when the chloramine residual is lower than that for ammonia oxidation; this suggests that NOB are more susceptible than AOB to disinfection by chloramines.

Occurrence in Water

Nitrification has been reported to occur in water distribution systems using chloramines throughout the United States, Europe, and Australia. In 1993, a survey of water utilities was conducted to determine the extent of nitrification in the United States (15). The criteria for nitrification indicators included loss of chloramine residual, elevated heterotrophic bacteria, increased nitrate or nitrite, depletion of oxygen, and other evidence. The results indicated that 63% of the 42 utilities surveyed that serve over 50,000 customers had some indication of nitrification (Fig. 3). Region or climate did not seem to make a difference in repeated occurrence of nitrification problems.

Although many utilities may have nitrifiers in source waters and in effluents from the treatment plants (11,16), nitrification episodes tend to occur in the distribution systems, where conditions are optimal for the growth of AOB (12,16,17). Because AOB grow relatively slowly, they are frequently found in those areas of the distribution

systems that have extended detention times (e.g., finished-water reservoirs, storage tanks, and dead ends). During several nitrification episodes in a southern California distribution system, it was observed that AOB levels had increased up to 2,400 MPN/mL (Table 2; 12,16,18,19). In comparison, during periods when nitrite was not detected, the AOB levels ranged from less than 0.2 to 20 MPN/mL (16,18,20). In both cases, actual levels are likely to be much higher, given the low recovery efficiency of the MPN technique (9).

In the distribution system, AOB have been recovered from water in covered reservoirs and distribution system pipelines (12,13,16,19). They have been detected in biofilms attached to surfaces such as Hypalon^{TM} (52 to 1,500 MPN/cm^2) and polypropylene floating covers of reservoirs and epoxy-coated steel tank reservoirs (11 to 860 MPN/cm^2) (Table 2; 16,19) (Table 2). These results suggest that AOB are more densely concentrated in the biofilms than in the water column. Nitrifiers have also been recovered from tubercles on pipelines made of iron, old cement-lined cast-iron pipes, sediment on the bottoms of reservoirs or pipelines, and filter media — for example, sand, anthracite, and granular activated carbon (GAC) — in filter beds (11,19,21). Attachment to surfaces offers the bacteria protection from inactivation and serves as a sink for seeding the water column.

Nitrification Indicators. Because of the difficulties in cultivating and enumerating AOB, most water utilities use several surrogate parameters to detect nitrification. The monitoring parameters include nitrite, ammonia,

Table 2. Levels of Ammonia-Oxidizing Bacteria in the Distribution System

Source	Site	Ammonia-Oxidizing Bacteria MPN/mL	MPN/mg	MPN/cm^2	Reference
Raw		<0.2—70			12,16

HPC bacteria, and chloramine levels. Once AOB have been established within the system, nitrite is one of the primary parameters measuring the nitrification process. During nitrification episodes, nitrite-nitrogen (NO_2^-–N) levels of 5 to 500 μg/L have been reported, with levels more frequently ranging from 15 to 100 μg/L (12,13,15,17,18). Any nitrite level distinctly above background (typically 0.005 mg/L) is considered evidence of nitrification and warrants further analysis by the water utility to ensure that water quality does not deteriorate. Ike and colleagues (20) observed nitrite levels increasing from the detection limit (5 μg/L) to 30 μg/L NO_2^-–N within six days, resulting in nitrification and general deterioration of water quality in a 65-million-gallon finished-water reservoir. At other utilities, such as that in Ann Arbor, Michigan (13), where the finished water leaving the plant averaged 16 μg/L NO_2^-–N, it is important to evaluate other nitrification parameters (e.g., HPC and chloramine levels) to determine nitrification progression.

The chloramine residual is another frequently monitored parameter, and residual degradation rates beyond normal chloramine demand may be further evidence of ongoing nitrification. Wolfe and associates (12) reported a chloramine residual decline of 0.6 mg/L (from 1.4 to 0.8 mg/L in a southern California finished-water reservoir) within one day, which suggested that nitrification was occurring. Skadsen (13) determined that within the Ann Arbor system, chloramine decreases of 0.5 to 1.5 mg/L chloramines were a result of normal demand. Anything beyond this was suspect for nitrification. In 1991, Skadsen (17) observed an average chloramine residual decline of 3.2 mg/L chloramine in the distribution system; this correlated with a nitrification occurrence.

Increased HPC bacteria levels may also be observed during nitrification episodes, providing additional evidence that water quality is changing. During nitrification episodes, utilities have reported HPC levels ranging from 100 to 85,000 HPC bacteria/mL (12,13,16,18). Detection of coliforms, however, does not appear to be correlated with nitrification episodes, although it may occur simultaneously. Oxygen and pH have been reported to provide additional early warning information (10); however, most utilities do not routinely measure oxygen levels, and if the water is well buffered, as in hard water, pH is not noticeably affected.

Factors Influencing Occurrence. The basic constituents and conditions necessary for nitrifier growth include a source of ammonia and nitrite, carbon dioxide, oxygen, a dark environment, moderate temperatures, and a slightly basic pH. Rapid growth of nitrifiers occurs when the water is warm and relatively nonturbulent. Factors affecting the likelihood of nitrification in the distribution system can be grouped into the following categories: physical, biological, chemical, and operational.

Physical. Nitrification episodes appear to be more pronounced during the warmer months (Fig. 4; 12,13,16,20, 22,23). In chloraminated water, AOB may proliferate rapidly (to problematic concentrations) above a temperature threshold range of 15 to 18 °C (16). Wolfe and coworkers (16) found that AOB levels remained at or below 0.2 MPN/mL when temperatures were lower than 18 °C in a southern California distribution system (Fig. 5), and an increase was loosely linear with temperatures above this value. Kirmeyer and colleagues (15) found that water samples obtained from selected water utilities in the United States had nitrite levels of 50 μg/L or more (as NO_2^-–N) when the water temperatures were at or above 15 °C (Fig. 6). In a bench-scale study, Lieu and associates (4) found that logarithmic growth — from 40 to more than 1,000 colony-forming units (CFU)/mL — took 28 days at 10 °C but occurred two and three times at 15 and 25 °C, respectively, in dechloraminated tapwater. On corresponding days, nitrite levels were considerably higher (≥0.1 mg/L NO_2^-–N) at the warmer temperatures

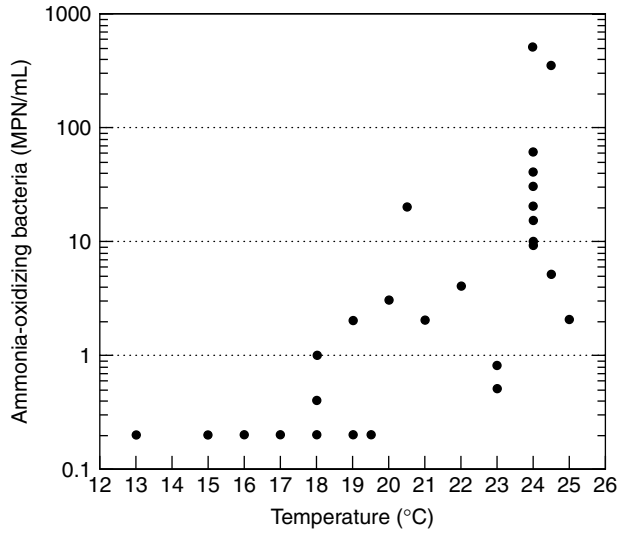

Figure 5. Relationship between AOB occurrence and temperature (16). Reprinted by permission of the American Society for Microbiology.

than at 10 °C. Clearly, at warmer temperatures and with a shorter lag phase, AOB can be more problematic in the distribution system.

Nitrifiers are very sensitive to near-UV, visual, and fluorescent light; consequently, nitrification episodes in distribution systems only occur in the dark (in covered reservoirs, pipelines, taps, etc.). Nitrifiers, however, do have an excision repair mechanism for DNA repair; therefore, low levels of nitrifiers may be recovered from partially shaded reservoirs or channels.

Biological. In addition to interactions with chemical and physical environments, nitrifiers may have a synergistic relationship with HPC bacteria. During growth, AOB produce metabolic by-products that may enhance

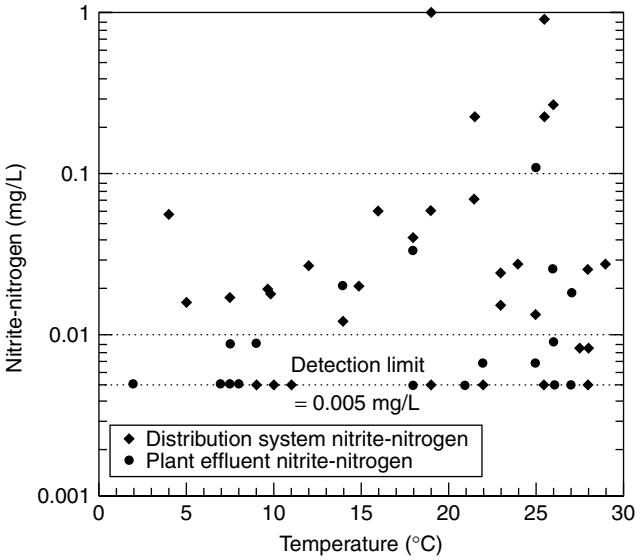

Figure 6. Relationship between nitrite levels and temperatures from water samples from water utilities in the United States (15). Reprinted with the permission of the AWWA Research Foundation.

the growth of HPC bacteria (6). Likewise, HPC bacteria may produce by-products such as acetate, formate, and pyruvate, which enhance AOB growth (3). In a southern California distribution system, Wolfe and coworkers (16) found a positive correlation between AOB and HPC bacteria when HPC levels exceeded 100 CFU/mL (Fig. 7). A positive correlation was also found between HPC bacteria and nitrite (13,15,17). It is not clear whether there is a synergistic relationship between nitrifying bacteria and other bacterial groups such as coliforms or pathogens.

Chemical. To study the effects of monochloramine residual and temperature on the inactivation of AOB, Lieu and

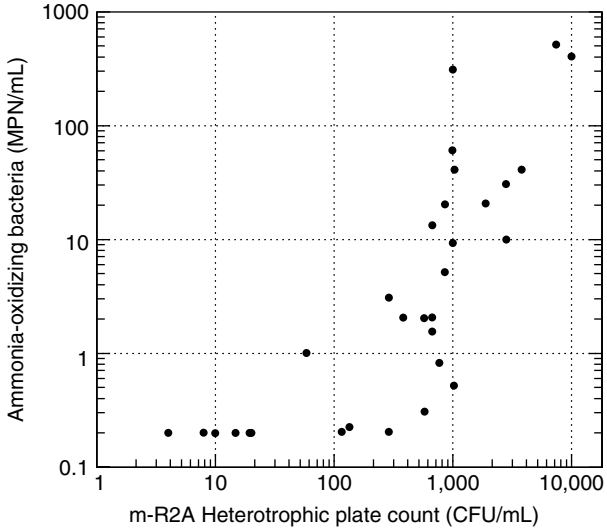

Figure 7. Relationship between AOB occurrence and HPC bacteria recovered on R2A medium (16). Reprinted by permission of the American Society for Microbiology.

colleagues (4) exposed a naturally occurring population of AOB to three chloramine residual concentrations — 1.7, 2.0, and 2.5 mg/L chloramines at a 4 : 1 chlorine-to-nitrogen (Cl_2 : N) ratio by weight — in a bench-scale study for an eight-day contact time at temperatures of 10, 15, and 25 °C (Fig. 8a–c). At 10 °C, the AOB were inactivated to below the detection level (<0.2 MPN/mL) and did not recover. At 15 °C, the AOB were able to recover at different rates following exposure to 1.7 and 2.0 mg/L chloramines, but not following exposure to 2.5 mg/L chloramines. At 25 °C, only the AOB exposed to 1.7 mg/L chloramines were able to recover, following two logs of inactivation and regrowth. Importantly, the rate of inactivation and regrowth was found to be faster at 25 °C than at 15 °C (Fig. 8b,c). Also, it is interesting to note that many utilities operate with chloramine residuals of 2 to 3 mg/L leaving the plant (15,24).

In another laboratory assay, Cunliffe (25) showed that 99% inactivation of a naturally occurring population of AOB was achieved with exposure to 0.6, 1.85, 3.05, 4.05, and 5.2 mg/L total chlorine in approximately 2,000, 250, 100, 75, and 40 minutes, respectively, in 30 °C tapwater.

When the monochloramine residual is at threshold levels of effectiveness, the Cl_2 : N ratios can enhance or hinder the inactivation and regrowth of AOB (12). Field and bench studies conducted independently by Knudsen — as discussed in Kirmeyer and coworkers (15) — and by Lieu and coworkers (4), respectively, have indicated that AOB and nitrite were more likely to increase at lower Cl_2:N ratios (e.g., a 3:1 Cl_2:N ratio, by weight) than at higher chloramine ratios (e.g., a 5:1 Cl_2:N ratio, by weight), presumably because of the available free ammonia present at Cl_2:N ratios of less than 5:1.

Potable waters high in organic matter, humic material, and color not only enhance nitrifier growth, but also have a high chlorine demand, creating unstable water. Under these conditions, nitrification can lead to pH changes in the system, growth of other bacteria (e.g., HPC, sulfate-reducing, or iron bacteria), and pipeline corrosion. Other chemical parameters, such as alkalinity, hardness, and electrical conductivity, are not thought to be significant to the survival and growth of AOB.

Operational Practices. Operational practices also affect the likelihood of nitrification in drinking water systems. In the distribution system, practices promoting degradation of chloramines, low flow rates, and long detention times can lead to proliferation of AOB.

Results from surveys of distribution systems indicate that higher levels of AOB, nitrite, and HPC bacteria were found in water with lower chloramine levels (13,15,25,26). Kirmeyer and colleagues (15) obtained water samples from selected utilities across the United States. Their findings indicated that samples with chloramine levels of 0 to 1 mg/L had an average NO_2^-–N level that was 30 times higher than samples with chloramine levels above 2 mg/L (Table 3). In Australia, Cunliffe (25) found AOB levels in the distribution system to be inversely correlated with total chloramine levels (Table 3). Total chlorine levels of less than 1 mg/L had median nitrifier levels 65 times greater than those for total chlorine levels of 1 to 2 mg/L.

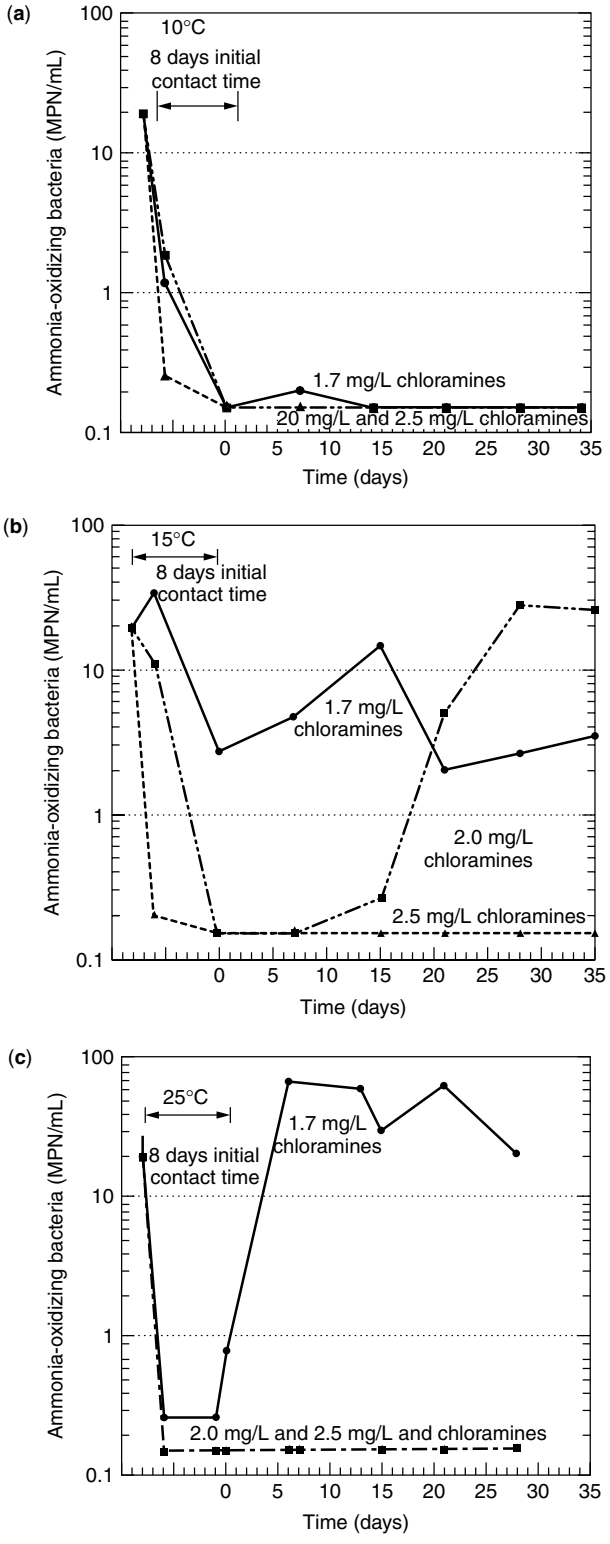

Figure 8. Regrowth of AOB following exposure to chloramines (4:1 Cl_2:NH_3–N) at (**a**) 10 °C, (**b**) 15 °C, and (**c**) 25 °C (4). Reprinted by permission of the American Water Works Association copyright © 1993.

Regrowth of nitrifiers to problematic levels is also highly dependent on residence time. Direct correlations between detention times and nitrification symptoms

Table 3. Average AOB and Nitrite Levels in Chloraminated Distribution Systems

Total Chlorine (mg/L)	AOB (nitrifiers/mL) (25)	NO_2–N (mg/L) (15)
0–1 mg/L	130	0.3
1–2 mg/L	2	0.075
>2 mg/L	0.5	0.01

have been observed in the distribution system (12,17,25). In a survey of nine United States water utilities during the summer, water samples with detention times of three days or less exhibited low or no nitrification symptoms as compared with water samples with detention times of more than three days, which did exhibit nitrification symptoms (15). Similarly, Wolfe and associates in southern California (12) and Skadsen in Michigan (17) found that mean detention times of three and two days, respectively, seemed to deter nitrification episodes in their systems. Other water utilities may have longer detention times in their distribution system (e.g., reservoirs without, experiencing nitrification; in such cases, although the longer detention times do heighten the potential for nitrification, this effect is apparently counterbalanced by other factors (e.g., cooler temperatures, higher residuals) that tend to inhibit nitrification.

The type and condition of the distribution system pipelines, reservoirs, and tanks can influence nitrification. For example, cast-iron pipes or old mortar-lined iron pipes with heavy turberculation are notorious for nitrification. Poorly maintained reservoirs and tanks not routinely cleaned or in need of a new inner surface coating are also excellent sources for AOB growth. Stewart and Lieu (19) reported that concrete materials appear to yield fewer AOB, presumably because of the high alkalinity leached from the concrete.

Treatment technologies may also affect nitrification occurrence. Oxidants such as ozone and chlorination increase the assimilable organic carbon (AOC) levels of the water and may thus increase the potential for nitrification (27). GAC has also been shown to have promoted nitrification when chloramines, at a low Cl_2:N ratio by weight, were added across the filter, resulting in growth of nitrifiers in the filters (13). Interestingly, low levels of chlorite, a product of chlorine dioxide, may inhibit nitrification (28,29). A survey conducted in Texas showed that utilities using chlorine dioxide as a predisinfectant and chloramines as a postdisinfectant had less nitrification symptoms than those utilities that used only chloramines (28).

PREVENTION AND CONTROL

Successful management of nitrification requires a thorough understanding of factors enhancing the nitrification process, early warning monitoring, and measures to prevent nitrification from increasing to problem levels.

Prevention and Control Plan

An optimization plan should be in place to minimize conditions favoring nitrification, and the actions needed to control nitrification should be identified before problems begin to occur. The plan should be both flexible and quick to implement. Speed is essential because degradation of water quality from nitrification can occur within days and increase within hours. The plan should include information on staff (i.e., knowledge, responsibility, and training), monitoring, and action levels (24,30).

Monitoring

Common parameters to be monitored as a part of early warning monitoring include nitrite, total and free chlorine (possibly monochloramine) residuals, HPC bacteria, total and free ammonia, and, particularly, nitrite. Monitoring of pH and oxygen levels may also be useful. These parameters will provide a picture of the status of water quality and nitrification symptoms. Each utility should determine acceptable background levels and implement action if levels increase beyond this. The type of action items called for should be established on the basis of the stage to which nitrification has progressed, as determined by the level of key parameters.

Prevention Methods

Nitrification prevention methods include optimizing the chloramine residual, chlorine-to-ammonia ratio, and system detention time or flow rate.

Maintaining a good chloramine residual throughout the distribution system is a key part of prevention. On the basis of surveys and reports, a chloramine residual of 2 mg/L or more is commonly used in the distribution system to control nitrification (15,24,25). However, the residual levels selected for use in a specific distribution system must be based on the chloramine demand, the water matrices, the physical parameters, and the water system. Utilities with high chloramine demand (e.g., Ann Arbor, Michigan; Broward County and Key West, Florida), use chloramine residuals of 3 to 5 mg/L (15,31).

Another method of prevention for early stages of nitrification is a distribution system flushing program. The flushing action removes stagnant water, scours biofilm, and provides freshwater with increased disinfectant dose. In many cases, this method helps for a short time, but it may have to be implemented frequently and regularly to be effective (17,22).

In areas of low flow, AOB have a greater chance to proliferate. Common inlet-outlet ports on storage tanks are well recognized for creating dead zones within the tanks. A solution is to enhance mixing, thereby increasing turnover rate.

Another method involves temporary switches to free chlorine, scheduled just before peak periods of seasonal nitrification, to oxidize biofilm; this has been done in Broward County (Florida)—as discussed by Kirmeyer and coworkers (15)—and elsewhere (18,24). In southern California, this method was used successfully for 10 years and applied during early summer for one month before peak nitrification periods, which occurred in midsummer.

However, some utilities have reported that when the system disinfectant is switched to free chlorine, elevated coliform levels are initially detected, presumably from dislodging biofilm, as was the case in Broward County (15).

Other options for prevention may include boosting the chloramine residual in some areas of the distribution system by adding booster stations at strategic locations, such as at reservoir effluents, where residuals tend to degrade. Also, the chloramine level leaving the treatment plant can be elevated to create an overall higher residual in the distribution system (24).

Two water utilities reported success in controlling nitrification by increasing the pH of their water to 9.0 (15,31,32). Although nitrification was not eliminated, one utility reported that nitrification was reduced and controlled in three out of four years (32).

Control Methods

When nitrification symptoms are detected early, less aggressive methods such as flushing and increasing circulation and flow rates may be sufficient. During this time, key parameters should be monitored daily or even more frequently. If nitrification symptoms become more severe, boosting the chloramine residual or increasing the Cl_2 : N ratio may eliminate the problem. If nitrification persists, switching disinfectants to free chlorine will eliminate nitrification problems almost immediately. However, switching to free chlorine would temporarily increase trihalomethane levels and is not without operational difficulties (18). As new experience is gained, it is important to reevaluate the action levels and the control plan and to readjust the parameter levels as needed.

CONCLUSION

Since the early 1980s, water utilities have switched from free chlorine to cloramines as one alternative to meeting trihalomethane regulations. A major disadvantage of chloramines, however, is the potential for nitrification. Nitrifying bacteria are found in drinking water distribution systems, and, under conditions that enhance the growth of these bacteria, nitrification may adversely affect water quality. Some water utilities have developed and successfully used prevention and control measures that minimize the impact of nitrification on water quality. Improved methods of identification and enumeration are needed, however, to enhance tracking and understanding of the occurrence and ecology of nitrifying bacteria. In the future, molecular methods may offer the best approach for studying these organisms in the distribution system.

NITROGEN CYCLE IN THE MARINE ENVIRONMENT

DOUGLAS G. CAPONE
University of Southern California
Los Angeles, California

Nitrogen (N) is an essential element required by all organisms in stoichiometric proportions to carbon and other essential elements for balanced growth. It occurs in a complex array of different chemical pools and states in the ocean. Microorganisms participate in, and in fact dominate, most of the transformations of nitrogen in the sea. They are intimately involved in the uptake of nitrogen into organic forms, its rerelease during regeneration, conversions between combined forms and the large gaseous pool of dinitrogen gas (N_2), and the production and consumption of nitrogenous greenhouse gases. Articles on the specific processes of nitrogen fixation (NITROGEN FIXATION IN THE MARINE ENVIRONMENT, this Encyclopedia), nitrification (NITRIFICATION IN AQUATIC SYSTEMS, this Encyclopedia), and denitrification (DENITRIFICATION IN THE MARINE ENVIRONMENT, this Encyclopedia) in the Encyclopedia, as well as on microbial nutrition (INORGANIC NUTRIENT USE BY MARINE MICROORGANISMS, this Encyclopedia) are included. [See also articles in Carpenter & Capone (1), Blackburn & Sorensen (2), and Kirchman (3).]

Nitrogen is thought to limit primary production through much of the world's oceans (4,5). The organic productivity of many marine ecosystems is intimately tied to the delivery and availability of nitrogen. Further impetus to better understand the relationship between nitrogen cycling and marine productivity has arisen from the observation of anthropogenically induced perturbations at regional and, possibly, global scales in the marine nitrogen cycle, a result of massive increases in fertilizer production. Concerns about greenhouse warming and climate change (6) have also focused attention on the marine nitrogen cycle as nitrous oxide (N_2O), a product of nitrification and a substrate and metabolite of denitrification, has been increasing in the atmosphere (7). Nitrous oxide can react with and destroy stratospheric ozone and is also a potent greenhouse gas (7).

NITROGEN INPUTS AND OUTPUTS

Nitrogen enters the sea by several pathways. Organic and inorganic forms of nitrogen arrives from land by riverine delivery (8), through runoff, and by wet and dry atmospheric deposition of inorganic and organic N (9–11). Some gaseous forms of combined nitrogen, for instance NH_3 and NO_x, may enter the coastal oceans from adjacent land areas (12). Soluble forms of nitrogen can also arrive through submarine groundwater discharge in coastal areas (13,14). The relative importance of each of these pathways of nitrogen delivery will vary with respect to location and climate — for example, the influence of the Amazon in the tropical Atlantic is profound (15), whereas riverine delivery may represent only minor inputs in other locations (e.g., southwest Pacific Ocean). Atmospheric inputs may be greater near landmasses, and the form of atmospheric input will vary as a function of land use and population density.

Nitrogen is removed from the sea by biological denitrification (DENITRIFICATION IN THE MARINE ENVIRONMENT, this Encyclopedia) and gaseous evasion (16), sedimentation to the seafloor (17), and biomass harvest.

MARINE NITROGEN POOLS

Once in the sea, nitrogen occurs in a variety of molecular forms, redox states, and phases (Table 1; 18). Specific pools of nitrogen show various and distinct spatial and temporal patterns of abundance, thereby providing important clues to the underlying biogeochemical dynamics crucial to our understanding of this cycle.

The largest reservoir of nitrogen in the sea is dissolved dinitrogen gas (N_2), which occurs in concentrations of about 1 mM (Table 1). Concentrations are relatively uniform and vary largely as a function of temperature and salinity dependent solubility (20,21). Nitrous oxide, which occurs as a trace constituent in seawater and is typically from 10 to 50 nM in seawater (22), arises from several microbial pathways (see in the following text). In the sea, one may observe relatively high transients in N_2O concentrations at redox boundaries (23). Nitric oxide (NO) also occurs in trace concentrations in seawater,

Table 1. Primary Pools and Concentrations of Nitrogen in the Ocean

Formula	Form/Pool	Typical Concentrations μM Oceanic	Coastal	Global Marine Pools Pg
Gaseous				
N_2	Dinitrogen	900–1,100	900–1,100	$22–23 \times 10^3$
N_2O	Nitrous oxide	0.006 –0.07	0 –0.25	0.2 –0.8
NO	Nitric oxide	?	?	?
Inorganic				
NO_{3-}	Nitrate	<0.03–40	<0.1–200	570–677
NO_{2-}	Nitrite	<0.03–0.1	<0.03–10	?
NH_{4+}	Ammonium	<0.03–1	<0.03–100	7–8
$(NH_2)_2CO$	Urea	<0.1–0.5	0–2	
Organic				
DON	Dissolved organic	3–7	3–20	63–530
PON	Particulate organic	0.07–0.5	0.1–30	3–24
Phyto biomass	Particulate organic			0.15–3
Animal biomass	Particulate organic			0.17

has biological sources and sinks and is highly reactive (NITRIFICATION IN AQUATIC SYSTEMS, this Encyclopedia). However, far less is known about the importance and cycling of NO in the sea.

Nitrate (NO_3^-) is the dominant inorganic form of nitrogen in runoff, riverine input, groundwater discharge, and atmospheric deposition to the ocean. In the sea, concentrations of NO_3^- can vary widely in space and time. Relatively high concentrations (10 s–100 s μM) are characteristic of eutrophic coastal and upwelling environments, whereas lower concentrations occur in the surface waters of the tropical gyres (19) and in suboxic and anoxic zones (Table 1).

Nitrite (NO_2^-) generally occurs in the sea in much lower concentrations than nitrate (Table 1), although higher concentrations are associated with redox interfaces both in the water column and sediments. The primary nitrite maximum of the open ocean occurs near the base of the euphotic zone and is generally associated with assimilatory NO_3^- reduction (and release of the NO_2^- intermediate), whereas a deeper, secondary NO_2^- maximum is associated with the differential inhibition of nitrification (24) (also, see NITRIFICATION IN AQUATIC SYSTEMS, this Encyclopedia).

Ammonium (NH_4^+) concentrations also vary widely among environments. In oligotrophic regions, ammonium concentrations are usually near the limit of detection by conventional colorimetric methods (<0.03 μM). In suboxic and anoxic environments NH_4^+ concentrations increase. In highly reducing nearshore sediments, mM levels of NH_4^+ can be observed. High concentrations of NH_4^+ are also associated with nearshore waters subject to sewage and waste discharges (25,26).

Dissolved organic nitrogen (DON) also represents a major nitrogen pool in marine systems (Table 1). Analyses of organic nitrogen have focused on both specific compounds such as individual amino acids and nucleic acids (19) as well as polymeric compounds (protein, DNA) and specific classes of DON (<0.3 to 0.7 μM fraction) (27) and particulate organic nitrogen (PON)(>0.2 to 0.7 μm). Amino and nucleic acids, although typically very low in concentration, are highly dynamic pools in many marine ecosystems (28). The bulk of the organic nitrogen pool remains yet to be characterized. Recent evidence indicates that much of the uncharacterized fraction may consist largely of refractory biopolymers, possibly peptidoglycan remnants of bacterial cell walls (29).

PROCESSES

Most of the transformations of nitrogen in the ocean are performed by bacteria, although even those that also occur in higher organisms are still dominated by microorganisms. The principal transformations of the marine nitrogen cycle include the uptake and incorporation of inorganic forms of nitrogen into organic nitrogen; the regeneration and release of inorganic nitrogen, primarily as NH_4^+, from organic forms of nitrogen; the oxidation of ammonium and nitrite in nitrification; the reduction of nitrate or nitrite to the gaseous end products, N_2 and N_2O in denitrification; and the reduction ("fixation") of N_2 to NH_4^+ (Fig. 1).

Inorganic nitrogen, as nitrate, nitrite, ammonium, and organic nitrogen, such as urea and other small molecular weight organic molecules (e.g., amino acids), often termed utilizable or combined nitrogen, can be taken up and incorporated into organic matter by a variety of organisms. Very high rates of nitrogen uptake and assimilation into organic matter occur in photic environments in conjunction with photosynthetic carbon assimilation (see PLANKTONIC ALGAE IN THE MARINE ENVIRONMENT, this Encyclopedia). These reactions are largely catalyzed by photoautotrophs including cyanobacteria, eukaryotic micro- and macroalgae and sea grasses. Heterotrophic bacteria and archaea (as well as some fungi) can also assimilate inorganic nitrogen and may compete with photoautotrophs for these resources (see INORGANIC NUTRIENT USE BY MARINE MICROORGANISMS, this Encyclopedia).

The capacity for nitrogen fixation, the reduction of N_2 gas to NH_4^+ for biosynthesis, occurs in a disparate

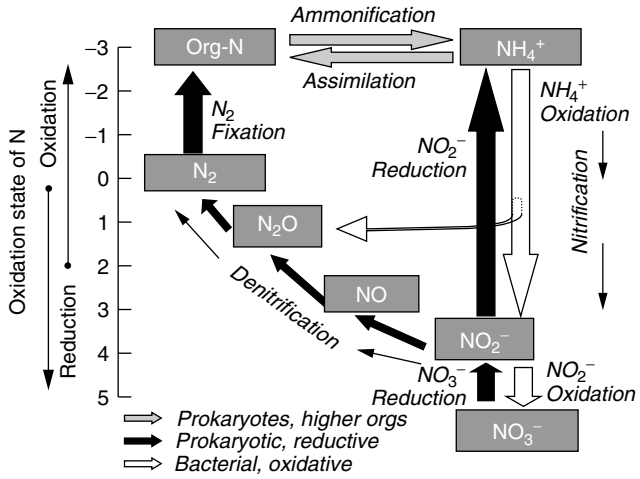

Figure 1. Marine nitrogen cycle emphasizing oxidation-reduction reactions and biological transformations. Adapted from D. G. Capone, in D. Kirchman, eds., *Microbial Ecology of the Oceans*, Wiley-Liss, New York, 2000, pp. 455–493.

array of prokaryotes, including representatives of both eubacteria and archaea. Organisms that can fix nitrogen are at an advantage in environments with low levels of combined nitrogen. Through this process, N_2 fixers provide a source of utilizable nitrogen to the biosphere from the large pool of N_2 (Table 1) and thereby balance losses of NO_3^- by denitrification. Marine N_2 fixers are found in greatest abundance in the tropical open ocean and in shallow tropical environments (see NITROGEN FIXATION IN THE MARINE ENVIRONMENT, this Encyclopedia).

Oxidized forms of nitrogen, such as NO_3^- and NO_2^-, that are taken up by cells must first be reduced to NH_4^+, at the −3 oxidation level, by assimilatory NO_3^- and NO_2^- reductase before being assimilated into cell biomass (30). In most marine organisms utilizing inorganic nitrogen, including nitrogen fixers (31), the assimilation of NH_4^+ is catalyzed by the enzymes, glutamine synthetase and glutamate synthase (GS/GOGAT pathway) with glutamate as the major end-products. Glutamate is subsequently utilized in the cell to synthesize other nitrogen-containing compounds.

Nitrogen is a constituent of a wide variety of simple and complex organic molecules, and the pathways of organic nitrogen breakdown largely remain to be detailed. The release of inorganic nitrogen from organic forms can occur through the metabolism of higher organisms by the urea cycle with release of various urea cycle end-products (e.g., NH_4^+, urea; 32). The degradative catabolism of organic nitrogen by heterotrophic microorganisms including many bacteria and fungi, often termed ammonification, also results in the release of NH_4^+ (33). Labile DON that is released by excretion or cell lysis can also be further catabolized by heterotrophs or assimilated by heterotrophs or autotrophs (32,34). A variety of algal taxa and bacteria possess cell surface oxidases (35). These may be important in liberating NH_4^+ from organic compounds and the NH_4^+ released is subsequently available for uptake.

Nitrification is a two-step process involving first the conversion of NH_4^+ to NO_2^- followed by the oxidation of NO_2^- to NO_3^- (see NITRIFICATION IN AQUATIC SYSTEMS, this Encyclopedia). These reactions are catalyzed by two specialized groups of aerobic, autotrophic bacteria: the ammonium oxidizers and the nitrite oxidizers. The fact that large reserves of NO_3^- are maintained in the deep sea attest the major role of nitrifiers in the oceans. However, nitrification occurs at relatively low rates in the deep sea (36) (also see NITRIFICATION IN AQUATIC SYSTEMS, this Encyclopedia). Direct measurements of nitrification are among the most challenging to make and therefore the scarcest among the major processes involved in the marine nitrogen cycle. Pathways of heterotrophic nitrification have been described for soils but have not been well characterized in aquatic environments. Autotrophic nitrifiers have been implicated in the production of N_2O in many marine environments (37,38).

Biological denitrification is the sequential conversion of oxidized forms of nitrogen to gaseous end-products (39) (see DENITRIFICATION IN THE MARINE ENVIRONMENT, this Encyclopedia; Fig. 1). These oxidized nitrogen substrates, including nitrate and nitrite, serve as terminal electron acceptors in respiration. Denitrification is generally coupled to the oxidation of organic compounds. The first step of the process, the reduction of NO_3^- to NO_2^- is termed dissimilatory NO_3^- reduction (to distinguish it from the assimilatory pathway — see preceding text) and occurs in a relatively wide variety of bacteria. The capacity to reduce NO_2^- to N_2O or N_2 — true denitrification — occurs in a smaller subset of these bacteria (39). These reactions generally occur where O_2 is low. In some bacteria, NO_3^- reduction is followed by dissimilatory reduction of NO_2^- to NH_4^+, and NH_4^+ released into the environment (40), a process referred to as dissimilatory nitrate reduction to ammonium.

The denitrification pathway represents a loss of utilizable (combined) nitrogen for marine ecosystems. When the first two reduction steps in either pathway are temporally or spatially uncoupled, NO_2^- may accumulate. Thus, $NO_2^-$is a key branch point in the nitrogen cycle as an intermediate in nitrification, assimilatory and dissimilatory NO_3^- reduction. Denitrification occurs at substantial rates in a variety of benthic and pelagic marine environments, including midwater areas of the Indian and Pacific Oceans (41), as well as estuarine, coastal and shelf sediments (42–44).

CONCEPTS IN MARINE NITROGEN CYCLE DYNAMICS

The multiplicity of chemical species of nitrogen, their distribution among different phases, and various biotic transformations among pools, makes the biogeochemistry of nitrogen relatively complex. In comparing the differences between systems, several key concepts regarding nitrogen distributions and their relationships to plant and animal production have emerged over the last several decades. These concepts are dynamically evolving and being refined as we learn more about marine systems.

Deep Nitrate, Redfield Ratios, and the Conveyor Belt

While surface waters are often depleted in inorganic nutrients such as NO_3^- and PO_4^{-3} throughout much of

the open oceans, relatively high nutrient concentrations are found in deep waters beneath the thermocline. Assimilation of nutrients by phytoplankton accounts for the depletion of nutrients in the upper water column in which light is available for photosynthesis (i.e., the euphotic zone), whereas the heterotrophic metabolism of bacteria is largely responsible for the regeneration of nutrients in deep water. The concentration of NO_3^- below the thermocline is greater in the Pacific Ocean than in the Atlantic Ocean, because of the large-scale circulation pattern of deep waters.

Redfield and coworkers (45,46) developed a geochemical model relating the increase of nutrients at depth in the sea to the aerobic bacterial regeneration, coupled with nitrification, of planktonic organic matter sedimenting through the subeuphotic zone. The stoichiometric relationships, termed the Redfield Equation, between the composition of generic plankton organic matter and the macronutrients released during aerobic decomposition is:

$$(CH_2O)_{106}(NH_3)_{16}(H_3PO_4) + 138O_2 \Leftrightarrow 106CO_2 16HNO_3 + H_3PO_4 + 122\ H_2O \quad (1)$$

Using the Redfield ratio (106:16:1 for the mole ratio of CO_2: NO_3: PO_4) one can predict the inorganic nutrient concentrations resulting from regeneration of plant material based on the relative degree of O_2 utilization in deep water. Briefly put, the longer a parcel of water is at depth (i.e., removed from the euphotic zone), the greater the (*1*) decomposition of organic matter, (*2*) the O_2 consumed, and (*3*) the concentration of inorganic nutrients in that parcel of water.

Deep waters largely form in the North Atlantic Ocean and flow south through to the South Atlantic, whereas new deep water is entrained in the circum-Antarctic region. A portion of this water feeds the Indian Ocean deep-water flow before finally arriving in the Pacific Ocean. This large-scale interbasin circulation is often referred to as the Conveyor Belt (47). Upwelling occurs along the way, but waters entrained at depth the longest eventually upwell in the Pacific. The oldest waters, in equilibrium with atmospheric oxygen when they first sink, can take upwards of 2000 y to make this transit. Along the way, organic carbon sedimenting from the surface fuels heterotrophic oxygen consumption and the regeneration of nutrients in these waters. Consequently, the highest concentrations of NO_3^- are found in midwaters of the Pacific Ocean that have remained at depth the longest.

Indeed, waters found at middepths in the Indian Ocean and in the tropical Pacific Ocean have very low O_2 levels and lower-than-predicted concentrations of NO_3^- due to initiation of bacterial nitrate reduction and denitrification processes that consume NO_3^-. Large expanses of anoxic midwaters in the Indian Ocean, and eastern tropical North and South Pacific are major global sites of denitrification (41).

Recently, a new parameter, termed N*, which considers departures from Redfield stoichiometry occurring during the decomposition of organic matter and regeneration of nutrients has been derived (48,49). It is defined as:

$$N* = (NO_3^- + 16PO_4^+ + 2.90) * 0.87 \quad (2)$$

The value of 2.90 adjusts N* to 0 when considering global pools of nitrogen and phosphorus. The N* parameter has been used to identify both negative and positive deviations from canonical Redfield values. For example, large areas of the tropical North Atlantic have been found to exhibit an excess of inorganic nitrogen relative to phosphorus at middepths (49,50). It has been suggested that this excess of regenerated N, relative to P at these depths, results from the sedimentation of material enriched in nitrogen by nitrogen fixation in near surface waters.

Nitrogen as a Limiting Nutrient

Much of the interest in the nitrogen cycle derives from the general observation that N is often the nutrient factor limiting plant growth and/ or biomass accumulation in the ocean (4,5,25). The concept of limiting nutrients, still actively debated today, was originally derived from the application of Liebig's "law of the minimum." Liebig first proposed that the chemical factor in shortest supply would limit plant growth in agricultural systems. Oceanographers, observing the reciprocal relationship between the increase in phytoplankton biomass in the spring in the temperate North Atlantic Ocean with the decrease in NO_3^- (and PO_4^{-3}) concentrations, inferred nitrogen as the limiting nutrient factor resulting in the termination of the spring bloom (51). Biotic factors, such as grazing, also contribute to bloom termination and this has promoted considerable discussion about the relative extent of "top-down" (i.e., herbivore) versus "bottom-up" (i.e., nutrient) control of plant biomass and production (52). The observation that coastal eutrophication frequently results from nitrogen enrichment of systems (25,53), see following text) also provides additional evidence for a controlling role of nitrogen in these systems.

Various approaches have been used to assess nutrient limitation and can give widely divergent results, depending on the ecosystem component or process considered (e.g., biomass limitation versus net plant production versus net ecosystem production), the timescale of the observation or the particular parameter assessed as an index of limitation and cellular capacity for growth (5,54). Nutrient bioassays in which nutrients (N or P) are added to incubations of natural water are commonly used to assess nutrient limitation. Short-term (e.g., hours) nutrient bioassays often focus on physiological responses, for instance in gross photosynthetic capacity as determined by $^{14}CO_2$ uptake, whereas somewhat longer (days) term assays are needed to monitor biomass (often as chlorophyll *a*) accumulation that approximates net production. Biologists generally focus on nutrient limitation of growth on timescales of hours to days, whereas geochemists are typically more interested in net ecosystem production at larger spatial dimensions (e.g., basin scale) and often on much longer timescales (54).

The simplistic view that nitrogen is the key limiting nutrient throughout most of the ocean is being rapidly

replaced with a much more dynamic view of seasonal variation in limiting nutrients in estuaries (55,56) and coastal waters (57). The high nitrate/low chlorophyll (HNLC) concentration oceanic regions are primarily Fe-limited (58). Phosphorus may be a key limiting nutrient in shallow tropical ecosystems (54,59,60) and even the North Atlantic (61). Moreover, we have also come to recognize that nutrient limitation may differ between contemporaneous species within a system (e.g., Si or Fe limitations of diatoms (57,62), or Fe (63,64) or P (65) limitation of nitrogen-fixing cyanobacteria in ostensibly nitrogen-limited ecosystems).

New Nitrogen and Oceanic Productivity

A useful conceptual framework for placing oceanic nitrogen-cycle studies in the broader context of carbon productivity is the "New Production Model" (66). This model recognizes two types of phytoplankton primary production: (*1*) "recycled" production supported by nitrogen (termed "recycled nitrogen") regenerated from organic matter within the euphotic zone, and typified by NH_4^+ and (*2*) "new production" that is supported by nitrogen imported from outside the euphotic zone and exemplified by NO_3^- diffusing or advecting up from deep pools, nitrogen fixation, atmospheric nitrogen deposition as well as nitrogen derived from rivers and runoff in nearshore areas, all representing sources of "new nitrogen" (Fig. 2).

One very useful aspect of the concept is to provide a constraint on organic export from the euphotic zone, independent of more conventional (and controversial) procedures such as direct measurement of export flux (67). Interest in the capacity of the upper water column to draw down and export to depth atmospheric CO_2 reinvigorated interest in estimating new production (68). Initial attention was focused on the role of deep NO_3^- in promoting atmospheric CO_2 drawdown, but the recognition that NO_3^- codiffuses or advects from depth with greater than stoichiometric amounts of CO_2 with respect to phytoplankton needs, mitigates the potential for deep NO_3^- to affect atmospheric CO_2 sequestration (69). On the other hand, new production dependent on nitrogen fixation or atmospheric combined nitrogen deposition can support CO_2 sequestration (70,71).

Benthic-Pelagic Coupling

Although the deep benthos of the open ocean receives organic debris from overlying waters and may exhibit seasonal responses to input (72), only a small fraction of the export production reaches the sea bottom (73), and the benthos is sufficiently far removed that it has essentially no affect on processes on the upper, photic layers on short (annual-decadal) timescales. However, as one moves closer to the continents, the ability of the benthos to interact on biologically relevant timescales with the euphotic zone increases dramatically. In general, the higher levels of new production found in coastal surface waters (68) results in a higher delivery of exported production to the sediments (73) and higher sediment organic content (17). Low O_2 and higher concentrations of NH_4^+ are often associated with nearshore and coastal sediments, both a result of the intense heterotrophic metabolism by the dense populations of bacteria in the sediments. Fluxes of inorganic nutrients from the benthos, in turn, can support a large fraction of the nutrient demand of water column primary productivity (53). The high levels of spring production fueled by high nutrients in spring freshets in estuaries, or winter overturn in coastal waters often result in organic accumulation in sediments that are metabolized through the year providing a steady supply of inorganic nutrients to overlying waters (74).

Coupling of Biogeochemical Cycles

In the sea as elsewhere, the nitrogen cycle does not operate in isolation but is directly coupled to the cycling

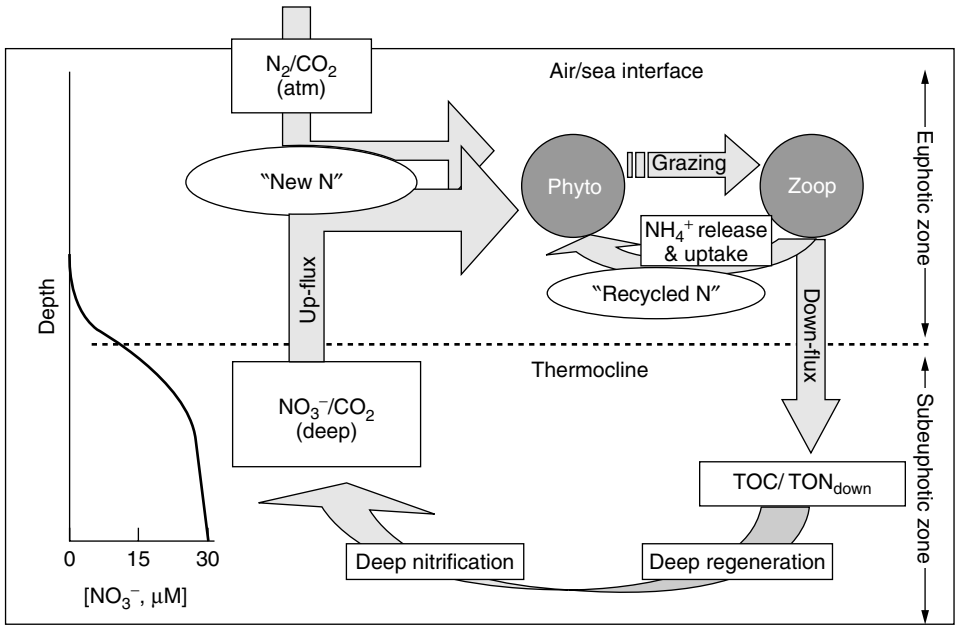

Figure 2. Conceptual representation of the new nitrogen model after R. C. Dugdale and J. J. Goering (66). Abbreviations: TOC = total organic carbon; TON = total organic nitrogen.

of carbon and other biologically relevant elements. In addition to a carbon source, all organisms have a biosynthetic requirement for a suite of essential nutrients (e.g., N, P, S, Mg, Fe, etc.; see INORGANIC NUTRIENT USE BY MARINE MICROORGANISMS, this Encyclopedia), needed in stoichiometric proportions for balanced growth (33). Nitrogen is a macronutrient because it often constitutes several percent of cell biomass. Hence, all organisms regardless of their physiology devote portions of their overall energetic metabolism to nitrogen acquisition and incorporation. Furthermore, forms of inorganic nitrogen are directly involved in the energetic metabolism of certain heterotrophic (e.g., NO_3^- reducers and denitrifiers), and autotrophic (e.g., nitrifiers) bacteria.

Within particular biogeochemically significant species of bacteria and archaea, one can find the capacity to link sulfate respiration and methanogenesis with nitrogen assimilation and ammonification, to couple sulfide, NH_4^+ or H_2 oxidation to denitrification (75), or methane oxidation, sulfate reduction or denitrification to nitrogen fixation. Interestingly, bacteria and archaea of different presumed physiologies can exhibit considerable plasticity in metabolism: CH_4 oxidizers often have a capacity to nitrify although many nitrifiers can oxidizers CH_4 (76); some bacteria classified as denitrifiers can reduce metals (and vice versa) (77).

Controls on Nitrogen Cycle Pathways

Controls on nitrogen cycle processes range from molecular and physiological regulation (e.g., product feedback inhibition and substrate limitation of enzyme activity and gene transcription), to broad-scale physical phenomenon (light, temperature, diffusion, convective mixing; see NITROGEN FIXATION IN THE MARINE ENVIRONMENT AND NITRIFICATION IN AQUATIC SYSTEMS- this volume). The mix of controlling factors determining the processes that dominate various environments result in the characteristic nitrogen cycle of particular systems.

As alluded to earlier (in *N as a Limiting Nutrient* section), the availability of elements other than nitrogen are often controlling factors in particular ecosystems, or of subpopulations within ecosystems. For instance, although the concentration of a particular substrate or product of a nitrogen transformation pathway may directly modulate a reaction rate in nature, the rate of transformation of specific forms of nitrogen can also be constrained by the availability of other required elements. Iron availability, which has been found to limit primary productivity in certain areas of the ocean (58), may constrain the rates of NO_3^- assimilation or nitrogen fixation because the enzymes responsible for the utilization of these compounds are Fe-containing (i.e., NO_3^- reductase and nitrogenase, respectively) (30,63). Atmospheric deposition of aeolian dust is thought to be a key pathway of Fe flux into the sea (78) and appears to stimulate primary productivity in some areas of the oceans (see following text), possibly through enhancement of NO_3^- assimilation and N_2 fixation (64).

The availability of other chemical constituents may also limit or determine the relative importance of particular nitrogen cycle pathways. Organic substrates can limit denitrification (39) or heterotrophic nitrogen fixation (79). Oxygen concentration can profoundly influence the relative importance and rates of nitrogen cycle reactions such as nitrification, denitrification and nitrogen fixation. The source of phosphorus for planktonic nitrogen fixers, such as the cyanobacterium *Trichodesmium*, which proliferate in highly oligotrophic tropical oceanic waters remains to be identified (65,80). Phosphorus can be an important controlling factor in benthic nitrogen fixation in shallow carbonate systems (59). Most recently, important interactions of silicon, nitrogen, and iron have been shown for oceanic systems dominated by diatoms (57,62,81).

Increased nutrient input into nearshore environments from anthropogenic sources can uncouple controls on natural biogeochemical processes. Such impacts can cause direct perturbations on rates of nitrogen cycling, with dramatic and profound effects on nearshore ecosystems. Examples of anthropogenic disturbance include the effect of duck excreta in stimulation of plankton blooms in Great South Bay, New York (25), and the overgrowth of coral reef ecosystems by macroalgae resulting from increased nitrogen loading (82,83). More dramatic examples are the apparent increases in the extent of anoxia over the last few decades in systems such as the Chesapeake Bay (84,85) or coastal waters of the Mississippi plume (86), which have been related to increased nitrogen fluxes to these systems.

CONTRASTING SYSTEMS

The details of the nitrogen cycle vary greatly among ecosystems with respect to the mode of N delivery and removal, the relative sizes of nitrogen pool and species and the relative importance of particular nitrogen transformation pathways. Contrasts with respect to nitrogen distributions and processes are easily seen along the various spatial gradients that define the major oceanic provinces (87,88)—for example, with respect to distance offshore, mixed layer, and photic zone depth, and as a function of overall depth to the sea floor. Sharp contrasts in nitrogen distributions and transformation processes are evident along latitudinal gradients. Relatively nutrient-poor waters in the oceanic tropics grade into nitrogen-rich waters at temperate and boreal latitudes. In surface waters at higher latitudes, the processes of the nitrogen cycling exhibit strong seasonality. Substantial variations in nitrogen cycling and nitrogen distributions occur with depth in the water or sediment column.

Temperate Estuarine and Coastal Shelf Waters

In nearshore environments, such as estuaries and, to a lesser extent, coastal shelf waters, inorganic nutrient fluxes are often dominated by external inputs, arriving from riverine flow, runoff, atmospheric deposition and groundwater discharge (53). Large inorganic nutrient inputs and pools, combined with a high capacity for primary production, result in rapid incorporation of inorganic nitrogen into organic material. Subsequently, this dissolved and particulate organic material can be exported to the sediments or advected from the system. Because of high plant biomass and suspended inorganic

particles from runoff and resuspension, nearshore systems are typically characterized by a shallow euphotic zone, with relatively strong benthic-pelagic coupling (see earlier). Fluxes of nutrients and biological processes are strongly phased by season and vary spatially along gradients from land to sea. Primary productivity is low in winter. Spring freshets bring large nutrient pulses to estuaries and nearshore waters (74) and promote intense primary production and nutrient cycling in mesohaline regions. Maxima in primary production, nutrient uptake and drawdown, and organic export often occur in the spring or early summer, with recycling becoming more prominent in the summer and fall.

In such organic-rich systems, high NO_3^- concentrations can promote considerable levels of denitrification (42,43), which may otherwise be constrained by in situ nitrification rates (40,89). In general, because relatively high supplies of externally loaded and recycled inorganic and organic nitrogen are available for plant growth, nitrogen fixation is not generally of significance in temperate estuaries or shelf waters (79,90).

Temperate and Boreal Oceanic Waters

The open ocean receives substantially less continentally derived nutrient input (48), and exhibits a far greater dependence on the seasonal injection of deep nutrients into the euphotic zone. In temperate and boreal areas, plant production and nutrient drawdown are a cyclic, seasonal phenomena (51). During the winter, convective mixing of deeper waters recharges the euphotic zone with nutrients. The classical spring diatom bloom of the North Atlantic is initiated when day length increases and a seasonal thermocline is established (88,91). Phytoplankton are confined to the upper mixed layer in which there is abundant NO_3^-. As plant biomass increases, there is a corresponding drawdown of NO_3^- concentration. The bloom is terminated when NO_3^- is drawn down and, concurrently, active grazer populations have developed. Populations shift to a dinoflagellate-dominated community in the summer, which depends largely on recycled nitrogen, vertical migration to deep NO_3^- and the slow diffusion of NO_3^- across the thermocline (51).

Coastal and Circum-Antarctic Upwelling Regions

Wind-driven circulation patterns in ocean gyres result in strong regional upwelling along the eastern flank of the major oceanic basins and in the circum-Antarctic region. NO_3^- and PO_4^{3-}-rich deep waters are upwelled and create areas of intensive water column primary production (92). Phytoplankton populations are often dominated by diatoms and uptake of NO_3^- is a predominant process in the nitrogen cycle. However, iron and silicon may play key roles in controlling overall export production (93,94) (see preceding text). Much of this production can reach the sediments (68). Although these areas represent only a small fraction of the surface area of the global ocean, they account for a disproportionate fraction of global productivity and are often associated with high fish production (92,95). Shelf sediments underlying upwelling areas can receive large amounts of sedimenting organic matter, which supports high levels of denitrification (42).

Equatorial Upwelling

In the equatorial Pacific, there are large areas of equatorial divergence that drive weak upwelling. These zones exhibit enhanced productivity relative to the surrounding oligotrophic gyres (96). Despite the upwelling of NO_3^- in these HNLC areas, levels of phytoplankton biomass do not attain the concentrations expected, given the ambient nutrient concentrations. Among key nutrients, upwelled NO_3^- is not drawn down completely (58,97,98). Martin and coworkers (58) hypothesized that export production and nitrogen cycling in these systems far removed from continental sources was in fact be Fe-limited. Recent experimental research has confirmed that iron is indeed a major factor in limiting phytoplankton populations in HNLC areas (99,100). Silicate also plays a key role in regulating the uptake of nitrate by diatoms and their export in these regions (81).

Subtropical/Tropical Oceanic Gyres

The subtropical and tropical oligotrophic gyres are vast areas of the worlds' oceans, representing 40 to 60% of the total ocean area. In these systems, continental influences are at a minimum, surface water temperatures are high and relatively constant seasonally, the upper water column is permanently stratified and chronically depleted in nutrients and, consequently, primary productivity is also low. Primary production is largely dependent on recycled nitrogen (68). The euphotic zone is typically very deep ($\geq >80$ m), and there is generally a chlorophyll *a* and algal biomass maxima toward the base of the euphotic zone (typically at 60 to 80 m). One source of "new" nitrogen for these systems is the slow vertical diffusion of NO_3^- across the thermocline (4,101) and, possibly, periodic eddy pumping (102). Some NO_3^- transport from depth to the near surface is effected by vertically migrating diatom mats (*Rhizosolenia* nitrogen) (103). Most of the NO_3^- moving upward is intercepted by the phytoplankton populations near the base of the euphotic zone. Atmospheric deposition of dissolved inorganic nitrogen (DIN) (104) and dissolved organic nitrogen may also provide inputs of new nitrogen to these very nutrient-poor systems (10). Nonetheless, the upper mixed layers are generally typified by very low biomass and nutrient concentrations well below the limits of detection by conventional colorimetric measurements (typically estimated to be about 30 nM for NO_3^- and NH_4^+).

Nitrogen fixing organisms, such as the filamentous cyanobacteria *Trichodesmium* spp., inhabit the upper water column in these environments (71). In the subtropical portions of these gyres, nitrogen fixers may only flourish for a few months each year and are of limited significance in nitrogen cycling (105). However, recent research has indicated a much more significant role of nitrogen fixers in tropical systems (48,49,80,106) and a much greater diversity of diazotrophs than previously thought (107) (see NITROGEN CYCLE IN THE MARINE ENVIRONMENT, this Encyclopedia). In the tropical Atlantic Ocean, nitrogen fixation can be of quantitative significance as a source of new nitrogen through the year (71). Moreover, *Trichodesmium* and the diatom endosymbiont

Richelia, which can be observed by ocean color satellite (e.g., SeaWiFS), can bring large pulses of nitrogen into these systems during episodic blooms (108,109).

In the tropical waters of the Indian Ocean, and in the eastern tropical North and South Pacific Ocean, anoxia develops in subsurface waters that have been out of contact with the atmosphere for long periods (see preceding text). Areas of globally significant denitrification occur at the oxic–anoxic interfaces of the intermediate waters of these areas (41). At these interfaces, substantial N_2O production can also occur (110).

Our understanding of the subtropical oligotrophic ocean has greatly benefited over the last decade from the establishment of two time series stations under the U.S. Joint Global Ocean Flux Study (JGOFS): the Hawaiian Ocean Time (HOT) series station north of Oahu in the subtropical Pacific and the Bermuda Atlantic Time Series (BATS) station have provide unmatched data sets with which to discern complex interactions between biogeochemical processes and to detect subtle changes and shifts in major processes over time. Karl and coworkers (70,111) have noted fundamental shifts in phytoplankton populations and predominant nitrogen cycle processes at HOT over the last decade, leading from a previously eukaryote-dominated nitrogen-limited system to a prokaryote-dominated phosphorus-limited system with a substantial input of nitrogen by nitrogen fixers in the present state. Similarly, Michaels and coworkers (112) have detected large drawdown of dissolved inorganic carbon at the BATS site each summer, which cannot be sustained by available pools of inorganic nitrogen or phosphorus. Along with large positive N* anomalies at middepths, they have concluded that a substantial amount of nitrogen fixation must be occurring at this station (48).

Coral Reef, Algal Mats, and Large Plant-Dominated Communities

In shallow marine systems, a variety of benthic plant communities proliferate. These systems exhibit particularly intense rates of primary production and nitrogen cycling and include temperate salt marshes (113), the rooted seagrasses of the tropics and temperate zones (114), tropical mangroves (115), kelps (116) and coral reefs (117). Macroalgal communities (118) and algal mats often occur in association with each of these communities.

Rooted plant systems such as the seagrasses and salt marshes, are very productive and, therefore, plant nitrogen demand is high (see SEAGRASSES COMMUNITIES AND PLANT–MICROBE INTERACTIONS IN THE MARINE ENVIRONMENT, this Encyclopedia). Much of this demand is met by root uptake of nitrogen from sediment pore waters (119). Intensive nitrogen regeneration and nitrogen fixation in the sediments provide ample dissolved nitrogen in these systems to meet demand (120). Algal mats are notable for their vertical compression of processes. Coral reefs, which are largely defined by the coral-algal symbioses (but which may also be dominated by macroalgae) are generally thought to proliferate in nutrient-poor tropical waters because of high levels of nitrogen fixation occurring in these environments (117,120).

GLOBAL PERSPECTIVES

Nitrogen Budgets and Balances

Processes and pools in the marine nitrogen cycle are often placed in the context of the terrestrial and global nitrogen cycles. Estimates of the gaseous nitrogen pools and some inorganic nitrogen (e.g., NO_3^-) pools have been refined on the basis of results from diverse and far-ranging oceanographic studies such as the GEOSECS (Geochemical Sections) and WOCE (World Ocean Circulation Experiment), as well as intensive monitoring programs in many nearshore and coastal areas. Because of the difficulty in the analytical approaches involved in measuring organic DON, PON pools, far fewer measurements are available for these nitrogen compounds. Consequently, our projections of global pools of DON and PON are less robust. Although we broadly understand the distribution and relative importance of nitrogen processes, we still lack quantitative estimates of the fluxes and internal transformations of nitrogen within many systems.

With increasing evidence of large-scale perturbations of the nitrogen cycle (see following text), it has become more pressing to develop capabilities to predict changes that may occur in the near term. Estimating the overall current size of the various pools and magnitude of specific processes of the nitrogen cycle in the sea, improving our estimates as new data become available, and attempting to retrospectively infer changes that have occurred in earlier earth history will foster that ability.

Current estimates of the major fluxes of nitrogen in the ocean indicate that riverine inputs into the oceans are relatively well constrained and are thought to account for an input of between 21 and 110 Tg N/y. Atmospheric deposition to the sea surface accounts for an input of about 56 to 154 Tg N/y (Table 2). This value has recently been revised upward to include DON deposition (10). Current estimates for pelagic nitrogen fixation range from about 80 to more than 190 Tg N/y (121) (Galloway and coworkers in prep.). Benthic nitrogen fixation has been estimated to account for an input of about 15 Tg N/y (122).

The demand for nitrogen by primary producers can be inferred from extensive surveys of primary production in the world's oceans. Current estimates suggest that nitrogen demand for total oceanic primary productivity to be about 7,200 Tg N/y (123). Of this total, export ("new") production is thought to account for about one-third, or 2,400 Tg N/y. In theory, in a steady state ocean, the demand for new nitrogen should be met by the sum of external inputs (atmospheric deposition and sources from land), nitrogen fixation and NO_3^- from depth (22,38). Even assuming maximum values for the other sources of nitrogen (Table 2), NO_3^- from depth (arising from regeneration and nitrification) must account for the bulk of new nitrogen demand (Fig. 2).

The oceans are currently estimated to be taking up atmospheric carbon dioxide at a rate of about 2 Pg/y (124). This occurs through both chemical solution of CO_2 (referred to as the solubility pump) and by biological uptake (the biological pump) (125). The amount of nitrogen that would be required to biologically assimilate 2 Pg

Table 2. Major Nitrogen Fluxes in the Ocean

Process	Flux Tg N/y	Source
Inputs		
Riverine & runoff	21 to 110	8, 126, 163
Atm deposition	56 to 154	10
N_2 fixation Water column	80 to 190	49, 71, 122
Benthic	15	122
Total	172 to 469	
Production demand		
Planktonic		
Total Prod	7,200	123
Export Prod	2,424	123
Benthic-net annual	160	164
Outputs		
Sedimentation	20 to 38	127, 165, 166
Denitrification Water column	64 to 290	41, 129, 130
Benthine	60 to 300	41, 42, 43, 44
Total	144 to 628	

of carbon dioxide assuming Redfield stoichiometry is about 350 Tg. This is approximately equivalent to upper projections for all external inputs including nitrogen fixation (Table 2).

Estimates of rates of nitrogen losses from the sea through sedimentation of PON and burial over the vast expanses of the sea floor are difficult to make and are therefore also rare. However, given the great depth and relatively low productivity over much of the oceans, little detritus makes it to deep sediments (73). Continental margins are thought to be key areas of organic burial in the current ocean (126,127). Current estimates of N burial range from 20 to 38 Tg N/y (Table 2).

Denitrification in the oceans has been examined more intensively, particularly in the Indian (128) and tropical Pacific Oceans (41,129), and on the continental shelves (42,44) (see preceding text) over the last few decades, and there have been several upward revisions of its quantitative significance (130). Water column denitrification has been estimated to account for losses of about 64 to 290 Tg N/y, whereas denitrification losses from coastal and shelf sediments has been estimated to be approximately 60 to more than 300 Tg N/y (42,44). Other mechanisms, whereby nitrogen may be lost from the system include gaseous evasion of nitrogen (16) and fisheries harvest.

Although lower end estimates are about equivalent, current upper end values indicate total nitrogen inputs are about 160 Tg N/y less than estimates for its removal, suggesting an imbalanced nitrogen cycle. This may be because of underestimates of nitrogen inputs or overestimates of nitrogen losses. However, there is no a priori reason to assume a balanced nitrogen cycle, which may only be achieved over longer timescales (e.g., timescales of oceanic mixing; 131).

Large-Scale Perturbations of the Nitrogen Cycle

Current evidence indicates large-scale natural (70) and human-induced (6) perturbations in the marine nitrogen cycle, paralleling those occurring in the carbon cycle (132). River loads of nitrogen to the sea have increased dramatically over recent time (133). Resultant coastal eutrophication and increasing hypoxia have been mentioned earlier (see Controls on N cycle pathways, this Encyclopedia). Increasing nutrient loading in coastal areas may account for stimulated uptake and burial of carbon dioxide on the shelf in these areas (126).

Nitrous oxide has been implicated in atmospheric reactions leading to the destruction of ozone in the stratosphere (7). It is also a potent greenhouse gas with a several hundredfold greater capacity for absorption of radiation per molecule than carbon dioxide and can thereby contribute to radiative heating in the troposphere (134). Direct manifestation of global perturbation has also been detected in atmospheric N_2O pools. The atmospheric concentration of N_2O, which is about 330 ppb at present, has been increasing at about a rate of 0.2 to 0.3% per year (134). The role of the oceans as a source or sink of N_2O to the atmosphere is uncertain (21,38). As indicated earlier, the seas play a central role in N_2O cycling (38) and may act as source (16,135) or sink for this gas.

The suggestion by Martin and coworkers (93), that fertilization of HNLC areas of the ocean with Fe to stimulate oceanic primary production and carbon export in these areas could help ameliorate increasing atmospheric CO_2, created a lively discussion during the early 1990s about the merits of such a scheme (136). Although much of the debate centered on the factors controlling phytoplankton populations in these areas, discussions of the feasibility and merits of large-scale environmental engineering also entered the debate. The possibilities that such a scheme would work was met with skepticism by many oceanographers (69,137). Among possible scenarios proposed, Fuhrman & Capone (138) proposed that fertilization could stimulate the production of other gases with potential impacts on climate, such as N_2O and dimethyl sulfide (DMS), through the production of suboxic waters with increased surface production and flux. Although N_2O wasn't analyzed during the IRONEX experiment, Turner and coworkers (139) did observe increases in DMS.

Interest in ocean Fe fertilization has been reinvigorated with the positive results of several more open-ocean iron enrichment experiments in two HNLC regions, the IRONEX II experiment in the equatorial Pacific (100), and the SOIREE experiment in the Southern Ocean (140). Furthermore, the proposition that nitrogen fixers are largely nitrogen limited in low-nutrient low-chlorophyll (LNLC) (141) regions presents the prospect of stimulating this process by Fe fertilization as well.

HOW WE STUDY THE NITROGEN CYCLE

The approaches to study the marine nitrogen cycle are many and varied, and new methods are constantly evolving. As in all analytical fields, we are ever seeking to improve our sensitivity for detecting analytes and for specific transformations, to develop methods to detect new compounds and pathways, to minimize our perturbations of systems studied, to reduce the

introduction of experimental artifacts and to increase the efficiency, frequency, and coverage of our sampling (142,143).

It is beyond the scope of this article to detail and critique the various analytical methods involved in assessing nitrogen cycling. Parsons and coworkers (144) publication serves as a starting point for methods involved in routine determination of major inorganic and organic pools. D'Elia (145) has reviewed methods for determination of nitrogen compounds in seawater.

Methodology for the various microbiological and biogeochemical assays involved in nitrogen cycling may be found in several recent compendia. See articles in: Kemp and coworkers (146), including Capone (147,148) and Seitzinger (149); in Hurst et al. (150) including Capone (151); and in Knowles & Blackburn (152) including (153). See also (154).

At the broadest level, our approaches to studying the marine nitrogen cycle can be regarded as either observational or experimental, and the earliest insights into the marine nitrogen cycle came from observations of the spatial and temporal distributions of key nutrients such as NO_3^- in marine waters and sediments. The application of the natural abundance of stable isotopes of biologically relevant elements has greatly enhanced the utility of observational approaches (155). Using the small differences in the ratio of the stable isotopes of nitrogen, ^{14}N and ^{15}N, with a knowledge of source materials and the extent of fractionation by particular biological and chemical transformations, one can glean substantially more information than from just the distributions of particular pools of the nitrogen cycle.

In parallel with observational studies, experimental studies using natural and cultured populations have expanded our understanding of microbially mediated nitrogen transformations. The isolation and characterization of nitrifying (156), denitrifying (41) and nitrogen-fixing (79) marine bacteria and archaea has allowed us to identify and characterize the microbiological basis of the major nitrogen transformations. Experimental approaches examining nitrogen transformations have allowed direct confirmation of inferences and hypotheses developed using observational and classical microbiological methods. Direct tracer methods are preferred to directly quantify specific pathways of biological nitrogen transformation (157). Although nitrogen does have a radioisotope, ^{13}N, its very brief half-life and the sophisticated facilities necessary to generate it, precludes its usefulness in field applications (148,151). In contrast, the stable isotope of N, ^{15}N, is available in a variety of forms useful for determining rates of specific pathways.

The enzymes mediating various nitrogen transformations (e.g., assimilatory NO_3^- reductase, glutamine synthetase) have been characterized and assays developed to estimate the activity in natural populations of marine microbes (30). Recently, immunological and molecular methods have provided sensitive means to detect proteins and genes involved in nitrogen cycle transformations (158,159).

Providing mathematical formalisms, which describe the cycling of nitrogen in the sea and which test our conceptualizations of processes is an activity dating back to Redfield (160), Riley (161) and Dugdale (162). "Modeling" has become an indispensable tool with which to integrate our knowledge of the marine nitrogen cycle and to place this knowledge in a broader framework.

CONCLUSION

The biogeochemical cycle of nitrogen is relatively complex, with forms of nitrogen occurring over a range of oxidation states, and in a variety of chemical forms and phases. A diversity of biological nitrogen transformations are linked to reactions of energetic metabolism and basic nutrition. Many of the reactions are restricted to prokaryotes. The uptake and release of nitrogen to and from organic pools are quantitatively important pathways in many plant-dominated environments. The bacterial nitrogen transformations of nitrogen fixation, nitrification and denitrification, largely determine the form and relative availability of key nitrogen species and there is considerable variation among systems with respect to the relative importance of these pathways. The nitrogen cycle is an important feature of all marine ecosystems and is a factor affecting the net productivity of many of these systems: it is susceptible to perturbation at various levels. Components of the marine nitrogen cycle may provide important feedbacks to marine carbon cycling and to global climate change.

NITROGEN FIXATION IN SOILS — FREE-LIVING MICROBES

DAVID A. ZUBERER
Texas A&M University
College Station, Texas

Biological dinitrogen (N_2) fixation, the conversion of atmospheric dinitrogen to ammonia for incorporation into cell components, is often described as the second most important biological process on earth after the process of photosynthesis. In fact, it would be seen as equally important from certain points of view. It is true that life on earth depends on the use of solar energy and the fixation of carbon dioxide by photosynthetic plants and microbes to produce the biomass that is at the base of all food webs. However, primary production (i.e., CO_2 fixation and biomass production) is generally limited by the availability of fixed nitrogen (N), for example, ammonium (NH_4^+) and nitrate (NO_3^-). Thus, high rates of photosynthesis and plant production are dependent on a ready supply of fixed nitrogen.

Before the advent of industrial fertilizer factories, agricultural production relied on the use of animal manures, green manures (crops such as legumes grown to enrich the soil), and the use of dinitrogen-fixing grain and forage legumes. Natural, unfertilized ecosystems rely on nitrogen from wet and dry deposition and from any of a number of associations that involve free-living (nonsymbiotic) dinitrogen-fixing microbes (bacteria and cyanobacteria) or symbiotic plant-microbe associations involving root-nodule bacteria such as *Rhizobium* and *Bradyrhizobium* or the actinomycete *Frankia* (1).

This review explores the fundamentals of the process of biological dinitrogen fixation and the role of free-living dinitrogen-fixing microbes in soil. Root-nodule symbioses are covered in detail in NITROGEN FIXATION (IN SOILS, SYMBIOTIC) this Encyclopedia.

THE SIGNIFICANCE OF DINITROGEN FIXATION

Global agricultural consumption of synthetic nitrogen fertilizer increased 27-fold between 1950 and 1990 to approximately 80 million metric tons per year, which is about 50% of the total amount of nitrogen fixed by biological and physical processes (2). Nitrogen is absolutely essential for microbes and higher organisms to synthesize proteins and other important biochemicals (e.g., nucleic acids), and it is a fundamental tenet of agriculture and plant physiology that plants require relatively high levels of nitrogen to produce abundant biomass (yield). Nitrogen is generally the most limiting nutrient for plant and microbial growth (assuming adequate available carbon for microbes) in soils not receiving supplemental fertilizer nitrogen. In natural systems, nitrogen for plant growth comes from the mineralization of soil organic matter, from rainfall or other atmospheric deposition, or through biological dinitrogen fixation.

About 85 million metric tons of nitrogen is fixed annually through industrial processes (3–5). The expense

factor of nitrogenous fertilizers is derived in part from the requirement for substantial inputs of energy, usually in the form of natural gas (see Section Energy costs of nitrogen fixation). However, industrial fixation provides only about 1/3 to 1/2 the amount of fixed nitrogen acquired through biological dinitrogen fixation. Accurate estimates of the magnitude of biological dinitrogen fixation are hard to derive but reported values range from 100 to 180 million metric tons per year. About 65% of the nitrogen used in agriculture is biologically fixed nitrogen (6). Most of this is through symbiotic dinitrogen fixation (see NITROGEN FIXATION IN SOILS (SYMBIOTIC)) but nonsymbiotic and associative dinitrogen fixation is reportedly of significance in crops such as sugarcane and sorghum, which have a C_4 photosynthetic pathway and may be grown in ecosystems where nitrogen for plant growth is a limiting factor. Paddied rice, because of its cultivation in flooded soils, derives significant benefit from the activities of free-living diazotrophic bacteria and cyanobacteria that find favorable habitats (root exudates, low oxygen concentrations, etc.) in the flooded soils.

Biological dinitrogen fixation remains an effective alternative to the use of expensive ammonium-based fertilizer nitrogen but it must be emphasized that the high-yielding agricultural systems of the U.S. and elsewhere are difficult to sustain by relying only on biological dinitrogen fixation and the use of animal manures. The growing world population will probably dictate production systems that will require judicious use of synthetic and, where possible, organic fertilizers. Legumes, other dinitrogen-fixing systems (e.g., the *Azolla-Anabaena* symbiosis), and perhaps genetically modified plants yet to be developed will continue to play an important role in sustainable agricultural production. Nitrogen-fixing plants are also of high value in restoring disturbed or impoverished soils. They serve as excellent cover crops, green manures, and forage crops for livestock production. Use of dinitrogen-fixing crops also has the potential to reduce the contamination of groundwater with nitrate. Further aspects of the utility of symbiotic nitrogen fixation in agriculture and other ecosystems are discussed elsewhere in this volume (NITROGEN FIXATION (SYMBIOTIC) IN SOILS).

THE NITROGENASE ENZYME COMPLEX

It is believed that the process of biological dinitrogen fixation is restricted to procaryotic microbes, including many genera of soil bacteria, cyanobacteria (formerly the "blue-green algae"), and a few actinomycetes (most notably, *Frankia*). Microbes that can use dinitrogen as their sole nitrogen source are often referred to as "diazotrophs" (a term coined by R.W.F. Hardy in the early 1970s). When used in this article, the term applies to any dinitrogen-fixing microbe (bacterium or cyanobacterium) that is capable of fixing dinitrogen independent of any higher-plant host if given sufficient supplies of energy and carbon sources. These microbes can fix dinitrogen as free-living forms (i.e., not plant associated) in loose associations with higher plants called associative symbioses (e.g., many grass-bacteria associations) (1) and in truly symbiotic partnerships with higher plants called root-nodule symbioses, involving rhizobia and *Frankia*.

A trait shared by all the microbes mentioned earlier is that they produce the enzyme complex called "nitrogenase," which mediates biological dinitrogen fixation. It is most appropriately called the "nitrogenase complex" because it is actually composed of two protein components (dinitrogenase and dinitrogenase reductase), each of which is composed of multiple subunits. The nomenclature of the nitrogenase complex is as follows (7,8):

- The overall complex is known as nitrogenase.
- The MoFe protein is dinitrogenase (the "type species" substrate is dinitrogen; enzymes conventionally are named relative to their substrate).
- The Fe protein is designated dinitrogenase reductase; the general consensus is that its function is the reduction of dinitrogenase.
- Functional aspects of the nitrogenase complex are shown schematically in Figure 1. Unusual properties of the nitrogenase complex (8) are summarized in the following section:
- It consists of two proteins; the MoFe protein (dinitrogenase) and the Fe protein (dinitrogenase reductase);
- it is destroyed by oxygen;
- it contains iron and molybdenum or vanadium;
- it needs Mg^{2+} ions to be active;
- it converts ATP to ADP when functioning;
- it is inhibited by ADP;
- it reduces dinitrogen and several other small triply bonded molecules;
- it reduces H^+ to H_2 even when dinitrogen is present.

The overall reaction for biological dinitrogen fixation using nitrogenase is as follows:

$$N_2 + 8H^+ + 8e^- + 16\text{Mg-ATP} \xrightarrow{\text{Nitrogenase}} 2NH_3 + 16\text{Mg-ADP} + \text{nPi} + H_2 \uparrow \quad (1)$$

Two MgATPs are required for each electron transferred from dinitrogenase reductase to dinitrogenase. Thus, the reaction, as written, shows a requirement for 16 molecules of ATP (470 kJ; 112 kcal). This is the equation for the reaction as mediated by cell-free enzyme extracts. Under natural conditions, however, probably 20–30 MgATPs may be needed as the process is less efficient than when observed under optimum laboratory conditions (9,6). A consensus on the general model for the mechanism of nitrogenase has evolved over quite a few years. The mechanism can be summarized as follows:

- Dinitrogenase reductase (the Fe protein) accepts electrons from a low-redox donor such as reduced ferredoxin (Fd_{red}) or flavodoxin (Fld) and it binds two MgATPs (Fig. 1).
- It transfers electrons, one at a time, to dinitrogenase (the MoFe protein).

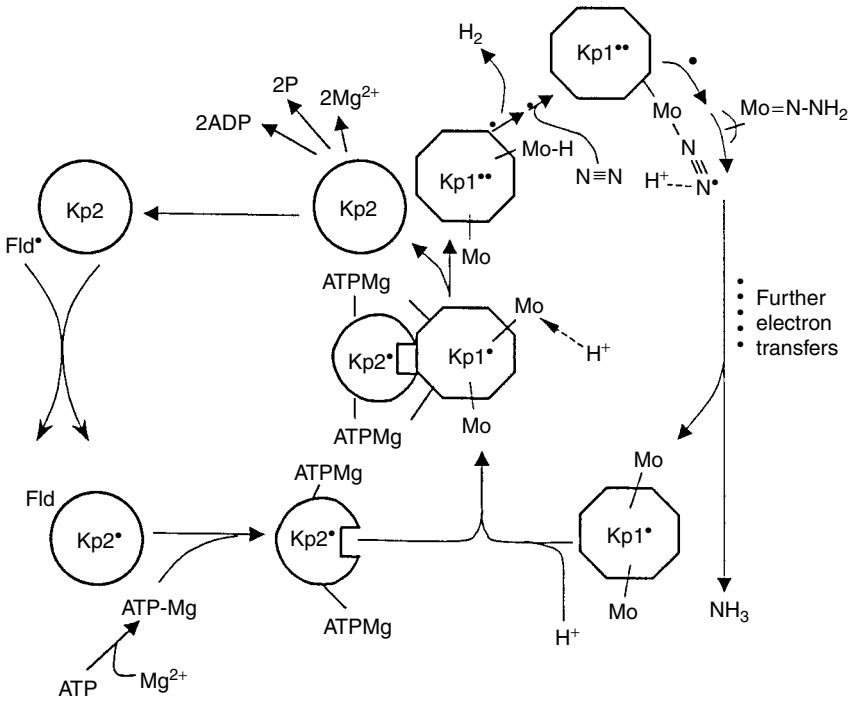

Figure 1. A scheme for the action of the Klebsiella nitrogenase complex. Kp1 is the larger protein, containing iron and molybdenum atoms (dinitrogenase, the MoFe protein); Kp2 is the smaller protein with iron atoms only (dinitrogenase reductase, the Fe protein). Fld is flavodoxin, which donates an electron (black dot) to iron atoms in Kp2. ATP reacts with magnesium ions to produce a compound which activates the reduced form of Kp2. Meanwhile Kp1, with a "spare" electron among its iron atoms, has bound a hydrogen ion from water at a transition metal atom depicted as molybdenum. Activated Kp2 joins Kp1 carrying substrate to form a complex, assisted by ATPMg, within which an electron from the iron atoms in Kp2 is transferred to the iron atoms in Kp1, prior to reaching the bound substrate. After two such electron transfer events, the two bound hydrogen atoms are displaced by N_2 and released as hydrogen gas (H_2). Further electron transfers lead to hydrogen ions binding to the bound N_2 and so by way of at least one metal-bound intermediate stage (depicted as $-Mo-N-NH_2$) the product, NH_3, of enzyme action is released. Each electron transfer requires a new electron from Kp2 and each time the transfer takes place two molecules of ADP are formed from the ATP. The two proteins have to come together and separate eight times to reduce one N_2 molecule. The scheme is one of several that could be proposed based on the experimental findings that Kp2 is concerned with ATP consumption and electron transfer, Kp1 with substrate binding and reduction. Redrawn from J. R. Postgate, Nitrogen Fixation. 3rd Ed., Cambridge University Press. Cambridge, UK, 1998. Reprinted with permission of Cambridge University Press.

- Dinitrogenase reductase and dinitrogenase form a complex, the electron is transferred, and two MgATPs are hydrolyzed to two MgADP + Pi (phosphate).
- Dinitrogenase reductase and dinitrogenase dissociate and the process is then repeated.
- When dinitrogenase has collected enough electrons, it binds a molecule of dinitrogen, reduces it, and releases NH_3.
- The MoFe protein (dinitrogenase) then accepts additional electrons from dinitrogenase reductase (the Fe protein) to repeat the cycle.

In each cycle of dinitrogen fixation, dinitrogenase and dinitrogenase reductase bind together, MgATP is hydrolyzed and an electron is transferred. The dissociation of the MoFe protein–Fe protein complex is the rate-limiting step of the process. In fact, the nitrogenase complex is "remarkably slow — it takes 1.25 seconds for a molecule of enzyme to form two of NH_3. The two proteins have to come together and separate eight times to reduce one dinitrogen molecule" (8). A consequence of the slowness of nitrogenase is that dinitrogen-fixing bacteria must synthesize a lot of the protein. Nitrogenase can commonly account for 10% of the cell's proteins, and levels up to 40% have been recorded (10).

Returning to the reaction of biological dinitrogen fixation described earlier, we can see that for every eight electrons (e^-) transferred via "nitrogenase," $2e^-$ are consumed in the formation of H_2. The production of H_2 that accompanies the fixation of dinitrogen is obligatory. One H_2 (requiring 4 MgATP) is released for each dinitrogen reduced to $2NH_3$ (requiring 12 MgATP). Thus, 25% of the energy from MgATP is "lost" in the production of H_2. Interestingly, some diazotrophs contain an uptake hydrogenase that allows them to oxidize some of the H_2 and to generate a reduced electron carrier or MgATP. This can then be used in the dinitrogen fixation reaction, thereby recapturing some of the energy lost.

The Alternative Nitrogenases

Before the early 1980s, researchers believed that there was only one type of nitrogenase and that molybdenum was essential for dinitrogen fixation. However, in the early 1980s, Dr. Paul Bishop and his colleagues in North Carolina isolated a second nitrogenase (nitrogenase 2) from *Azotobacter chroococcum*, which was produced only under conditions of molybdenum starvation (11). With this

discovery it became evident that molybdenum was not an obligatory requirement for dinitrogen fixation in all bacteria but that it could be substituted with vanadium. Nitrogenase 2 is like nitrogenase 1 in that it consists of two proteins, a VFe protein and an Fe protein, produces H_2, and is sensitive to O_2. Nitrogen binds to the VFe protein, suggesting that metals other than Mo can participate in binding the nitrogen to the protein for reduction. Subsequently, a third nitrogenase, nitrogenase 3, was described (8). This complex does not appear to contain either Mo or V and is synthesized under starvation for both of the metals.

All of the "nitrogenases" are complexes of a dinitrogenase reductase and a dinitrogenase component. Nitrogenases 2 and 3 appear to produce more H_2 than nitrogenase 1 and reduce acetylene to ethane (C_2H_6) rather than ethylene. Quite recently, yet another nitrogenase has been described. *Streptomyces thermoautotrophicus* is a unique, thermophilic (it can grow at 65 °C) actinomycete that can use carbon monoxide (CO) as an energy source and oxidize it to CO_2 or can use H_2. It fixes dinitrogen and is unique in that its nitrogenase is not inhibited by CO and neither reduces acetylene nor is poisoned by O_2. It also relies on a manganese-containing protein that apparently functions as the dinitrogenase (12,8).

The finding that dinitrogen can be fixed in the absence of molybdenum (Mo) is interesting because prior to the discovery of the alternative nitrogenases it was believed that Mo was mandatory for dinitrogen fixation. It now seems that the predominance of bacteria containing nitrogenase 1 (the Mo-containing enzyme) may have been due to the fact that researchers habitually used Mo-containing media to isolate dinitrogen-fixing bacteria. The other nitrogenases may be quite common in nature although this is not yet known. The study of alternative nitrogenase systems is quite young and many fundamental questions remain unanswered.

Substrates for Nitrogenase

The natural primary substrate for nitrogenase is dinitrogen (N≡N). In addition to reducing N_2 to NH_3 and protons to H_2, nitrogenase also reduces several other small, triple-bonded molecules (Table 1). Of particular interest among this list of substrates is the gas acetylene. In the late 1960s, it was discovered that nitrogenase could reduce acetylene (HC≡CH) to ethylene ($H_2C{=}CH_2$) (13). The significance of this finding lay in the fact that acetylene and ethylene can be very easily measured using a gas chromatograph to separate the two gases. This gave rise to the simple, sensitive, and rapid acetylene-reduction assay for nitrogenase activity, the development of which led to an explosion in research on dinitrogen fixation. It eliminated the need to have an expensive mass spectrometer for studies using ^{15}N or to deal with the tedious and insensitive Kjeldahl analyses to measure nitrogen in soil or biological materials. The technique is currently widely used, but one should become familiar with the limitations of the technique before extrapolating its results to actual rates of dinitrogen fixation in field samples (14,15).

Table 1. Substrates for Nitrogenase: The Triple Bond Connection

Name	Formula	Major Products
Proton	H^+	H_2
Dinitrogen	N≡N	$NH_3 + H_3$
Nitrous oxide	$N{\equiv}N^+{-}O^-$	$N_2 + H_2O$
Azide	$[N{\equiv}N^+{-}N^-]$	$N_2 + NH_3 + N_2H_4$
Acetylene	HC≡CH	$H_2C{=}CH_2$
Cyanide	$[C{\equiv}N]^-$	$CH_4 + NH_3$
Carbon monoxide	C≡O	C≡O apparently binds to the N-binding site but is not reduced. It blocks reaction with other substrates.

The Genetics of Nitrogenase

As one might surmise from the complexities of the system described earlier, the genetics of the process are equally complex. Much of our knowledge of the genetics of the nitrogenase system has come from the intensive study of the bacterium *Klebsiella pneumoniae*, a member of the family Enterobacteriaceae and a close relative of *Escherichia coli*. Thirty years of research on this bacterium and, more recently, other diazotrophic bacteria has shown that the nitrogenase complex and supporting systems are under the control of 20 or more genes (Fig. 2); Table 2). The functions of the nitrogen-fixation genes are summarized in Table 2, starting with the gene on the right-hand side of Figure 2. Clearly, the complexity of this system does not make it an easy target for genetic manipulation and transfer to higher organisms. Still, some hold out the prospect that we may someday see genetically engineered crops such as corn, wheat, and other cereals that fix their own nitrogen. However, this is one of the more elusive goals facing nitrogen-fixation researchers.

Physiological Prerequisites for Dinitrogen-Fixing Microbes

The physiological requirements for a free-living diazotroph to fix dinitrogen (8) are summarized in Table 3. These stem

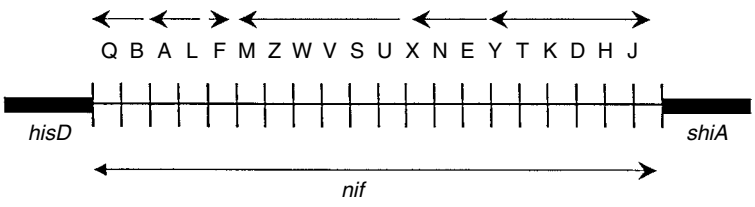

Figure 2. Map of the nitrogen fixation genes of *Klebsiella pneumoniae*. The capital letters denote the separate genes that make up the *nif* cluster. The upper arrows indicate subclusters (operons) in which genes are sequentially transcribed as a group and the directions in which they are read. Brief descriptions of the function(s) of each gene are given in Table 2. Redrawn from J. R. Postgate, Nitrogen Fixation, 3rd ed., Cambridge University Press, Cambridge, U.K., 1998. Reprinted with permission of Cambridge University Press.

Table 2. Currently Recognized or Postulated Functions of the Genes for Nitrogen Fixation in Diazotrophic Procaryotes

nifJ codes for an enzyme (pyruvate oxido-reductase) that generates from pyruvate the electrons used for the reduction of dinitrogen.
nifH codes for a peptide molecule, two of which combine to form dinitrogenase reductase, the smaller of the proteins constituting nitrogenase.
nifD codes for a peptide molecule (called the α-subunit), two of which combine to form part of dinitrogenase, the molybdoprotein of nitrogenase.
nifK codes for a somewhat different peptide molecule (called the β-subunit). Two of these combine to form the other part of the dinitrogenase protein, which is thus an $\alpha_2\beta_2$ tetramer composed of two pairs of similar peptides.
nifT codes for a very small protein molecule of unknown function.
nifY codes for a protein of uncertain function.
nifE codes for a peptide molecule, two of which combine to form the NifE product.
nifN codes for a peptide molecule, two of which combine to form the NifN product. The NifE and NifN proteins combine together to form a protein that somewhat resembles dinitrogenase, which appears to act as a template for synthesizing FeMoco.
nifX codes for a protein, which may have a regulatory function.
nifU codes for a protein possibly concerned with the iron-sulfur center of dinitrogenase reductase.
nifS codes for a protein, which may also be concerned with the Fe-S center of dinitrogenase reductase.
nifV codes for a peptide, two molecules of which combine to form an enzyme which makes homocitrate, a part of FeMoco, from 2-oxoglutarate and acetyl-coenzyme A.
nifW codes for a protein necessary for full activity of dinitrogenase.
nifZ codes for a protein, which seems to be involved in the insertion of FeMoco into dinitrogenase.
nifM codes for a protein concerned with rendering dinitrogenase reductase active.
nifF codes for the flavodoxin, which accepts electrons from pyruvate, via the *nifJ* product, and passes them to dinitrogenase reductase.
nifL codes for a regulator protein, which switches off the whole *nif* cluster.
nifA codes for a regulator protein, which switches on the whole *nif* cluster.
nifB codes for a protein involved in the synthesis of FeMoco.
nifQ codes for a protein involved in the uptake of molybdenum for FeMoco synthesis.

Table 3. Physiological Requirements for Nitrogen Fixation by Free-living Diazotrophic Microbes

- The need for trace elements
  - — Molybdenum or Vanadium, Iron — for "nitrogenase"
  - — Magnesium — for production of "MgATP"
- The need for ATP
  - — A minimum of 16 ATP per N_2 fixed. Probably 20–30 under natural conditions.
  - — Needed for nitrogenase activity and for nitrogenase synthesis.
  - — The high ATP requirement means an abundant supply of energy-yielding substrates must be readily available for vigorous N_2 fixation.
- The need to minimize H_2 evolution
  - — Up to 35% of the ATP diverted to nitrogenase may be consumed in H_2 evolution.
- Acceptable Temperature
  - — Most diazotrophs are mesophiles.
  - — Many will not grow on media at 37 °C.
  - — Nitrogenase activity falls off rapidly at about 40 °C.
- The need to exclude O_2 from the enzyme complex
  - — Nitrogenase is destroyed by O_2
- A source of low-redox reductant
  - — This is restricted to the naturally occurring ferredoxins and flavodoxins.
- Low concentrations of "fixed N"(NH_4^+, NO_3^-, organic N)
  - — Nitrogenase synthesis is repressed by very low levels of combined N and activity of existing enzyme is inhibited.

Note: Adapted from J. R. Postgate, Nitrogen Fixation, 3rd ed., Cambridge University Press, Cambridge, U.K., 1998.

primarily from the unique properties and intricacies of the nitrogenase complex, including its exceptional sensitivity to molecular oxygen, the metal content of the complex (Fe and Mo or V), and the need for adequate supplies of reducing power and MgATP.

As is the case with all soil microbes, diazotrophs are also subject to the limitations imposed by physical, chemical, and biotic factors in their environments. Thus, factors such as moisture content, pH, soil nitrogen (through its effects on enzyme synthesis and activity), temperature, and competition with other microbes, especially for limited supplies of energy sources, can adversely affect their abilities to grow and fix dinitrogen.

Most of the diazotrophs listed in Table 4 are mesophiles (microbes growing at moderate temperatures) and fail to fix appreciable quantities of nitrogen above 37°–40°C.

Table 4. List of Genera of Microbes That Include Dinitrogen-Fixing Species or Strains. The List Is Not Intended to Be All-Inclusive. [Adapted from J. R. Postgate, Nitrogen Fixation, 3rd ed., Cambridge University Press, Cambridge, U.K., 1998. See also Eady (17) and Young (18)

	Genus or Type	Species (Examples Only)

It is noteworthy that three diazotrophic microbes have now been confirmed as thermophiles (microbes growing at high temperatures) (8). These include *Methanococcus thermolithotrophicus*, a methanogenic bacterium that fixes dinitrogen at 64 °C; *Mastigocladus*, a cyanobacterium from hot springs that can fix dinitrogen at 60 °C; and *Streptomyces thermoautotrophicus,* an actinomycete isolated from a smoldering charcoal heap that can fix dinitrogen at 65 °C.

The Energy Costs of Dinitrogen Fixation

Dinitrogen is described as the most stable diatomic molecule known. The two atoms of nitrogen in the diatomic molecule are joined by a very stable triple bond. Breaking the triple bond requires a large amount of energy (945 kJ (226 kcal) per mole) and perhaps therein lies the greatest challenge of fixing dinitrogen chemically or biologically. Dinitrogen fixation is "energy expensive" because it requires much energy to break the triple bond of dinitrogen and also to provide the hydrogen necessary to reduce dinitrogen to $2NH_3$. The chemical fixation of nitrogen is accomplished most widely through the high-pressure catalytic method called the Haber-Bosch process named after the German scientists who developed the process in 1914. The process served as a source of ammonium and nitrates for manufacture of explosives during World War I. The reaction for chemical fixation of nitrogen can be written as follows:

$$N_2 + 3H_2 \xrightarrow[K_2O,\ Al_2O_3]{} 2NH_3(\text{aqueous})$$

$$\Delta G = -53 \text{ kJ}(12.7 \text{ kcal})$$

To obtain high yields from this reaction in reasonable time, high pressures (approximately 200 atm; 20,265 kPa.) are applied to the reaction vessel and the temperature is raised to 400–500 °C. Natural gas (methane) is usually employed as the feedstock for the hydrogen needed to reduce the dinitrogen and is also required to heat the reaction vessel. That is, it takes about 31,000 cubic feet of natural gas, 5.59 barrels of oil, or two tons of coal to fix one ton (2,000 lbs) of ammonia (16). About 40% of this is used to provide the necessary heat and the remainder to provide the H_2 needed for the reaction. It is because the production of ammonium-based fertilizers relies on fossil fuel (natural gas, etc.) that fertilizer costs are high and are, at present, somewhat inextricably linked to fossil fuel prices and the whims of that market. For example, an oil embargo against the United States in the early 1970s resulted in long lines at gas pumps and quadrupled fertilizer prices. The high fertilizer prices were due also, in part, to short supplies at a time of peak demand. Currently, the industrial production of fertilizer nitrogen is a major consumer of fossil energy and "a huge and growing economic cost of more than U.S. $20 billion per year" (2).

The chemical fixation of dinitrogen is energy-intensive, as is its fixation in biological systems (Table 5). The principal differences lie in the sources of reductant and energy and the fact that biological dinitrogen fixation takes place at ambient pressures and temperatures — quite a feat when one considers the rigors of the Haber-Bosch process described earlier. Energy for biological dinitrogen fixation comes from the oxidation of organic carbon sources such as glucose or from light in the case of photosynthetic diazotrophs. It can take several

Table 5. Carbon and Energy Source Requirements for Heterotrophs Grown in Chemostats Limited by the Carbon and Energy Source

Organism	C and Energy Source	Efficiency of N Incorporation During Growth (mg N g^{-1} C and Energy Source Used)		Carbon and Energy Expenditure for N_2 Fixation	
		N_2	NH_4^+	(g C $g^{-1}N_2$)	lb C used per 100 lb of N_2 fixed
		Anaerobic growth by fermentation			
Clostridium pasteurianum	Sucrose	11	22	46	4,600(2,054)[†]

thousand pounds of carbon substrate to fix 100 pounds of nitrogen!

NONSYMBIOTIC NITROGEN-FIXING BACTERIA

Biological dinitrogen fixation is restricted to procaryotic organisms such as bacteria (cyanobacteria and actinomycetes are specialized bacteria). Of the 10,000 or so bacterial species named, only about 100 currently contain bonafide diazotrophic species. While this may appear to be a somewhat limited representation, it encompasses species representing all sorts of physiological types and occupying all sorts of ecological niches. Some of the genera of free-living diazotrophs are listed in Table 4 (8,17,18). With respect to carbon metabolism, these organisms include heterotrophic and chemoautotrophic bacteria, photoautotrophs (bacteria and cyanobacteria), and photoorganotrophs. With regard to Oxygen (O_2) requirements, they are well represented by aerobes, microaerophiles (growing best at low O_2 tension), facultative anaerobes, and obligate anaerobes. Such metabolic diversity enables some type of diazotroph to colonize almost any conceivable microhabitat. In fact, diazotrophs occur widely in nature as free-living microbes and also in a large variety of associations with plants and animals. The great range of metabolic diversity suggests that diazotrophs contribute to the supply of "fixed" nitrogen for growth of nonfixing microbes and higher forms of life in all sorts of environments.

Nitrogen Fixation in Soil

Soils may contain several thousands to millions of diazotrophic bacteria in a single gram of soil. These can represent a wide range of physiological types as discussed previously. It can be surmised that substantial quantities of nitrogen are fixed biologically in the soil. However, this is far from the actual situation. Early estimates of nitrogen fixation in soils free of legumes ranged from tens to hundreds of kg $ha^{-1}\,yr^{-1}$ (see the extensive review of early literature by Moore) (19). These early studies were based on short-term (<1 yr) accumulations of nitrogen in soils incubated under a variety of laboratory conditions, with or without carbon amendments, or on nitrogen-balance studies of field soils in a range of cropping systems from grasslands to cultivated row crops. There is a strong consensus, backed by decades of research that rates of dinitrogen fixation in soil are quite low and fixation rates in intensively managed agricultural soils are often considered insignificant. In fact, Postgate (8) states "It is important to be clear that free-living nitrogen-fixing bacteria, at least when in the free-living state, are rarely of great importance in the terrestrial nitrogen economy." This is not to say that dinitrogen fixation by free-living bacteria does not

make meaningful contributions in some ecosystems and even in some agriculturally important crops. In some semi-arid soils, the contribution of biological dinitrogen fixation may be as much as 50% of the annual nitrogen inputs (20).

Currently, there is general agreement that the quantities of dinitrogen fixed by free-living heterotrophic bacteria (i.e., nonsymbiotic dinitrogen fixation) in soil are on the order of 1 to 5 kg ha^{-1} $year^{-1}$ (5,20) (Table 6). Higher rates may occur in flooded soils in which the diazotrophic cyanobacteria can be quite active until they are "shaded out" by the crop canopy. Estimates of as much as 25–50 kg nitrogen fixed per hectare annually in rice paddies appear frequently in the literature. Also, there are reports of high rates of dinitrogen fixation in cryptobiotic crusts containing diazotrophic cyanobacteria. Such crusts are usually active for relatively short periods following rainfall. However, their inputs of fixed nitrogen are ecologically significant in these fragile communities. In comparison, nitrogen fixation rates in symbiotic systems [*Rhizobium, Bradyrhizobium*/legumes, *Frankia* in the actinorhizal symbioses, *Azolla* (aquatic fern)/*Anabaena* (cyanobacterium)] may be one to several orders higher in magnitude (Table 6).

Factors Limiting Dinitrogen Fixation by Free-Living Diazotrophs

It is clear from this discussion that free-living heterotrophic diazotrophs make relatively small contributions to the nitrogen budget of most soils. One might reasonably ask why, with nitrogen being such a critical soil nutrient, the free-living bacteria do not fix greater quantities of nitrogen in soil. The answer to this question most likely lies in the nature of the nitrogen fixation process itself. Recall from Table 3 that there are very specific physiological requirements for nitrogenase function in intact cells. It is these requirements which most often constrain the diazotrophic bacteria in soil, especially soils not receiving abundant plant remains (senescent roots, leaves, etc.) or supporting an active plant population. Primary factors affecting free-living diazotrophs in soils are listed in Table 7 and discussed later. Briefly, these include a supply of available carbon and energy sources, limitations imposed by oxygen, combined nitrogen and competition from nonfixing microbes. Thus, dinitrogen-fixing bacteria face a variety of biotic and abiotic forms of stress in most upland soils.

Supply of Readily Utilizable Carbon/Energy Sources

The most limiting factor for nonsymbiotic dinitrogen fixation in soil is probably the lack of abundant, readily available supplies of organic carbon. Little dinitrogen fixation occurs in habitats low in carbon. Numerous studies show that dinitrogen fixation rates increase markedly upon the addition of useable carbon sources such as carbohydrates, cereal straws, and so on, to soil.

As a rough approximation, it takes one to several tons of glucose to fix 100 lbs of nitrogen biologically (see Table 5). Free-living diazotrophic bacteria typically fix about 10 to 15 mg of nitrogen per gram of carbon consumed. In most natural soil systems, organic inputs are limited and there is intense competition among soil microbial populations for the limited resource. Estimates of the amounts of carbon contributed to soils from crops and grasslands have been expanded over the years. As much as 24 to 50% of the carbon fixed in photosynthesis may appear in soil as roots and root exudates (21). Barber (22) estimated a fine root production under corn to be 1.2 to 1.5 tons ha^{-1} yr^{-1} and Gregory and coworkers (23) reported 1.2 to 1.3 tons ha^{-1} yr^{-1} under winter wheat. Fine root production in a native tallgrass prairie was reported to be as much as 5.6 tons ha^{-1} yr^{-1} (24). Thus, several tons of carbon may be translocated below ground (Table 8), where it is potentially available for microbial growth. However,

Table 7. Biotic and Abiotic Factors Affecting Dinitrogen Fixation by Free-living Soil Bacteria

Factor	Biotic or Abiotic	Effect on N_2 Fixation
Carbon/Energy source	Biotic/ Abiotic	Lack of an abundant supply of available organic C is considered the principal limiting factor for N_2 fixation by free-living soil diazotrophs. (Recall the need for large quantities of ATP for nitrogenase activity.)
Oxygen	Abiotic	Nitrogenase is in most cases irreversibly damaged by exposure to O_2. N_2 fixation by aerobes is usually most vigorous when the O_2 level is much reduced and it must generally be absent for the anaerobes and facultative anaerobes.
Combined nitrogen	Abiotic	Nitrogenase is strongly controlled by the presence of combined nitrogen [i.e., ammonium, nitrate and organic N compounds (amino acids, etc.)] in soil.
Competition	Biotic	N_2-fixing bacteria must compete with all other soil microbes for carbon supplies, etc. It is generally agreed that diazotrophs constitute 1–10% of the cultivable bacterial population.
Others	Biotic	Like all other soil bacteria, diazotrophs are subject to predation by protozoa and lysis by bacterial viruses (bacteriophages).
	Abiotic	pH, temperature, trace element availability, etc.

Table 8. Quantities of Carbon Lost from Roots (Rhizodeposition) of Prairie Plants Under Field Conditions

System	Rhizodeposition (root C + Soil C + CO_2 − C) tons ha^{-1} yr^{-1}	Reference
Agropyron/*Koeleria*-dominated mixture	1.3	Warembourg and Paul (26)
Tall grass prairie (large mixture of species)	2.1*	Kucera et al. (27)
Tall grass prairie	2.0*	Dahlman (24)

*Probably underestimates since these values do not include CO_2 respired.
Note: After Whipps (25).

Table 9. Mechanisms Through which Dinitrogen-fixing Microbes Protect Nitrogenase from Exposure to Oxygen

Avoidance — Anaerobes and facultative anaerobes fix N_2 only in the absence of O_2 with the exception of Klebsiella *pneumoniae*, which can tolerate very low levels of O_2. In fact, O_2 is one of the factors that regulates the synthesis of nitrogenase in this bacterium.

Microaerophily — Most aerobic diazotrophic bacteria fix nitrogen maximally at low partial pressures of O_2 thereby lessening the exposure of nitrogenase to O_2. For example, it has been reported that *Azospirillum* fixes N_2 most rapidly at 0.007 atm O_2 (29).

Respiratory protection — Respiration functions in all aerobes to divert O_2 away from nitrogenase to some extent. In certain *Azotobacter* species, an exaggerated form of respiratory protection is observed. In fact, this bacterium exhibits one of the highest respiration rates of all life-forms. The high respiration rate serves to scavenge O_2 and to keep it away from nitrogenase. As a consequence, the bacterium must consume large amounts of substrate to scavenge O_2 and growth is very inefficient in terms of carbon consumed under these conditions.

Conformational protection — Some *Azotobacter* species produce a protein that binds to the nitrogenase and protects it from damage by O_2. In the presence of O_2, and when respiration cannot keep up with the incoming O_2 supply, the protein binds to the nitrogenase complex and alters its conformation (shape) in such a way that it is protected from O2. Upon exposure to O_2 the organism stops fixing N_2 abruptly but when conditions of oxygenation return to a more favorable state, the organism resumes N_2 fixation. The enzyme is not destroyed.

Production of specialized cells — Many diazotrophic cyanobacteria produce specialized, thick-walled cells called heterocysts in which the nitrogenase is compartmentalized. These cells do not evolve O_2 in photosynthesis and the thick wall excludes external O_2. The diazotrophic actinomycete, *Frankia*, produces vesicles in which nitrogenase is protected from O_2. The vesicle wall becomes thicker as the O_2 concentration increases in the medium.

Slime — Aerobic diazotrophs grown on nitrogen-free agar media frequently produce large gummy colonies due to the production of extracellular polysaccharides. The gum serves as a diffusion barrier to the free flow of O_2 into the colony such that cells in the interior of the colony are not as exposed to O_2. The efficacy of this mechanism is questionable.

Temporal or spatial separation of dinitrogen fixation and oxygen-evolving processes — Non-heterocystous cyanobacteria solve the O_2 problem by fixing N_2 primarily during the dark phase of growth (i.e., temporal separation) when O_2 evolution is not occurring and respiration serves also to scavenge O_2 away from nitrogenase. Others form aggregates of cells and some of these cells then function in a microaerophilic environment (i.e., spatial separation).

After J. R. Postgate, Nitrogen Fixation, 3rd ed., Cambridge University Press, Cambridge, U.K., 1998.

there is not enough carbon channeled to the diazotrophs to support the fixation of substantial quantities of dinitrogen. Consider the following calculation put forth by Giller and Day (28) for nitrogen fixation under a wheat crop. They assumed (*1*) an efficiency of 10 g of carbon for fixation of one gram of nitrogen; (*2*) dinitrogen-fixing bacteria comprised 10% of the total population (they stressed this was "a high estimate"); and (*3*) all the carbon translocated below ground was equally available for use by all bacteria. On the basis of these assumptions, 1,500 kg carbon ha^{-1} translocated below ground by a wheat crop would allow for a maximum potential nitrogen fixation of 15 kg nitrogen ha^{-1} yr^{-1}.

The limited availability of substrates in most systems means that diazotrophic bacteria are frequently found in loose associations with plant roots because roots release carbon in the form of root exudates, lysates, and sloughed cells. These loose associations between roots of plants, especially the grass species that include major cereal crops, have been the subject of much research since the 1970s and are still under active investigation. Estimates of dinitrogen fixation by these "associative symbioses" (see

following section) range from about 5 to 15 kg of nitrogen fixed per hectare per year. While this does not strictly represent "dinitrogen fixation in soil," the nitrogen fixed in these associations does enrich the soil upon decomposition of plant and microbial cells.

Oxygen Concentration versus Dinitrogen fixation

As mentioned earlier, nitrogenase is "poisoned" by molecular oxygen (O_2). For this reason dinitrogen fixation rates tend to be highest in environments where the O_2 tension is considerably reduced. Most aerobic diazotrophs fix dinitrogen most efficiently at O_2 concentrations that would be described as microaerophilic. For example, *Azospirillum* fixes dinitrogen most rapidly in culture when the pO_2 has been reduced to 0.007 atm (29). Similarly, *Azotobacter* is much more efficient under low-oxygen conditions (Table 5). Alexander and Zuberer (30,31) demonstrated that bacteria-associated roots of intact maize and sorghum plants exhibited maximal nitrogenase activity (acetylene reduction) when the O_2 content surrounding the roots was lowered to 2 kPa (2% O_2). Similar results have been shown for soils incubated under a range of O_2 conditions. Interestingly, dinitrogen-fixing bacteria tolerate higher levels of O_2 when there is more carbon substrate available to them, presumably because high respiration rates divert O_2 from nitrogenase.

The sensitivity of nitrogenase to molecular O_2 has led to some unique adaptations or strategies allowing diazotrophs of one kind or another to deal with exposure to it (Table 9) (8). These range from simple avoidance to complex physiological mechanisms and morphological adaptations. Anaerobic diazotrophs are not faced with the oxygen problem because, to begin with, they do not grow in its presence. Most of the facultatively anaerobic diazotrophs only fix dinitrogen when they are functioning as anaerobes, with the exception of *Klebsiella*, which appears to tolerate very low levels of O_2 (8,9). It is the aerobic bacteria and cyanobacteria that are faced with the larger challenge of managing exposure to O_2 while operating the nitrogenase complex. *Azotobacter* engages in respiratory protection in which very high rates of respiration are thought to keep O_2 away from the enzyme complex. In fact, *Azotobacter* exhibits perhaps the highest respiration rate among living organisms. *Azotobacter* is also capable of a process called "conformational protection" in which nitrogenase is protected by a separate protein during exposure to too much O_2. Upon return to lower O_2 levels, the nitrogenase complex resumes activity, having avoided the usual destruction by O_2. Other diazotrophs protect nitrogenase by packaging it in specialized cells that exclude O_2. Many dinitrogen-fixing cyanobacteria produce thick-walled cells called "heterocysts." These cells contain the nitrogenase complex and lack Photosystem II, which catalyzes the oxygen-yielding reactions of photosynthesis. Thus, compartmentalization keeps O_2 away from the sensitive complex. The root-nodulating actinomycete, *Frankia*, produces thick-walled structures called "vesicles" that protect nitrogenase from O_2. Some diazotrophs produce copious quantities of slime (extracellular polysaccharides) thought to create a diffusion barrier to O_2 and some produce aggregates of cells in which some individuals find conditions suitable for expressing nitrogenase activity. Finally, some diazotrophic cyanobacteria fix dinitrogen during periods of darkness when photosynthetic O_2 production does not interfere with nitrogenase activity.

It is apparent that O_2 plays a significant role in governing the occurrence of dinitrogen fixation in various environments. It is not surprising that the higher rates of nitrogen fixation reported in the literature are generally associated with seasonally or chronically wet soils because here the O_2 levels tend to be lower due to saturation. It is for these reasons that paddied rice is one of the few agricultural crops that derives significant benefit from the activities of nonsymbiotic diazotrophs and dinitrogen-fixing cyanobacteria.

Combined Nitrogen

Since nitrogenase activity is very costly to the bacterium in terms of energy consumption, it is carefully regulated by the availability of nitrogen in the culture medium or in the soil. Generally, nitrogenase activity does not occur unless there is an acute shortage of combined nitrogen (ammonium, nitrate, organic nitrogen). Thus, in most fertilized agricultural soils, there is usually sufficient nitrogen available to repress nitrogenase synthesis at least during most of the growing season. Alexander and Zuberer (30) showed that as little as 4 mg $L^{-1}NH_4^+$–N in a hydroponic system was sufficient to stop dinitrogen fixation associated with roots of whole maize plants exposed to 2 kPa (2% v/v) O_2. However, it has been proposed that nitrogen fixation could be of significance late in the growing season when nutrient-depletion zones may have established around roots. Nitrogen fixation might also occur in nitrogen-deficient microsites such as those that might occur in rhizosphere soils in which root and microbial nitrogen uptake deplete the soil solution of available nitrogen. In soils and grasslands not receiving fertilizers, available nitrogen is usually quite low and conditions would be more favorable for nitrogen fixers. In fact, it is in ecosystems such as these that the contributions of nonsymbiotic dinitrogen fixers are most significant, possibly representing as much of 50% of the annual nitrogen inputs (20).

Other Environmental Factors

Soil Moisture. As with all other bacteria, free-living diazotrophs require adequate moisture for growth and reproduction. Besides, moisture is probably most influential in terms of its effects on the O_2 tension of the soil. Waterlogged soils with low O_2 contents and containing available carbon generally show higher rates of dinitrogen fixation than drier soils. It is also likely that dinitrogen fixation occurs in seasonally flooded soils, for example, pastures during wet seasons. In such situations, both nonsymbiotic bacteria and diazotrophic cyanobacteria might make an important contribution.

pH. Most soil microbes are sensitive to extreme pH levels, with the majority favoring environments ranging

from 6.8 to 7.2. Nitrogen-fixing bacteria are no exception. However, the pH of the environment can have marked effects on the distribution of diazotrophs. *Azotobacter* is characteristically absent from acid soils whereas *Beijerinckia* may be particularly abundant. The latter appears to be more tolerant of the higher iron and aluminum contents of acid soils. Cyanobacteria are also sparse or absent in acid soils and tend to be favored by soils of slightly higher pH (7.5 to 8.5) (32).

Temperature. Temperature affects microbial growth in the usual manner. Growth and activity tend to be slow at cool temperatures and increase up to a point with increasing temperatures. Most diazotrophs are mesophilic, preferring temperatures in the range of 15° to 35 °C. Nitrogenase activity tends to decrease rapidly beyond 37 °C; however, there is at least one species of thermophilic cyanobacteria that grows in hot springs. *Methanococcus thermoautotrophicus* fixes dinitrogen at 64 °C and the recently discovered *Streptomyces thermoautotrophicus* fixes dinitrogen at 65 °C (8,12).

Other Nutrients. Recall that iron and molybdenum or vanadium are essential for the nitrogenase enzyme complex. Magnesium is needed to form the MgATP complex required for nitrogenase activity. Also, it is probable that the "nitrogenase" system of *Streptomyces thermoautotrophicus* requires manganese for its activity. In general, soils contain sufficient quantities of these elements to not limit dinitrogen fixation. One possible exception might occur in acidic soils in which the availability of molybdenum is decreased because it is a metal that becomes less soluble (less available) at low pH. Currently, however, we know that not all diazotrophs have an obligate requirement of Mo so its deficiency in soil does not necessarily preclude the occurrence of dinitrogen fixation. Alternatively, high concentrations of soluble iron and aluminum in acid soils might be inhibitory to some bacteria. Phosphorus (P) is required in large quantities by dinitrogen-fixing microbes because of the high demand for ATP to support nitrogenase activity. Thus, soil P must also be adequate for microbial growth.

The Associative Symbioses — Grass-Bacteria Associations

This section explains why rates of dinitrogen fixation in soils, especially those free of significant vegetation, are in general quite low. The requirements for an operative nitrogenase system place substantial demands on a bacterium, whether in culture or in natural habitat. As discussed earlier, chief among these requirements is provision of an abundant supply of carbon or energy sources. Available organic carbon, assuming moisture for growth is adequate, is the most limiting factor for growth of heterotrophic bacteria in soil.

Almost throughout the history of soil microbiology (since 1900) scientists have known that there is pronounced stimulation of microbial growth in the rhizosphere (the zone of soil immediately surrounding the root) of most, if not all, plants. This so-called rhizosphere effect is due to the provision of carbon and energy sources for heterotrophic soil bacteria among which are a large number of genera of dinitrogen-fixing bacteria, many of which are listed in Tables 4 and 5. It is a reflection of the carbon limitation of microbial growth in soil. To the soil microbe, the root is an oasis of sorts, a source of nutriment in an otherwise nutrient-poor environment.

In the late 1960s and the early 1970s, considerable interest was rekindled in the possibility that important agricultural crops, mainly cereals such as corn, sorghum, and millet and forage grasses, might derive significant inputs of nitrogen from dinitrogen-fixing bacteria associated with their roots. These more or less loose associations between roots of higher plants and free-living diazotrophs are now commonly referred to as "associative symbioses." In these associations, the bacterium obtains carbon for growth and dinitrogen fixation in the forms of root exudates, lysates, sloughed cells, and root-derived mucilage, which is sometimes called "mucigel." Recall from the earlier discussion that plants translocate substantial quantities of carbon below ground (Table 8). At least part of this carbon supports dinitrogen fixation by root-associated diazotrophs.

Considerable interest was focused on the soil bacterium *Azospirillum*, which was isolated from the roots and rhizosphere of a number of important tropical C_4 grasses. Early reports suggested that as much as 90 kg of nitrogen $ha^{-1}\,yr^{-1}$ were being fixed by bacteria associated with grasses such as *Paspalum* (bahia grass) and *Digitiaria* (digit grass) and cereals such as millet (*Pennisetum*) and sorghum (*Sorghum*). On closer examination, over 10 to 15 years of further research, it became apparent that rates of dinitrogen fixation in these associations are more on the order of 10 to perhaps 25 $kg\,ha^{-1}\,yr^{-1}$. Early estimates of high rates of dinitrogen fixation in these systems were based mainly on the use of the acetylene reduction assay using excised roots incubated under ideal conditions and after prolonged incubations. It soon became apparent that rates determined using such methods could not be extrapolated to rates of fixation under field conditions and across entire growing seasons. Later studies using the stable isotope ^{15}N led to estimates in the range of 5 to 25 $kg\,ha^{-1}\,yr^{-1}$, which are widely accepted today. It should be mentioned that the enthusiasm for the study of the associative symbioses was at least partly fueled by a worldwide oil embargo and high fertilizer prices at the time. Although nitrogenous fertilizers are not directly linked to fossil fuels other than methane, part of their expense is due to transportation and application costs, which are petroleum-dependent. Thus, because of an unusual set of circumstances, this research area was catapulted to the forefront along with the intensified study of many aspects, both basic and applied, of symbiotic dinitrogen fixation (see NITROGEN FIXATION IN SOILS (SYMBIOTIC)).

While the optimism about dinitrogen-fixing cereals may have subsided somewhat since the earlier years, nitrogen fixation associated with two agriculturally important crops, rice and sugarcane, deserves special mention. Each of these nonleguminous crops, one a C_3 plant (rice) and the other a C_4 plant, derive benefit from nonsymbiotic diazotrophs in different ways. As

was mentioned earlier, rice crops receive about 25 to 50 kg of nitrogen $ha^{-1}\,yr^{-1}$ as a result of the combined activities of diazotrophic cyanobacteria and free-living heterotrophs in and on the flooded paddy soils. Here, the cyanobacteria find favorable conditions, especially during the early growth of the crop when shading is minimal. Bacteria in the flooded soils use root- and possibly algae-derived carbon to derive dinitrogen fixation. The low pO_2 associated with submerged soils also tends to favor the diazotrophic bacteria by lowering the O_2 stress on nitrogenase.

Some varieties of sugarcane have been found to support populations of the bacterium *Acetobacter diazotrophicus* in the vascular tissues. This bacterium is unique in occupying these tissues as an endophyte. Here, the bacterium has direct access to a ready supply of sugars and is free from the competition that it would have were it located on the outside of the roots. Reliable estimates of dinitrogen fixation by these sugarcane-*Acetobacter* associations are in the range of 100 to 200 kg of nitrogen $ha^{-1}\,yr^{-1}$ (1,33).

CONCLUSION

This article attempts to introduce the nuances of the process of biological nitrogen fixation by free-living, that is, nonsymbiotic, soil bacteria. An understanding of the potential and limitations of these bacteria can only be gained by appreciating the intricacies of the enzyme complex nitrogenase, which I hope I have presented at a level that is neither too simplistic nor too complex. It is a remarkable enzyme system that mediates a remarkably important process for life on earth. Given the list of prerequisites for dinitrogen fixation is so long, it is almost a marvel that the process is so pervasive in aquatic and terrestrial habitats.

Also described is the diversity of the microbes, bacteria, and cyanobacteria, which are known to carry out nonsymbiotic dinitrogen fixation. This list is, no doubt, far from complete and it is exciting to think of what lies ahead in the discovery of new, previously undescribed, organisms and possibly even different mechanisms for dinitrogen fixation. The discovery of the alternative nitrogenases and even more recently, the chemoautotrophic thermophilic actinomycete, *Streptomyces thermoautotrophicus*, give reason to believe there is yet much to discover.

I have included information about the associations between dinitrogen-fixing bacteria and higher plants such as the grasses. The intent is to emphasize the importance of vegetation in natural as well as agroecosystems in providing the carbon sources needed to "fuel" nitrogen fixation by soil bacteria. It is only in environments receiving abundant supplies of carbon and energy sources that one can expect to find significant rates of dinitrogen fixation. Only the photoautotrophic dinitrogen-fixing cyanobacteria and perhaps a few chemoautotrophic bacteria are free of this constraint. Nonetheless, it is encouraging to realize that at least two major crops, rice and sugarcane, are at least in part "fertilized" by dinitrogen-fixing bacteria.

No one can accurately predict the future, especially with regard to the role of biological dinitrogen fixation in feeding an expanding global population. Undoubtedly, dinitrogen-fixing crops, especially the legumes, will figure prominently in food-production systems as we strive to reduce dependence on fossil energy supplies and to minimize the negative impacts of excessive use of nitrogen fertilizers. It is tantalizing to think that the secrets of the nitrogenase complex might be unveiled and put to use for a less energy-intensive industrial process to produce nitrogen for crop growth. Or perhaps that molecular biologists may someday figure out how to transform nonfixing cereal crops into symbiotic systems such as the legumes. No matter what, it is reasonably certain that nitrogen fixation will probably continue to be viewed as "the second most important biological process on earth."

NITROGEN FIXATION IN SOILS (SYMBIOTIC)

PETER GRAHAM
CARROLL VANCE
University of Minnesota
St. Paul, Minnesota

Symbiotic nitrogen (N_2) fixation involves the association between specific nitrogen-fixing prokaryotic microorganisms and eukaryotic, usually photosynthetic, hosts. In these often long-term relationships, the microsymbiont provides the host with nitrogen (N) from a source that the host could not otherwise access, while the microbe receives carbohydrates and organic acids from the host for growth and nitrogen fixation. In some cases, symbiosis also results in the development of a special structure within which the microbe is housed and protected from external stresses or from the negative effects of oxygen on nitrogen fixation. Symbiotic nitrogen-fixing associations that are of significance in soil include:

- leguminous plants and root- or stem-nodule bacteria from the genera *Allorhizobium, Azorhizobium, Bradyrhizobium, Mesorhizobium, Rhizobium,* and *Sinorhizobium* (collectively called "rhizobia");
- actinorhizal plants in association with the actinomycete *Frankia*, and
- the water fern *Azolla* and cyanobacterial microsymbionts belonging to the species *Anabaena azollae*.

This article emphasizes the more extensively studied legume/rhizobial and actinorhizal/*Frankia* symbioses. Readers are referred to articles by Lumpkin and Plunkett (1), Roger (2), Wagner (3), and Lejuene and coworkers (4) for more information on the *Azolla*/*Anabaena* symbiosis.

THE IMPORTANCE OF SYMBIOTIC NITROGEN FIXATION IN SOIL

Symbiotic nitrogen fixation is, after photosynthesis, the second most important biological process on earth, and the single greatest contributor to the global nitrogen economy. Nitrogen fixation adds about 90 Tg of nitrogen annually to the soils of the world, and accounts for more than two-thirds of all the N used in agriculture (5).

Legumes have been used in crop rotation and agriculture since the time of the Romans, but an understanding of their potential for soil improvement is of relatively recent origin. Thus, it was only in the 1800s that such plants were shown to accumulate nitrogen from sources other than soil and fertilizer, and in 1886 that Hellriegel and Wilfarth associated this ability with the presence of swellings or nodules on the legume root (6). Isolation of the microsymbiont responsible for this nitrogen fixation followed soon thereafter. Rates of nitrogen fixation in the legume/rhizobial symbiosis vary with growing season, soil fertility, and water supply, but range from essentially 0 to 450 $kg\,ha^{-1}$ $annum^{-1}$. Nitrogen fixation can meet as much as 97% of the plant's nitrogen needs (7). Nitrogen left in the field following the harvest of crops such as soybeans or peas can result in a buildup of the organic nitrogen content of the soil, can limit soil acidification, and substantially reduce the nitrogen-fertilization needs of a subsequent nonlegume crop. Ley farming systems in which regenerating pasture legumes replace the fallow period of traditional dry-land agricultural systems are also a major contributor to soil nitrogen in some regions (8).

Nitrogen is also a key limiting element in many natural ecosystems, with legumes required to maintain productivity (9). Towne and Knapp (10) found annually burned prairies to be often nitrogen-limited, supporting diverse leguminous plants; Leach and Givnish (11) noted legumes in remnant oak savannahs present across much of the light and soil gradients, with best growth in well-lit sandy locations. Knops and Tilman (12) followed the

dynamics of carbon and nitrogen in sand-plain agricultural fields abandoned between 1927 and 1982, noting that carbon accumulation after abandonment was dependent on nitrogen deposition and symbiotic nitrogen fixation. These abandoned fields essentially retained all nitrogen, meaning that even minor inputs from fixation could have significance.

Sprent and Parsons (13) recognized 25 genera and 225 species of actinorhizal plants, coming from eight plant families. All are perennial dicotyledons, and most are woody trees and shrubs. *Casuarina* and alder species are the predominant commercial species, but a number of species are important as pioneers under low temperature or arid soil conditions. Documentation of rates of nitrogen fixation in tree species is highly variable, with only 8 to 32% of plants in an arid environment bearing nodules (14). Silvester (15) reported average annual nitrogen-fixation rates for *Coriaria* over a 20-year period as 90 $kg\,ha^{-1}$, Dommergues (16) noted rates of 15 to 94 $kg\,ha^{-1}\,y^{-1}$ or 6 to 47 $kg\,N\,tree^{-1}\,y^{-1}$.

Use of *Azolla* as a green manure in rice cultivation dates back to the 11^{th} century (2). Wagner (3) reported rates of nitrogen fixation under propagation conditions in a rice paddy of 1.10 $kg\,ha^{-1}\,day^{-1}$, Roger (2) rates of nitrogen fixation of 224 $kg\,N\,ha^{-1}$ crop $cycle^{-1}$. Both authors, however, noted marked variation in nitrogen fixation under field conditions. Thus, Roger (2) found only 10 to 50 $kg\,N$ fixed ha^{-1} across 37 sites in 10 countries. This author also noted a marked decline in *Azolla* usage in Vietnam and China during the 1980s, with 6.5×10^6 ha planted before 1978, but only 0.7×10^6 ha in 1982, attributing this to inexpensive sources of urea and the disbanding of many agricultural communes.

Graham and Vance (17) have contrasted the declining role for biological nitrogen fixation in American, European, and Chinese agriculture with the continued dependence on nitrogen fixation in countries such as Brazil, Australia, and Southern Africa. For the former, the availability of inexpensive fertilizer nitrogen, the need to land-farm animal wastes, and even population pressures that limit the land available for *Azolla* propagation are factors affecting adoption of nitrogen-fixation technologies. Indicative of these changes, Brockwell and Bottomley (18) have noted static or declining production of legume inoculants worldwide, and van Kessel and Hartley (19) have noted a gradual decline in the rates of nitrogen fixation reported in the field studies of bean and soybean. Graham and Vance contrast this with the need for improved nitrogen fixation technologies in areas of extensive agricultural production where rainfall is erratic and unreliable, or for production under conditions of subsistence agriculture. How these needs will change over the next 30 years remains in question. Mannion (20) and others have suggested that an increase in the world's population to 8.3 billion by 2025 will necessitate significantly enhanced food production, while Tilman (21) has projected a threefold increase in nitrogen-fertilizer usage and an 18% increase in land for cultivation over this period. The rapid consumption of fossil fuels, the pollution and land degradation associated with such increased fertilizer usage, and declining soil quality (22) are likely to be major issues. Tilman and others have argued for a more logical and efficient use of nitrogen in agriculture, with the development of improved nitrogen-fixation and green manure technologies for subsistence farmers being a major thrust.

THE LEGUME-RHIZOBIAL SYMBIOSIS

Mechanisms of Infection

Mechanisms used by rhizobia to gain entry into their hosts and establish symbiosis include:

- root hair penetration and infection-thread formation as occurs in root-nodule formation on peas and clovers
- entry by wounds or sites of lateral root-emergence as found in root nodule formation in peanuts and the tropical pasture legume *Stylosanthes*, and
- penetration of the root primordia found on the stem of plants such as *Sesbania* and *Neptunia*.

A single rhizobial strain may infect one host species by root hair penetration and infection thread formation, another by wounds or sites of lateral root emergence. In this article, we will emphasize root hair infection. Additional details of these processes are provided by Hirsch (23), Boogerd and van Rossum (24), and Boivin and coworkers (25).

The Fahraeus slide technique (26,27) and the root tip marking procedure (28) are seminal to our knowledge of root hair infection. The former allowed repeated observations of the infection process in small-seeded legumes such as clovers, whereas the latter showed differences in the susceptibility to infection of root hairs according to their age, and allowed research to focus on those parts of the root where infection was in process. Compatible rhizobia begin to attach to the immature root hair of their host within minutes of contact. Characteristic deformation and curling of the root hair follows (Fig. 1a) with the root hair cell wall at the point of infection degraded to permit rhizobial penetration. Rhizobia never gain intracellular access into their host. Fresh plant-derived material is deposited around them as they penetrate the root hair, and as they move down the root hair in the direction of the cortex they remain enclosed within a plant-derived infection thread (Fig. 1b). Even when released into cells of the host root cortex, the rhizobia remain enclosed within a membrane that serves to minimize host recognition of invasion and initiation of defense responses.

Biochemical, genetic, and mutational studies have shown that initial infection events are accompanied by molecular signaling between host and rhizobia. These are reviewed in detail in the papers of Long (29) and Schultze and Kondorosi (30), with some 50 rhizobial genes thought to be involved in the nodulation process. Some affect host recognition, or the regulation of nodulation, but most function in the synthesis of specific lipo-chitooligosaccharide "nodulation factors." Depending on the species of rhizobia, these genes may be located on the bacterial chromosome (*Bradyrhizobium*) or associated with nonchromosomal plasmid DNA (*Rhizobium)*.

(a)

Figure 1a. Root hair deformation, curling, and infection; an early stage in the nodulation of clover by *Rhizobium leguminosarum* bv *trifolii* (From K. Sahlman and G. Fahraeus, *J. Gen. Microbiol.* **33**, 425–427 (1963) used with permission). See color insert.

(b)

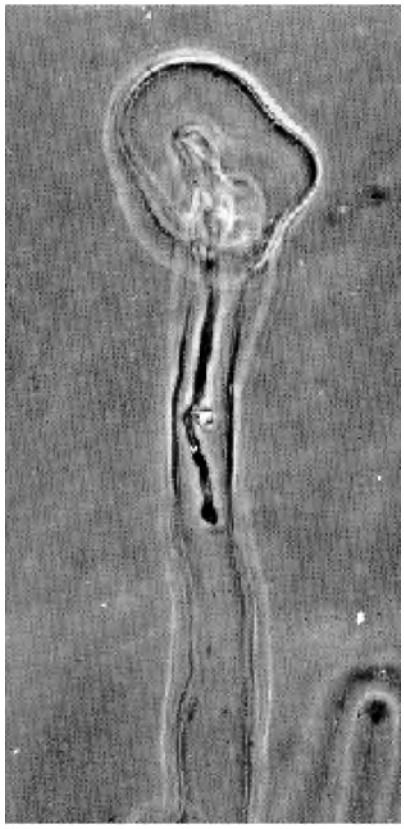

Figure 1b. Rhizobia contained within a plant-derived infection thread move down the root hair in the direction of the root cortex (From G. Fahraeus, *J. Gen. Microbiol.* **16**, 374–381 (1957) used with permission). See color insert.

Organisms living saprophytically in soil do not express the majority of their nodulation genes. However, flavonoid excretion by a suitable host leads to *nod*-gene expression, followed by synthesis of the nodulation factor. Legumes differ in the spectrum of flavonoids that each produces, whereas species of rhizobia react differently to specific flavonoid compounds. Thus, naringenin and daidzein stimulate *nod*-gene expression in soybean rhizobia; luteolin is required for the rhizobia from alfalfa. Variation in the structure and range of *nod*-factors produced by rhizobia also contributes to specificity in nodulation. These substances have the same core structure, but vary in the side chains that each carries, affecting host range (Fig. 2).

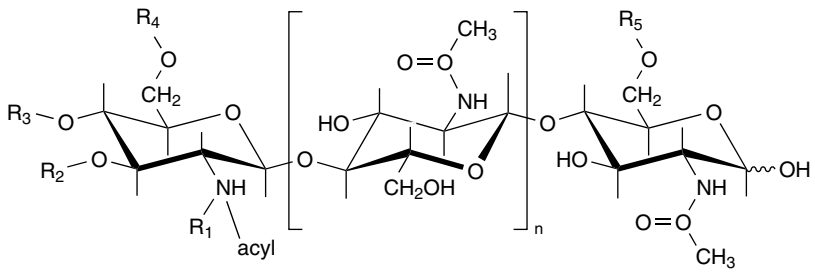

Figure 2. The general structure of *nod* factors elicited by rhizobia. In this structure $N = 2$ or 3, and the substitutions possible at each position are:

R_1	H or methyl
R_2 and R_3	H, carbomoyl, or 4-O-methylcarbomoyl
R_4	H, acetyl, or carbomoyl

Modified from Schultze and Kondorosi M. Schultze and A. Kondorosi, *Curr. Opin. Genet. Develop.* **6**, 631–638 (1996) and used with permission.

Table 1. Some Parameters of Nodule Infection and Nitrogen Fixation in Legumes

With pure cultures of rhizobia/bradyrhizobia	
Attachment to root hairs	~60 seconds
Increasing attachment with time	Up to 4 h
Root hair curling	3 to 5 h
Visible infection-thread formation	~72 h
Nodules visible to the naked eye	6 to 12 d
With purified *nod* factor at 10^{-9} to 10^{-12} M	
Depolarization of root hair plasma membrane	~15 seconds
Modifed root hair pH	~15 seconds
Calcium spiking in root hairs	10 min
Expression of early nodulin genes	6 to 24 h
Root hair curling	~18 h
Cell division in the root cortex	days

Nod factors act as powerful plant hormones that alone, and at concentrations as low as 10^{-9} M, can bring about many of the physiological and developmental responses associated with nodule formation. These include depolarization, calcium spiking, and pH changes within the root hair (31,32,33) and break down and rearrangement of actin filaments at the root hair tip (34,35). Table 1 lists some of the changes induced by rhizobia and their nodulation factors, and the time frame against which these changes can occur. Prithiviraj and coworkers (36) have also noted enhanced germination and early plant growth in a number of crop species, including some non legumes, following treatment with nod factor.

Nodule Development and Function

Stimulation of plant cell division and enlargement in the root cortex results in the formation of a visible nodule. The shape of this nodule is a characteristic of the host, and regulated by the pattern of cortical cell division following infection. Thus, pea, medic, and clover nodules are elongated, with a pronounced meristematic region, and increase in length over the course of the growing season. As shown in Figure 3a, such indeterminate nodules contain four quite distinct regions:

- A meristematic zone, with little evidence of infection by rhizobia, but where host cells are undergoing active division;
- A region where many plant cells are infected, but the rhizobia they contain have not yet undergone significant change in size, shape, or surface chemistry. Rhizobia in this region of the nodule fix little, if any, nitrogen;
- An area of active nitrogen fixation, which is usually red or pink in color because of the presence of leghemoglobin. Host cells in this region may contain many rhizobia, and a number of these may be misshapen and modified in surface composition. They are referred to as *bacteroids*; and
- A region of nodule senescence where the symbiosis is degenerating. In this region, proteolytic activity is high, bacterial cells may be undergoing lysis, and the degradation of leghemoglobin often results in a green or brown coloration.

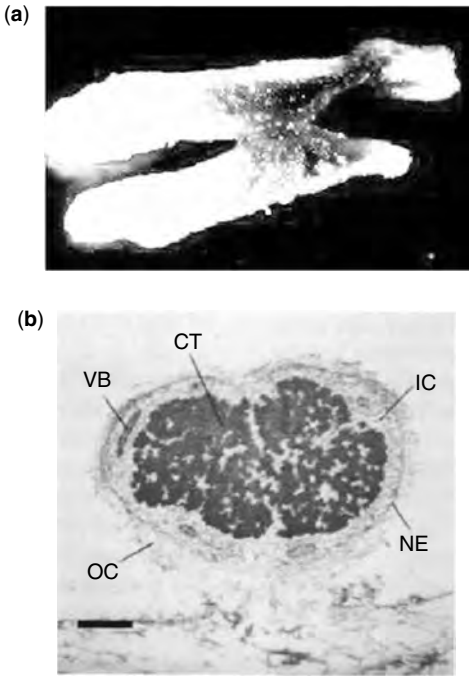

Figure 3. (**a**) The internal organization of mature nodule from *Medicago sativa*. Note the progression from the white uninfected meristematic region, through zones of active nitrogen fixation and leghemoglobin production, to the onset of nodule senescene on the right. (Photo C.P. Vance, used with permission). (**b**) The internal organization of a mature nodule from *Phaseolus vulgaris*. The determinate bean nodule is shown in transverse section. It has been stained with toluidine blue and includes central tissue (CT), an inner cortex (IC) with vascular bundles (VB), the nodule endodermis (NE), and outer cortex (OC). (From R. Tate et al., *MPMI 7*, 582–589 (1994) used with permission.) See color insert.

Nodules that are actively fixing nitrogen, with a large region that is pink or red in color, are termed *effective*, whereas those in which the nitrogen fixation is limited and the nodule green or white in internal color are termed *ineffective*. In contrast to the nodule morphology described earlier, the nodules found on hosts such as *Phaseolus* and *Glycine* are rounded and determinate, and lack a persistent meristem (Fig. 3b).

Nodule number plant^{-1} is influenced by the host genotype, by the number and efficiency of the inoculant rhizobia, and by nutritional and soil stresses. It can vary from very few to more than 300 nodules plant^{-1}, and nodule number and nodule size are usually inversely related. Because of this, nodule mass plant^{-1} measured several times throughout the growing season is probably the best simple indicator of nodulation success.

The indeterminate alfalfa nodule shows a progression from the white uninfected meristematic area on the left, through stages of infection by *Sinorizhobium meliloti,* active nitrogen fixation and leghemoglobin production,

to the onset of nodule senescence on the right. (Photo; C. P. Vance, used with permission)

The determinate bean nodule is shown in the transverse section. It has been stained with toluidine blue and includes central tissue (CT), an inner cortex (IC) with vascular bundles (VB), the nodule endodermis (NE), and outer cortex (OC). (From R. Tate, E. J. Patriaca, A. Riccio, R. Defez, and M. Iaccarino, *MPMI* **7**, 582–589 (1994)) used with permission)

Nodule-Specific Gene Expression

Interaction of host and rhizobia is accompanied by the expression of nodule-specific proteins or "nodulins", which were initially thought to be specific to infected root hair or nodules and required for nodule initiation, formation, or function. Some nodulins have now been detected in other tissues, and some have also been identified in actinorhizal or mycorrhizal symbioses. Nodulin expression can vary both temporally and spatially. "Early" nodulins expressed within six hours of rhizobial addition are more likely to be involved in infection and nodule development; later nodulins are more generally related to nodule function and nitrogen fixation. At least 50 putative nodulins have been identified at the protein and mRNA level but functions for many of these remain to be determined. Nodulins that have been characterized include leghemoglobin, phosphoenol pyruvate (PEP) carboxylase, and a number of enzymes involved in allantoic acid synthesis. More detail is provided by Pawlowski (38). Spatial differences in the distribution of leghemoglobin and uricase within the nodules of *P. vulgaris* is shown in Figure 4 (37).

Chemistry of Nitrogen Fixation

The enzyme nitrogenase that catalyzes the reduction of atmospheric nitrogen in nodules comprises two oxygen labile proteins (39,40):

- Dinitrogenase (MoFe protein or component 1) an $\alpha_2\beta_2$ tetramer of MW ~220,000, which contains two [$MoFe^6S^8$] clusters per molecule,
- Dinitrogenase reductase (Fe protein or component 2) an α_2 dimer of MW ~60,000, and containing a single [4Fe-4S] cluster and two Mg. ATP binding sites. The Fe protein donates electrons to the MoFe protein.

In studies of nitrogen fixation a distinction is usually made between *nif* genes needed for the synthesis of the MoFe and Fe proteins, and *fix* genes involved in the regulation of nitrogen-fixing activity (41). Alternative dinitrogenases in which vanadium replaces molybdenum or iron alone is present have been identified in some organisms.

Both dinitrogenase and dinitrogenase reductase are oxygen labile, with all nitrogen-fixing organisms needing mechanisms to avoid exposure of these enzymes to oxygen. In the case of the legume nodule, these mechanisms include barriers to oxygen diffusion and the presence of leghemoglobin as an oxygen carrier (42).

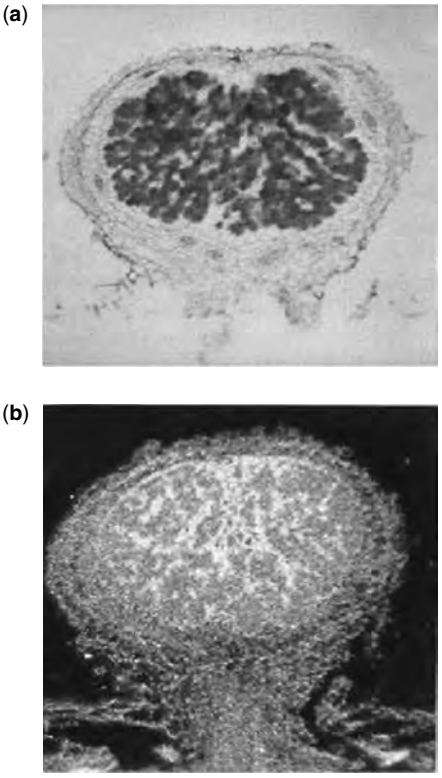

Figure 4. Longitudinal section of a mature *P. vulgaris* nodule showing the in situ localization of the (**a**) leghemoglobin and (**b**) uricase II transcripts. Figure 4a was taken using bright-field and Figure 4b using dark-field microscopy. Leghemoglobin is synthesized in invaded cells of the central tissue, and is not detected in uninfected cells of this region or in peripheral tissues, whereas uricase II is found only in uninvaded cells. (From R. Tate, E. J. Patriaca, A. Riccio, R. Defez, and M. Iaccarino, *MPMI* **7**, 582–589 (1994) used with permission). See color insert.

Specificity in Legume Nodulation

Given the complex signaling involved, specificity in nodule formation by legumes is to be expected. This can be evident at a number of levels:

- Many caesalpinioid legumes, including all species of *Cassia* never form nodules,
- Each rhizobial isolate has the ability to nodulate some but not all legumes. Cross-inoculation groups comprising legume species nodulated by the same rhizobia can often be further subdivided into effectiveness subgroups that differ in their ability to fix nitrogen with particular rhizobia.
- Cultivars of the same plant species can vary in the level of nitrogen fixation achieved.
- Mutation can lead to loss of nodule-forming ability in the host or rhizobia.

Legume collection from different regions of the world is often complicated by the need to match collections of the host with those of suitable rhizobia. Thus, the pea cultivar Afghanistan nodulated normally with pea rhizobia from

the Middle East, where it was collected, but carried a single recessive gene-limiting nodulation with most pea rhizobia from Europe. Similarly, the narrow germ plasm base used in breeding American soybean varieties has affected their ability to symbiose with indigenous soil rhizobia in other areas of the world. When the variety Bossier was introduced into Africa, it nodulated poorly, and had to be inoculated, whereas landraces such as Orba and Malayan nodulated with the indigenous rhizobia and benefited little from inoculation.

This specificity means that legumes introduced into new areas of production will often require artificial inoculation to ensure good nodulation and effective nitrogen fixation. Many such inoculant preparations are now sold commercially, with more than 100 different preparations needed to satisfy the requirements of all currently important crop, pasture, and tree legumes. The *Rhizobium* Research Laboratory website at *http://www.rhizobium.umn.edu* (43) details strain requirements and types of inoculants available.

Legume Inoculation

Where legume inoculation is required, the strain or strains of rhizobia employed must meet the following specific criteria:

- Form highly effective nodules with all commonly used cultivars of the legume species for which it is intended;
- Be competitive in nodule formation with such indigenous rhizobia as may occur, and persist well in the soil;
- Be tolerant of soil environmental stresses such as pH and high temperature;
- Grow well in simple, inexpensive culture media;
- Be genetically stable; and
- Survive well on the seed before sowing and in the soil.

Once identified as being of suitable quality, a rhizobial strain(s) used in inoculation, must be grown to a suitable cell density in culture vessels, and then inoculated into one of the several carrier materials. It survives in this carrier until used by the farmer (44). Initially sterile peat flour preparations are usually preferred as the carrier, but nonsterile peat flour, granular peats, other granular preparations, and even frozen liquid concentrates may be used. Essential features of such carriers include:

- high water-holding capacity;
- nontoxicity to rhizobia;
- ready availability, low cost, and easily processed;
- sterilizable; and
- good buffering capacity.

Such preparations should be properly prepared, inoculated, and stored and should maintain counts in excess of 10^8 to 10^9 rhizobia per g^{-1} or mL^{-1} for periods of up to a year. When appropriately used the expectation is that they will supply 10^3 to 10^5 rhizobia $seed^{-1}$ when applied to the seed, or 10^{11} cells ha^{-1} when applied to the soil (45). Quality control for such inoculant preparations can be quite variable, but is strictly regulated in countries such as Australia, Canada, France, and Uruguay.

Four alternate procedures can be used to introduce rhizobia into the soil with the method used determining the type of inoculant preparation needed. Procedures include:

- seed inoculation, with the inoculant mixed with milk, sugar solution, or other adhesive sticker and then applied to the seed to provide uniform coverage. Ideally, seed should be inoculated, dried in the shade and planted the same day, a procedure that is often irksome for larger scale farmers.
- seed pelleting using a stronger adhesive (40% gum arabic, 10% methyl ethyl cellulose), with the seed first inoculated as described earlier, and then rolled in finely ground limestone or rock phosphate. Seed pelleting has been used extensively to counteract the impact of unfavorable soil conditions or in range-seeding. Commercial preinoculation of seed for subsequent sale is also common, but decline in rhizobial numbers during seed storage is significant, and preinoculated seed only rarely meets inoculation standards.
- soil inoculation with granular peat or liquid preparations. The inoculant is banded in soil below the seed and makes contact with the emerging radical. Soil inoculation is most useful when the seed to be planted has been treated with fungicide, or soil conditions dictate higher than normal levels of inoculation.
- cover inoculation in which inoculant rhizobia are introduced during irrigation, and at high cell numbers.

Inoculation of legume seed by sprinkling it with inoculant in the planter seed box, often used as an insurance procedure when soils are thought to already contain some rhizobia, provides very patchy nodulation, and cannot be recommended.

Production of inoculants and legume inoculation is not a difficult procedure. Properly carried out, the results can be spectacular, with yield increases of more than 50% compared with uninoculated controls (Fig. 5). However, inoculation can fail, especially where inoculation quality is not well regulated. Lupwayi and coworkers (45) reported a steady improvement in inoculant quality in Canada following regulation of inoculant production in 1975. In contrast, Gomez and coworkers (46) evaluated 18 soybean inoculants produced in Argentina, and found rhizobial numbers to vary from 0 to $\log_{10}$ 9.94 rhizobia g^{-1} product. Many of the products were contaminated with other organisms, and only 5 of the 18 would have met Canadian standards. Catroux and coworkers (47) assessed the current status of legume inoculants, and concluded "We enter the era of biotechnology knowing more and more about the mechanisms of nitrogen fixation at the gene level, but except for some ..... developed countries still lacking good quality and reliable inoculants."

Figure 5. Response to inoculation in soybean planted in newly cultivated production areas in Puerto Rico. (photo: R Stewart Smith, used with permission). See color insert.

Unsatisfactory products aside, poor response to inoculation can be because of:

- delays between inoculation and seeding;
- use of inoculant rhizobia preparations that will not nodulate the legume in question;
- use of old, dessicated, or improperly stored products in which most of the rhizobia have died;
- high soil temperature or acid-soil conditions leading to the death of inoculant rhizobia in the soil;
- interaction between inoculant rhizobia and seed-applied pesticides or fertilizers;
- deviation from inoculant manufacturer's recommendations resulting in too few rhizobia added or poor contact between seed and inoculant bacteria;
- competition for nodulation with indigenous rhizobia; and
- inadequate extension information for, especially, third world farmers.

Once a particular plant species has been correctly inoculated, it is not usually necessary to reinoculate in subsequent years. Rhizobial numbers released from the nodule following senescence can exceed Log_{10} 10 rhizobia g^{-1} nodules (48), with sufficient rhizobia persisting in the soil such that reinoculation is not necessary. Diatloff (49) and others have returned to sites previously used in inoculation experiments, and shown that the original inoculant rhizobia still dominated nodulation some 10 to 15 years later. In contrast, Hungria and Vargas (50) have recommended annual reinoculation for legumes seeded into the acid and high-temperature soils of the Brazilian cerrados, where the rate of die-off of rhizobia in soil is much greater.

Factors Affecting Legume Nodulation and Nitrogen Fixation

A number of factors, including several already mentioned, can affect successful nodulation and nitrogen fixation. These include:

Host Cultivar. As indicated earlier, it is usual for different cultivars of the same species to differ in nitrogen-fixing ability with specific rhizobia. With crop legumes, this often relates to flowering and maturity differences (51) with early flowering varieties more likely to be limited in ability to fix nitrogen. However, genetic differences in earliness of nodulation, nodule mass $plant^{-1}$, onset of nodule senescence and enzyme function have been reported, and appear amenable to genetic manipulation (52–54). In several situations, coadaptation of host and rhizobia has been reported, with hosts from a particular region likely to perform better with local, than with introduced, rhizobia (55,56).

A simple approach to improve nitrogen fixation in crop plants is to select for both seed and biological yield in plants grown under conditions of low nitrogent content in soil. The situation with soybeans suggests that even here, however, more than one approach might be possible. Thus, in the Cerrado of Brazil where soils are nitrogen-deficient and response to inoculation is dramatic, an emphasis on inoculation has resulted in cultivars deriving a high percentage of their nitrogen requirements from symbiosis (57). By contrast in Africa, Mpepereki and coworkers (58) have advocated the use of symbiotically promiscuous cultivars that are able to nodulate and fix nitrogen with indigenous bradyrhizobia as better suited to the needs of subsistence farmers with limited access to inoculants.

Soil Acidity. There are more than 800 million ha of Oxisols and Ultisols with a pH less than 5.0 in Latin America alone. Progressive soil acidification is also a common consequence of ley farming and specific nitrogen-fertilization practices. Such low pH levels limit rhizobial survival in soil, and affect various steps in nodulation and nitrogen fixation. Their influence may be related to H^+ concentration per se, to the presence of toxic levels of aluminum and manganese, or to induced deficiencies of phosphorus, calcium, or molybdenum.

Species of rhizobia differ sharply in pH tolerance, with *R. tropici, R. loti*, and some bradyrhizobia known for their acid-tolerance (59), and *S. meliloti* being particularly acid sensitive. Brockwell and coworkers (60) recovered an average of 89,000 *S. meliloti* g^{-1} from soils with near-neutral pH, but only 37 cells g^{-1} from soils of pH below 6.0. Even the latter rhizobia are more likely to have come from microsites of more favorable pH in the soil, than to be pH tolerant. Failure to nodulate under such conditions can be related to poor survival of the rhizobia, or to inhibited attachment of the rhizobia to their host at low pH. Although lime is commonly applied to alleviate the pH problems of soil in the United States, the areas involved and the cost and availability of limestone can limit the use of lime in other regions. Further, where minimum tillage approaches are needed to maintain soil organic matter content, as in large areas of Brazil (50), lime is often surface-applied, and must infiltrate the soil over time, leading to variation in soil pH with depth. Practices that mitigate the need for high rates of lime application in acid soil include the pelleting of seed with finely ground lime or rock phosphate to create microenvironments of more suitable pH, and the use of more acid-tolerant cultivars and strains. In Australia, the use of the somewhat acid-tolerant strains such as WSM419 together with annual

medics collected from acid-soil areas in Sardinia has extended the area sown to *Medicago* species by some 350,000 ha since 1985 (61). The genetic basis for some differences in acid-tolerance among strains of *S. meliloti* are reviewed by Dilworth and coworkers (62). The acid-tolerant *R. tropici* strains CIAT1899 and PRF81 also have been extensively used for bean inoculation in Brazil.

Mineral Nutrition. Several elements have functions in nodulation and/or nitrogen fixation above and beyond those associated with nitrogen-fertilized plants. These include:

- molybdenum, iron, and sulfur as components of the nitrogenase enzyme;
- iron needed for leghemoglobin and in nodule development;
- calcium required for rhizobial attachment and for cell wall integrity in both plant and *Rhizobium*;
- phosphorus needed for energy transformation and supply to the microsymbiont;
- cobalt for nodule coenzyme function;
- boron needed for cell wall formation and the development of the diffusion barrier to oxygen in the inner cortex; and
- nickel as a component of the hydrogen uptake system present in some rhizobia, and used to recapture hydrogen released during fixation.

Legumes deficient in one or more of these elements may be limited in their ability to nodulate or fix nitrogen, and have the generalized yellow chlorosis typical of nitrogen-deficient plants. The need for phosphorus in symbiosis is such that the nodulated plants have a much higher requirement for phosphorus than do those supplied fertilizer nitrogen. A consequence is that legumes are commonly dependent on a three-way symbiosis with both rhizobia and AM mycorrhizal fungi.

THE ACTINORHIZAL-*FRANKIA* SYMBIOSIS

Mechanisms of Infection

Because *Frankia* were not isolated in pure culture until 1978, and in some cases are still difficult to isolate, knowledge of the actinorhizal-*Frankia* symbiosis lags behind that available for the nodulated legume. The suggestion by Soltis and coworkers (63) of a single phylogenetic clade of plants predisposed to nodule formation, and including both legume and actinorhizal species, has focused studies toward overlaps and differences in these two systems, with significant recent progress.

Actinorhizal plants group into four clusters (64). In the Betulaceae, Casuarinaceae, and Myricaceae (cluster 4), infection proceeds intracellularly through root hairs, with mitotic activity in cortical cells adjacent to infected root hairs leading to a slight but visible protruberance called the *prenodule* (65). *Nif*-gene expression in *Frankia* cells from the prenodule has been reported, but no indication was given of relative rates of nitrogen fixation. A nodule primordium separately formed in the root pericycle then becomes infected with *Frankia* from the prenodule. Multilobed *Alnus* nodules are shown in Fig 6. In this host, lobes arise from modified lateral roots without root caps, have a significant periderm, a central vascular cylinder, and infected cells in the cortex (66). Nodule induction by rhizobia in the nonlegume *Parasponia* follows a similar sequence, although the rhizobia enter the plant intercellularly and not through root hairs.

Figure 6. Nodules of *Alnus* showing a typical multilobed structure that is derived from modified lateral roots. (Photo: P.O. Lundquist, used with permission). See color insert.

Infection in the Eleagnaceae, Rhamnaceae, and Rosaceae (clusters 1 and 2) is predominantly intercellular. Thus, in *Discaria trinervis*, infection involves intercellular penetration between epidermal and cortical root cells, and root hair deformation is not common (67). Nodule primordia can be detected in young roots around six days after inoculation, with invasion of host cortical cells occurring some seven to nine days after inoculation, and associated with hypertrophy of the primordium cells. Differentiation of nitrogen-fixing vesicles of the microsymbiont occurs within already infected cells, with numerous uniformly distributed vesicles evident within cells of the host by 16 days after inoculation. Nitrogen fixation begins at about the same time. Berg and coworkers (68) described the intercellular infection process associated with *Datisca* and *Coriaria* (cluster 3).

Infection by *Frankia* provides some interesting similarities and contrasts with that found in legumes. Thus,

- flavonoid-containing preparations from seed washes of *Alnus rubra* influenced nodulation by *Frankia* (69), although in *Alnus glutinosa*, van Ghelue and coworkers (70) found no correlation between root hair deformation and infective ability.
- root hair–deformation bioassays developed for the study of the *Alnus-Frankia* infection process, suggest involvement of "*nod*-factors" analagous to those found in *Rhizobium* (71). In at least some *Frankia* strains, however, these *nod* factors are constitutive, heat-stable, hydrophilic, and chitinase-resistant, suggesting structural differences with those found in rhizobia. As a further indication of this, a *Frankia* genomic DNA library-tested by Ceremonie

and coworkers (71) failed to complement nodulation mutants of *Sinorhizobium*.

- infection threads produced in the *Comptonia, Casuarina, Alnus, Datsica*, and *Myrica* symbioses (68) do not result in release of *Frankia* into cells of the host (72). Instead, host cells are filled with branched infection threads.
- regulation of nodulation in some symbioses with *Frankia* parallels that found with *Rhizobium*. Thus, Valverde and Wall (73) noted nodules in *Discaria* mainly located around the position of the root tip at the moment of inoculation, showed nodule distribution affected by culture age and inoculum dosage, and found that taproot nodule initiation resulted in distal suppression of nodulation. Similar regulation of infection occurs in the legume *Rhizobium* symbiosis.
- although nodule-specific gene expression occurs both in the legume-*Rhizobium* and actinorhizal-*Frankia* symbioses, it has been more extensively studied in legumes. Known nodulin genes in the *Frankia* symbiosis include a serine protease expressed early in symbiosis (65) and a nodule-specific hemoglobin (72).
- *Frankia* nitrogenase, like that of *Rhizobium*, must be protected from oxygen. In most of the hosts with which *Frankia* associates, the microsymbiont produces vesicles, and it is within these structures that nitrogenase activity is found. The vesicular envelope contains layers of hopanoid lipids that increase or decrease in thickness with oxygen tension and stress (74), and with oxygen regulation, thought to be a function of envelope-thickness. In *Casuarina* and *Myrica*, vesicles are not found in the nodule, and oxygen diffusion is limited by lignin and suberin-like materials that gird the nodule. In these nodules, as in legumes, hemoglobin facilitates the required oxygen supply to the microsymbiont (75).

Specificity in the Actinorhizal Symbiosis

Data on cross-inoculation specificity among actinorhizal plants is incomplete, and particularly affected by the limited availability of pure cultures from the Rhamnaceae, Rosaceae, and Coriariaceae. As with legumes, many plant species of lesser importance have not been studied.

16S rDNA sequence analysis (76–78) has permitted identification of four main clusters within the genus *Frankia*:

- A large group including isolates from both *Alnus* and *Casuarina*;
- Uncultured isolates from *Dryas, Coriaria*, and *Datisca*;
- Strains from *Eleagnus, Hippophae*, and *Gymnostoma*;
- Atypical and non- nitrogen-fixing isolates.

Cross inoculation somewhat parallels these groupings, although *Alnus* and *Casuarina* require separate inoculant strains, and *Myrica* spp. are promiscuous and nodulate with isolates from *Alnus, Casuarina*, and the *Eleagnus–Gymnostoma* complex. *Atriplex cordobensis* is also promiscuous, nodulating with *Frankia* strains from *Colletia, Ceanothus, Hippophae*, and *Casuarina* (79). Many additional studies need to be undertaken to resolve infective and effective subdivisions among these organisms. Thus, Simonet and coworkers (80) found seven phylogenetically distinct groups of *Frankia* in the nodules of Australian *Casuarina* and *Allocasuarina* species, but noted that these species require inoculation when planted in other countries. They examined *Casuarina* nodules from plants grown outside Australia, and recovered only one of the seven phylogenetic groups. Because these *Frankia* were more easily cultured, had a wider host range, and appeared to survive in soil apart from their host, saprophytic competence is likely to be as important for *Frankia* as for the rhizobia.

Inoculation

Frankia inoculation may be by cultured cultures, crushed nodules, or infective soil (13). Encapsulated, alginate bead formulations have also been used (81), but inoculation procedures for actinorhizal plants are much less satisfactory than for legumes. Best results are achieved by transplantation from inoculated nursery stocks (82,13) but the inability to culture specific *Frankia* is still a major impediment.

CONCLUSION

This presentation has emphasized recent improvements in our knowledge of nodulation and symbiotic nitrogen fixation. It is clear that these processes contribute significantly to crop and pasture production in both the developed and developing world. What is less obvious, and what needs to be pointed out in conclusion, is that the role for symbiotic nitrogen fixation and the consequent research requirements differ markedly among regions.

For countries such as the United States where fertilizer nitrogen is relatively inexpensive and animal manure plentiful, symbiotic nitrogen fixation is not emphasized for crop production, and dependence on symbiotically-fixed nitrogen is only critical for range, forage, revegetation, and natural environments. Applied research requirements are limited, allowing emphasis on the molecular and genetic basis of nodulation and on host and *Rhizobium* biodiversity. It is not surprising that inoculant production is stagnant or in decline, nor that the percentage of legume crop nitrogen derived from nitrogen fixation is also dropping.

In contrast, developing countries with burgeoning population and extensive soil degradation have urgent applied requirements. In these countries, small landholders are frequently unable to afford or obtain fertilizer nitrogen, edaphic factors (low soil pH, high soil temperature, drought, and nutrient deficiencies) constrain nitrogen fixation, and inoculant quality is often poor. For these regions, varietal improvement in the ability to fix nitrogen in symbiosis, cultivar and strain selection for the tolerance of edaphic constraints, a better understanding of the factors

affecting rhizobial strain survival in soil, and above all, improved inoculant quality and availability are urgently required. It has been suggested that nitrogen fixation worldwide will have to increase threefold over the next 30 years to meet the increasing food requirements. Much of that increase will have to occur in developing countries, emphasize crop as well as other legumes and nonlegumes, and stress the more applied side of symbiotic nitrogen fixation.

NITROGEN FIXATION IN THE MARINE ENVIRONMENT

JONATHAN P. ZEHR
University of California
Santa Cruz, California

DOUGLAS G. CAPONE
University of Southern California
Los Angeles, California

Nitrogen (N) is one of the most abundant elements in biological materials and is used by most organisms in its inorganic chemical forms, nitrate (NO_3^-) and ammonium (NH_4^+), or as organic nitrogen (e.g., urea, amino acids, protein). These chemical forms of nitrogen can be rapidly depleted in many marine environments, and the availability of nitrogen often limits the productivity of marine and estuarine habitats (see NITROGEN CYCLE IN THE MARINE ENVIRONMENT). Nitrogen has a complex biogeochemical cycle that is largely mediated by biological transformations. Chemical forms of nitrogen range in oxidation state from $+5(NO_3^-)$ to $-3(NH_4^+)$, with N_2 having an oxidation state of 0 (1). Briefly, major components of the nitrogen cycle are ammonification (remineralization, liberation of NH_4^+) resulting from decomposition of organic materials, oxidation of NH_4^+ ultimately to NO_3^- by nitrifying bacteria, denitrification of NO_3^- to N_2 by denitrifying bacteria, and fixation of N_2 into ammonium and ultimately organic matter by nitrogen-fixing bacteria (including cyanobacteria) (1). Plants, both multicellular and unicellular, are the organisms responsible for fixation of carbon dioxide into organic matter (primary production) and are dependent upon the availability of NH_4^+, NO_3^-, and some simple organic forms of nitrogen. Thus, the interplay between the different components of the nitrogen cycle, in particular the balance between nitrogen fixation and denitrification, can control the productivity of aquatic environments.

Nitrogen gas (N_2), readily dissolved in seawater, is not available to most organisms, except for "nitrogen-fixers" (also commonly referred to as diazotrophs), which reduce nitrogen gas to ammonium that is then assimilated into organic matter. Thus, N_2 is an important potential source of nitrogen in nitrogen-depleted waters, and can be a quantitatively important process in the nitrogen cycle that contributes to the productivity of marine systems. In this section, we will review the basic aspects of biological nitrogen fixation and discuss the significance of nitrogen fixation in open oceans and estuaries, and touch on coral reefs.

BRIEF REVIEW OF NITROGENASE BIOCHEMISTRY AND GENETICS

Nitrogen can be fixed into combined forms abiotically: industrially reduced to ammonium by the Haber process, or naturally to nitrogen oxides by lightning. Although the nitrogen fixation reaction is thermodynamically favorable and nitrate is the most stable form, the transition state requires a large input of energy to break the triple bond between the nitrogen atoms of N_2. The ability to fix N_2 biologically appears to be restricted to prokaryotes, and is catalyzed by the enzyme nitrogenase. This enzyme is very similar (in both its gene and amino acid sequences) among very distantly related microorganisms, which implies that the enzyme may have evolved early (2). The chemical reaction for biological nitrogen fixation is:

$$N_2 + 8e^- + 8H^+ + 16\text{MgATP} \rightarrow 2NH_3 + H_2 + 16\text{MgADP} + 16P_i$$

Thus, the physiological costs of N_2-fixation are high with respect to adenosine triphosphate and reducing equivalents. Most N_2-fixing microorganisms will preferentially use ammonium, if it is available, and the synthesis of the nitrogenase enzyme is regulated in response to

ammonium availability (enzyme synthesis is repressed in the presence of high concentrations of ammonium). Elaborate molecular and biochemical mechanisms control the transcription of the nitrogenase genes and activity of the proteins themselves (3). In addition to being energetically expensive, nitrogenase is rapidly inactivated by oxygen, at least in vitro (4). Recently, a nitrogenase has been described that is not sensitive to oxygen inactivation (5), but its relationship to "conventional" nitrogenases, or its prevalence in nature are not yet known.

The nitrogenase of most nitrogen-fixing microorganisms is composed of two metalloproteins, the molybdenum (MoFe) protein and the iron (Fe) protein (6,7). The genes that encode proteins necessary for nitrogen fixation are called *nif* genes. The *nifD, nifK*, and *nifH* genes encode the subunits of the MoFe protein (*nifD* and *K*) and the iron protein (*nifH*) of the enzyme nitrogenase. These genes are found in diverse prokaryotes, representing most, if not all, major evolutionary lineages (including both Archaea and Bacteria), and many different physiological groups (e.g., phototrophs, chemoautotrophs, chemoheterotrophs) (8). Two additional nitrogenases are very similar to the conventional nitrogenase, but molybdenum is replaced by vanadium ("first alternative" encoded by *vnfHDGK*) or by iron ("second alternative, *anfHDGK*) in these nitrogenases. Other multiple copies of *nif* genes have also been reported (there are six copies of *nifH* in *Clostridium pasteurianum*). In some organisms different copies of the molybdenum nitrogenase are regulated differently (e.g., 9). Microorganisms can contain one or multiple copies of nitrogenase. Although the alternative nitrogenases have been detected in the environment (10), the ecological and paleoecological significance of the different nitrogenases is not known.

There are about 20 known nitrogen fixation genes that are involved with various functions of nitrogen fixation or assembly of nitrogenase, including molybdenum uptake, providing reducing equivalents, providing scaffolding for assembly of MoFe cofactor, and so on. The functions of these genes are beyond the scope of this article but are discussed elsewhere (11).

THE DIVERSITY OF MARINE NITROGEN-FIXING MICROORGANISMS

Many different types of microorganisms can fix nitrogen, but the genetic capability is not uniformly distributed throughout evolutionary lineages such that not all representatives of an evolutionary lineage that contain nitrogen-fixers fix nitrogen. For example, some cyanobacterial species can fix nitrogen, but other morphologically very similar cyanobacteria cannot. Taxonomic information alone is not sufficient to predict whether a given species is able to fix N_2. There is a large number of known N_2-fixing species, but there are undoubtedly many more that have simply not been shown to fix nitrogen, either because they have never been tested or because the right conditions have not been used (8).

There are nitrogen-fixing representatives in most branches of the Prokaryotic tree, including representatives of Archaea and Bacteria (Fig. 1). The Archaea include the major clades Crenarchaeota and Euryarchaeota. Thus far, nitrogen fixation has only been found in the methanogens that are included in the Euryarchaeota (12). Given that it is now recognized that there are many uncultivated Archaea in marine systems (13), it is possible, if not likely, that other Archaea phyla will be detected as more organisms are brought into culture.

Nitrogen-fixing microorganisms are scattered throughout the proteobacteria and cyanobacteria groups within the Bacteria (Fig. 1). N_2-fixing bacteria have been isolated by conventional microbiological techniques from many marine environments. Common diazotrophic marine groups in the γ proteobacteria are *Azotobacter* and *Klebsiella* (Table 1). Representatives of N_2-fixers in the δ proteobacteria are the sulfate reducers, such as *Desulfovibrio* (Table 1). Diazotrophic α proteobacteria include relatives of *Rhodobacter* and *Rhizobium*.

The diverse array of diazotrophs represents many modes of metabolism (Table 1). Cyanobacteria, major N_2-fixers in many marine environments, from the water column of the open ocean to mats occurring in shallow-water coastal intertidal areas, are oxygenic phototrophs. In certain habitats, such as marine mats and anoxic water columns within the euphotic zone, anoxygenic purple and green sulfur and purple nonsulfur bacteria can be abundant and are potentially diazotrophic.

There are many different types of heterotrophic microorganisms that fix nitrogen, spanning a wide range of heterotrophic modes of metabolism, including aerobes, microaerophiles, facultative and strict anaerobes (*Clostridium*) (14). It is unclear whether heterotrophs are important in N_2-fixation in the water column, but they are undoubtedly more active in sediments (15) and in association with invertebrates (16). N_2-fixers have been isolated from sea urchins and other marine invertebrates (17) and from estuarine waters (18,19).

Molecular phylogenetic approaches have shown that marine microbial cultures are not in general representative of natural marine open ocean microbial assemblages (20,21), which implies that probably our N_2-fixing culture collections also are not representative of natural assemblages. There are two general kinds of microbiological information from marine systems: experiments and enumerations using cultivation or enrichment, and culture-independent information. This is particularly relevant to the discussion of nitrogen fixation. Molecular phylogenetic information is usually obtained from 16S ribosomal RNA genes, which provides no direct information on the ability to fix nitrogen. Cultivation studies, on the other hand, do not necessarily reflect the microorganisms that are most active or most important in situ. Culture-independent methods that target nitrogenase genes provide some information on the organisms present in situ (22,23), but do not provide as high resolution phylogenetic information as studies with ribosomal genes, as all microorganisms have ribosomal genes. Results of culture-independent studies targeting *nif* genes have provided evidence for the presence of many N_2-fixing microorganisms that have not previously been described. Diverse N_2-fixing microorganisms have been detected from marine

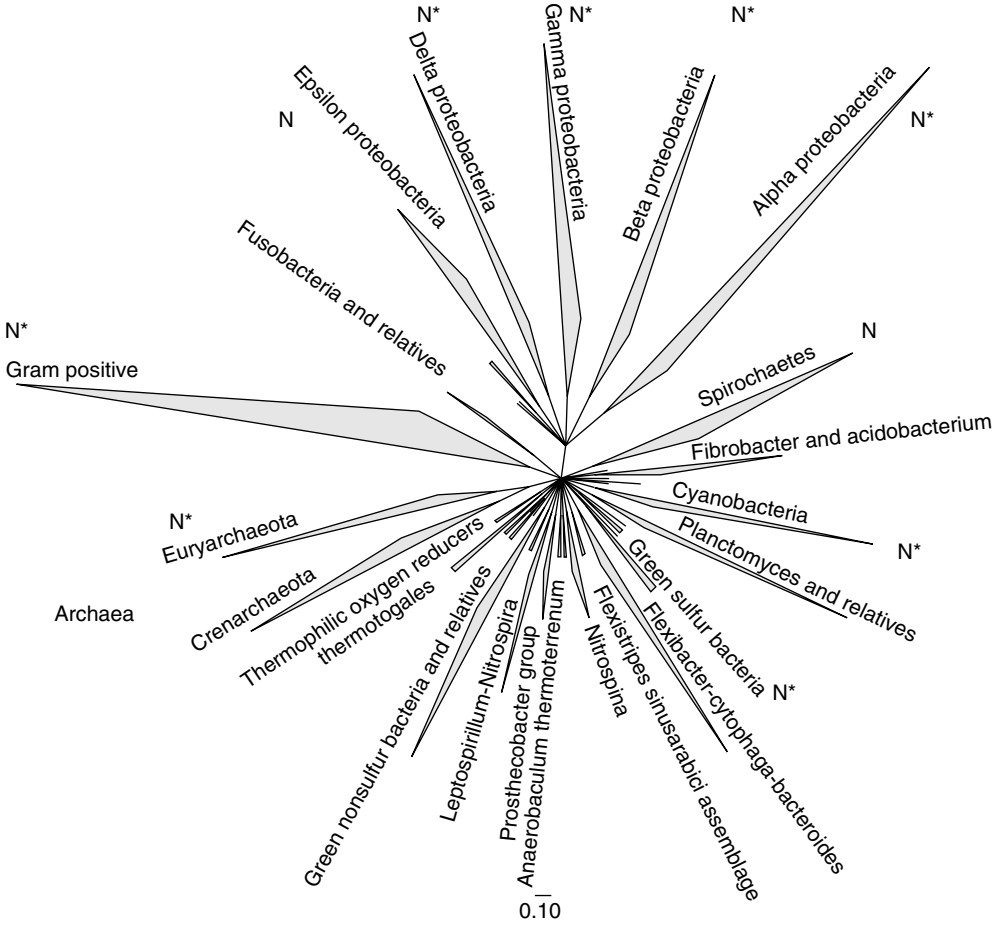

Figure 1. Cartoon of phylogenetic tree based on 16S ribosomal RNA sequences showing the distribution of N_2-fixing capability (N) and groups for which *nif* genes have been sequenced (*) among the major prokaryotic lineages. Tree derived from the ARB database (*http://www.biol.chemie.tu-muenchen.de/*).

environments ranging from cyanobacterial mats (24), sediments (25), and seagrass sediments (26,27) to the open ocean (28). Nitrogenase gene sequences recovered from these environments cluster in the γ proteobacteria, α proteobacteria, and cyanobacterial clades. In environments such as mats and in association with invertebrates, sequences have been recovered that cluster (cluster III of nitrogenases) with typical anaerobes (*Clostridium* and sulfate reducers) (28,29). These N_2-fixing microorganisms cannot be identified to the genus, as the sequences are not similar enough to sequences from cultivated isolates. This molecular technique can also be used to determine which microorganisms are expressing the nitrogenase apparatus (23), and these studies are currently in progress.

FACTORS THAT REGULATE NITROGEN FIXATION RATES

Nitrogen fixation in marine environments is controlled by a complex suite of chemical and physical factors (30). The major factors are oxygen (nitrogenase is rapidly inactivated by oxygen), iron, and perhaps molybdenum availability (trace metal components of nitrogenase), and availability of other forms of nitrogen (which are used by non-N_2-fixing microorganisms and preferentially used by N_2-fixing microorganisms).

Nutrient availability is probably one of the most important factors controlling nitrogen fixation. When fixed nitrogen forms are present, N_2-fixing microorganisms do not have an ecological advantage and non-N_2-fixing microorganisms are more competitive. Most N_2-fixing microorganisms will preferentially use ammonium, and sometimes nitrate, rather than fix N_2. Thus, ammonium or nitrate availability tends to inhibit N_2-fixation. Other important nutrients are phosphorus and trace metals. The growth rate of N_2-fixing organisms can greatly exceed that of competing microorganisms that are dependent upon other forms of nitrogen when the supply rate of nitrogen is low, when the ratio of nitrogen to phosphorus supply is low (31), or when phosphorus loading is high (32). These conditions can lead to blooms of N_2-fixing cyanobacteria, which are often nuisances because of taste, odor, and toxicity problems (33). Such blooms have been observed worldwide in coastal and estuarine regions. Iron and molybdenum are important components of conventional nitrogenases, and therefore, N_2-fixation is dependent upon the availability of these trace elements as well (30).

Table 1. Some Representative Marine N_2-fixing Species Showing Breadth of Phylogenetic Distribution of Marine Prokaryotes

Phylogenetic Group	Mode Metabolism
α Proteobacteria	
Rhodobacter sp. ATCC 35206	Aerobic heterotroph or facultative anaerobic phototroph
δ Proteobacteria	
Desulfovibrio africanus ATCC 19997	Anaerobic heterotroph
Desulfobacter curvatus ATCC 43919	Anaerobic heterotroph
γ Proteobacteria	
Chromatium purpuratum ATCC 700430	Anaerobic phototroph
Vibrio diazotrophicus ATCC 35885	Aerobe, facultative anaerobe
Methylophaga thassica ATCC 33146	Aerobic chemotroph
Roseobacter denitrificans ATCC 33942	Heterotroph
Gram-Positive	
High GC (Thallobacteria)	
Deleya marina	Aerobe, facultative anaerobic
Low GC (Firmibacteria)	
Clostridium oceanicum	Anaerobic heterotroph
Bacillus marinus	Aeribem facultative anaerobe
Cyanobacteria	
Trichodesmium sp. IMS101 WH9601 filamentous nonheterocystous	Phototroph, oxygenic
Richelia sp. uncultivated heterocystous symbiotic	Phototroph, oxygenic
Anabaena sp. CA ATCC 33047 Filamentous heterocystous	Phototroph, oxygenic
Cyanothece sp. ATCC 51472 unicellular cyanobacterium	Phototroph, oxygenic
Arclaea	
Methanococcus maripaludis	Anaerobe, chemoautotroph

Note: See Young (1990) for extensive list of prokaryotic N_2-fixers, and Pearl and Zehr (2000) for more extensive list of cultivated marine N_2-fixing strains available in culture collections.

The relative availability of fixed nitrogen, phosphorus, and iron varies among freshwater, coastal, and open ocean habitats and may be some of the primary factors determining when and where N_2-fixation occurs. Blooms of N_2-fixing cyanobacteria are often found in lakes, but less frequently found in temperate coastal regions and oceans even though fixed nitrogen is generally thought to be the primary limiting nutrient (in shorter supply relative to phosphorus) in many of these areas (30). The reasons for this are still not fully understood, but could be related to the relatively high mass of combined nitrogen often found in coastal waters and estuaries, despite relatively low N/P ratios (34). Other factors such as turbulence or iron availability could also limit marine N_2-fixation.

Temperature and light can have direct effects on the growth and activity of microorganisms. The distributions of some diazotrophs appear to be constrained by temperature. For example, *Trichodesmium*, an important open ocean marine diazotroph, has been observed primarily in waters with temperatures greater than 20 °C (35).

Phototrophic microorganisms such as cyanobacteria and phototrophic bacteria are dependent upon light to obtain energy to support nitrogen fixation. In microbial assemblages composed of both phototrophs and heterotrophs, light-stimulated carbon fixation by phototrophs can secondarily stimulate nitrogen fixation via associated heterotrophs. Some cyanobacteria, such as *Trichodesmium*, contain gas vacuoles that allow them to migrate up and down the water column. This buoyancy mechanism may allow cyanobacteria to optimize photosynthetic carbon fixation and nitrogen fixation.

Although salinity can affect the growth and activity of microorganisms along salinity gradients in estuaries (36), and high salinities have been shown to affect certain N_2-fixing microorganisms (37), at least some N_2-fixing bacteria can have wide salt tolerances (15). Furthermore, there are many examples of N_2-fixing systems in coastal regions, implying that salinity does not ultimately constrain N_2-fixation.

Nitrogenase is sensitive to inactivation by oxygen, and protecting nitrogenase from oxygen is important for diazotrophic microorganisms. Microorganisms use a diverse array of strategies to avoid oxygen inhibition or inactivation. Anaerobes do not need to protect nitrogenase from aerobic conditions, but facultative microorganisms, aerobes, and oxygenic phototrophs need specific mechanisms to prevent nitrogenase from being damaged by oxygen. Facultative bacteria often repress expression of nitrogenase under aerobic conditions, and some aerobic

heterotrophic bacteria are believed to maintain high respiratory rates to keep intracellular oxygen levels low. Oxygenic phototrophs have the biggest disadvantage as they evolve oxygen through photosynthesis. Cyanobacteria usually prevent oxygen from inhibiting nitrogen fixation either by fixing nitrogen at night or by using specialized cells called *heterocysts* that fix nitrogen but do not perform oxygenic photosynthesis (38). There are a few cases that remain enigmatic, most notably in *Trichodesmium*, where it appears that N_2-fixation occurs at the same time as photosynthesis without heterocysts (39).

Physical and chemical factors can control N_2-fixation because of indirect effects. For example, turbulence of water can affect the rate of oxygenation of water, causing indirect effects on oxygen-sensitive diazotrophs such as heterotrophs. The chemical form of iron (Fe) is affected by the presence of other ions and pH that determines the solubility of iron. Iron can precipitate, effectively limiting the availability of iron for diazotrophs (and other organisms). Iron can also be complexed with organic materials (30), and so there may be an interaction between the concentration of dissolved organic matter and the biological availability of iron. It may be that iron availability ultimately limits the rates of N_2-fixation in the oceans and that global climate factors controlling dust inputs to the oceans over long timescales set the balance between global N_2-fixation and denitrification, and ultimately the productivity of the oceans (40,41). There is some evidence the iron can limit the growth of the cyanobacterium *Trichodesmium* (42).

ECOLOGY OF NITROGEN FIXATION

N_2-fixing microorganisms can be found in a multitude of habitats throughout the marine realm, but nitrogen fixation activity is usually restricted to times and places where other more easily assimilated forms of nitrogen are depleted. N_2-fixation is ecologically advantageous when competing microorganisms are limited by the availability of dissolved inorganic nitrogen (ammonium or nitrate), but when other forms of nitrogen are available in high enough concentrations, or are rapidly cycled, N_2-fixation is not competitive because of the costly energetics of the nitrogen fixation process. However, in some environments, N_2-fixation appears to persist, even when high ammonium concentrations are present, such as in some sediment environments (14).

The physiological costs can mean slower growth rates when microorganisms are dependent upon N_2-fixation, compared with growth on fixed inorganic forms (30,43). The higher growth rate of non-N_2-fixers has been interpreted as being the result of increased competitive ability for other resources such as light or phosphorus according to resource competition theory (44).

In terrestrial environments there are many examples of symbiotic relationships between plants and N_2-fixing microbes. Undoubtedly there are diverse symbiotic relationships in the marine realm that are yet to be uncovered. One notable symbiotic relationship is between eukaryotic diatoms (of the genera *Rhizosolenia* and *Hemiaulus*) and *Richelia*, a filamentous heterocystous cyanobacterium (Table 1). Many associations between cyanobacteria and eukaryotes have been observed microscopically, but it remains to be seen how many of the interactions involve N_2-fixation (45).

Interactions among microorganisms that stimulate N_2-fixation span the entire range from loose associations to mutualistic symbiosis. In addition to N_2-fixing cyanobacterial symbioses with eukaryotes, there are symbiotic associations between bacteria and cyanobacteria. Bacteria have been shown to be associated with heterocysts of cyanobacteria, and there may be mutual benefits for both microorganisms. Bacteria can help to keep oxygen concentrations low and may benefit from nitrogenous compounds leaked or excreted from the heterocyst. Some bacteria that fix nitrogen are associated with non-N_2-fixing species of cyanobacteria (25).

MEASURING NITROGEN FIXATION RATES

Procedures for determining the presence of nitrogen fixers and their contribution to nitrogen inputs are varied and steadily evolving (1). Nitrogen-fixing bacteria and cyanobacteria have been isolated from diverse marine ecosystems (46,47) and the number of nitrogen fixers in particular environments may be estimated by classical microbiological procedures involving serial dilution and growth on nitrogen-free media (48). However, both isolation and conventional enumeration methods rely on selective media and cannot provide an unbiased or comprehensive analysis of the physiological diversity of organisms, such as nitrogen fixers, or a quantitative evaluation of their numbers (49). Conventional procedures are being largely supplanted by molecular methods that aim to determine the presence of specific genes of the nitrogen-fixing complex (22). Besides the potential to quantify the abundance of *nif* genes as a proxy for abundance, extraction, cloning, and sequencing of these genes may provide a less-biased assessment of the true diversity of diazotrophs in particular environments.

Methods for determining the rate of nitrogen fixation are key to evaluating whether nitrogen fixers are active in situ as well as for assessing the quantitative importance of this process in specific ecosystems. There are two common procedures for determining nitrogen fixation: the uptake of $^{15}N_2$ into microbial biomass, and the fortuitous conversion of acetylene to ethylene by the nitrogenase enzyme (50). The uptake of dinitrogen gas isotopically enriched with the heavy isotope of nitrogen, ^{15}N, provides a direct measure of this process to the level of incorporation of the recently fixed N_2 into organic matter and biomass. However, the analysis of the amount of $^{15}N_2$ does require relatively sophisticated and specialized sample preparation and instrumentation, either an emission spectrometer or mass spectrometer capable of resolving the isotopes of nitrogen. The "acetylene reduction method" is an indirect enzymatic method that takes advantage of the capacity of the nitrogenase enzyme to convert acetylene (C_2H_2) to ethylene (C_2H_4). In the presence of added acetylene, actual N_2-fixation is inhibited, and the increase over time in ethylene is taken as a measure of the enzyme activity. Acetylene reduction can be expressed in terms of nitrogen

fixation by assumption of a conversion factor based on the stoichiometries of the two reactions (typically given as three or four molecules of acetylene reduced per molecule of N_2), or derived by direct comparisons with $^{15}N_2$ uptake. The acetylene reduction procedure is relatively simple and sensitive. Analysis of acetylene and ethylene requires only a simple gas chromatograph equipped with a flame ionization detector.

Another approach gaining wider use for detecting active nitrogen fixation in marine ecosystems is the analysis of the natural abundance of the stable isotopes of nitrogen, which relies on the subtle differences among different biological reactions to discriminate against the heavier (^{15}N) isotope of nitrogen relative to the more abundant lighter isotope, ^{14}N. The natural abundance of ^{15}N nitrogen in the largest reservoir of nitrogen, atmospheric N_2 gas, is generally given as 0.3663 atom% ^{15}N. ^{15}N isotope abundance is most often expressed in $\delta^{15}N$ notation:

$$\delta^{15}\mathrm{N}(‰) = \left[\frac{(^{15}\mathrm{N}/^{14}\mathrm{N})_{\mathrm{sample}}}{(^{15}\mathrm{N}/^{14}\mathrm{N})_{\mathrm{air\ standard}}} - 1\right] \times 1,000$$

where atmospheric N_2 is defined as 0. The largest reservoir of combined inorganic nitrogen in the sea is nitrate, which has a $\delta^{15}N$ of about 4.5 to 5‰, somewhat higher than atmospheric N_2. Whereas most processes of uptake discriminate slightly in favor of the lighter isotope, the base of marine food chains dependent upon nitrate is typically about 2 to 3‰, and the $\delta^{15}N$ increases up the food chain about 3.5‰ per trophic step (51). Nitrogen fixation, however, effects little fractionation, and results in biomass with an isotopic signature similar to that in atmospheric N_2, or near 0. Food webs that have a substantial input of nitrogen through nitrogen fixation are generally "lighter" (i.e., have a lower content of the heavy isotope, ^{15}N) at comparable trophic levels than those dependent upon nitrate (e.g., from deep water sources).

Lastly, recent advances in the application of molecular techniques to environmental systems have demonstrated the feasibility of detecting the presence of transcripts of functional genes, such as *nifH*, as might be expected in actively nitrogen-fixing organism (23).

Nitrogen Fixation in the Open Ocean

The biological productivity of the oceans is based largely on the primary producers, single-celled eukaryotic and prokaryotic phototrophic microorganisms collectively called *phytoplankton*. These organisms obtain their nitrogen predominately from inorganic nitrogen in the form of nitrate and ammonium. The production of the phytoplankton and the rest of the food chain that ultimately derives nitrogen from the phytoplankton is based on the use of nitrate, ammonium, and other forms of nitrogen, including atmospheric nitrogen gas. Because different forms of nitrogen have different sources and fluxes, a model of nitrogen-based production in the oceans was constructed that described production as "new" or "regenerated," depending upon whether the production was based on new inputs of nitrogen (which includes nitrate in rain, runoff, diffusion and upwelling from deep water, and atmospheric nitrogen gas) or regenerated

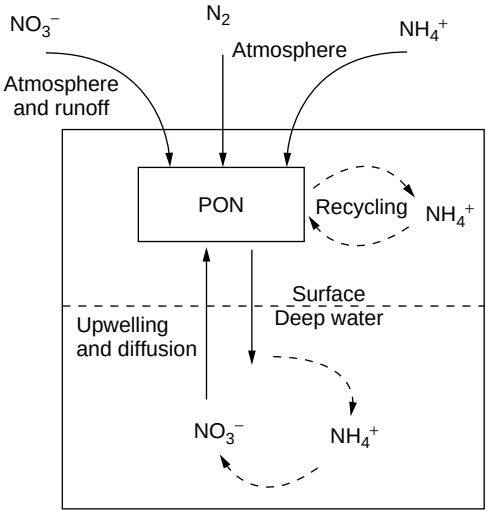

Figure 2. Nitrogen cycle in the water column of the oceans showing major inputs and sinks of dissolved inorganic nitrogen. The cycle through the dissolved organic nitrogen pool is ignored in this simplification, to highlight the importance of N_2 as new nitrogen and to demonstrate the fate of nitrogen in biological materials (PON, particulate organic nitrogen).

(largely ammonium derived from the decomposition and recycling of nitrogen in organic matter) (52). Inputs of new nitrogen can increase ecosystem production, whereas regenerated production is supported by internal recycling (Fig. 2). Nitrogen fixation, therefore, represents a new input of nitrogen to the open ocean, as it can support production beyond that supported by internal decomposition and recycling of organic matter (53). This concept is important for understanding the importance of N_2-fixation in the oceanic realm, as it can enhance the productivity of the oceans, which is analogous to the use of nitrogen-fixing legumes in agriculture to enhance crop yields in nitrogen-poor soils and rice paddies.

N_2 in seawater in equilibrium with the atmosphere is about 800 μM, whereas nitrate and ammonium in nutrient-poor waters are often less than 1 μM and substantially less (nM) in the oligotrophic gyres (1). Relatively low bioavailability of combined forms of nitrogen that constrain biological growth and productivity is termed *nitrogen limitation* (for a review, see 40). Under these conditions, N_2-fixation can alleviate nitrogen limitation until the availability of some other nutrient (e.g., phosphorus) or trace element (e.g., iron) limits the growth of N_2-fixing microorganisms.

In some regions of the open ocean, nitrate is present in relatively high concentrations as a result of upwelling of nutrient-rich deep water (which contains nitrate resulting from decomposition of particulate matter from the surface ocean, and nitrification of ammonium to nitrate) (Fig. 3). In these regions, N_2-fixation is not important from an ecosystem perspective as nitrogen fixation is not ecologically advantageous and N_2-fixation rates are low relative to rates of uptake of nitrate. In large regions of the oceans, including the major gyres of the Atlantic and Pacific oceans, however, there is minimal upwelling, and N_2-fixation can, at times, be significant relative to

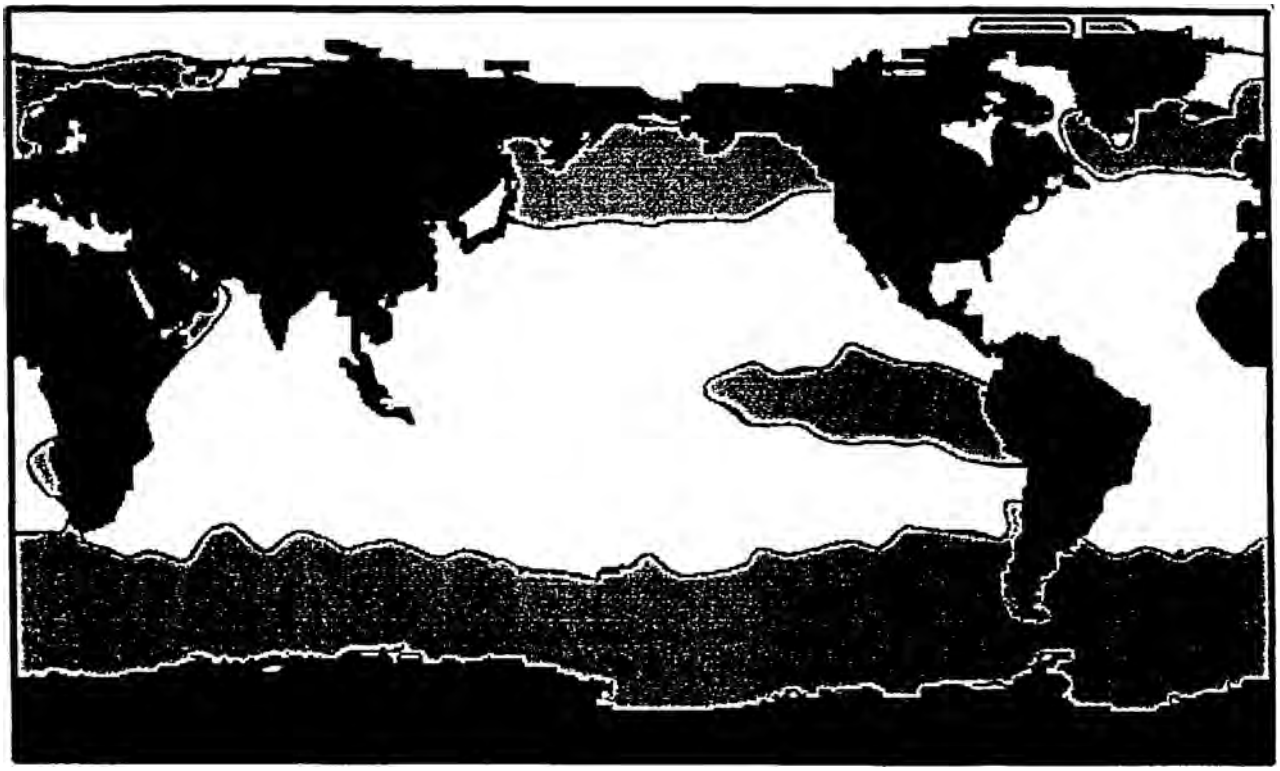

Figure 3. Map of nitrate in surface waters of the world's ocean. Data obtained from the NOAA World Ocean Atlas 1994 (*http://dpo.ori.u-tokyo.ac.jp/ocean/toolmap/Levitus-zonal.html*). Land masses are shown in black. Ocean areas in white correspond to waters with less than 0.5 μM concentrations of nitrate in surface water, and gray areas indicate regions with nitrate concentrations greater than 0.5 μM.

sources of nitrate (54). Dissolved inorganic nitrogen and phosphorus are depleted to depths below 100 m in these areas (Fig. 4). *Trichodesmium*, the best-known diazotroph in oligotrophic oceans, is usually found predominantly in the upper 50 m (Fig. 4).

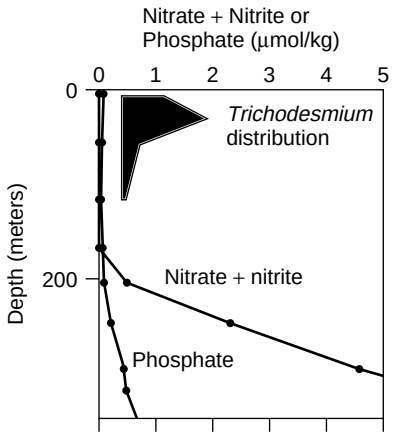

Figure 4. Depth profile of dissolved inorganic nitrogen (nitrate + nitrite) and dissolved inorganic phosphorus in a central oligotrophic ocean gyre. Data from the Hawaii Ocean Time series station ALOHA in July 1999. A typical depth distribution of *Trichodesmium* (see 55) is shown relative to the depletion of inorganic nitrogen in the mixed layer.

The seemingly consistent ratio of major elements in marine plankton, compared to the ratios of inorganic forms of nutrients dissolved in seawater was an early observation that has been called the *Redfield ratio* (40,56). This ratio, a C/N/P of 106 : 16 : 1, is often assumed to be a constant, at least when integrating the biological activities and nutrient fluxes over long timescales. The significance of the constant nutrient ratios with respect to N_2-fixation is that N_2-fixation and denitrification can add nitrogen to or remove nitrogen from the biological pools involved in nutrient cycling in the sea (Fig. 5), uncoupling the ratios of supply of nutrients through mineralization of organic matter.

Nitrogen is only one of a number of nutrients that are important for the growth of microorganisms. In general all organisms have an elemental composition (e.g., C/N/P ratios) that reflects a balance between the optimal composition for maximum growth rate and the ratio of the elements supplied in the environment (Fig. 5).

Deviations from the general constancy and correspondence of elemental ratios in the oceans with respect to marine biological materials have been used to identify regions where excess nitrogen may be formed through N_2-fixation or removed by denitrification. One derived parameter, termed N^*, compares the relative concentrations of inorganic nitrogen and phosphorus along surfaces of equal density (isopycnals) discerning regions of excess nitrogen relative to phosphorus (57,58). Using GEOSECS

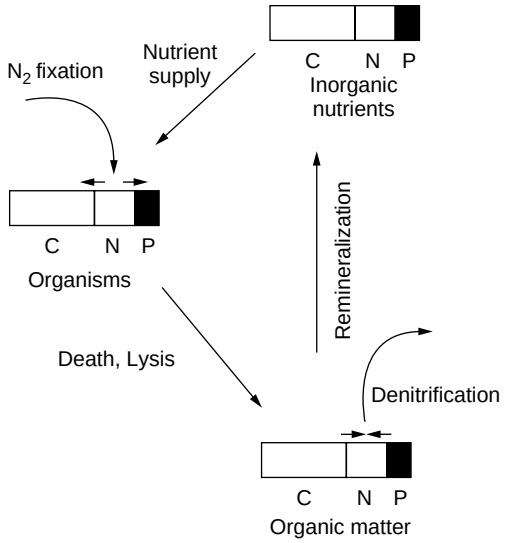

Figure 5. Diagram of cycling of nutrients and the effects of nitrogen fixation and denitrification on the stoichiometry of carbon, nitrogen, and phosphorus in organisms, remineralized nutrients, and nutrient supplies.

data, Gruber and Sarmiento (58) found evidence for N_2-fixation in the North Atlantic Ocean, as well as in the Mediterranean Sea ($N^* > 2.0\ \mu mol\ kg^{-1}$). These data indicate very large inputs by nitrogen fixation in the North Atlantic, exceeding most measured rates of N_2-fixation.

Hence, there are still major uncertainties in these N_2-fixation estimates (59). Ground truthing of these measurements is difficult for a number of reasons. First, N_2-fixation is currently assumed by most biogeochemists to be caused by primarily the filamentous nonheterocystous cyanobacterium *Trichodesmium*, but other diazotrophs clearly are present in the open ocean (45) and are probably contributing to N_2-fixation over different time and spatial scales than *Trichodesmium*.

Including these microorganisms in the nitrogen budgets may require a major change in the way we perceive the nitrogen cycle to operate in the open ocean (41). The sporadic nature of the growth and bloom formation of *Trichodesmium* (and other organisms) makes it hard to obtain statistically reliable data on the distribution and in situ N_2-fixation rate that can be used to assess N_2-fixation over long, integrative time scales.

Nitrogen Fixation in Coastal Zones

Nitrogen fixation occurs in a range of habitats in the coastal zone, from estuarine waters to benthic sediments, salt marshes, and cyanobacterial mats (14,46). Rates can be high in some of these environments, cyanobacterial mats in particular, because of the high concentration of microorganisms, but N_2-fixation in these systems often contributes only a small fraction of the overall nitrogen budget (14).

Estuarine Water Column. The biology and chemistry of estuaries is complex because of variations in hydrologic features, tidal cycles, and extent and characteristics of human development and use of the watershed. Large temporal and spatial variations in nutrient inputs, including both nitrogen and phosphorus, are observed throughout the world's estuaries, depending on geological factors, but more importantly, the types of land use and regulations and policies controlling water quality. Many of the world's estuaries are affected by anthropogenic factors, one being increases in nitrogen and phosphorus runoff (60,61). In many estuaries nitrogen concentrations can be high (in the form of nitrate, dissolved organic nitrogen, and ammonium), but sometimes the ratios of nitrogen to phosphorus still can stimulate nitrogen-fixing microorganisms and even blooms of cyanobacteria (62). Blooms of nitrogen-fixing cyanobacteria often have important implications as a result of the toxicity of some cyanobacteria (harmful algal blooms) (63). Even in estuaries with high nutrient loading, N/P ratios can decrease substantially over the length of the estuary, setting up conditions that could stimulate the growth of N_2-fixing microorganisms (Fig. 6). Blooms of N_2-fixing cyanobacteria such as *Anabaena, Aphanizomenon*, or *Nodularia* have been observed in estuaries throughout the world (62).

Cyanobacterial Mats. Cyanobacterial mats occur in many intertidal regions, but are often localized in restricted areas. Cyanobacterial mats are composed of complex assemblages of phototrophs, dominantly cyanobacteria and heterotrophs. These can be highly structured, with layers of cyanobacteria, phototrophic bacteria, and heterotrophic microorganisms (29). The mat assemblages demonstrate complex interactions among microorganisms that result in strong diel patterns of N_2-fixation (Fig. 7). As both phototrophs and heterotrophs in the mats can fix nitrogen, it is sometimes difficult to determine which organisms are fixing N_2. The cyanobacteria often fix N_2 at high rates during the day when heterocystous species are involved, and during the night when nonheterocystous species are the primary fixers (64). However, dark fixation by heterotrophs can also potentially be fueled by photosynthates synthesized by phototrophs during the day.

Sediments. Nitrogen fixation is associated with marine sediments from shallow estuaries to the deep sea (46). Sediments in estuaries and coastal areas are often organically enriched through deposition of material, either imported from terrestrial environments or formed by microplankton or macrophytes, or through growth of rooted macrophytes such as seagrasses and macroalgae. Intense microbial activities associated with organic decomposition promote anoxia within millimeters of the sediment–water interface, a feature that should favor anaerobic diazotrophs. Sulfate respiration is often the predominant anaerobic process in such sediments, and many sulfate respirers are capable of N_2-fixation (Fig. 1). Similarly, fermentative bacteria such as clostridia, known diazotrophs, have been isolated from marine sediments. Organic-rich sediments are also associated with high concentrations of ammonium, which should inhibit the development of active nitrogen fixers. Nonetheless, low

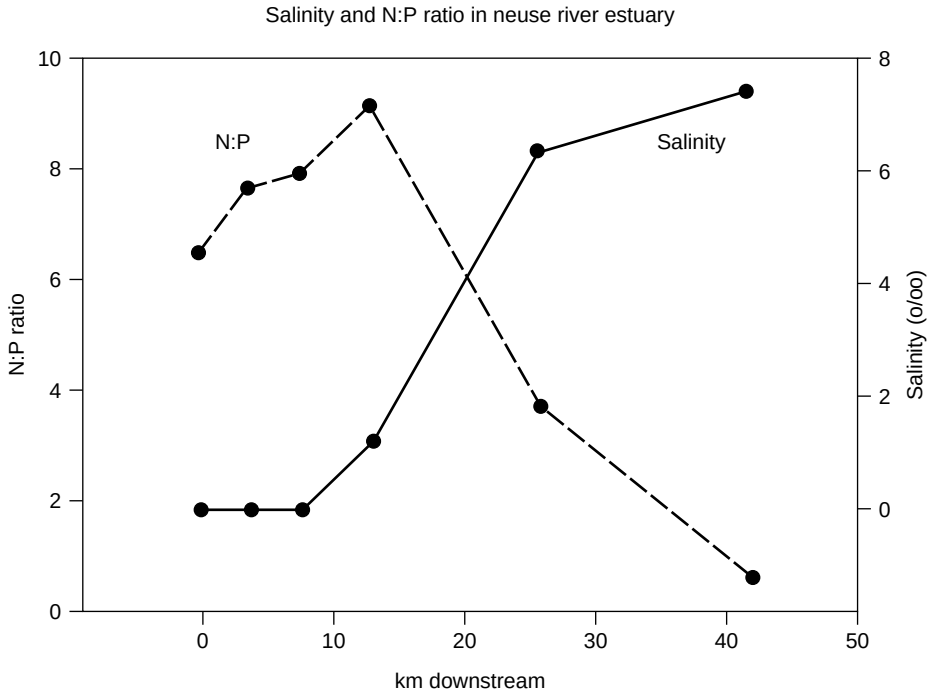

Figure 6. Transect of N/P ratio (nitrate:phosphate) and salinity along an estuary (the Neuse River, North Carolina, data courtesy of H. W. Paerl, University of North Carolina at Chapel Hill), showing how nitrogen depletion along the length of the estuary may provide nitrogen-fixing conditions.

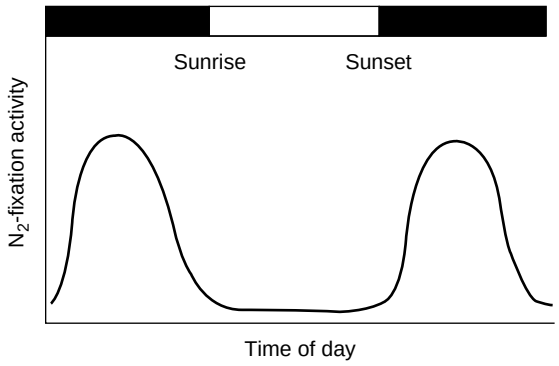

Figure 7. Daily pattern of nitrogen fixation in a marine mat dominated by nonheterocystous cyanobacteria (see 64).

levels of nitrogenase activity are detectable in shallow sediments, and this activity can be stimulated by removal of ammonium pools or addition of organic substrates (46). Moreover, the *nif* genes can be recovered from shallow, organic-rich sediments, demonstrating the existence of populations of bacteria with this metabolic potential.

Sediments vegetated by seagrasses can have much higher levels of nitrogen fixation than surrounding unvegetated sediments (46). This may be a result of the enrichment of the rhizosphere of these sediments by organic exudates from the seagrass roots as well as potential associative symbioses between the seagrass and rhizosphere bacteria as are found in terrestrial grasses. Although relatively little is known about the nitrogen-fixing microbes in vegetated sediments, a few isolates and *nifH* sequences have been obtained from seagrass root–associated sediments (26) and from vegetated salt marsh sediments (65). These communities are diverse, yet remarkably similar between vegetation types and stable through the season (27).

Coral Reefs. Coral reefs are biologically diverse and highly prolific ecosystems that exist as shallow oasis bathed by the nutrient-poor waters of the tropical oceans. An important role for nitrogen fixation formed part of an early hypothesis to explain their richness (66), and subsequent research has confirmed this in identifying various sites of intensive nitrogen fixation on coral reefs (67). These include monospecific mats of heterocyctous cyanobacteria, epiphytes on reef macroalgae, symbionts of giant clams, bacteria and cyanobacteria associated with sponges, coral rubble, as well as the carbonate sediments interspersed within and surrounding the reef (46).

Recent analysis of the natural abundance of nitrogen in various components of the reef has found a generally low signature, indicative of the overall quantitative importance of nitrogen fixation to the overall nitrogen budget of the reef (68).

CONCLUSION

Our perspectives on nitrogen fixation in the marine environment are rapidly changing as a result of our understanding of the biochemistry, biology, and ecology of its role in global carbon cycling. The capability of nitrogen fixation is found in a diverse array of microorganisms and in a wide array of habitats. Recent advances in molecular biology techniques and data obtained from genomic sequencing, are providing new information on the diversity of diazotrophs, the evolution of nitrogenase, and the regulation of the nitrogen fixation apparatus. Diverse nitrogen-fixing microorganisms are found in many benthic and near-shore habitats, and rates can be very high in these localized habitats. Nitrogen fixation in the open ocean, previously believed to occur at low rates in only

a handful of organisms, now appears to be significant in the oceanic nitrogen budget, and is caused by a diverse array of bacteria and cyanobacteria. Increasing numbers of studies are targeting the nitrogenase gene in ecological studies of the factors controlling nitrogen fixation in the marine environment. These studies will help to understand nitrogen fixation in the marine environment in a new way, one based on linking the diazotroph diversity and the microbial population dynamics to the observed nitrogen fixation rates.

NORWALK-LIKE VIRUSES: DETECTION METHODOLOGIES AND ENVIRONMENTAL FATE

JOHN S. MESCHKE
MARK D. SOBSEY
University of North Carolina,
Chapel Hill, North Carolina

Norwalk-like viruses (NLVs), the most common type of human caliciviruses, are important agents of acute nonbacterial gastroenteritis. NLVs are regularly implicated in food and waterborne outbreaks. The U.S. Environmental Protection Agency has listed caliciviruses on their contaminant candidate list for regulatory consideration in drinking water (1). The lack of a cell culture system has hindered investigation of the basic virology of NLVs and their fate in environmental systems. However, immunological and molecular methods have been developed for detection and characterization of NLVs. In this article, methodologies for detection (including application to environmental and epidemiological investigation) and the fate and persistence of NLVs in environmental systems will be reviewed.

The basic virology and epidemiology of NLVs is reviewed in a companion article (see HUMAN CALICIVIRUSES: BASIC VIROLOGY AND EPIDEMIOLOGY, this Encyclopedia). In short, NLVs are a genetically and antigenically diverse group of nonenveloped, RNA viruses. NLVs have a positive sense, single-stranded RNA genome, approximately 7.5 kB in length. Their protein capsid is composed of 90 archlike dimers of a single major capsid protein. Phylogenetic analysis of the genetic sequences of NLV strains supports their division into at least 12 specific genetic clusters within two distinct genogroups (2–6). As many as 14 distinct antigenic types of NLV have been suggested (7–9). Although several attempts have been made to separate the NLVs into antigenic types, there is currently no universally accepted scheme for antigenic typing of human caliciviruses. The genetic and antigenic diversity of NLVs poses a particular challenge to detection methodologies and the study of environmental occurrence, transport, survival, and fate.

ISOLATION AND RECOVERY

The basic framework for isolation, recovery, and detection of NLVs in any sample is: (*1*) primary concentration, (*2*) separation, (*3*) secondary concentration, (*4*) purification, and (*5*) detection. The techniques used at each step are sample type dependent. Indeed, processing of some sample types may not require one or more steps for effective processing, whereas other sample types may require multiple techniques at each step of the framework. This section will discuss specific aspects of sample collection, transport, and storage, followed by a discussion of general approaches to processing and preparation of different clinical and environmental samples before detection. Additionally, individual concentration, separation, and purification techniques at each step of the basic framework will be reviewed.

Sample Collection, Transport, and Storage

There are major differences between clinical and environmental samples with respect to isolation, recovery, and detection of NLVs. Positive clinical samples have relatively high NLV titers [up to 10^8 reverse transcription-polymerase chain reaction (RT-PCR) detectable units/g stool or vomitus]. Consequently, a clinical sample of as little as 100 mg of stool or vomitus can be sufficient for molecular detection of NLV. However, CDC guidelines recommend collection of sample volumes of at least

10 mL (10). Samples should be collected within the first 48 hours of clinical illness to maximize at possibility of NLV detection because this is often the peak time for virus excretion (11). However, samples collected within the first week of illness are likely to be positive for NLVs (12). Stool specimens should be stored at 4 °C, and shipped in specimen cups (or other secure container) on ice or cold pack to the laboratory performing the viral analysis. Specimen cups should be sent clearly labeled with waterproof label and placed in a waterproof bag with tissue or other blotting material to absorb any leakage during shipment (10). If possible, paired serum samples (acute and convalescent) should be obtained from people submitting stool specimens and also sent to the laboratory for performing analysis. Acute serum specimens can be obtained as long as five days after onset and convalescent serum can be collected as soon as 13 days after onset (13).

An early study of the storage of Feline Calicivirus (FCV) particles at −70 °C, −20 °C, and 4 °C, indicated that storage at 4 °C better preserved the integrity and infectivity of the viral particles over an eight week period (14). However, a later study examining stool specimens that were stored at −70 °C for 6 to 10 years indicated that long-term storage at ultracold temperatures does not pose a serious problem for microscopic identification of viruses (15). If samples are to be stored for very long periods and assayed by molecular methods, freezing at ultracold (−70 °C) temperatures may be preferable to prevent degradation of the viral nucleic acid.

In contrast to clinical samples, environmental samples typically have very low virus titers and may require large sample sizes for effective detection. Source water and treated drinking water may require 10 to 1,000 L per sample for detection. The U.S. Environmental Protection Agency (U.S.EPA) guidelines for enteric virus sample collection under the Information Collection Rule (ICR) called for 200 to 300 L of raw water and 1,200 to 1,500 L of finished water to be sampled (16). However, in field studies, NLVs have been detected in 1 to 40 L of water at contaminated sites (17–19). Research in the Netherlands suggests that as little as a few milliliters may be sufficient to detect NLVs in raw or primary treated sewage (20). The sample size of implicated food should be as large as possible, taking into consideration the limitations of processing and detection methods. Typical sample sizes are 10 to 25 g (with 4 to 10 mL of liquid/g food sample) (21). For sewage biosolids, sample sizes typically range from 0.5 to 1.0 L or about 50 g dry-weight solids (22,23). The sample-size range for enteric virus detection in soils and aquatic sediments is generally between 10 to 500 g (22).

Guidelines for water and sewage sample collection and transport in the U.S.EPA Manual of Methods for Virology state that samples must be placed on ice immediately after collection and should be shipped under conditions that maintain viability. All samples that cannot be processed within 24 hours are to be frozen at −70 °C, with subsequent freezing and thawing kept to a minimum (24).

Multistep Concentration, Separation, and Purification Methods

Several protocols for concentration and purification of NLVs from clinical and environmental samples have been reported and these are summarized in Figure 1 (18,25–33).

Foods. The general approach for separation and concentration of NLVs from various food items consists of homogenization, acid adsorption/elution, phase extraction, one or more polyethylene glycol (PEG) precipitations for concentration, and various purification steps (precipitate adsorption/elution, immunocapture, etc). This approach has been most extensively described for shellfish (26,30,31,34–36). A feature of this approach is the purification and concentration of intact virions from oyster extracts. Application of this method to 50 g quantities of artificially contaminated oysters resulted in an estimated detection limit of 10 to 100 NV particles (26,34). A minor modification of this method also was effective for simultaneous concentration and purification of additional enteric viruses [in particular hepatitis A virus (HAV)] from hard-shell clams that were assayed for both infectivity and RT-PCR (30). Modifications of the general protocol include addition of various RNA extraction methods for greater removal of RT-PCR inhibitors (31,35).

A second approach for separation and concentration of NLVs from food samples consists of an initial washing/elution step, PEG concentration, and RNA extraction. This approach attempts to minimize the corecovery of inhibitory compounds and the loss of virus by eliminating the homogenization and additional purification methods. Two methods using this approach were compared for the detection of seeded NLV and HAV on delicatessen foods. One method involved washing a 20 to 40 g sample of deli meat with phosphate buffered saline (PBS) several times, followed by organic extraction (fluorocarbon), PEG precipitation, and RNA extraction of the PEG pellet. The other method involved merely washing the deli meat twice with a guanidinium phenol–based reagent. Recovered RNA from both methods was assayed for seeded NV and HAV by RT-PCR. Both HAV and NV were detectable by either method, however, undiluted RNA extractions from first method were inhibitory to RT-PCR. Amplification was observed in tenfold and 100-fold dilutions of the extracts. For the simpler method, RT-PCR inhibition was observed for 62% of the samples at the tenfold dilution, but there was no inhibition at the 100-fold dilution. Inhibition was determined by failure to amplify an internal control (36,37).

Another direct RNA extraction method for separation and concentration of NLVs from food items was adapted from a protocol for recovery of rotavirus dsRNA in shellfish and other foods. The method involves repeated extraction of food samples with guanidinium isothiocyanate (GITC), followed by fluorocarbon extraction of pooled supernatants, viral RNA adsorption to and elution from hydroxyapatite or iodized glass powder, and RNA recovery from the eluate by cetyltrimethylammonium bromide (CTAB) (38). This method, or a slight modification, has been demonstrated to be effective for shellfish, fruit and vegetable coleslaw, milk and orange juice (38).

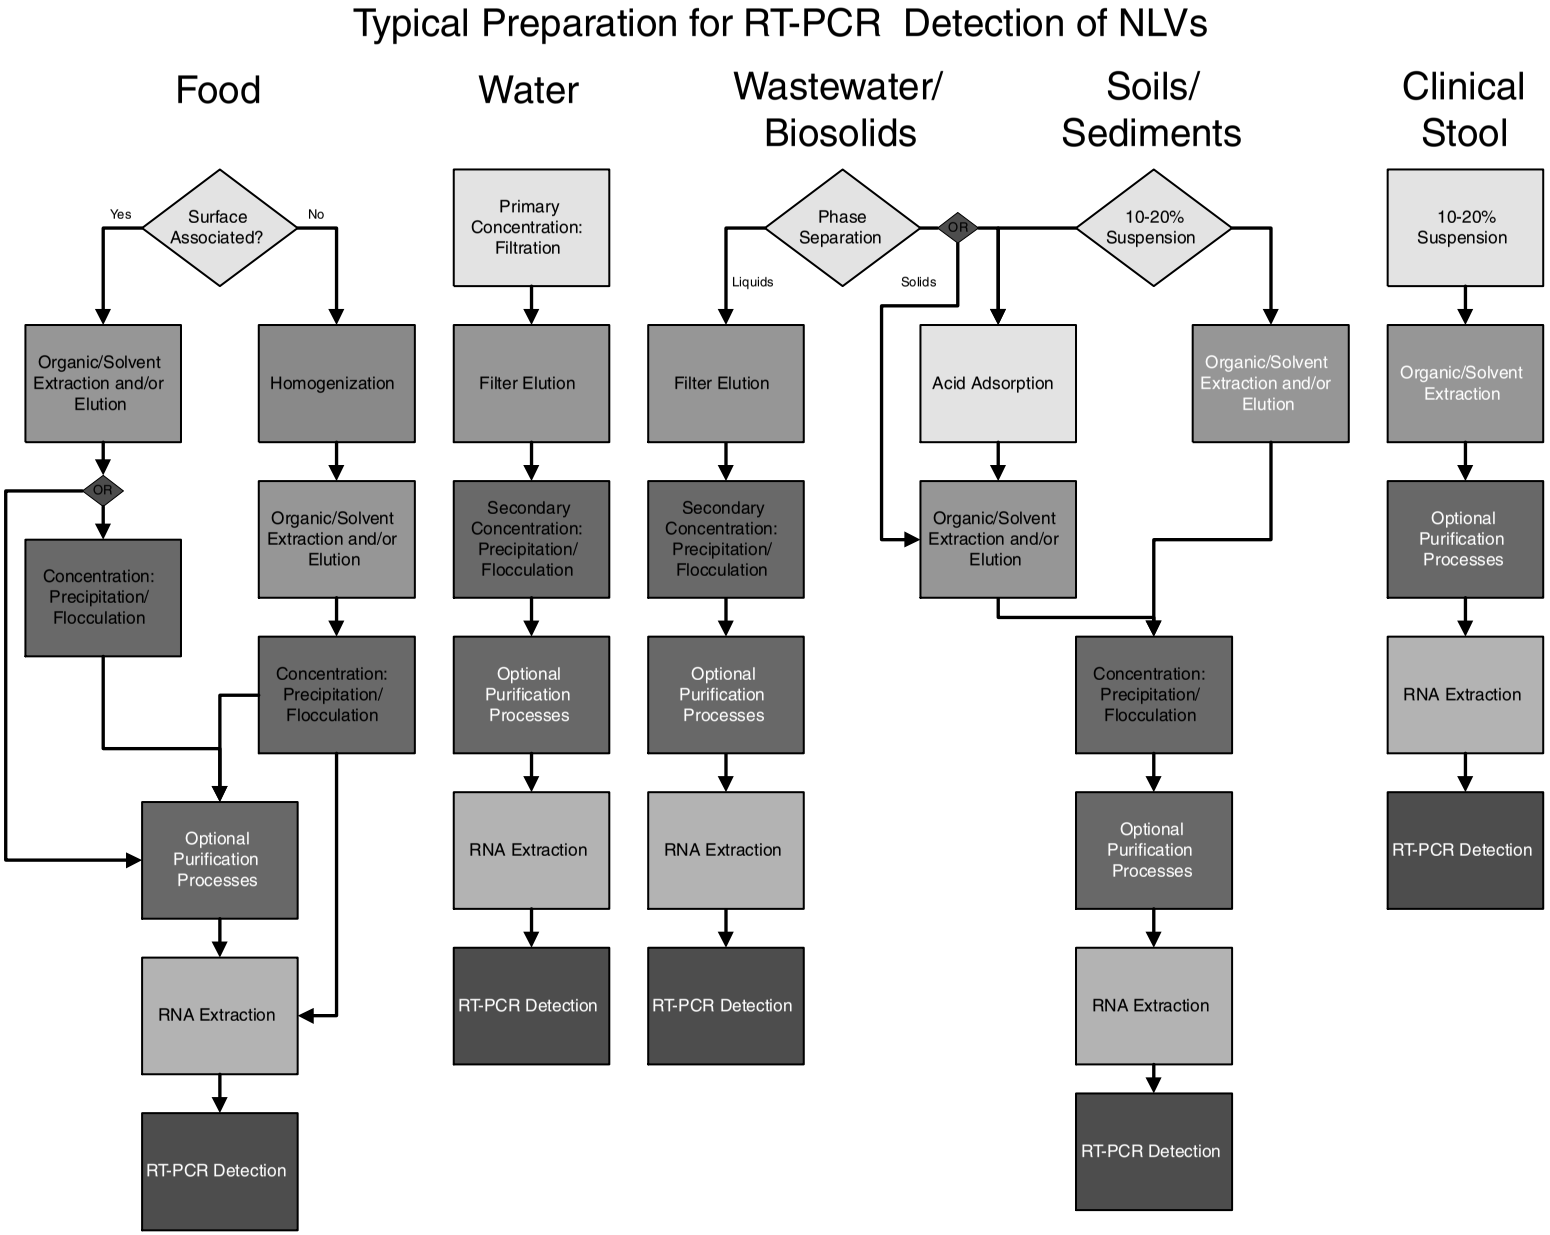

Figure 1. Typical preparation of various samples for RT-PCR detection of NLVs. Corresponding steps between samples types are indicated by the same colored polygon. See color insert.

Water. The general approach to processing of water samples involves a primary concentration step, usually by adsorption/elution to one of several types of filters. Primary concentration is generally followed by one or more secondary concentration steps using PEG or organic flocculation. One or more purification steps [immunomagnetic separation (IMS), organic extraction, RNA extraction, etc.] and, finally, detection by RT-PCR typically complete the protocol. Seeded virus studies, in which 10 L river water samples were filtered through glass wool columns, eluted, ultracentrifuged, and assayed by RT-PCR, demonstrated that NLVs could be concentrated from relatively large volumes of water (39).

A filter-elution method using 47 mm diameter flat filters (0.45 μm pore size) for NLV concentration from deionized water, raw water, and humic-rich bog water samples has been described (27). Samples were supplemented with $MgCl_2$ and pH adjusted to adsorb the viruses to the filter by hydrophobic and electrostatic forces. Filters were eluted with a urea arginine phosphate buffer, viruses in eluates were flocculated, the floc was centrifuged, and the pellets were RNA-extracted for RT-PCR detection. The method was able to detect low levels of NLV in 500 ml of deionized water, but sensitivity decreased as sample volume increased. In raw water, 0.5- to 5-seeded viral particles per milliliters could be detected. Number of viral particles seeded was estimated by comparison of end point RT-PCR with electron microscopy. Humic acid and metal ions prevented detection of NLV in the bog water (27).

A study using a culturable primate calicivirus (Pan-1) as a model virus for NLVs evaluated 1 MDS positively charged filters (Cuno, Inc., Meriden, Connectient) for concentration of seeded virus from 40 L water samples (40). Initially 200 mL volumes of deionized water, finished drinking water, groundwater, and surface water were each seeded with high concentrations of Pan-1, filtered through 1 MDS disk filters (Cuno, Inc., Meriden, Connectient), eluted with 3% beef extract (BE) at pH 9.0, PEG-precipitated, and then assayed by plaque assay. Recoveries ranged from 94% (deionized water) to 64% (surface water). Studies were repeated with 40-L volumes seeded with low levels of virus. Processed samples were assayed by plaque assay and RT-PCR. Recoveries in the larger volume experiments ranged from 38% (finished water) to 14% (surface water) by plaque assay. The detection limit by RT-PCR was estimated to be 0.75 to 1.5 PFU in 40 L (40). A similar method demonstrated recovery of NLVs from 1-L river water samples using positively charged Zetapore filters (0.45 μm nominal pore size) (18).

Negatively charged cellulose nitrate membranes have been used to evaluate 10-L tap water, river water, seawater, and sewage effluent samples for NLVs (17). Seeded studies demonstrated that the negatively charged filter/elution/flocculation protocol was capable of recovering NLVs from tap water and other waters. Subsequent detection of NLVs in analysis of unseeded water samples from sites with expected contamination validated this protocol. Briefly, water samples were filtered through a composite filter stack including a fiberglass prefilter and negatively charged membranes of decreasing pore diameter (5.0, 1.2, and 0.45 μm). Filters were eluted with 200 ml of 0.1% skimmed milk at pH 9.5. The eluates were then flocculated at pH 4.5, centrifuged, and the floc dissolved in 10 mL of neutral disodium hydrogen orthophosphate buffer. Similarly, 100 mL of raw sewage was directly eluted with 1% skimmed milk at pH 9.5 in a ratio of 10 : 4, centrifuged, supernatant-collected, flocculated, and floc-dissolved as described in the preceding text. Dissolved flocs were assayed by nested RT-PCR (17).

A seeded virus study described a volume reduction from 1 L to 20 to 50 μL in mock eluates (28). The protocol evaluated in this study precipitated mock 1-L BE-glycine eluates with a PEG precipitation (13% PEG, 0.2 M MNaCl), followed by chloroform extraction, followed by another PEG step and ultrafiltration (28).

NLV recovery from sewage has been described for 10-L samples by a conventional adsorption-elution method, followed by a modified two-phase polymer extraction using Dextran T40 and 10% PEG 6,000. After phases were separated, the bottom phase and interphase were additionally purified by Sephadex spin column chromatography and finally concentrated by centrifugal ultrafiltration (20).

Individual Techniques/Steps for Virus Recovery

Homogenization. For food items in which viral contamination is not surface-associated (e.g., shellfish, meat), an initial homogenization is used to disperse the sample, uniformly distribute the viruses, and thereby maximize recovery by subsequent processing steps. However, homogenization may release many compounds that may be inhibitory to detection methods. Researchers have found that processing only that portion of a sample most likely to be contaminated, for example, the stomach and digestive diverticula in shellfish, minimizes amount and release of RT-PCR inhibiting compounds. Processing of dissected stomachs and digestive diverticula rather than whole shellfish meat resulted in consistently better NLV detection limits by reducing RT-PCR inhibitory compounds (36,41). For food items and other samples in which viral contamination is surface-associated, homogenization may not be advisable. Instead, elution of viruses from the surface may be preferred. The most common method of homogenization is mechanical, by simply blending in an industrial blender approximately seven sample volumes of a diluent such as phosphate-buffered saline (PBS). However, a simple method has been described for extraction of viruses from shellfish by enzymatic (protease) homogenization (42).

Extraction. Organic solvent extraction is used for selectively causing the virus to preferentially distribute in the aqueous phase and cause impurities to enter an organic phase. This technique has been applied to both clinical and environmental samples for NLVs (26,28,34,43). The organic solvent, typically Freon (1,1,2-trichloro-1,2,2-triflouroethane) or chloroform, extracts lipids and other hydrophobic constituents from the sample, leaving the hydrophilic viruses in the aqueous phase. Environmental and health concerns have prompted evaluation of Freon substitutes of purification of NLV from

samples, including dichloromethane, 1 : 1 chloroform-butanol, Vertrel XF (1,1,1,2,2,3,4,5,5,-decaflouropentane), and a 7 : 3 mix of isopentane/1-chlorobutane.

Adsorption/Elution. In the case of food or sewage biosolids, adsorption/elution typically refers to the process of lowering the pH below the isoelectric point of the viruses such that the viruses will more efficiently adsorb to the negatively charged solids. The sample may then be centrifuged to pellet the solids and adsorbed viruses. The pellet can then be resuspended in a neutral eluant to desorb the viruses with subsequent removal of solids by centrifugation. In some cases, viruses are solids adsorbed initially, in which case, the adsorption step is skipped and viruses directly eluted from the sample. In a study comparing acid adsorption-elution (with glycine buffer at pH 7.5) to direct elution (with glycine buffer at pH 9.5) in shellfish samples, the former was shown to retain fewer inhibitors of RT-PCR than the latter (31).

In water samples, adsorption/elution refers to the process by which viruses are initially retained by and then recovered from filters. Typically filters for primary concentration in water have a nominal pore size that is 10 to 100 times the diameter of NLVs. Adsorption to filters is by both hydrophobic and electrostatic interactions (44).

Precipitation/Flocculation. PEG precipitation is an effective method for concentration of NLVs from volumes up to a few liters (28–30,45). Flocculation methods also have been described for concentration of NLVs (17,27,32). One study used PEG instead of organic flocculation for reconcentration of the viral particles in eluates. The authors cited a concern about coprecipitation of constituents in BE that would interfere with RT-PCR (40).

IMS/IC. Immunomagnetic separation (IMS), which is also known as *immunocapture* (IC), has been demonstrated as an effective secondary concentration step for NLVs in environmental samples. This technique removes many of the compounds inhibitory to RT-PCR (46,47). Rabbit polyclonal antibodies, raised against recombinant NLV antigens and attached to magnetic beads, have been used to separate NLVs from water concentrates (47). Efficiency of IMS concentration was reported to be volume dependent due to complications with collection of beads and possibility of antigen-antibody contact in larger volumes (47). The effectiveness of IMS is dependent on the quality of the antibodies, which in turn is influenced by the considerable antigenic diversity of NLVs. Unfortunately, the utility of IMS for NLVs has limited effectiveness because of the lack of broadly reactive antibodies. An exception to this is the use of pooled human serum IgG (HSIG) rather than mono- or polyclonal antibodies specific to NLV. This technique has the added benefit of broad immunocapture of enteric viruses; however, the sensitivity and recovery efficiency is typically less than virus-specific antibodies (29,30).

Indirect immunomagnetic capture (IC) coupled with guanidinium isothiocyanate (GITC)-RNA extraction was reported to be as effective in removing inhibitory substances from clam extracts as GITC alone. Recoveries with the combined method were lower than those with GITC alone, although more consistent. However, the difference in recoveries between GITC alone and IC/GITC was offset by the ability of IC/GITC to effectively assay ten times the volume of clam tissue as GITC alone (30). Immunomagnetic capture with virus-specific antibodies has also been evaluated for reduction of inhibition of RT-PCR in clinical stool specimens (46). The IC/RT-PCR method outperformed direct heat-release RT-PCR and antigen-detection enzyme-linked immunosorbent assay (ELISA) on a panel of 100 stools. Also, the IC step greatly reduced the number of stools in which RT-PCR was inhibited (46).

Spin Column Chromatography. Dextran gel (Sephadex) spin-column chromatography has been used for the removal of RT-PCR inhibitors in both clinical and environmental samples (27,28,43). However, this method has been reported to cause unacceptable losses of virus from the sample (28,48). Two factors, particle diameter and water-regain value, are important in determining the fractionation range of a Sephadex column. The water-regain value refers to the swelling capacity of the gel and is related to the fractionation properties of the gel. A low water-regain value corresponds to a low molecular-mass fractionation (49). The dry-particle diameter is important in determining the range of fractionation, especially for Sephadex with a higher water-regain value (28,49). Column to sample-volume ratios of 4 : 1 to 8 : 1 are reported to maximize removal of inhibitory substances and minimize virus loss (28).

Ultrafiltration. This method reduces sample volume by about 10- to 100-fold (e.g., from 0.5 to 5 mL to 20 to 100 μL) (18,28). Virus losses by adsorption to the ultrafilter are minimized by pretreatment of the filter. Samples must be relatively clean (low in particulates and high molecular weight macromolecules) before centrifugation to prevent clogging of the filter.

Gradient Centrifugation. Sucrose velocity gradient centrifugation and CsCl buoyant density gradient centrifugation have been described for purification of NLVs from stool specimens (50). However, these techniques typically are not recommended for samples containing low virus concentrations, such as food and water samples, because of the potential for virus losses by adsorption and other mechanisms.

RNA Extraction. Several methods have been described for extracting NLV RNA from the virion for subsequent analysis by RT-PCR. The four main techniques are: (*1*) heat release, (*2*) PEG/CTAB method (polyethylene glycol/cetyltrimethylammonium bromide), (*3*) GITC/silica, and (*4*) the single-step GITC method of Chomsczynski and Sacchi (43,51–53). Heat release of NLV RNA is accomplished as a first step in a RT-PCR reaction by heating the viral sample to 95 °C for five minutes (43). The benefits of heat release are simplicity, speed, and protection of viral RNA from degradation by RNAses. The primary drawback is its failure to remove RT-PCR inhibitors. A comparison of heat release and a conventional

RNA-extraction method on a panel of 45 stool specimens indicated that heat release had a similar sensitivity to the RNA extraction (54).

CTAB is a cationic detergent used to remove inhibitory factors in stool extracts during RNA extraction (53). The PEG/CTAB method has proven effective for processing of shellfish samples (36). Wolfaardt and coworkers found a modified PEG/CTAB method superior to the GITC/silica method on NLV-positive stool samples, and seeded samples of sewage, sludge, and tap water. However, on spiked river water concentrates, the effectiveness of these methods was comparable (39).

Single-step RNA isolation by GITC/phenol chloroform extraction has proven effective for isolation of calicivirus RNA in stools and from environmental samples (delicatessen meat) (37,55). The drawbacks of the method are related to RNA recovery by ethanol precipitation, which may cause the recovery of small quantities of viral RNA, as found in environmental samples, to be difficult.

The GITC/silica method improves recovery of RNA by adsorbing it to and eluting it from silica. Comparison of the PEG/CTAB and GITC/silica methods found PEG/CTAB to be 2- to 50-fold less sensitive than GITC/silica (56). A simple modification of the GITC/silica method incorporated the silica into a gel membrane within a spin column. This modified method has been shown to be simple and capable of removing RT-PCR inhibiting substances from environmental concentrates and clinical samples (18,31,35). In a comparison of single-step RNA extraction, RNA extraction incorporating Sephadex spin column chromatography, and silica gel–based extraction, the silica gel protocol was most efficient at removing RT-PCR inhibitors and yielding the most consistent viral RNA templates (31). Other modifications of the GITC/silica method include the use of a vacuum-manifold system, and binding the viral capsids to the silica in suspension, followed by centrifugation and resuspension in the GITC solution (17,42).

DETECTION METHODOLOGIES

Several methods have been described for the detection and diagnosis of NLVs, including microscopic, immunological, and molecular (nucleic acid) methods. Detection of NLVs in clinical samples is more reliable than detection in environmental samples for several reasons. First, in comparison to environmental samples, positive clinical samples have much higher virus titers. In addition, clinical symptoms of a patient may be indicative of NLV infection, which increases the possibility of a causal relationship between virus presence and a health effect. Detection of NLVs in the environment is made difficult by the very low levels, and perhaps sporadic presence of the viruses, and when investigating outbreaks, by the inevitable delay in initiating virus examination until after health effects have been observed such that implicated samples are no longer available.

Microscopic Methods

Because NLVs are much too small (~27 nm in diameter) to be visualized by light microscopic methods, electron microscopic (EM) techniques are required to visualize them. Electron microscopic detection and conclusive identification of NLVs is difficult because of the lack of a distinctive morphology, low virus titers (EM requires a minimum of 10^6 viral particles/mL and 10^8 preferred), and the need for relatively clean preparations for virion visualization (57). None of the microscopic methods described in this section are sensitive and specific enough to reliably detect NLVs in environmental samples, although they continue to be valuable and perhaps essential in clinical diagnostic virology and epidemiology.

Immune electron microscopy (IEM) take advantage of antigen–antibody interactions to aggregate virus particles, concentrate the immune aggregates, and facilitate virus identification (58). IEM also has been adapted for quantification of serological response to infection. Paired (acute and convalescent) sera from infected individuals are incubated with the virus particles, centrifuged, and the pellet resuspended and negatively stained. The antigen–antibody reaction typically is rated on a 1+ to 4+ scale, with a higher positive rating indicating a stronger reaction and higher antibody titer (58,59).

Solid phase immune electron microscopy (SPIEM) is a variation on IEM, in which the viral particles are immunocaptured on the EM grid. Grids are prepared by binding high-titer convalescent serum to a carbon-coated copper grid using antihuman IgG or protein A (60,61). SPIEM increases the sensitivity of diagnostic EM up to 100-fold (61). Other variations to EM include the use of electron dense markers, such as ferritin or colloidal gold attached to the antibodies to improve locating and visualizing viruses (62,63).

Norwalk virus, the prototype genogroup I NLV, was originally observed using IEM on stool material from a volunteer infected with a bacterial free stool filtrate derived from an outbreak in Norwalk, Ohio. When stool material from the infected volunteer was incubated with the volunteer's convalescent sera, centrifuged, negatively stained, and visualized by EM, and the pellet was resuspended, "fuzzy," 27-nm diameter, antibody-coated virus particles were observed (59). The isolated virus particles were used to determine serological response of other experimentally infected volunteers and individuals naturally infected during the outbreak. The serological response of these individuals to the virus particles suggested that the virus particles were the etiologic agent responsible for the outbreak. Other NLVs have since been identified using the same approach, including the Hawaii virus (HV), Montgomery County virus (MCV), and Snow Mountain virus (SMV) (64,65). IEM remains the basic clinical diagnostic examination method for NLVs and other diarrheal viruses. The continued value of EM for NLV clinical diagnosis and epidemiology was demonstrated by a recent report in which specimens from two outbreaks were positive for NLVs by EM, but negative by RT-PCR, although EM had the lower overall detection rate (66).

IEM has also been used to demonstrate antigenic relatedness among NLVs and to investigate outbreaks. Montgomery County virus was found to be related to NV, Hawaii virus was antigenically distinct from NV, and Snow Mountain virus was found to be distinct from

both HV and NV (64,65). Studies in the United Kingdom have described a SPIEM method using whole convalescent sera and purified IgM that distinguishes at least six NLV antigenic types. These studies also have demonstrated specific IgM responses to these antigenic types in infected individuals, although there was some cross-reactivity between certain serum pairs and at least three antigenic types (67–69). Separate studies in Japan have described as many as nine antigenic types of NLVs by cross-reactive IEM (70).

The benefits and advantages of EM techniques for detection of NLVs are rapid diagnosis and broad detection (61). The time for completion of EM detection techniques ranges from 15 minutes for direct EM to a few (two to four) hours for IEM techniques. Other techniques for NLV detection based on antigenic and nucleic acid methods may also be rapid, but they may not have the breadth of detection that EM techniques have. EM visualization also detects unexpected or novel viruses that may be missed by specific molecular or antigenic methods. The major disadvantage of EM techniques for detection of NLVs is the requirement of a highly purified and/or high-titer sample. Another disadvantage of EM techniques is the lack of readily available sera that are reactive to all antigenic types of NLV. In addition, EM requires a highly skilled technician and expensive equipment. For these reasons, EM techniques have little utility for detection of NLVs in environmental samples and are better suited for diagnosis of clinical illnesses and epidemiological investigations.

Immunologic Methods

As for the EM methods, immunologic methods lack the sensitivity to reliably detect low levels of NLVs in environmental samples, but they are very useful for clinical diagnosis of NLV infections and for epidemiological investigations. Early immunologic techniques for NLVs were severely limited by the lack of availability and poor quality of reagents. However, the production of recombinant, viruslike particles (rVLPs) generated from the baculovirus expression of NLV capsid genes has allowed an unlimited supply of reagents, both as antigen and for the production of antisera/antibodies (71). At least seven NLV capsid genes have been cloned into baculovirus vectors (71–79). The baculovirus-expressed NLV capsid gene protein self-assembles into VLPs with a yield of up to 12.5 mg of protein per 100 mL of culture medium. VLPs are purified typically by rate-zonal centrifugation in a sucrose gradient and perhaps further purified by CsCl density-gradient centrifugation (80). Recombinant NLV capsid protein expression has also been described in *Escherichia coli* and mammalian cell lines (81,82). So far, no intact VLPs have been generated using *E. coli* or mammalian expression of NLV capsid proteins, but *E. coli* expressed proteins have been used to produce anti-NV monoclonal antibodies (81,82).

RIA/BAI. Solid-phase microtiter radioimmunoassays (RIAs) have been described for both NV and SMV antigens in crude stool and for their antibodies in sera (83,84). They were used in early epidemiological studies of seroprevalence, seroconversion in volunteers, and outbreak investigations (85–87). Studies have reported RIA to be either 10 to 80 times more sensitive than, or at least as sensitive as, IEM, and more sensitive than an immune-adherence assay (84,88). Still, the sensitivity of RIA is not as great as newer EIA/ELISA techniques, and it has the additional drawbacks of requiring six days to complete and the use of radioisotopes (89).

A simplified technique, called *biotin-avidin immunoassay* (BAI), was developed that has the following advantages over the RIA: (*1*) added sensitivity in detecting Norwalk antibody, (*2*) less time consuming, (*3*) not requiring frequent labeling of antibody, and (*4*) no use of radioisotopes (90). BAI detects NLV infections by a fourfold titer rise in serum antibody titer or by antigen in stool, with a sensitivity similar to or greater than that of the RIA, and BAI appears to be more sensitive than the RIA for detecting antibody in single serum specimens.

EIA/ELISA. RIA and BAI techniques have been succeeded by more sensitive enzyme immunoassays, particularly with recent advances in production of immune reagents. Antigen and antibody detection enzyme immunoassays (EIAs) have been described for several NLVs (12,71,73,81,91–98). Early EIA/ELISA relied on human sera and viral antigen from human stool specimens (95,98). Current antigen and antibody detection EIAs employ rVLPs for the generation of hyperimmune antibodies in laboratory animals and as a source of antigen (99–102).

A typical antigen-detection protocol involves sandwiching the target antigen, generally from purified stool, between antibodies to the target antigen generated from two species of animal (one of which is used to coat the plate and the other labeled for detection) (80). Assays using monoclonal antibodies for NLV rather than polyclonal hyperimmune sera have also been described (96). Epitope mapping of NLVs using monoclonal antibodies against rVLPs have led to the production of unlimited quantities of reagents that recognize epitopes on regions of the capsid protein that are highly conserved among different NLV capsid proteins (103). Analysis of a panel of monoclonal antibodies to genogroup I NLV has identified a common epitope not found in genogroup II NLVs (104).

Antibody-detection EIAs that are used to examine serum specimens are very sensitive and more broadly reactive than antigen-detection EIAs. Initial protocols used recombinant NLV capsid proteins to coat wells of a microtiter plate to measure total NLV immunoglobulin in human sera. Later modifications of the protocol allowed detection of individual isotypes of immunoglobulin. Typically, isotype-specific, antihuman antibodies are used to coat the microtiter plate, thus selecting a specific isotype in human sera for reaction with recombinant capsid antigens (92,93). Monoclonal, antibody ELISAs for IgM have been described for genogroup-specific NLV detection (99,105). Detection of IgM-class antibody has proved useful for diagnosis of recent infection, especially complementary, paired sera immunoassays when sera and stool specimens have not been collected early in an outbreak (99,106).

Antigen-detection EIA was demonstrated to be nearly as sensitive as RT-PCR and dot blot hybridization for virus detection in the stools of volunteers infected with homologous virus, but one study reported unexpectedly a low detection in field specimens (80). An EIA, based on the capsid of Lordsdale virus (a genogroup II NLV), compared favorably with IEM and RT-PCR, with detections of 71%, 63%, and 84% of 213 outbreaks, respectively (107). However, the high specificity of antigen-detection EIA also limits its application because of the antigenic diversity of the NLVs. The more broadly reactive antibody-detection EIAs have important application in epidemiological investigation, in particular for determining the seroprevalence, geographic, and temporal distributions of different groups of NLV (80).

Molecular Methods

RT-PCR. The first RT-PCR assays were described for NLVs within two years of cloning of the NV genome (43,53). Early RT-PCR assays were very specific to NV and proved to be very sensitive (53). RT-PCR of serial tenfold dilutions of NV demonstrated that RT-PCR sensitivity was similar to the actual virion titer by EM and at least 100 times as sensitive as RIA (43). Examination of outbreak stool samples by IEM, ELISA, and RT-PCR suggest that RT-PCR is more sensitive than IEM or ELISA (39). A Norwegian study found RT-PCR to be more sensitive in detection of NLV in stool specimens than direct EM (55). Numerous protocols have been described for RT-PCR amplification of NLV RNA, and no single standardized method is currently accepted. Early application of RT-PCR to specimens from a series of outbreaks indicated that efficiency of detection was affected by the sequence diversity of the NLVs (108,109).

RT-PCR assays targeting the NLV capsid of the genome have been described (110,111). However, the majority of assays have targeted the more conserved polymerase region (43,53,112–119). Several approaches have been described for broad RT-PCR detection of NLVs. A multiplex approach to broad detection has been described using a mixture of several primers (120). Another approach has been the selection of primers from a highly conserved region of the NLV genome (113,114). A lowered annealing temperature has been incorporated into this approach to increase overall detection by allowing mismatching of base pairs (113). Another approach is the use of primers with equimolar degeneracies to facilitate less-specific template annealing (115–117). The incorporation of inosine into the primers to allow mismatches at specific locations has also been described (110,118,121). None of these approaches has consistently detected all NLV strains. Experimental comparison of several primer sets found at least three primer pairs, G1 set, G2 set, and Sapp35/Sapp36, which were required to detect viruses in the NV and SV clades (119).

Both random and specific priming have been described for reverse transcription (RT) of NLVs. A recent study found no significant difference in sensitivity or specificity when using random priming and specific priming during the RT step (122). Other studies have reported slightly higher sensitivities when using specific priming (53).

Several groups have examined different RT and polymerase enzymes for NLV RT-PCR. The most commonly used RT enzymes are AMV and MULV, originating from avian myeloblastosis virus and murine leukemia virus, respectively (43,53). Additionally, modified versions of MULV that are rendered RNAse H^- and more thermostable by a point mutation have proved effective for RT of longer regions of viral RNA (123). Bidirectional enzymes for RT and PCR steps also have been evaluated (41,124). Willcocks and coworkers compared the amplification efficiency of the combination of AMV reverse transcriptase and taq polymerase with a bidirectional polymerase, Tet-z, and found that the two enzyme system give more efficient detection than the Tet-z (124). A traditional two-enzyme protocol and a single-enzyme protocol using rTth were found to have comparable sensitivity for NLV detection (41). The benefit of a bidirectional enzyme is that it allows a higher-temperature RT than possible with normal RT enzymes, thus maximizing specificity of reverse-primer annealing and minimizing failure of annealing because of secondary structures. Cocktails of polymerases have also been evaluated, generally to maintain the activity of the Taq, and add a proofreading component (3′ to 5′ exonuclease activity that discriminates between correctly and incorrectly paired bases at the 3′-OH end of an extending strand), as with Pwo (123). The use of Tfl in a one-step system in concert with AMV has also been described for the amplification of NLV RNA transcripts (42). Additives, such as Triton X, bovine serum albumin (BSA), 2-mercaptoethanol, dithiothreitol (DTT), and dimethylsulfoxide (DMSO), have been incorporated into several RT-PCR assays to enhance the performance (18,112,114).

A multiplex RT-PCR method has been developed for the simultaneous detection of the human enteroviruses, HAV and NV. Three different sets of primers were used to produce three size-specific amplicons of 435 bp, 270 bp, and 192 bp for PV1, NV, and HAV, respectively. When tested on mixed, purified virus suspensions, the multiplex method was able to detect all three viruses at levels of detection similar to monoplex RT-PCR methods (125).

Current methods for the detection of nucleic acid from enteric viruses in environmental samples usually involve extensive concentration and purification of target viruses before detection by RT-PCR. Environmental samples may contain certain compounds (such as organic acids, proteins, and polysaccharides) that may inhibit or completely shutdown RT-PCR. Many of these compounds will coconcentrate with the isolated viruses or nucleic acids. Several methods have been described to overcome or eliminate inhibitory compounds including spin-column chromatography, modified nucleic acid extraction, and immunomagnetic separation. However, none of these methods completely and efficiently remove inhibitory substances without reducing viral titer. Some of the previously mentioned additives have also been incorporated into RT-PCR assays to minimize inhibition and enhance amplification (18,112,114).

Recent studies have described the incorporation of internal control template RNAs into the RT-PCR to indicate whether the samples contain inhibitory substances (36,40, 54,126). Failure of the internal standard

control to be amplified in samples confirms the presence of RT-PCR inhibitors (36). The internal controls are typically constructed as a deletion or insertion of the target RNA and are similar in size to the target RNA, such that it will not significantly affect the amplification. One study developed an internal RT-PCR standard allowing differentiation of the internal standard amplicon from wild-type NLV amplicons during southern hybridization and by size difference on a gel (54).

Highly sensitive, seminested RT-PCR systems for the specific detection of genotype I and II NLVs have been described (18,38,122,127–131). The estimated sensitivity of a nested RT-PCR method for detection of genogroup 1 NLV is less than 10^2 to 10^3 particles per milliliter of feces (27).

Typical RT-PCR protocols for NLVs amplify targets of a few hundred base pairs. However, a protocol has been described to amplify 3-kb products from 24 NLV strains previously characterized into four genetic groups, and overcome stable secondary structures between the RNA polymerase gene and the 5′ end of the second open-reading frame that made long amplifications difficult (123).

The use of thermolabile uracil N-glycosylase (HK-UNG) (Epicentre Technologies, Madison, WI) has been described for the prevention of carryover contamination in NLV RT-PCR. Efficacy of carryover prevention was validated by seeding NV amplicons containing dUTP (by replacing dTTP during amplification) into subsequent RT-PCR reactions (41).

Confirmation/Sequence Analysis. It is crucial that presumptive, positive RT-PCR results from agarose gel electrophoresis be confirmed by another method. RT-PCR analysis on environmental samples often results in the generation of multiple nonspecific product bands (37,124,132). Although one study suggests that these additional bands may be completely removed by DNAse treatment just before cDNA synthesis, presumptively positive amplicons still must be verified (122).

DNA sequencing and phylogenetic analysis is still the gold standard for confirmation of NLV PCR amplicons (108,133–137). Because it is expensive and time consuming, alternatives to DNA sequencing have been described for confirmation and analysis of NLV amplicons. Restriction fragment length polymorphism (RFLP) has been used to confirm NLV-positive RT-PCR results and to establish that all isolates from an outbreak were identical (18,38,138). A heteroduplex mobility assay (HMA) has been described as a presequencing screen for characterization of PCR amplicons among the commonly circulating NLV strains. Amplicons are mixed with and annealed to similar amplicons from reference strains and those of less than 90% sequence identity form visible heteroduplexes, allowing the strains to be categorized (139).

Oligoprobe hybridization is a convenient and sensitive way to confirm RT-PCR positives (37). It further offers the advantage of an increased sensitivity in addition to confirmation of RT-PCR product. Oligoprobe hybridization has detected positive RT-PCR samples that were not visible by ethidium bromide staining of an agarose gel (132,140). Additionally, probing may detect a product when a smear appears on the gel and sequencing is not possible.

The most common format described for oligoprobing is southern hybridization (43,112). The benefit of this method is discerning positives of the appropriate amplicon size. Its main drawbacks are the length of time required and the genetic diversity. Overcoming the genetic diversity is attempted using diverse sets of probes either in a cocktail, in parallel, or in sequence (112,116,117,136). Minimizing the length of time has been attempted by skipping the agarose gel step. Reverse line blot, a variation of a dot-blot hybridization, allows simultaneous confirmation of RT-PCR and genotyping of NLVs using a large set of probes in an array format (141). A liquid-format oligoprobe hybridization protocol using microplate hybridization provides a rapid confirmation of PCR products than does agarose gel electrophoresis (136).

Hybridization Assay. A dot blot hybridization assay has been described using ^{32}P labeled cDNAs to directly probe for NV RNA. However, this assay never gained favor because it was described the same time as the first RT-PCR assays and was reported to be about 100 times less sensitive (53).

APPLICATION OF METHODS

Outbreak Investigation

Newer methods have allowed sensitive detection of NLVs in clinical and sometimes environmental samples and have improved the ability to track specific NLV strains or antigenic types during the course of an outbreak or series of outbreaks. For example, an investigation of a large, multistate outbreak linked to contaminated oysters used molecular epidemiology to determine the dominant outbreak strain and a cocirculating strain (120).

Monitoring. Although methods now exist for the detection of NLVs in environmental samples, application of these methods to routine monitoring is still impractical in most situations. The available methods of NLV concentration, purification, and detection are not well standardized. Considering the range of environmental samples and conditions, and the numerous strains of NLVs, the accuracy and precision of NLV concentration, purification, and detection techniques have not been adequately established for routine application to field studies. Current methods are also expensive, with costs approaching $1,000 per sample for water, and they require experienced, highly trained personnel working in specialized laboratories. The widespread and diffuse nature of NLV contamination of environmental vehicles, such as water and food, suggests that the number of samples for effective monitoring within a surveillance framework would have to be numerous. Additionally, the time required to complete analysis of a single sample may be several days for confirmation of results, even with rapid molecular detection techniques. Further, none of the current molecular techniques can adequately determine whether a detected viral particle is infectious.

Recent advances in microarray technology, real-time RT-PCR, increased availability of NLV immunoreagents, an expanding database of NLV sequence data, and the development of ligand binding assays employing the cellular receptors for virus infectivity may eventually lead to reliable and definitive methods suitable for routine monitoring of NLVs in environmental samples.

ENVIRONMENTAL OCCURRENCE, FATE, AND PERSISTENCE

NLVs are excreted in the feces of infected individuals, and have been isolated from a wide variety of fecally contaminated samples. As evidenced by point-source outbreaks, NLVs may persist for long periods in the environment. This section discusses the environmental occurrence, fate, and persistence of NLVs.

Early Studies (Heat, Ether, Acid Sensitivity)

Studies in human volunteers indicate that NLVs are relatively heat-stable, ether-resistant, and acid-stable (8). Volunteer-feeding studies demonstrated that NV remained infectious after three hours at pH 2.7 at room temperature, after treatment with 20% ether at 4 °C for 18 hours, or after heating to 60 °C for half an hour (8).

Water. Studies with seeded virus in sea, river, and tap water have demonstrated the ability of available methods to recover and detect NLVs (17). NLVs have been detected in a range of water types including sewage-effluent, receiving water (fresh and seawater), seawater samples from swimming beaches, untreated well water, and occasionally municipal tap water (17,19).

RT-PCR analysis for NLVs on six 1-L samples from various sites on the River Aare near Berne, Switzerland, identified genogroup I NLV in every sample and genogroup II in two samples (18). In another study, NLVs were presumptively detected in three of six seawater samples tested and river water from downstream of a wastewater treatment plant (17). However, detection in two of the seawater samples was not confirmed by the nested reaction. It is not clear whether this was caused by false positive reactions in the initial reaction or lack of primer specificity for the nested reaction (17).

Investigation of a municipal water supply linked to an ongoing outbreak resulted in detection of genogroup II NLVs in untreated source water, finished water, and four tap water samples from various points in the distribution system. Additionally, both genogroup I and II NLVs were identified in the municipal sewage and genogroup II in the sewage effluent (19). Additional investigation linked the genogroup II NLV to an outbreak four months earlier in a city 70 km upstream. The time calculated for sewage effluent from the upstream outbreak to reach the downstream water supply and cause the described outbreak corresponded to the four-month period separating the outbreaks. During this period lakes and rivers were covered with ice, which may have increased the persistence of the viruses in the water (19).

A waterborne outbreak in Alaska and the Yukon Territory was associated with a well used as a restaurant's water supply, which had been contaminated by connection with a septic pit. NLV genetic sequences isolated from the well and from stool specimens of infected individuals were identical (142).

A survey of the presence of NLV in 63 types mineral water of 29 different brands found NLV sequences in 21 types mineral water by seminested RT-PCR. Representatives of both NLV genogroups I and II were randomly found in the contaminated samples, and NLV presence did not correlate with bottle characteristics or chemical properties (143).

Epidemiological evidence often implicates a water source, even when NLVs cannot be identified in the water source. For example, an outbreak of NLV was linked to a community water system in which surface runoff from heavy rainfall may have contaminated a spring, which served as the water source for the community system (144). A 1995 waterborne outbreak of NLV at a Wisconsin high school was linked to contamination of the drinking water supply by a back siphonage that occurred through submerged hoses on a flooded football field (145).

A large NLV epidemic in a Finnish municipality (1,500 to 3,000 people, i.e., 25 to 50% of the population) was most probably associated with contaminated drinking water. Although multiple pathogens were identified, Norwalk virus was the main cause of the outbreak. The source of contamination was a groundwater well situated in the embankment of a river. The well was contaminated by polluted river water during the spring flood by a back flow from the river through a forgotten drainage pipe (146). Waterborne outbreaks of NLVs in 1979, 1987, and 1996 were associated with recreational use of fecally contaminated lake water (145,147,148).

A Canadian epidemiological study on drinking water implicated conventionally treated tap water, meeting water quality requirements, in sporadic gastrointestinal illness (GI). Using a specific EIA, NV was evaluated as a possible agent responsible for the 35% excess of GI symptoms in tap water drinkers versus reverse osmosis treated water drinkers. It was concluded that NV was not responsible for the excess 35% (149). However, only the Norwalk antigen, and not other NLVs, was used to evaluate the sera. Because NV has been relatively uncommon compared with other NLVs and much of the observed GI illness was consistent with NLVs, it is possible that NLVs other than Norwalk were at least partly responsible for the 35% excess in illness attributed to tap water.

Wastewater

NLVs have been detected in raw sewage (17,20). In a seeded study, NLV was detected in raw sewage at low levels. Three volumes of a NLV-positive stool extract (200 μL, 20 μL, and 2 μL) were added to 20 mL aliquots of raw sewage. NLVs were detectable in the seeded sewage for all three seed volumes. Interestingly, analysis of 100 mL of unseeded raw sewage by the same method did not detect NLV, although NLVs were detectable in 10 L of unseeded final sewage effluent by seminested RT-PCR (17). Under outbreak conditions, 10 L sewage samples from three cities with ongoing NLV outbreaks

were positive for NLV. RT-PCR analysis of serial tenfold dilutions of extracted viral RNA from each of the sewage samples indicated that NLVs were present in high concentration (positives observed at up to 10^{-7} dilution). Follow-up analysis on additional sewage samples from one of the cities detected NLV in 10 of 11 samples over a period of three months. NLVs detected at two of the sites were closely related, whereas the virus detected at the third site was another genotype. The outbreak strains of NLV corresponded to those detected in the sewage at each site. Several additional strains of NLV (from both genogroup I and II) were isolated from follow-up samples (20).

Soils

Laboratory studies using seeded NV in soil and groundwater determined that NV was strongly adsorbed to clay soils (>4 $\log_{10}$ adsorption), moderately adsorbed to organic soils (1 $\log_{10}$ adsorption), and poorly adsorbed to sandy soils (<1 $\log_{10}$ adsorption). These studies, using poliovirus type 1 (PV1) and coliphage MS2 as benchmarks, determined that NV was less strongly adsorbed than PV1 (a strongly adsorbing virus) and equally or more adsorbed than MS2 (a poorly adsorbing virus). Additionally, these studies examined the persistence of NV, PV1, and MS2 over a six-month period in soil and groundwater. PV1 was the most persistent of the three viruses. NV was found to be similarly or less persistent than MS2 (150). Other studies on soil removal of NV in treated wastewater demonstrated similar results (151). Another study investigated the filtration and surface charge of NV in quartz sand, using recombinant VLPs. The surface charge of rNV particles and their filtration through quartz sand were demonstrated to be strongly influenced by pore water pH, suggesting that filtration of NV is dependent on electrostatic interactions between the virus and the quartz media (152).

Inactivation/Disinfection Studies

Early chlorine disinfection studies indicated that NV was more resistant to chlorine than poliovirus, rotavirus, or bacteriophage f2 (153). A study using seroconversion of volunteers to assess the disinfection efficacy of free chlorine on NV indicated that doses up to 10 mg/L were necessary to inactivate the virus in water (153). However, the NV preparation used in that study had a very high infectivity titer, exerted appreciable free chlorine demand, and caused free chlorine residual to disappear completely at the lower doses tested (3.75 mg/L). Parallel studies with bacteriophage f2 also indicated virus survival under similar experimental conditions. More recent studies using purified NV and sensitive RT-PCR detection suggest that NV is not more resistant than poliovirus (PV1) to free chlorine and a variety of other disinfectants (154,155). NV was found to be more susceptible than PV1 and coliphage MS2 to monochloramine (154). Free chlorine (1 mg/L), chlorine dioxide (1 mg/L), and ozone (0.37 mg/L) were shown to be as effective or more so on NV than PV1 and MS2 (155).

No cell culture or animal infectivity assay exists for human NLVs. However, certain animal caliciviruses may be grown in cell culture. Feline calicivirus (FCV) has been used as a surrogate for NLVs to study inactivation under environmental conditions (156,157). In one study, FCV was used to estimate the heat inactivation of NLVs in cockles and was found to be more sensitive to heat than hepatitis A virus (HAV) (157). When cockles were heated to an internal temperature of approximately 78 °C (by immersion in boiling water), infectious FCV was recovered after immersion for 30 seconds but not after 1 minute, and RT-PCR detection was positive at 1 min 30 seconds (157). In a study examining the inactivation of FCV by commonly employed disinfectants, such as gluteraldehyde (0.5%), hypochlorite (5,000 ppm), iodine (0.8%), gave 5 $\log_{10}$ reduction at one minute of contact time (156). A quaternary ammonium compound (1 : 10), 75% ethanol, 1% anionic detergent, and lower levels of hypochlorite gave no or only low levels of inactivation after one minute of contact time, ranging from 0 to 2.75 $\log_{10}$. Studies on heat inactivation of FCV in suspension demonstrated no titer reduction at 56 °C for one or three minutes, 3 $\log_{10}$ and 6 $\log_{10}$ at 70 °C for one or three minutes, and complete inactivation after boiling for one minute (156). FCV survived either dried or in suspension at 4 °C, with only a 4 to 5 $\log_{10}$ reduction in titer after about 60 days. At room temperature, 9 $\log_{10}$ reduction was observed in suspension between two and three weeks and in a dried state between three and four weeks. At 37 °C, infectivity reduction in suspension was approximately 1 $\log_{10}$ per day, but in a dried state there was complete inactivation within one day (156).

It should be noted that the appropriateness of FCV as a surrogate for NLVs in inactivation studies is questionable because NLVs are enteric pathogens and FCV is a respiratory pathogen. Although they do have similar capsid structures, the obvious differences in the route of infection calls into question the similarities of their environmental stability. Analogously, enteroviruses, which are enteric pathogens, and rhinoviruses, which are respiratory viruses, are both members of the picornaviridae, but they have very different stabilities under a variety of conditions.

Shellfish

Outbreaks of gastrointestinal illness associated with NLVs in shellfish are well-documented, and the risk of NLV illness has been shown to increase with the amount of contaminated seafood eaten (111,130,158–171). Steaming or cooking oysters does not appear to prevent NLV illness (164,171).

Outbreaks have occurred even when bacterial indicators of fecal contamination were within acceptable levels. The importance of adequate sanitation practices to protect shellfish and their harvest water was highlighted by a Florida outbreak of oyster-borne NLV gastroenteritis linked to overboard dumping of feces from harvest boats (164). Occurrence of NLV in shellfish has been shown to correlate to bacteriophage indicator levels, but not fecal coliform levels (172,173). In 48-hour oyster depuration experiments, 95% of bacteria were removed, but only 7% of NV titers were removed from the digestive diverticulum tissues (174). Occurrence of enteric virus

contamination, including NLVs, in shellfish harvesting areas has been shown to correlate with the incidence of epidemics of gastroenteritis in coastal population consuming bivalve mollusks (135,175). Additionally, heavy rainfall may be a contributing factor in the level of viral contamination (176).

A seeded study on the uptake, localization, and removal of NV in shellfish (oyster and clam) tissues found NV in the digestive diverticulum and stomach for all concentrations of seeded virus (174). At higher levels of seeded virus, NV was also detected in adductor muscle and hemolymph tissues. Another study reported marked differences of NLV detection in different seafoods. NLV detection in mussels was 10 to 100 times more sensitive than in shrimps and oysters (35).

NLVs have been identified in clam and oyster specimens by RIA (165). Using advanced molecular methods, NLVs have been detected in shellfish linked to outbreaks and shellfish from high contamination areas and commercial harvest areas (31,131,140,163). Analysis of sequence data from viruses detected in outbreak-associated shellfish have shown them to be the same or very similar to viral sequences found in outbreak stools (31,140,163). Some shellfish samples have been shown to contain a mixture of NLV strains (up to three different strains) with both genogroups I and II represented (135). Multiple genotypes of NLV in a single-oyster specimen or stool specimen also has been reported by others (130).

Other Foods

A seeded virus study demonstrated that NLVs could be recovered from fruits and vegetables in addition to clams and oysters. The study showed effective recovery and detection by nested RT-PCR of NLVs in milk, orange juice, coleslaw, fresh-cut melon and lettuce (38). Green salad has often been linked to NLV outbreaks (177,178). A simple method has been reported in seeded studies for consistent recovery and detection of NLVs from deli meat. Application of this method to an outbreak implicating deli meat from a university cafeteria allowed detection of a genogroup II NLV on sliced ham (37).

Other Exposure Vehicles and Settings

NLV outbreaks result in a high level of secondary cases as a result of low infectious dose, environmental persistence, and transmission by person-to-person contact. Direct person-to-person transmission, aerosol transmission, and fomite transmission of NLVs are a high risk in situations of close contact, such as on shipboard, in schools, or in nursing facilities (179–183). Under such conditions, outbreaks may persist or repeat (179,184). Investigators documented person-to-person contact as the means of transmission between members of two college football teams on the playing field (185). One team suffered a food-borne outbreak epidemiologically associated with turkey sandwiches from box lunches. That team passed the NLVs to the other team during the game. Other than contact on the field, there was no contact between the players on the two teams. NLVs, with identical genetic sequences, were detected in the stools of players from both the teams (185).

NLVs have been detected in RT-PCR analysis of environmental swabs collected during a hospital outbreak, with 11 of 36 swabs positive. Positive swabs were confined to the immediate environment of symptomatic patients, but were from items as diverse as lockers, curtains, and commodes. In the ninth week of an outbreak in a United Kingdom hotel, 144 environmental swabs were taken from around the hotel and tested for NLV by nested RT-PCR. Directly contaminated carpets had the highest rate of positive samples. NLVs were also detected from swabs of sites above 1.5 m, which are unlikely to have been contaminated directly, but could have been contaminated by NLV-containing aerosols. Retesting of the same sites, five months after the outbreak ended, yielded no positive RT-PCR results (186).

CONCLUSION

NLVs are environmentally persistent and are infectious at low doses. Worldwide, NLVs are an important cause of viral gastroenteritis. Outbreaks are explosive and are frequently linked to common sources of food or water. A wide variety of contaminated food items and water sources have been documented as the source of NLV outbreaks. Microscopic and immunologic methods have been described for the detection of NLVs and NLV antibodies in clinical samples. However, these methods are not sensitive enough for reliable detection of NLVs in environmental samples. Current molecular methods targeting viral nucleic acids, with RT-PCR and oligoprobe hybridization being most widely used, offer sensitive detection of NLVs in both clinical and environmental samples. However, these methods are frequently affected by inhibitory compounds associated with the samples that concentrate from environmental samples along with the viruses and their nucleic acids. Therefore, the most robust recovery and detection methods include processing steps to separate the viruses or their nucleic acids from these inhibitory materials before nucleic acid amplification

NOSOCOMIAL INFECTIONS

PATRICIA DE Q. F. MOTA
STEPHEN C. EDBERG
Yale University School of Medicine
New Haven, Connecticut

Nosocomial infections (NIs) have been recognized for more than a century as a critical problem adversely affecting patients' outcomes and quality of health care (1). Approximately 2.5 million NIs occur annually in the United States, meaning that approximately 5% of hospitalized patients will develop a documented infection acquired from the hospital (2,3). The rates may be even greater in intensive care units (ICUs). Even though they account for only 5 to 10% of hospital beds, the prevalence of NIs in ICU patients represents over 20% of hospital-acquired infections (4). Age and underlying diseases are established intrinsic risk factors for acquiring NIs (5,6); however, it is noteworthy that a number of current patient-care procedures in hospitals, such as immunosuppressive agents and broad-spectrum antibiotics, invasive devices, surgical procedures, and nutritional support also increase the risk for developing those infections (7). Of all the major complications of hospitalization, NIs account for 50% (8), resulting in prolonged hospital stays with an excess in health care costs of $ 4.5 billion per year (9–12), as well as high mortality rates (more than 88,000 deaths annually in the United States — one death every 6 minutes) (10,13). One-third of NIs are preventable, yet several infection-control measures should be taken in order to meet this level (14), and hand washing is still the cornerstone strategy for controlling transmission of infections in hospitals (10).

DEFINITIONS

From the combination of the Greek *nosos* (disease) with *komein* (to take care of) as *nosokomeion* (hospital) and through the Latin *nosocomium* (hospital) came the English *nosocomial* (pertaining to a hospital). Today, the term nosocomial infection (NI) is used worldwide (15).

The National Nosocomial Infection Surveillance (NNIS) is a 30-year surveillance system used by the Centers for Disease Control and Prevention (CDC, the former Communicable Disease Center) in Atlanta, GA. This program allows personnel from CDC to standardize and compare data routinely reported to them by over 200 affiliated American hospitals with regard to their nosocomial infection rates (16). The NNIS system defines NI as a localized or systemic condition that results from an adverse reaction to the presence of an infectious agent or its toxin and which was neither present nor incubating at the time of admission. For many bacterial nosocomial infections, this means the infection usually becomes evident 48 hours or more after admission, although this time may vary from agent to agent (17,18). Likewise, any infection acquired in the hospital, but which only becomes evident after hospital discharge, as well as any newborn infection resulting from the passage through the birth canal, is included under the subject of nosocomial infections (19). There are two conditions — colonization and inflammation — which have not been considered infectious. The former has been understood as the presence of microorganisms on the skin, mucous membranes, open wounds, or secretions that are not causing adverse clinical signs or symptoms. The latter is a condition that results from tissue response to injury or stimulation by noninfectious agents (17).

Table 1. Nosocomial Infection Rates from Different Intensive Care Units in the United States

Reference	Author	Unit	Rates (%)
31	R. P. Wenzel	Coronary	1.5
31	R. P. Wenzel	Burns	64
32	P. H. Chandrasekar	Medical	14
32	P. H. Chandrasekar	Surgical	35.2
11	N. A. Khuri-Bulos	Neuro-surgical	18.5

INCIDENCE

In 1964, the first hospital-acquired infection (HAI) rates from U.S. hospitals were collected and reported to be as high as 13.5% (20) (see Table 1). In the late 1960s and 1970s, some survey programs developed by CDC-enrolling community and tertiary hospitals revealed lower rates of nosocomial infections, which were between 3 and 6% (21–23). The current data shows that approximately 2.5 million NIs occur annually in the United States, meaning that approximately 5% of the hospitalized patients will develop some documented infection acquired from the hospital (2,3). Among these 2.5 million patients, almost 250,000 will suffer from bloodstream infections (2). The Second National Prevalence Survey conducted at teaching and nonteaching hospitals in the United Kingdom and Ireland revealed an overall NI rate of 0.9% (24). The prevalence shown by survey studies among other European countries varied between 6 and 10% (25,26). By contrast, the incidence of HAIs can be considerably higher in developing countries, reaching up to 25% (11,27). In a five-year review of published articles on NIs originating from developing countries (such as India, Brazil, Mexico, Chile, Nigeria, Panama, and Zimbabwe), the overall rates varied from 3 to 13.5% (28,29). However, rates as high as 35.4 and 68% have been observed in Burn and Surgical Units, respectively (30).

Rates of NIs differ greatly according to the site of infection, the population of patients, and the clinical service involved (26,33,34). Although ICUs account for only 5 to 10% of all hospital beds, currently the rates of NIs in ICU patients represent over 20% of all HAIs (4). In a surveillance study performed with four Swiss University Hospitals, the prevalence of NIs in ICUs was almost three times higher than the rate observed in medical wards and two times the rate in surgical wards (35).

HISTORICAL BACKGROUND AND TRENDS IN MICROBIOLOGY OF NOSOCOMIAL INFECTIONS

The first nosocomial outbreak of staphylococcal disease throughout the world occurred in the mid-1950s. In 1957 by the time of the viral influenza pandemic, rates of nosocomial staphylococcal infection reached high numbers, presenting mainly as pneumonia (36). By the end of the 1960s, a shift toward gram-negative organisms was noted. One of the first survey studies in the United States showed an overall HAI rate of 3.5%, with gram-negative bacilli accounting for 60% of all infections recorded (23). In the late 1960s and early 1970s, gram-negative organisms, such as *Klebsiella* sp. and *Proteus rettgeri*, emerged as multidrug resistant pathogens in tertiary hospitals all over the United States (37,38). During the following years, cases of aminoglycoside-resistant, gram-negative organisms, such as *Escherichia coli*, *Serratia marcescens*, *Pseudomonas aeruginosa*, and *Proteus* sp. were observed (39,40). Nevertheless, *Staphylococcus aureus* became the main focus of attention during that decade owing to its increased resistance to methicillin (from 2 to 5%) and gentamicin (from 1 to 13%) between 1975 and 1979 (40,41).

In contrast to the 1970s, major shifts in the etiology of NIs occurred during the 1980s (42). In 1986, data published by the CDC revealed overall NI rates between 2.4 and 4.1% and found *Enterococcus* sp. to be the third most common isolate from HAIs (43). Moreover, the increased use of vancomycin to treat enterococcus infections in the 1980s, as well as the overuse of in-dwelling vascular devices in immunocompromised patients, were closely correlated with an increased incidence of nosocomial infections caused by coagulase-negative staphylococci (CNS) (42,44). The CNS organism, previously considered a skin contaminant, has emerged as an important blood and prosthesis pathogen (45–47). By 1988, the first vancomycin-resistant *Staphylococcus hemolyticus* was isolated from a blood culture (48). Similar to CNS and enterococci, detection of *Candida* sp. in blood cultures, as well as in cultures from other sites, increased between 1980 and 1990 (48,49). During the seven-year period between 1978 and 1984 of statewide surveillance by Wenzel and coworkers (50), a significant rise in nosocomial *Candida* bloodstream infections from 0.1 to 1.5 infections per 10,000 discharges was noted. Analysis of data from NNISS hospitals showed that the total number of fungal infections increased from 6% in 1980 to 10.4% in 1990, and approximately 80% of these infections were caused by *Candida* sp. (51). Moreover, *Candida albicans* accounted for 76% of 25,000 primary bloodstream infections reported to the CDC during the same period (52).

The ten most commonly isolated pathogens accounting for NIs during the decade between 1980 and 1989 were as follows: *E. coli*, *P. aeruginosa*, *Enterococcus* sp., *S. aureus*, *Klebsiella* sp., CNS, *Enterobacter* sp., *Candida* sp., *Proteus* sp., and *Serratia* sp. (49,53,54).

In the 1990s, changes in the etiologic pattern of nosocomial infections were noticed. Studies showed progressive increases in the prevalence of organisms, such as *Stenotrophomonas* (formerly *Xanthomonas* and *Pseudomonas*) *maltophilia* and, more recently, *Burkholderia* (formerly *Pseudomonas*) *cepacia* in cultures from the respiratory tracts of cystic fibrosis (CF) patients (55–57).

Isolation of *Acinetobacter* sp. and *P. aeruginosa* has increased markedly, primarily in cases of ventilator-associated pneumonia in ICUs (58). Although recent publications demonstrated a tendency to a decreased incidence of nosocomial *P. aeruginosa* bacteremia (59,60), it is still the third most common nosocomial pathogen among gram-negative rods, accounting for up to 15% of all nosocomial bacteremias (58). There has been an increased observation of *Candida* sp. as a urinary tract infection pathogen, which has been isolated almost as frequently

Table 2. Species Distribution of *Candida* Blood Stream Isolates (SENTRY Program, January Through December 1997)

Species	% Isolates by Geographic Area (# Isolates Tested)			
	United States (203)	Canada (61)	South America (42)	All (306)
C. albicans	56.2	52.5	40.5	53.3

as *E. coli* (61,62). Studies from the United States and other countries have shown that *C. albicans* is the leading pathogen in all episodes of candidemias (63–65). Nevertheless, recent data also showed an increase of non-*albicans Candida* species causing bloodstream and other significant infections (66–68). An international surveillance of BSI owing to *Candida* sp. in the United States, Canada, and South America published in 1998 detected 306 episodes of candidemia among 34 medical centers. The overall rates of *C. albicans* and non-*albicans* BSI were 53 and 47%, respectively (69) (see Table 2). In some institutions, the proportion of non-*albicans Candida* isolates from blood cultures has equaled (70,71) or exceeded that of *C. albicans* (64) (see Table 3).

New gram-positive and gram-negative organisms have emerged among a special population of patients — patients with neutropenia (an abnormally small amount of mature white blood cells) and patients undergoing chemotherapy for cancer (72) (see Tables 4 and 5). Intestinal colonization with *Enterococcus* sp., has become a greater concern among these patients as well, because of its resistance to vancomycin and high mortality rates. A recent report described an outbreak of bacteremia owing to vancomycin-resistant *Enterococcus faecium* in the oncology unit of a teaching hospital where the mortality rate was 73% (73).

Surveillance studies have shown that the most commonly isolated organisms may vary depending on the infection site (see Table 6 and references). During the 1990s, the three most common, gram-positive pathogens (*S. aureus*, CNS, and enterococci) accounted for 34% of NIs, whereas the four most frequent gram-negative organisms were *E. coli*, *P. aeruginosa*, *Enterobacter* sp., and *Klebsiella pneumoniae*, accounting for 32%.

Table 3. Etiologic Agents in 145 Cases of Candidemia

Etiologic Agent	# Isolates	% Isolates
Candida albicans	52	37

RISK FACTORS FOR NOSOCOMIAL INFECTIONS

Age and Gender

Studies have shown that host characteristics, such as age and underlying diseases, are intrinsic risk factors for acquiring nosocomial infections (5,6). As human life expectancy increases, more elderly people have been hospitalized with chronic diseases, resulting in longer exposure to nosocomial environments and antibiotic-resistant pathogens (76,77). Moreover, older patients have

a greater need for intravenous therapy and critical care settings, which carry poorer prognoses (78,79). Likewise, children may suffer from high morbidity and mortality owing to HAIs (80). In particular, it is low birth weight infants and preterm newborns who may have their clinical course complicated by opportunistic, life-threatening pathogens (81,82). The site of infection differs between these two extremes of age. Respiratory infections in children and urinary tract infections in the elderly are the most common HAIs diagnosed (6). Although gender has not been established as a risk factor for HAI, most of the survey studies have shown predominating rates in men (83–85).

Ganguly, and coworkers (86), assessed 422 prospective patients and found higher rates of NIs in patients with underlying diseases, such as anemia (53.7%), diabetes mellitus (85.2%), hypertension (82%), and obesity (51.5%), than in controls with no comorbidities. These underlying diseases reduce the immunological resistance significantly, making the patient more vulnerable to infection (86). Among 100 diabetic patients studied who were undergoing elective surgery, the risk for development of early postoperative nosocomial surgical site infections was 2.7 times higher when it was related to perioperative hyperglycemia (31.3% vs. 11.5%) (87). Hematologic and oncologic patients may present with periods of extreme neutropenia (with less than 500 neutrophils per mm^3) because of powerful chemotherapy and radiotherapy, which also make them vulnerable targets to life-threatening HAIs (88). During a 42-month period of surveillance in a cancer center, 920 neutropenic patients were detected. A total of 444 NIs was identified for an overall rate of 48.3 HAIs per 100 neutropenic patients (89).

It is noteworthy that a number of current patient-care procedures in hospitals, such as immunosuppressive agents and broad-spectrum antibiotics, invasive devices (intravenous and urinary catheters and mechanic ventilation), surgical procedures, and nutritional support — so-called extrinsic risk factors — also greatly increase the risk for developing NIs (7).

Parenteral and Enteral Nutrition

Although enteral nutrition has an important task in the maintenance of gastrointestinal immunological function, thereby decreasing bacterial translocation and the risk of infection, cases of NI have been reported owing to contaminated feeding solutions (90,91). The stomach alkalinization induced by the enteral nutrition may allow gastric microbial growth, which can be translocated to the trachea resulting in tracheal colonization and, ultimately, pulmonary aspiration and nosocomial pneumonia (92). Total parenteral nutrition has been associated with HAIs, as well (93,94). A prospective study in a pediatric ICU showed that patients on parenteral nutrition support were 22 times more likely to develop NI than those patients not receiving it (95).

In contrast to healthy people, critically ill, hospitalized patients become colonized more rapidly with gram-negative bacteria during mechanical ventilation and carry a higher risk for ventilator-associated pneumonia (VAP) caused by such bacteria (96–98). The stomach is normally almost sterile because of the bactericidal activity of the hydrochloric acid that prevents colonization of the gastrointestinal tract with ingested pathogens (99). However, gastric bacterial colonization is associated with a number of factors frequently present in hospitalized patients, including advanced age, underlying gastrointestinal disorders, achlorhydria (an absence of hydrochloric acid from the gastric juice), malnutrition, and administration of antacids (100,101). Direct aspiration of small volumes of secretions from the trachea or gastrointestinal tract with large concentrations of bacteria is the most common event responsible for development of VAP (97). In addition, endotracheal tubes probably play an important role in predisposing such patients to aspiration, bypassing the normal protective mechanisms of the upper airway and allowing secretions to pool into the upper part of the trachea. This is particularly important in the presence of impaired levels of consciousness (102) (see Fig. 1). It has been speculated that *Pseudomonas* sp. may also cause VAP by a route different than other gram-negative bacteria, since this organism has an enhanced capacity

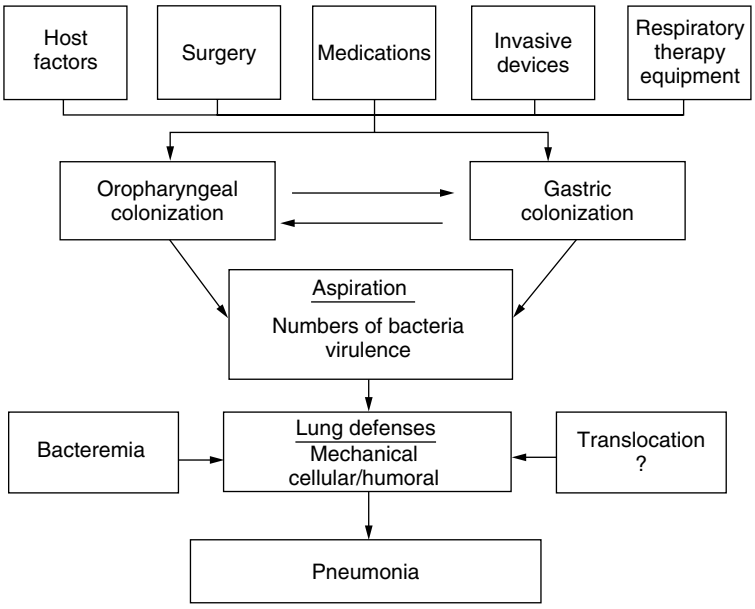

Figure 1. Factors related to the development of ventilator-assisted pneumonia. Taken from Reference 97.

for binding to the tracheobronchial tree of patients on mechanical ventilation without previous colonization of the oropharynx (103).

Intravenous Devices

Each year in the United States, 150 million intravascular devices are used by hospitals and clinics. The vast majority are peripheral venous catheters; however, about 5 million central venous devices of various types are sold in the United States (104). As early as 1977, Maki (105) suggested that device-related bacteremia develops in more than 25,000 patients in the United States each year. These numbers have continued to increase (106,107). Cases of device-associated bacteremia are referred to as primary bacteremia because there is no obvious infection focus (108). Primary bacteremia accounts for one-fourth of the sporadic cases of nosocomial primary bacteremia, whereas more than three-fourths of the nosocomial bacteremia occur in clusters. Approximately 75% of the primary bacteremia cases are reported to be device-associated (108). Bacteria may gain access to an intravascular device at several points during the entire process of infusion therapy (see Fig. 2) (109). In a prospective study by Maki and Ringer (110), colonization around the catheter insertion site was the most strongly associated risk factor for catheter infection. Hub contamination was the second most heavily weighted risk factor.

There are many patient- and hospital-related factors, which have been incriminated as a risk for increasing device-associated infections (see Tables 6 and 7). Staphylococci account for one-half to two-thirds of the episodes of catheter-related bacteremia, and most of those are because of contamination at the junction or at the device insertion site (110,111). Although *S. aureus* is still a frequent pathogen, coagulase-negative *Staphylococcus* has become predominant, especially among immunocompromised patients and those in whom long-term central venous access is required (42,44). When unusual isolates are identified, including gram-negative bacteria or fungi, the possibility of contamination of the infusion product rises (112—114).

Urinary Catheters

At least 25% of patients hospitalized in the United States annually are placed with an in-dwelling transurethral urinary catheter (115). Urinary catheters have been used since the 1800s for accurate measurement of urinary output, to relieve urinary retention or incontinence, to facilitate urinary flow in some neurologic patients, and for instillation of drugs or irrigation of the bladder (116). The duration of catheterization is directly related to the development of asymptomatic bacteriuria, which may result in nosocomial urinary tract infection (UTI), bacteremia, and sepsis (117,118). The incidence of bacteriuria in short- and long-term catheterized patients is 3 to 10% and 8 to 10%, respectively, per day of catheter placement. This means that patients who are catheterized late in their hospitalization have an increased rate of bacteriuria (115,119,120). Other risk factors for bacteriuria have been reported, including diabetes mellitus, abnormal serum creatinine, renal stones, and inadequate catheter care (121). In females, between 70 and 80% of UTIs are caused from a periurethral route contaminated with rectal flora (122,123). After removal of a catheter, the patient may remain at risk for bacteriuria up to 24 hours, possibly because of the increased urethral colonization associated with an in-dwelling catheter (124). In males, the predominant route is intraluminal. Bacteria may grow in the urine in suspension and ascend via lumen or they may grow in so-called biofilm outside of the catheter and then infect the bladder (122,125). Biofilm formation is a pathogenic process triggered when a bacteria attaches to the catheter surface resulting in encrustation of the catheter lumen by layers of organisms (125,126). In addition, microorganisms that are present on the meatus or

distal urethra can be transferred directly into the bladder during the insertion of the catheter (127). Among short-term catheterized patients, *E. coli* is usually the bacteriuric species most frequently isolated. Other common organisms are *P. aeruginosa*, *K. pneumonia*, *Proteus mirabilis*, *Staphylococcus epidermidis*, *Candida* sp., and enterococcus (118,128).

Use of Antimicrobial Therapy

Many years ago, studies already showed that prior exposure to antibiotic therapy was a decisive factor in selecting normal gastrointestinal flora, facilitating colonization and infection of patients (37,38,129,130). Rose and Schreier (131) compared 50 hospitalized patients treated with antibiotics with 50 untreated patients and noted a significant increase in the intestinal carrier rate of *Klebsiella* sp. among those patients receiving antibiotics. A retrospective survey at Boston City Hospital between 1935 and 1957 showed a favorable impact of new antimicrobial drugs in controlling primary bacterial pathogens and reducing the number of deaths by organisms such as pneumococcus and hemolytic streptococcus. On the other hand, there was a greater increase in the incidence and mortality caused by opportunistic agents such as *S. aureus*, *Pseudomonas* sp., *Enterococcus* sp., and *Proteus* sp. — organisms, which had not previously been considered highly pathogenic (129). A few years later, it was observed that the widespread use of antibiotics led to enhanced rates of carriage of resistant bacteria among both sick patients and healthy individuals from the community (132). Caugant and coworkers (133), found a genetic relationship between resistant strains of the *E. coli* that colonized and infected people in a specific region, demonstrating that excess resistance in the bacteria that colonize may also be an indicator of excess resistance in the bacteria that infect.

Pallares and coworkers (48), showed that the percentage of in-patients receiving at least one antibiotic increased from 23% in 1978 to 44% in 1992 in a tertiary hospital. Following the changes in antimicrobial usage, the susceptibility patterns of some microorganisms has changed, as well. The emergence of antibiotic resistance has been a global problem (134) since the

1940s when the first cases of penicillin-resistant staphylococci were identified (135). By the late 1950s, approximately 50% of the staphylococcal strains were resistant to penicillin (136). Methicillin and other semisynthetic penicillins were introduced in the 1960s and successfully treated penicillinase-resistant *S. aureus* until the mid-1970s, when methicillin-resistant *S. aureus* (MRSA) strains became endemic in many European and U.S. hospitals. This resistance mechanism was characterized by a low-affinity of penicillin-biding protein (PBP) (137 — 139).

Data from NNIS hospitals showed that the overall percentage of MRSA among the U.S. hospitals rose from 2.4% in 1975 to 29.0% in 1991 (140). The glycopeptide vancomycin has been the only uniformly effective treatment for methicillin-resistant staphylococcal infections during the past 30 years (141). However, the recent emergence of glycopeptide resistance among coagulase-negative staphylococci (142–144) and enterococci (145,146) has heightened concern about whether *S. aureus* could acquire such resistance. To this end, the morbidity and mortality produced by this organism would be alarming (147). In fact, all MRSA strains demonstrated sensitivity to vancomycin until 1996, when the first isolate of *S. aureus* with reduced sensitivity was reported in Japan (136). At least four new cases of infection caused by *S. aureus* with minimum inhibitory concentration (MIC) higher than 4 meg/mL to vancomycin have been isolated in the United States (147–149).

Enterococcus strains typically have intrinsic low-level resistance to aminoglycoside (150,151). High-level streptomycin- and kanamycin-resistance have been shown as early as the 1970s (152); whereas, high-level gentamicin-resistance has only been detected more recently (153–155). Studies have suggested that hospitals may be the major source for the spread of clonal-resistant strains (156,157). Highly resistant *Streptococcus pneumoniae* isolates recovered from European, African, and U.S. cities (158–160) were shown to be clonally related, suggesting intercontinental spread of such multiresistant bacteria (161).

Elaboration of inducible, chromosomal- and plasmid-mediated ß-lactamase among gram-negative bacteria has also been reported (162–167). In 1983, the first case of extended-spectrum ß-lactamase (ESBL) was described in Europe (168). The mechanism was recognized as either a plasmid- or chromosomal-mediated resistance present among Enterobacteriaceae, which conferred resistance to broader spectrum antibiotics than ß-lactamase enzymes can confer (169). ESBL enzymes initially became increasingly prevalent in Europe and later in the United States (170,171). Now, the ESBL represent a major group of ß-lactamases known worldwide (172,173).

Normally present in the digestive tract of healthy people, the frequency of nosocomial yeast infections has increased dramatically (174). Therapy for serious yeast infections has been difficult because of the limited number of available antifungal agents and the treatment toxicity associated with drugs such as Amphotericin B and Flucytosine® (fluconazole) (175). Because of its widespread prophylactic and therapeutic use, mainly in patients with AIDS, reports about the emergence of resistance by some species of *Candida* appeared very quickly (176,177). One particular *Candida* species, *C. krusei*, is intrinsically resistant to fluconazole, whereas isolates of *C. glabrata* and *C. albicans*, which are initially susceptible, may become resistant during treatment (178,179).

SPECIAL PATIENTS AND NOSOCOMIAL INFECTIONS

Elderly Patients

Higher incidence rates of HAIs have been documented among patients older than 60 years of age (5,6). The period between birth and the sixth decade has a constant and estimated risk for NI at approximately 10 per 1,000 discharged patients. After age 70, the risk rises sharply to 100 per 1,000 discharges (180). Gross and coworkers, showed that although the elderly (over 60 years old) made up 23% of hospitalized patients, they accounted for 64% of all NIs recorded. Moreover, when the group size was narrowed to patients over 70 years of age, the numbers were even more amazing, comprising only 9.9% of the patient population but accounting for 43.4% of the HAIs (180). Another study showed that more than 40% of NIs occur in persons 70 years of age and older; however, this age group accounts for only 10% of the discharges (77). One probable reason for progressive impairment of host defenses with aging leading to elevated rates of NIs, is the diminution in cell-mediated and humoral immune responses in the elderly population (77). In addition, many age-associated physiologic and anatomic changes, such as diminished ciliary function in clearing secretions, alteration of oral flora, decline of gastric acidity, and drier and thinner skin with less circulation, may predispose these patients to potentially severe nosocomial infections (181). Urinary and respiratory tract infections are the most common HAIs in the elderly (182). Most cases of UTI among elderly patients, whether or not symptomatic, are related to the use of an in-dwelling urinary catheter, particularly in females (5). In a surveillance study, 123 out of 300 elderly patients had in-dwelling urinary catheters, and 44% of these developed UTIs (183) (see Tables 7 and 8).

Table 8. Hospital-Related Risk Factors for Catheter-Associated Infection

Type of catheter (more risk with plastic than with steel)
Location of the catheter (central more than peripheral; femoral more than jugular/subclavian)
Type of placement (cutdown associated with greater risk than percutaneous placement)
Duration of placement (at least 72 hours is associated with greater risk than placement less than 72 hours)
Emergence (emergent placement carries more risk than elective)
Skill of venipuncturist (others associated with greater risk than IV team)
Type/use of catheter (percutaneously placed central venous catheters [CVC] carries greater risk than implanted CVC)

Source: Taken from Reference (109).

HIV-Infected Patients

The overall hospital-acquired rates for HIV-infected patients and patients with Acquired Immunodeficiency Syndrome (AIDS) fall within the range of 6 to 10% (184–186); however, this data may be underestimated owing to delayed or atypical presentation of nosocomial infection in that particular category of patients (187). When patients with AIDS are hospitalized, they carry greater risk for NIs and higher mortality rates by virtue of their compromised host status (184,186,188). Although no established relationship between $CD4^+$ cell counts and the rate of NI has been recorded in these patients to date, the depletion of $CD4^+$ lymphocytes below 250 per mm^3 may increase their risk for HAIs (189). The risk for HAIs may be even more significant when those patients have their immune status impaired because of non-Hodgkin's lymphoma, CMV infection, and wasting syndrome (188). In comparison to non-HIV-positive patients, bloodstream, urinary, and respiratory tracts are demonstrated to be more often associated with NIs in HIV-infected patients (186,190). At least five opportunistic diseases (tuberculosis, cytomegalovirus, herpes simplex virus, bacterial pneumonia, and cryptosporidiosis) are known to be transmitted nosocomially among immunosupressed patients, affecting HIV-infected patients in particular (191).

Mycobacterium tuberculosis infects one-third of the world's population, with a mortality rate of three million deaths per year (192). The incidence of HIV-associated tuberculosis has been increasing worldwide since the beginning of the AIDS pandemic in the 1980s (193), particularly because HIV-infected patients seem to be at increased risk for tuberculosis infection and tuberculosis patients are at increased risk for HIV infection (194,195). The World Health Organization estimated there will be approximately 10.2 million new cases of active tuberculosis among HIV-infected patients by the year 2000 (196). Africa comprises 77% of the world's coinfected patients, with Asia accounting for 10%. In the United States, rates range from zero (Montana) to 47% (Florida) (197). The coexistence of *M. tuberculosis* and HIV-1 accelerates the development, worsens the severity, and amplifies the transmission of tuberculosis (198). During an outbreak documented in a chronic-care facility in San Francisco, 35% of patients with AIDS who were exposed to the index case developed active tuberculosis within four months (199). Among exposed HIV-infected patients, high attack rates of active disease associated with high mortality rates justify the concern of early diagnosis and the isolation of suspected new cases before nososcomial transmission can occur, in particular, when there is a chance for the spread of multidrug-resistant tuberculosis (MDR-TB) cases (191). In an outbreak affecting 27 HIV-infected patients in a New York hospital within a median time range of 7 weeks after the diagnosis of MDR-TB, 21 had died (200).

In a setting of nontuberculous nosocomial respiratory diseases, bacterial pneumonia represents 21% of the NIs diagnosed in HIV-infected patients (185,187,201), and *S. pneumoniae*, *S. aureus*, and *Pseudomonas* spp. are the most common pathogens isolated from respiratory specimens (185,202). In fact, among all gram-negative organisms, *Pseudomonas* spp. accounts for 16 to 67% of nosocomial pneumonias. Nosocomial bacteremia is another clinical problem diagnosed in patients with AIDS (203). *Staphylococcus* sp. and *Pseudomonas* sp. account for a higher proportion of the bacteremias seen in patients with AIDS, most of which appear to be related to in-dwelling venous catheters (204). Urinary tract infection is also a common NI in HIV-infected patients related to the use of plastic devices. Goetz and coworkers (185), showed that among 32 NIs in HIV-infected patients, the urinary tract accounted for nine infections, and eight of these patients had a urinary catheter.

Oncologic Patients

Oncologic patients account for as many as 12% of HAIs (205). When the concept of empiric antibiotic therapy was first introduced, bacteremia was reported to affect approximately 20% of febrile patients with neutropenia (206). The advances in antimicrobial therapy and supportive measures (such as blood and nutrition supplies), as well as more potent antineoplastic chemotherapies and bone marrow transplantation, have improved the long-term survival and quality of life in patients with hematological malignancies and solid tumors (205,207,208). Nevertheless, infection remains the most significant complication of therapy in these patients, particularly when they had undergone myelosuppression (reduction of blood cell production by the bone marrow). Neutropenia, regardless of whether induced by therapy or as a consequence of the underlying disease, is the main risk factor for the development of serious and life-threatening infection (89,209). The cytotoxic chemotherapy can decrease the absolute neutrophil count below 500 cells/mm^3 and worsen its function, therefore dramatically increasing the patient's susceptibility to infection (207,210). A prospective study of bacteremia in neutropenic patients from a single institution showed an increase in the rate of nosocomial infection over an eight-year period by 40% (211).

Until the 1990s, gram-negative bacteria, especially *P. aeruginosa*, were responsible for 60 to 70% of the infections in oncologic patients with an elevated mortality rate (212,213). Among 22 patients with a diagnosis of lymphoma, leukemia, or solid tumor who developed *P. aeruginosa* bacteremia, half died within 72 hours from the time the first positive blood cultures were drawn (206). Likewise, in nononcologic patients, there was a clear shift in the etiologic agents responsible for NIs among patients with cancer during the 1980s, with an upward trend in gram-positive organisms (214). Of these gram-positive organisms, *S. aureus* and coagulase-negative *Staphylococcus* were the most frequent isolates (215,216), followed by *V. streptococci* and *Enterococccus* sp. (76,217). Since the 1990s, and continuing recently, 60 to 70% of bacteremias with a single organism affecting granulocytopenic patients with cancer have been because of gram-positive cocci (218–220) (see Table 9).

Extensive use of in-dwelling intravenous catheters, potent chemotherapeutic regimens resulting in oral and gastrointestinal mucosal damage and neutropenia, and the use of antacids, fluoroquinolone, and

Table 9. Bacterial Isolates from Cases of Bacteremia Owing to a Single Organism from the IATC of the EORTCT

Trial	Total No. of Isolates	Gram-Negative	Gram-Positive
I: 1973 to 1976	145	103 (71%)	42 (29%)
II: 1977 to 1980	111	74 (67%)	37 (33%)

trimethroprim-sulmethoxazole prophylaxis are factors that have been associated with the high frequency of infections caused by gram-positive bacteria in oncologic patients (217,221–223). Moreover, the use of empiric, broad-spectrum antibiotic therapy and antifungal prophylaxis on febrile neutropenic patients has predisposed them to fungal infection, mainly caused by *Candida* sp. (224,225). *Candida albicans* is the most prevalent (70), yet other more resistant non-*albicans* species of *Candida* have been found colonizing and infecting these patients (226). Although the outcome in these patients have improved more recently, the mortality rate of NI is still around 20 to 25% (227,228) and varies according to the pathogen responsible for the infection (211,226,229). Poor prognostic factors such as uncontrolled cancer, shock at the onset of bacteremia, and prolonged neutropenia have been reported (227–230).

Intensive Care Unit Patients

Patients in ICUs represent only a very small percentage of hospital admissions (231); however, these patients suffer a disproportionate percentage of NIs compared with patients in noncritical care areas (31,62). Nosocomial bloodstream infections may occur two to seven times more often in ICU patients than in general ward patients (47). Usually, patients in ICUs are more severely ill and more often require invasive procedures and life support (62). Intravenous central-line and cardiovascular monitoring, mechanical ventilation, in-dwelling urinary catheters, and surgery can breach normal host defenses allowing progression of endogenous flora from colonization to infection in individual patients, as well as exogenous flora transferred from other patients or the environment (231–233). The crescent use of empirical, broad-spectrum antibiotic therapy in ICU patients is another important issue influencing their outcomes. Among 6,250 ICU patients studied in a point prevalence survey over 17 countries in Europe, 62.3% were receiving at least one antimicrobial on the day of the study (233).

Survey studies in ICUs in the United States have shown different pathogen distribution according to the site of infection (47,231). Richards and coworkers (62), found that 65% of bloodstream infections in adult medical ICUs were caused by gram-positive agents (coagulase-positive staphylococci, *S. aureus*, enterococci), whereas gram-negative aerobes (*K. pneumonia* and *P. aeruginosa*) and *C. albicans* were reported in only 17 and 11% of the cases, respectively. On the other hand, gram-negative organisms accounted for 64% of the nosocomial pneumonias and 40% of urinary tract infections, whereas gram-positive bacteria were less frequently identified at approximately 20% of each. A sharp increase in *Candida* sp. isolation was noticed when it was related to nosocomial UTIs. Species of *Candida* accounted for more than 30% of the nosocomial UTIs.

PROGNOSIS

HAIs have been recognized for more than a century as critical problem adversely affecting a patient's outcome and the quality of health care (1). In the United States today, NIs affect more than two million patients annually and contribute to more than 88,000 deaths — one death every 6 minutes (10,13). Of all the major complications of hospitalization, NIs account for 50%; the other 50% is related to medication errors, falls, and other noninfectious adverse events (8).

The adverse effects of HAIs have been measured by either increased mortality rates or prolonged hospitalization leading to an excess of health care costs of $4.5 billion per year (9–12) (see Table 10 with references). A survey study in France showed that the cost of antibiotic treatment for NIs represented a significant part of the hospital expenditure and, among the currently available drugs, third generation cephalosporins and parenteral fluoroquinolones are the most expensive (234). Pittet and coworkers (12), reported approximately 24 days extra length of hospital stay time and extra costs of $40,000 per survivor attributable to the average nosocomial bloodstream infection.

Despite the entire relevant progress in the management of critically ill patients, the fatality rates associated with HAIs remain very high (35). The mortality attributable to NI (which means the mortality associated with the infection and apart from the mortality related to underlying disease) averages between 7 and 9% (35,236) and may vary according to the organism involved (83,229,236–240) and site of infection (see Tables 11 and 12 with references). Shock is another variable that has been found to be independently associated

Table 10. Overall Estimated Morbidity, Mortality, and Cost of Nosocomial Infections

Author	Location	Number of Infected Patients	Infection Rate (%)	Mortality (%)		Excess Length of Stay (days)	Average Cost per Patient ($)
				Overall Mortality	Attributable Mortality		
Haley	All patients	9,423	5	—	—	4 (max. 68)	1,833 (max. 41,628)

with increased mortality, especially among patients with gram-negative bacteremia, even though gram-positive organisms are the most common causes of nosocomial bloodstream infections (228,230,239,241,242). Other issues significantly associated with poor prognosis include sepsis, inappropriate empiric antimicrobial use, severity of the underlying disease, polymicrobial bacteremic episodes, hospitalization in ICUs, multiorgan failure, and adult respiratory distress syndrome (243–246). Moreover, it has been observed that disseminated nosocomial candidemia can itself be an independent predictor of mortality, overcoming the expected mortality rate of severe underlying diseases (224,229).

ENVIRONMENT AND NOSOCOMIAL INFECTIONS

Many reports have demonstrated the important role played by the hospital environment on the development of NIs among both sick patients and healthy people (247,248). The hospital environment is the most significant reservoir of resistant microorganisms (249). In the 1950s, extensive contamination of the environmental surfaces by *S. aureus* was documented in the rooms of patients with staphylococcal infections (247). At that time, investigations showed that healthy adults exposed to a hospital environment had a four time greater chance of developing NIs by *S. aureus* than those not exposed (247). Even higher indices of environmental contamination occur when patients have methicillin-resistant *S. aureus* in a wound or urine. They frequently contaminate objects in their rooms including bed lines, over-bed tables, patient gowns, and pressure cuffs (250). *Staphylococcus aureus*, *P. aeruginosa*, and *E. coli* can survive for approximately four weeks on a clean, dry surface. In addition, *S. aureus*appears to be viable on cotton strings and blood protein coagulum for up to six months, whereas the *P. aeruginosa* and *E. coli* survival can be even longer on similar wet and fibrous surfaces (248). Vancomycin-resistant enterococcus (VRE) is another microorganism with prolonged survival on hands, gloves, and environmental surfaces, predisposing patients to nosocomial transmission (146). In a survey study, Enterococcus was recovered from countertops, bedrolls, telephones, and the diaphragmatic surface of stethoscopes after 7 days, 24 hours, 60 minutes, and 30 minutes after inoculation, respectively (251).

An estimated 8,000 to 18,000 cases of Legionnaires' disease occur each year in the United States (252). Of the cases reported to CDC, approximately 23% are nosocomial with a mortality rate reaching as high as 40% (253). Even before the first bacterium was isolated, the first cases of nosocomial Legionnaires' disease dated back to the 1960s and 1970s (254) in patients suffering from underlying chronic disease, immunosuppression, or who were on corticosteroid therapy (255–257). Since then, numerous nosocomial outbreaks have been frequently described among transplant patients (258,259). The hospital water distribution systems have been implicated as the source of transmission because there are restrictions on maximal hot-water temperatures, making these systems ideal for amplification of *Legionella* growth (260,261). Cooling towers and tap water used for cleaning respiratory-therapy equipment have been linked to some outbreaks, as well (262–264). One study conducted in a transplant center showed that *Legionella* can colonize a hospital potable water system for long periods of time, resulting in a silent nosocomial transmission for as long as 17 years (265).

The hospital environment also plays a crucial role in the spreading of *Aspergillus* spp. (266). This fungus releases spores, which remain airborne or on dry surfaces for prolonged periods (267–269). In the presence of water, spores will germinate and mycelial growth will occur with subsequent sporulation (270). The primary route of acquiring *Aspergillus* infection is by the inhalation of spores and their deposition in both the upper and lower respiratory tract (271). Several potential sources for *Aspergillus* spores in hospital air have been described as follows: inadequate filtration of outside air (272,273), dust with high concentrations of spores (274), spices that are used for food preparation (275), the soil of potted ornamental plants, and fresh fruits (276,277). Immunocompromised in-patients, especially neutropenic patients, may develop nosocomial invasive aspergillosis present with pneumonia when exposed to high concentrations of airborne *Aspergillus* spores, with *Aspergillus fumigatus* being the most clinically relevant species identified from these patients (271,278). There have been many studies addressing the relationship between the concentration of airborne spores and the risk of invasive disease, especially in neutropenic patients; however, a dose-response relationship has not been established. Arnow, and coworkers (275), showed that an increase in mean concentrations of *A. fumigatus* and *Aspergillus flavus* spores from less than 0.2 to greater than 1 spore cubic meter of air was accompanied by a fourfold increase in the incidence of invasive aspergillosis from 0.3 to 1.2% in immunocompromised patients. Yet, in a more recent study, the occurrence of six cases of invasive aspergillosis could not be linked to changes in the recovery of airborne *Aspergillus* spp. spores (268).

PREVENTION AND CONTROL MEASURES

Infection control and prevention has been proven not only effective in reducing the morbidity and mortality associated with NIs, but to also be cost-effective (279–281). Modern infection control is grounded in the work of Ignaz Semmelweis who, in the 1840s, demonstrated the importance of hand hygiene for controlling transmission of infection in hospitals (10). Hand washing with antiseptic soaps remains the cornerstone of infection control, especially in the ICUs where the most severely ill, and therefore more susceptible, patients are located (282,283). A survey study of physicians' stethoscopes showed that bacteria can survive on its diaphragmatic surface for long periods of time, suggesting that stethoscopes may be a vector of cross-transmission. In addition, the study also showed that no bacteria could survive after disinfection with 70% alcohol or liquid soap (284).

Approximately one-third of NIs are preventable; however, several strategies other than changing human

behavior about hand washing should be pursued in order to meet this level (281). Some of these measures represent improvement of the national surveillance of NIs among in-patients and post-discharge patients (10), implementation of antibiotic control programs in order to decrease the emergence of highly resistant strains (285), and development of newer microbiologic methods (mainly molecular epidemiology) for the investigation of and understanding about multiresistant pathogens (286).

Moreover, it is worth noting that some groups of pathogens need specific control measures. Filtration of air coming into patients' rooms by Hepa filters, laminar airflow, well-sealed rooms capable of achieving high rates of air changes, and positive room air pressure relative to the corridor are all crucial measures implemented by infection control personnel in order to avoid air contamination and cross-infection with *Aspergillus* spp., principally in transplant units (287,288). Likewise, effective *Legionella* eradication methods in the hospital water distribution systems with the superheat-and-flush method, hyperchlorination, and, more recently, copper-silver ionization, have proven to prevent most of the hospital-acquired Legionnaires' disease infections (289).

CONCLUSION

The relationship governing infection can be described as follows:

$$\text{Infection} = \frac{[\text{number of microbes encountered}] \times [\text{virulence characteristics}]}{\text{Immune status of the host}}$$

Environmental microbes in a hospital setting can pose a significant risk. Whereas the concentrations of environmental microbes found naturally in the environment tend to be low, there are abundant opportunities for amplification. For example, small numbers of microbes can colonize a faucet aerator and significantly multiply in numbers. Whereas the virulence factors of environmental bacteria tend to be low, during amplification those with human pathogenic potential may be selected. Hospitalized patients tend to lose levels of both passive (e.g., intact skin through intravenous device) and active, (e.g., through medical therapy) immunity. Accordingly, care and vigilance must be constant to avoid hospital-induced infections from environmental microbes.

NUCLEAR WASTE RESPOSITORY IN YUCCA MOUNTAIN: MICROBIOLOGICAL ASPECTS

PENNY S. AMY
University of Nevada
Las Vegas, Nevada

DANA L. HALDEMAN
Community College of Southern Nevada
Las Vegas, Nevada

Yucca Mt. is the proposed site for the United States' first permanent high-level nuclear waste repository. The mountain is composed of volcanic ash, compressed and geochemically modified over millions of years. It is located approximately 125-km northwest of Las Vegas, Nevada. Yucca Mt., rests on land owned by a variety of federal agencies, and is protected by the isolation afforded by the federal government. The mountain itself is considered to be a safe disposal site because of the arid climate of the region, a geologic structure composed of hundreds of meters of vadose zone (unsaturated rock), and a deep groundwater level. The site is now perhaps one of the best studied physical structures on earth, having been the center of concerted research efforts since the 1980s. Life abounds within the mountain, but it is invisible and unknown to the casual observer. This article describes the microbial life within, and its potential effects upon, the Yucca Mt. repository.

THE REPOSITORY

Yucca Mt. is a long sloping mountain that abuts the southwestern boundary of the Nevada Test Site (NTS) (Fig. 1). The mountain is composed of multiple layers of bedded or nonwelded, and welded, volcanic ash (tuff) that was deposited 9 to 13 million years ago (1). Welding refers to the high temperature at which a geologic stratum was deposited, making the rock extremely hard and of low permeability. In addition to the welded nature of the tuff, it also holds very little water. The repository layer is approximately 300 m from the mountain surface and 275 m above the water table (2). The welded nature of the tuff, the deep dry vadose zone, and the isolation from large population centers make Yucca Mt. a desirable site for the permanent burial of high-level nuclear waste.

In 2002, the Department of Energy (DOE) will apply to the Nuclear Regulatory Commission for a license to excavate the repository, transport nuclear waste from remote sites, and deposit it at Yucca Mt. High-level nuclear waste is currently located throughout the United States and consists of spent nuclear fuel from submarines and nuclear power plants. The development of a permanent repository site is critical because waste has been placed in temporary facilities in which long-term storage may not have been considered (Fig. 2).

The design of the repository is quite unique. It will be built at the midpoint of a large "U" shaped tunnel of approximately 8 km in length (Fig. 3). The tunnel, called the Exploratory Studies Facility ESF, is 7.6 m in diameter, with both north and south portals. As you enter the

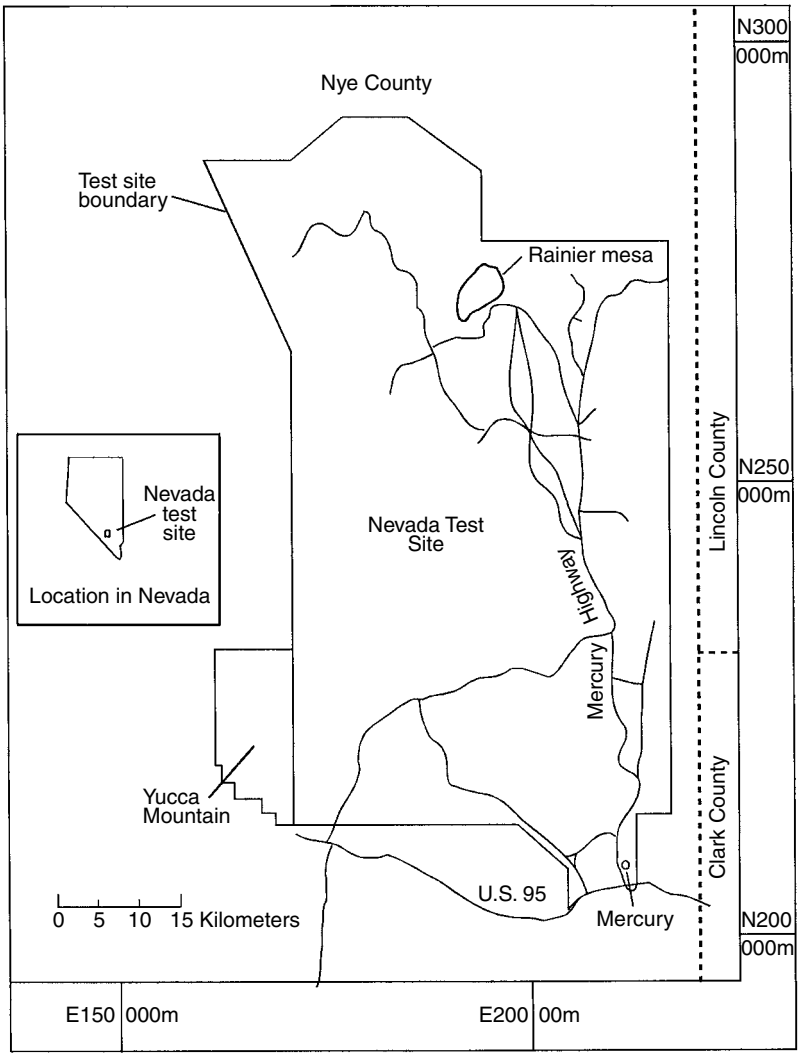

Figure 1. Location of Yucca Mountain relative to the Nevada Test Site. Reprinted from (3).

ESF, the tunnel slopes downward until reaching a welded tuff formation at the proposed repository depth: in the Topapah Springs member of the Paintbrush Tuff (Fig. 3). The ESF was mined using a tunnel boring machine (TBM) that was assembled just outside the north portal and disassembled outside the south portal when the shaft was completed. The TBM was electrically powered to reduce contamination of tunnel walls by diesel combustion products.

One aspect of repository design has been directed to the "near field," which is the environment immediately surrounding the waste packages. The near field is expected to initially experience high levels of radioactivity and heat following emplacement of high-level waste materials. As a result, water will be driven out of the near field by the intense heat. Desiccation of the immediate area will occur for an extended period of time. A second aspect of repository design concerns the "far field," an area surrounding the repository at a greater distance from the waste canisters. The far field merits investigation because it is a potential safe haven for microbes during the initial phase of the repository. This area is expected to be heated to a lesser degree and to contain higher than usual moisture content, conditions that will support microbial survival (6). In this article, we report on investigations that affect both the near- and far-field portions of the repository.

YUCCA MOUNTAIN

Yucca Mt. has been under investigation as a potential repository site since the mid 1970s. An extensive site characterization effort took place in the 1990s to investigate the geology, geochemistry, hydrology, and biology of the mountain. Microorganisms were known to be ubiquitous in subsurface environments (7–10), and therefore, investigation of their presence, abundance, metabolic potential, and taxonomy were of interest to the characterization effort. Characterization of the microbiology of Yucca Mt. was undertaken by scientists at several universities in conjunction with those at Los Alamos National Laboratory, a DOE facility in New Mexico.

Microbes are important to repository design because their activities may impact the long-term stability of the repository structures. Microbes can facilitate the

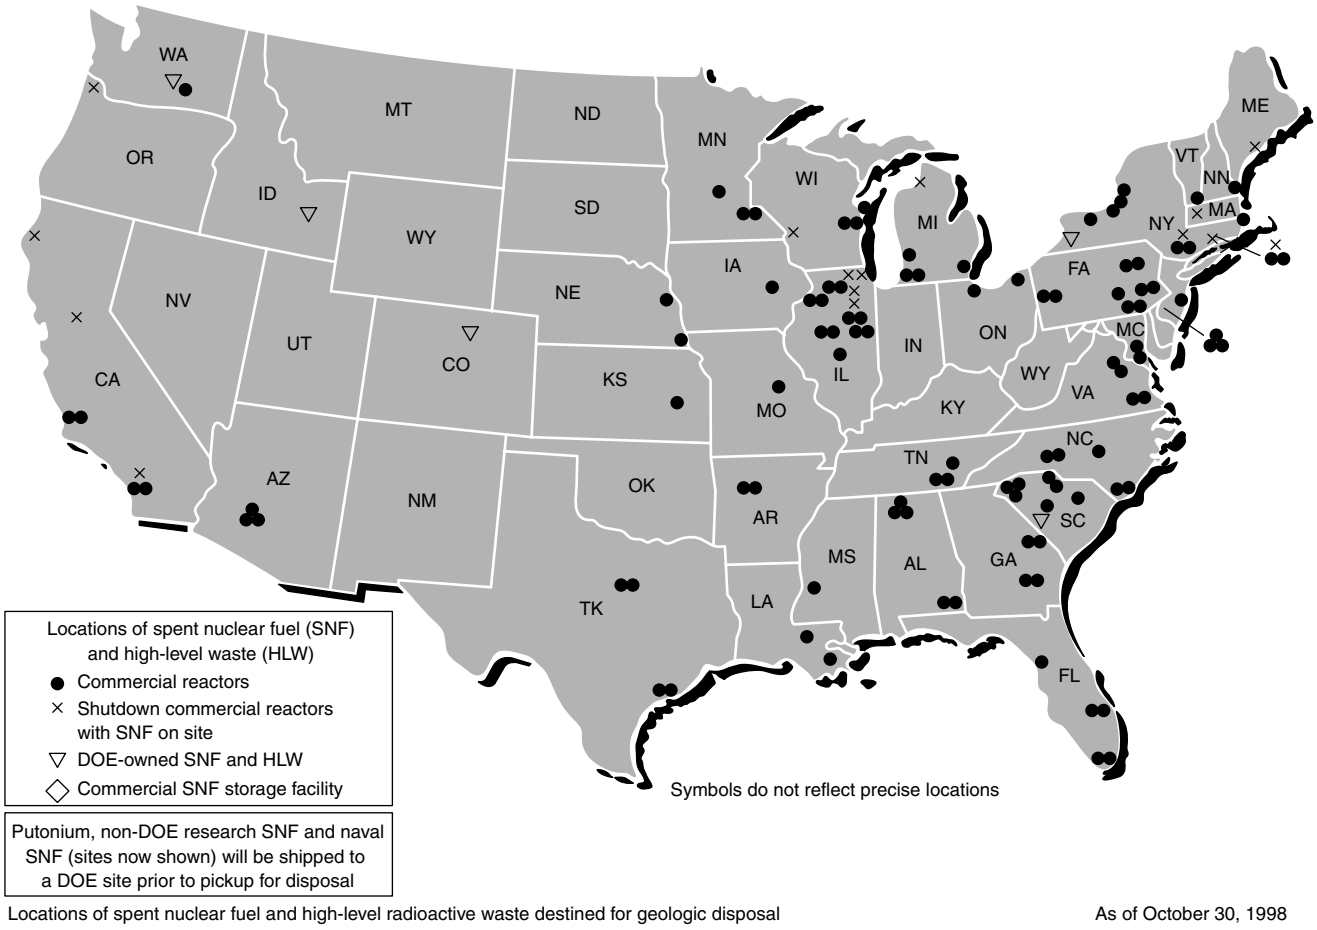

Figure 2. Locations of spent nuclear fuel and high-level radioactive waste destined for geologic disposal, as of October 1998. Reprinted from (4).

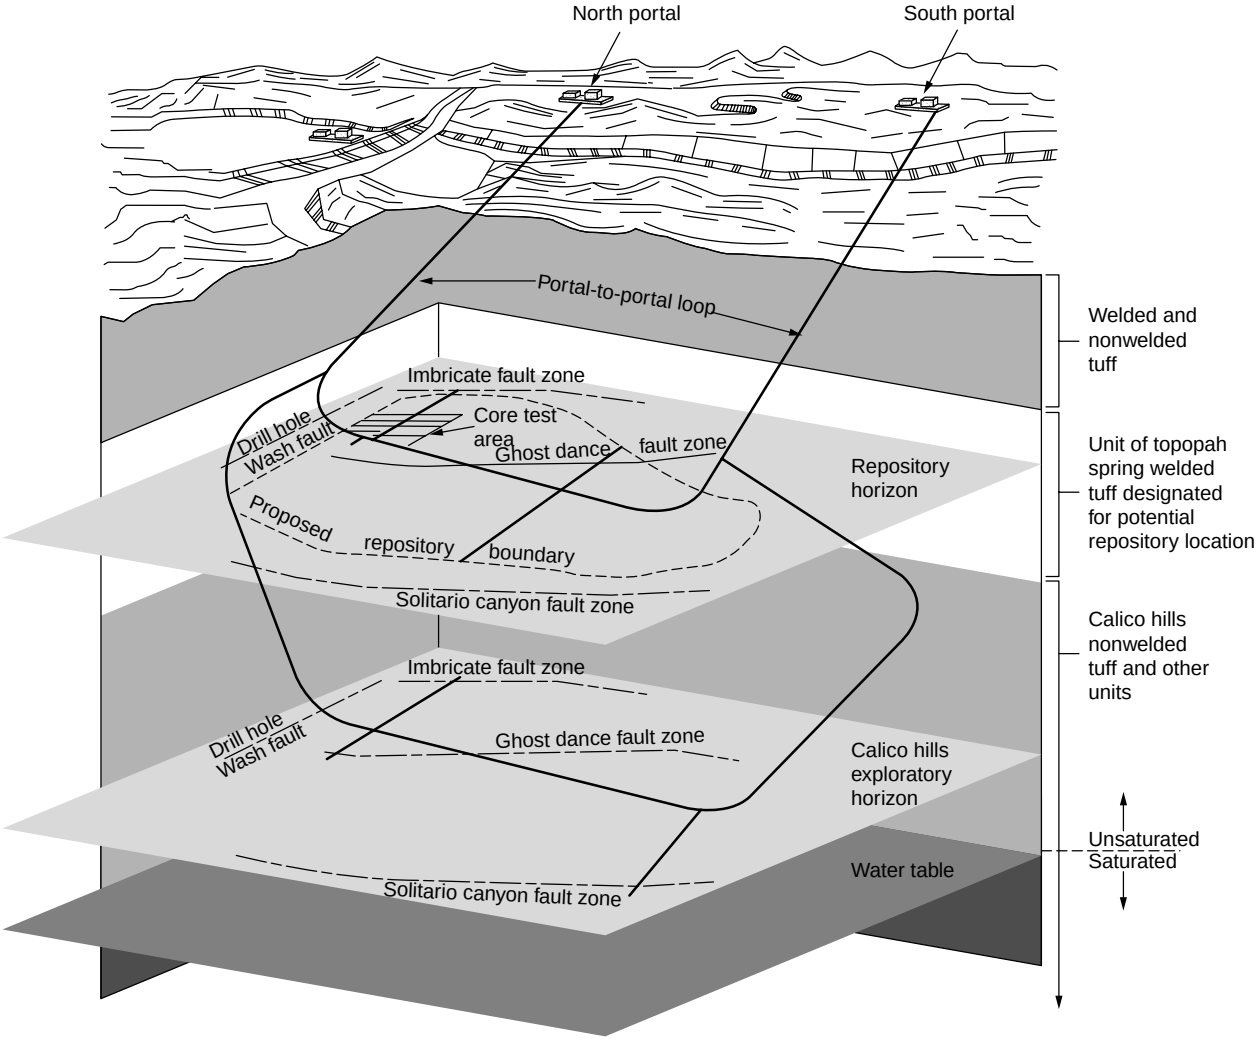
corrosion of waste-containment canisters (packages) and may bind radionuclides, enhance, or retard their transport. If microbes are present, they will impact repository stability. It is necessary to consider the potential activity of microbes, whether their actions are immediate or long-term, when building a repository that must last 10,000 years.

Site Characterization

During the excavation of the ESF in 1995, a team of investigators, led by Larry Hersman of the Los Alamos National Laboratory in New Mexico, sampled at nine locations in three geologic formations. The sampling scheme spanned the distance from the ESF portal to the repository depth (Fig. 4). The samples were obtained as the TBM progressed through the ESF; from rock remote to, adjacent to, and within large fractures shortly after the passage of the TBM (11). An extensive sampling and quality assurance plan was followed during the investigation (11,12).

The goal of this project was to determine bacterial abundance and diversity. Enumerations included total direct and culturable aerobic heterotrophic cell counts. Further analyses determined factors limiting microbial growth and activity and included enrichments to determine chemoautotrophic metabolic potential. Numbers of total and culturable aerobic heterotrophs were highly variable among samples and ranged from 3.2×10^4 to 2.0×10^5 and 1.0×10^1 to 3.2×10^3, respectively, per gram dry weight (11). Phospholipid fatty acid (PLFA) and diglyceride fatty acid (DGFA) analyses were used as a second measure of microbial abundance. This was particularly useful because the amount of PLFA is indicative of living biomass, whereas DGFA provides a measure of dead biomass. By comparison, total direct counting does not discriminate between live and dead cells and is less useful in determining community composition and metabolic status. The PLFA values were low compared with a similar subsurface environment at the NTS in which higher water content supported greater bacterial biomass (9,13). The nature of welded tuff and the lack of water in the vadose zone of Yucca Mt. were critical in repository site selection; nonetheless microbes were present in substantial numbers.

Experiments to determine factors that limit microbial growth involved nutrient addition to crushed rock; unamended crushed rock was used as a control. The act of perturbing the environment has been shown to stimulate microbial proliferation and perhaps resuscitation (14–16).



Note: Configuration of fault zones at depth is inferred.

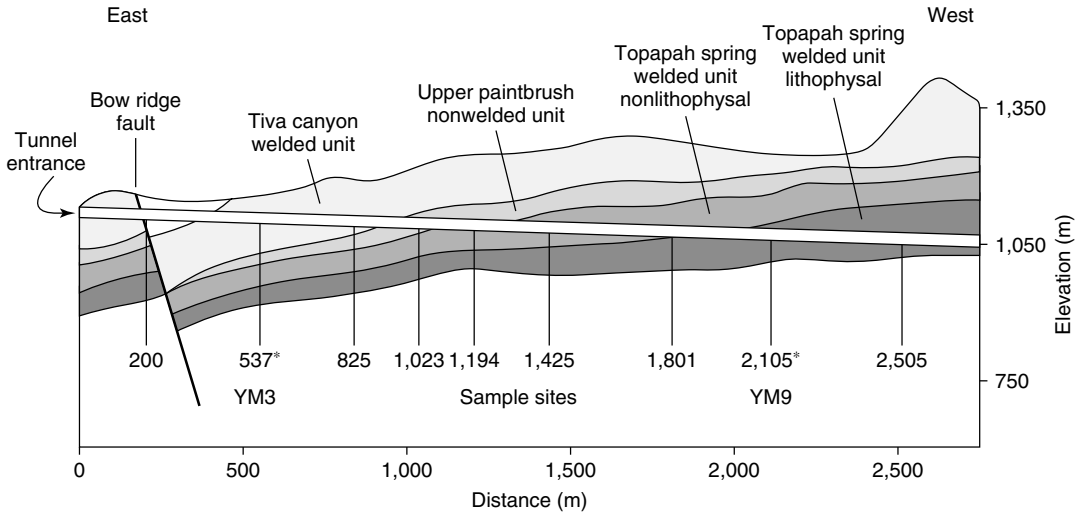

Figure 4. Cross section of Yucca Mountain showing the portal entry and proposed repository depths. Modified from (11) and reprinted from (3).

Crushed rock with no nutrient or water additions supported an increase in bacterial numbers. The original design of the repository placed crushed, mined rock around the packages as backfill in the repository structure. Because crushed rock demonstrated increased microbial numbers and activity, current design takes the potential for microbial activity into account and provides for quartz sand backfill and a protective drip shield over the packages (Fig. 5).

The addition of carbon substrates to the crushed rock further enhanced microbial growth compared with controls, a nitrogen source (ammonium nitrate), or a phosphorus source (potassium phosphate) during a 24-hr incubation (11). Mineralization of carbon substrates (glucose, glutamate, and acetate) was significantly increased by the presence of water but not further increased by nitrogen or phosphorus (11). It appears that lack of water is the most significant limiting factor to microbial growth and activity in the subsurface at Yucca Mt. Ironically, the TBM uses large amounts of water during the mining process so that previously dry rock increased in water content during the creation of the ESF. Additionally, water present in

Table 1. Metabolites of Bacteria

Microbial Types	Carbon Source	Oxidizable Substrate	Oxidized Product	Terminal Electron Acceptor
Ammonia oxidizers	CO_2	NH_4^+	NO_2^-	O_2
Nitrite oxidizers	CO_2	NO_2^-	NO_3^-	O_2
Sulfur oxidizers	CO_2	H_2S, S, $S_2O_3^{-2}$	SO_4^{-2}	O_2; sometimes NO_3^-
Iron Oxidizers	CO_2	Fe^{+2}	Fe^{+3}	O_2
Aerobic heterotrophs	Organic Carbon	Organic Carbon	CO_2	O_2

the repository structure and augmented by the TBM mining process will be concentrated during the initial heating phase of the completed repository as it is driven out of the near-field environment.

Using the same samples taken during the site characterization described above, personnel in the Environmental Microbiology Laboratory at UNLV prepared enrichment cultures for autotrophic microorganisms (Table 1). Autotrophic enrichments for nitrifying bacteria (nitric acid production), sulfur-oxidizing bacteria (sulfuric acid production) and iron-oxidizing bacteria [ferric oxide (rust)] production were prepared in appropriate media (18,19). Sterile rock served as a negative control and American Type Culture Collection (ATCC) cultures of *Nitrobacter* and *Thiobacillus* spp. served as positive control cultures. These bacterial types were investigated because of their importance to microbially influence corrosion. Nitric acid produced by nitrifying bacteria has been shown to degrade concrete (20,21), and iron and sulfur-oxidizing bacteria have been implicated in the corrosion of metals (21–23). In fact, microbes are so proficient at degrading some structural materials that researchers have recently used them to degrade radioactively-contaminated concrete in a purposeful manner (24). Heterotrophic bacteria are also implicated in microbially influenced corrosion (MIC) (see Section Microbially Influenced Corrosion).

Results indicated that all three types of autotrophic bacteria were present, although not in every sample. Iron-oxidizing bacteria were most common, being enriched from nearly all samples. In fact, iron-oxidizing bacteria are common across the entire NTS. They were easily cultured from Yucca Flats (25,26) and Yucca Mt. (28) and, therefore, if some sites do not currently contain iron-oxidizing bacteria, they have the potential to become contaminated with them as the repository is constructed. Sulfur-oxidizing bacteria were not as common, but were present in many samples, whereas nitrifying bacteria were more infrequently found, often in only one of several replicates (3).

Heterotrophic bacteria from the same rock samples were enumerated using the method of Haldeman and coworkers (13). Isolates were obtained, purified, and tested by the MIDI system (Microbial ID Inc., Newark, DE). MIDI uses a fatty acid methyl ester profile to render the identification of an unknown bacterial culture. MIDI analysis often led to only a tentative identification of individual isolates from heterotrophic platings; approximately 50% of the isolates were identified. Because environmental microorganisms have not traditionally been characterized to the same extent as those of medical importance, many have not yet been added to the MIDI database. However, the relationship of unknown or unidentified isolates to those that were known was provided by dendrograms of the isolates (Fig. 6).

Although attempts were made to isolate anaerobic bacteria from each of the strata, none were isolated (11). The endolithic environment of Yucca Mt. and surrounding tuffs is highly aerobic and perhaps shipment of samples to another site contributed to the loss of anaerobes after sampling.

Phylogenetic Study

Following the general site characterization of microbiology of Yucca Mt., a phylogenetic study of the types of culturable and uncultured bacteria from two rock strata, YM3 and YM9, was initiated (3). YM3 rock samples were obtained from the highly fractured Tiva Canyon welded unit located 537 m into the ESF from the portal. The second sample, YM9, was obtained from the Topapah Springs welded unit more than 2,105 m into the ESF. YM9 is at the repository level, approximately 300 m below the mountain surface, and is composed of unsaturated tuff with relatively low permeability (Fig. 4). The samples were obtained in the same fashion as those described above in the general site characterization study. Because under typical conditions a mere fraction of the total microbial community can be cultured using plating or enrichment techniques (29–34), DNA was also extracted directly from rock at the two sites for analysis of uncultured and cultured microbial types. A complex series of manipulations, including amplification of DNA fragments using polymerase chain reaction technology (PCR), cloning techniques, transformation into *Escherichia coli*, and sequencing of the ribosomal RNA gene (rDNA), was undertaken to compare recovered rDNA sequences with those of cultured isolates.

The rDNA of all 19 of the YM3 cultured isolates revealed that they were from gram-positive genera. Seven of the 19 isolates were *Arthrobacter* spp., and all but one of the 19 appeared to fit into either the high G + C gram-positive bacterial group or the Actinomycete group; one isolate matched the low G + C *Bacillus* group most closely. MIDI analysis of the 19 isolates also identified them as belonging to gram-positive genera. Similar results were obtained from the YM9 site. Of the 27 isolates from the YM9 sample, 24 were clustered with the Actinomycete group, a broad grouping of bacterial genera. Among them, *Arthrobacter* spp. were the most common (6 isolates). The remaining three isolates matched gram-negative bacterial sequences of the genera *Pseudomonas* and *Acinetobacter*. Unlike isolates from the YM3 sample, nearly half of these isolates were unmatched to the MIDI database.

Direct DNA extraction, cloning, and sequencing yielded a somewhat different picture of bacterial community composition than that provided by heterotrophic plate counting. After restriction fragment length polymorphism (RFLP) screening to ensure that direct DNA clones were

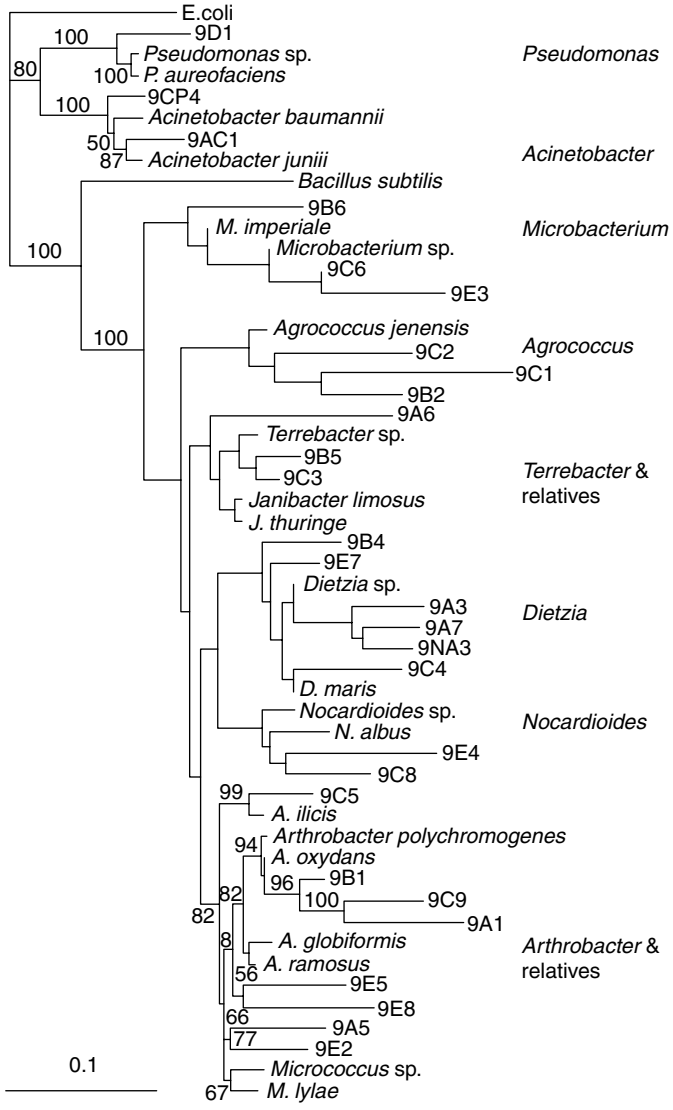

Figure 6. Dendrogram of isolates recovered from Yucca Mt. and analyzed by phospholipid fatty acid profiles (3). Dendrogram based on similarity indices. Euclidean distances of less than or equal to 25 are considered to be of the same genus (27).

each unique, cloned sequences were analyzed. Direct DNA clone sequences from YM3 suggested that the rock contained both gram-positive (43.5%) and gram-negative (56.5%) bacteria. Although gram-negative bacteria were not cultured, direct DNA analysis implied that they were abundant. Gram-positive cell types may be more capable of remaining culturable during long periods of isolation in extremely limited nutrient environments such as those found in the subsurface of Yucca Mt. The contrast between culturable isolates and direct DNA clones was even more dramatic in YM9. Here, only clones resulting from gram-negative bacterial DNA were recovered. Of 84 clones, 90% were from the γ proteobacteria and the remaining 10% were β proteobacteria. Obviously, the full nature of the microbial community was not appreciated when only culturable isolates were considered. For example, in YM9, gram-positive bacteria were cultured, however, they must have represented a minor portion of the bacterial DNA present in the rock because gram-positive sequences were not represented in cloning efforts. At first glance, one might think that perhaps gram-negative bacteria were preferentially amplified from direct rock extractions, however, bias in amplification was ruled out by experiments involving seeding of carbon-free rock with 10 known bacterial isolates, including both gram-negative and positive genera.

The discrepancy between culturable isolates and the nature of the community demonstrated by direct DNA extraction leads to the question: are gram-negative bacterial genes present in dead biomass or living biomass that is viable but nonculturable (VBNC)? Because of the extreme isolation and age of the rock under consideration (pore water age estimated by chlorine dating to be between 5 and 7×10^5 years (11,35); either scenario, or a combination, is possible. Gram-negative cells are well known to enter the VBNC state (28,34,36–39), therefore, some gram-negative DNA represented by direct DNA extraction may be present as VBNC. Alternatively, an indication that some of the microbial DNA is represented by dead biomass comes from the phospholipid fatty acid (PLFA) and diglyceride fatty acid (DGFA) analysis performed during the general site

characterization (samples taken before this study in the same rock formations). Approximately equal values of living (PLFA) and dead (DGFA) biomass lipids were found at YM3 and slightly more PLFA at YM9. In each case, if DNA in dead cells had been preserved, then much of the cloned DNA may have been from dead cells that lived during times up to 7×10^5 years ago.

APPLIED MICROBIOLOGY

Several issues related to the integrity of the repository at Yucca Mt. are considered in this section. The effect of radiation on bacterial survival is a primary concern for long-term stability of the packages and structural materials. Bacterial survival presents the potential for corrosion of the metal packages; whether bacteria survive in the near field or far field and return with condensing water as the near field cools. Biofilm formation, an initiator of the corrosion process, is a second area of concern. A third issue of concern is the potential of repeated upwelling of geothermally heated water within the mountain.

Effects of Radiation on Yucca Mt. Bacteria

Because most work concerning the effects of radiation on bacteria has been designed to deliver lethal doses of radiation for food preservation, little work has been done under conditions of low-dose exposure and with endolithic microbes. An experiment was conducted to supply relatively low doses of gamma radiation (1.63 Gy/min, 0 to 9.34 kGy total, over a six-day period) to native Yucca Mt. bacteria to test their ability to survive. The dose rate was designed to approximate that which might be experienced by bacteria in the far field (for unshielded canisters) or outer near field (if the canisters are shielded). Native bacteria were within rocks that had been aseptically sampled from Yucca Mt. and crushed before packing in sterile graduated cylinders (microcosms). Each microcosm began radiation treatment with approximately 10^7 CFU/gm wet weight. The number of culturable cells had been elevated by incubating the perturbed rock microcosms at room temperature for 14 days. Although culturable cells were obtained at time zero, by the time a dose of 2.33 kGy had been administered, no culturable cells remained. There were three lines of evidence that VBNC bacteria resulted from gamma irradiation doses of 2.33 to 9.34 kGy. Despite the lack of culturability, total direct and respiring cell counts remained relatively high in all samples, indicating that the cells may have lost culturability but not cellular integrity (direct cell count) or viability (respiring cell count). Additionally, rock slurries from irradiated microcosms contained microbes capable of utilizing carbon substrates in BIOLOG (40) carbon substrate microtiter plates through 7.01 kGy of irradiation. Likewise, PLFA and DGFA analysis revealed that although some cell death occurred at the early dosage points, considerable living biomass was still present at 2.33 kGy and remained stable throughout the remainder of the experiment (37).

VBNC cells have been resuscitated from the nonculturable state by a number of environmental stimuli, including changes in temperature, osmotic conditions, or nutrient addition (34,39,41–43). The VBNC cells produced during gamma irradiation were resuscitated by a 2-month long incubation at 4 °C. Culturable numbers of cells from each radiation time point were similar following resuscitation, that is, 10^3 to 10^4 CFU/gm wet weight. Nonirradiated controls, before and after resuscitation, contained 10^8 CFU/gm wet weight and maintained the considerable diversity seen in the original microcosms before irradiation. Irradiated microcosms lost diversity through cell death, and/or creation of VBNC cells. Although nonirradiated cells were capable of utilizing approximately 80% of 128 BIOLOG carbon substrates, irradiated microorganisms were only capable of utilizing 0 to 12% of the same substrates after irradiation. The same microcosm bacteria were capable of utilizing 25 to 30% of the substrates after radiation and subsequent resuscitation. There was no trend in substrate utilization associated with increasing radiation dose, however, carbohydrates and amino acids were most commonly metabolized following resuscitation.

MIDI analysis of isolates placed them into three general groups: approximately 50% mixed gram positives, approximately 30% mixed gram negatives, and approximately 20% *Gordona*/*Rhodococcus*. The percentage of culturable isolates falling into each broad group remained approximately the same between nonirradiated and resuscitated treatments, although the number of recovered colony types was reduced.

Although the time course of the experiments may seem brief compared with the life span of a functional repository, the experiments described here represent a first approach at investigating long-term radiation effects on environmental bacteria. That bacteria experienced a seemingly lethal radiation dose (by culturable counts) and resuscitated in just two months under a change in temperature is significant because cells will most likely remain viable and resuscitate in the repository at some point in the future. Perhaps cells closest to the repository will encounter radiation doses high enough to kill them, however, those more distant to the radiation sources may have the opportunity for resuscitation at a later date.

Isolation of Microbially Influenced Corrosion-Related Isolates from Yucca Mt.

Microorganisms have been implicated in the deterioration of organic, geologic, and metal materials in natural ecosystems (44). When the process involves metals, it is called microbially influenced corrosion or MIC. The bacterial communities associated with MIC can be divided into four metabolic categories: (*1*) sulfate-reducing bacteria (SRBs); (*2*) iron-oxidizing bacteria (FeOx); (*3*) exopolysaccharide-producing bacteria (EPS) and acid-producing bacteria (45,46). In an effort to evaluate the MIC corrosion potential of deep subsurface environments at the NTS, rock and water samples were taken from three locations to characterize and compare their indigenous microbial communities and determine which, if any, of three target MIC bacterial groups were present, that is, SRB, FeOx, and/or EPS-producing bacteria. Bacteria were isolated from Rainier Mesa, Yucca Flats, and Yucca Mt. on the NTS. Both Rainier Mesa and Yucca Mt. were

formed as the result of repeated volcanic ash deposition 9 to 13 million years ago (1) whereas Yucca Flats are the result of ancient alluvial deposits.

Iron-oxidizing bacteria are strictly aerobic and cause biologically initiated rust formation through the oxidation of reduced iron in metals; they were found in six of the eight samples analyzed. Sulfate-reducing bacteria are strictly anaerobic and result in the formation of hydrogen sulfide, which is directly corrosive to metals. Sulfate-reducing bacteria (SRBs) were found in only three of the samples; one from each site. Phospholipid fatty acid (PLFA) analysis of Yucca Mt. rock was indicative of sulfate-reducing bacteria and gram-negative bacteria in general. DNA extracted directly from Yucca Mt. rock also supported the idea of a predominantly gram- negative bacterial community (see earlier text).

Exopolysaccharide (EPS) producing bacteria may participate in both aerobic and anaerobic processes but function as the structural glue for the formation of biofilms on metal or other surfaces. Because of the nature of biofilms, there may be a very different electrochemical differential among parts of the biofilm, allowing for formation of microscale batteries and resulting in the dissolution of metal ions at the anode and deposition of same at the cathode (22,25,46). These activities are best known in aquatic systems in which metal corrosion is a serious problem (47).

Before human intervention at Yucca Mt., the repository level environment consisted of relatively undisturbed highly welded tuff containing very small amounts of water (4%) (25) and nutrients. Despite this, FeOx, SRBs, and EPS-producing bacteria have been cultured from Yucca Mt. We know that microbes of considerable diversity are present even within the deep repository level and that a significant number culturable even under the unfavorable conditions found in the welded tuff. Because of this, the potential for biofilm production and MIC exists under suitable conditions for growth and activity. Construction of the repository has and will continue to perturb the endolithic microbiota, provide considerable water through the drilling process, and add nutrients, either through the process of nutrient rearrangement by physical disruption, water flow, and/or the addition of nutrients (and additional microbes), simply because of human activity and equipment presence.

The next section describes work that has been done to date on MIC of metal candidates for repository packages.

Microbially Influenced Corrosion

Microorganisms known to produce MIC of metals were isolated from an alcove near the north portal of Yucca Mt. before the excavation of the ESF (25). These organisms included bacterial species capable of iron-oxidation, sulfate-reduction, and EPS production. Single bacterial types, combinations of two, and a combination of all three were placed in electrochemical cells designed to test for MIC (Fig. 7; 36). The test system consisted of a 1,020 carbon steel coupon (9.7 cm^2 surface area) embedded in soft R2A agar (0.5%, Difco), prepared using simulated Yucca Mt. pore water (27), in a 40×130 mm glass cylinder. Also, embedded in the soft agar was a platinum wire used as an electrode to supply electrical current to the

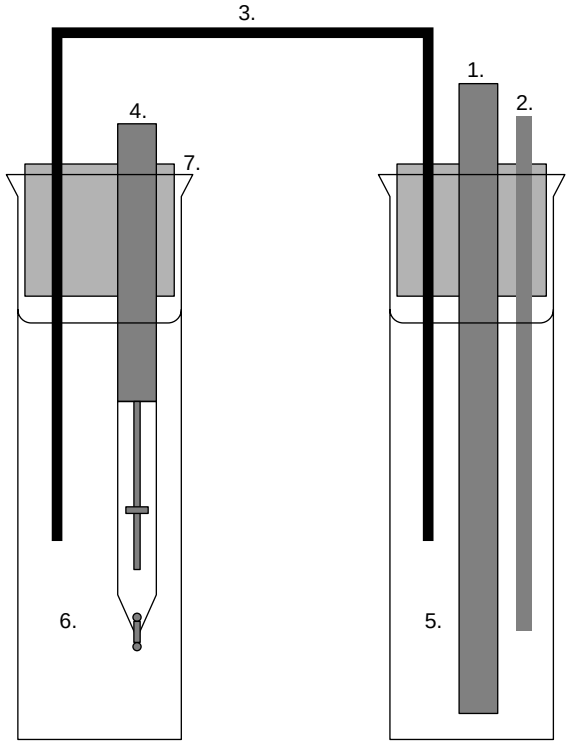

Figure 7. Schematic representation of the electrochemical corrosion cell apparatus (25).

metal coupon. The soft agar cylinder was connected to a reference electrode in a second cylinder containing 5% KCl by a salt bridge consisting of 1% KCl and 1.5% Bacto agar. The entire apparatus was sterilized before construction and monitored for bacterial contamination for three days before inoculation. One milliliter of each bacterial solution (10^7 CFU/ml) was deposited along the surface of the metal coupons just before sealing triplicate cylinders.

Corrosion potential was monitored using hardware from Gamry Instruments, Inc. (48,49). Using polarization resistance measurements, corrosion rates were calculated. Measurements were taken at multiple time points for up to 109 days. When acting independently, each bacterial type demonstrated a corrosion rate that was significantly higher than that of the uninoculated control: SRB > EPS-producers > FeOx. Combinations of microbial types demonstrated even higher corrosion rates with the highest rates occurring when all three bacteria acted in concert. A conditioning film formed on the uninoculated control coupons, although it represented a small fraction of the corrosion demonstrated when bacteria were also present.

In an attempt to measure corrosion potential in an environment more closely matching the Yucca Mt. repository, experiments using the electrochemical cell

apparatus were initiated using crushed Yucca Mt. rock and soft R2A inoculated with all three bacterial types. In addition, because placement of radioactive materials will increase the overall temperature of the surrounding rock environment, the electrochemical cells were incubated at ambient (25 °C), elevated temperature (55 °C), or ambient for three weeks followed by transfer to the higher temperature. Following incubation, biofilms were removed from the coupon surfaces by a freeze-fracture method and were sectioned for electron microscopy (50). Biofilm formation was seen in all inoculated tests at all temperatures. The uninoculated control produced a nonbiological film on the surface of the metal that resulted in low rates of corrosion. Elevated temperatures resulted in higher corrosion rates than the ambient treatment; however, the highest rates were observed when cells were allowed to colonize the coupon surfaces at ambient before a temperature upshift (51,52).

Investigations of MIC at Lawrence Livermore National Laboratory also confirmed the ability of Yucca Mt. microbes to corrode candidate materials for waste-containment packages in the repository. Under conditions similar to those described earlier, their studies demonstrated that titanium alloy, Alloy22, resisted corrosion induced by microbes to a much greater extent than other metals tested (53,54). They too have isolated a number of microorganisms from the endolithic environment of Yucca Mt.'s subsurface, many of which are responsible for MIC (55).

Characterization of microbial isolates and corrosion potential experiments have demonstrated that corrosion-associated microbes are present in Yucca Mt. and are capable of corroding 1,020 carbon steel (a material proposed as the outer shield for waste-containment packages). Elevated temperature enhanced corrosion effects and was particularly evident with the addition of crushed native rock. Hypotheses concerning the movement of water in the repository suggest that heat production will drive water out of the near field and into the far field for some period of time. The exact model for this depends on how the packages are made; some allow for a hotter repository and others a cooler one depending on the design of waste-containment packages. Meanwhile, high radiation levels will undoubtedly inactivate bacteria near the packages for a very long time. As the radiation decays, however, the near field will be cooler, becoming more hospitable for microbial life, and probably allowing surviving microbes to colonize the near field (56). Because it is known that Yucca Mt. bacteria can survive radiation (36,37) and corrode metal at elevated temperatures (51,52), it is probable that bacteria will colonize canister surfaces and be capable of corrosion at some time in the future.

If conditions are right, that is, water, nutrients, and permissive temperature, biofilms will form on canister surfaces. Biofilms formed with each bacterial type and the consortium from Yucca Mt., and therefore, it seems just a matter of time until they will form on metal canisters in the Yucca Mt. repository. The question is, how long will that take? Biofilm corrosive activity will require fairly short periods of time to breach standard carbon steel; however, the inner layer of the package is planned to be made of a titanium alloy.

Biofilms can also form on structural materials other than metal surfaces and are known to deteriorate virtually all materials, including concrete and synthetic polymers (44). To maintain structural integrity, MIC of other repository materials needs to be considered as well. It is difficult to predict what will happen in the next 10,000 years, and therefore, our predictions can be nothing more than educated guesses.

FUTURE STUDIES

Researchers in the Environmental Microbiology Laboratory at UNLV continue to investigate issues of interest to the stability of the Yucca Mt. repository. Biofilms are the most common cause of MIC. Their presence announces the eventual deterioration of a surface, whether it be of metal or other material. If boundaries for biofilm formation can be set using factors of heat and humidity, then models of the repository can more accurately predict the time needed for breaching the packages. Experiments using native rock microcosms with embedded metal coupons are currently under investigation.

ACKNOWLEDGMENTS

The research reported in this article was supported by the Yucca Mountain Site Characterization Office as a part of the Civilian Radioactive Waste Management Program, managed by the U.S. Department of Energy, Yucca Mountain Site Characterization Project. Additional work has been supported by the Yucca Mt. Project Office through TRW. We thank Patti Castro, Abi Igbinovia, Mona Khalil, Theodore Lagadinos, Mike Minev, Chuck Neuwahner, Henry Crossen, Beth Pitonzo, Lisa Ragatz Terry Else, and Yingchung Wu Curt Pantle for their help with sampling and experimentation.

O

OCCURRENCE OF PROTOZOA IN SPENT FILTER BACKWASH WATER

Harish Arora
Mark W. Le Chevallier
American Water Works Service Company, Inc.
Voorhees, New Jersey

In a conventional water treatment plant, raw water is treated by destabilizing the electrostatic charge on particles (coagulation), agglomeration of the destabilized particles (flocculation), settling of the heavier particles, and by filtration of the remaining particles. Filters have a limited capacity to retain solids, and therefore, must be backwashed to remove the retained solids. Accumulation of solids in a filter bed also creates resistance to the flow of water (measured as loss of head for the filter bed). Backwashing may be performed based on a number of different criteria — a terminal headloss, a fixed time interval, or breakthrough of solids (measured as turbidity or particle counts). Generally, plant finished water is used for backwashing the filters. The spent filter backwash water (SFBW) may be treated before its reuse, or disposal. Options for disposal may include discharge to a sewer or a receiving stream. Because backwash water may contain disinfectants and other chemicals, which may be harmful to a stream's biological life, direct discharge to streams is generally restricted. Similarly, discharge to sewers may be restricted based on the constituent and total quantity of the SFBW. However, for many water treatment plants, particularly in arid or water-scarce areas with limited raw water resources, reuse of the backwash water is a necessity.

REGULATION OF WASH WATER RECYCLE

The 1996 Safe Drinking Water Act Amendments require that the U.S. Environmental Protection Agency (USEPA) regulate the recycle of spent filter backwash water within the treatment process for public water systems by fall, 2000. In the Filter Backwash Recycling Rule (FBRR) (1), the USEPA has outlined the following provisions for all public water systems using surface water or ground water under the influence of surface water:

- The FBRR requires that recycled filter backwash water, sludge thickener supernatant, and liquids from dewatering processes must be returned to a location such that all processes of a system's conventional or direct filtration including coagulation, flocculation, sedimentation (conventional filtration only) and filtration, are employed. Systems may apply to the State for approval to recycle at an alternate location.
- Systems that practice recycle, must notify State (primacy) agencies and provide information on the origin of all recycle flows, the hydraulic conveyance used to transport them, and the location where they are recycled back into the plant; and the typical recycle flow (gpm), highest observed plant flow experienced in the previous year (gpm), the design flow for the treatment plant (gpm), and the State-approved operating capacity for the plant.
- Systems must collect and maintain information on recycle practices, for review by the State, on the all recycle flows and the frequency with which they are returned, the average and maximum backwash flow rate through the filters and the average and maximum duration of the filter backwash process in minutes, the typical filter run length and a written summary of how filter run length is determined (headloss, turbidity, time etc.), the type of treatment provided for the recycle flow, and data on the physical dimensions of the equalization and/or treatment units, typical and maximum hydraulic loading rates, type of treatment chemicals used and average dose and frequency of use, and frequency at which solids are removed where such units are used. The State after evaluating the information may require a system to modify their recycle location or recycle practices.

The concern for EPA and water purveyors is that recycling of SFBW (and other waste streams generated within a water treatment plant) can concentrate contaminants (microbes and chemicals) to a level that may be beyond the treatment capability of a plant, and thereby, potentially impact public health. The microbe of current concern in water treatment is *Cryptosporidium*, which is resistant to conventional water treatment disinfectants, and therefore, its physical removal during the treatment is very important. Craun and coworkers (2) reported 19 outbreaks of cryptosporidiosis in the United States with ten of them associated with community, noncommunity and private water systems (2). A number of these outbreaks have occurred at water utilities where recycle of a waste stream was identified as a contributing cause (3).

CURRENT SFBW RECYCLE PRACTICES

A survey of treatment schematics obtained from 362 water treatment plants serving populations greater than 100,000 people, showed that 226 plants practiced recycle of a waste stream (1). Of the plants that recycle, 88% used surface water as a source of supply and 65% provided treatment before recycle of the waste stream. Water was recycled to a point before the rapid mix process by 70% of these plants, before the sedimentation process by 15%, and before the filtration process by 10%.

Another survey conducted by the American Water Works Association (4) showed that 78% of 335 plants that recycle SFBW used surface water as a source of

supply. Conventional treatment was used by 51% (coagulation, sedimentation, and filtration), 21% used upflow clarification, 14% used lime softening, 10% used direct filtration, and 4% used other type of treatment schemes. SFBW was recycled in 83% of these plants to the head of the plant, 11% to a point before the sedimentation basin, 4% to the sedimentation basin, and 2% before the filtration process. The average generation of SFBW was 2.5% (2–10%) of the average water production. No treatment was provided in 30% of these plants before recycling SFBW; whereas, the others practiced sedimentation (54%), equalization (20%), sedimentation and equalization (14%), lagoon (4%), or other processes (7%) before the recycle of SFBW.

Occurrence of *Cryptosporidium* and *Giardia* in SFBW
